IV.A.4 Vitamin D

Definition and Nomenclature

Vitamin D is a fat-soluble substance required by most vertebrates, including humans, to keep blood calcium and phosphate levels within a narrow normal range and thereby maintain a normal skeleton and optimal cellular function. The term, vitamin D, is a misnomer. Vitamin D is not a vitamin. It is synthesized in the skin, and so, unlike other vitamins, which are essential dietary components, it does not satisfy the criteria for classification as a vitamin. Nor is it a hormone because it is biologically inactive and must be metabolized by the body into a multihydroxylated version, known as calcitriol, which is biologically active and the true hormonal form. Thus vitamin D is more accurately described as a *prohormone.* The natural form of the vitamin, known as vitamin D_3, is a cholesterol-like substance produced in the skin by a nonenzymatic process involving ultraviolet light and heat. An artificial form of the vitamin, with an altered side chain, known as vitamin D_2, is derived from the plant sterol ergosterol and is often used instead of vitamin D_3 as a dietary supplement.

Most of the complexity associated with the nomenclature in the vitamin D field stems from confusion surrounding its discovery during the period 1919 to 1922. Early research showed that the deficiency associated with lack of vitamin D (rickets in children or osteomalacia in adults) was cured by seemingly unrelated treatments: exposure to sunlight or ingestion of a fat-soluble substance. The early nutritional pioneers of that period, including Sir Edward Mellanby and Elmer V. McCollum, realized that several related factors would cure rickets and that one of these substances, vitamin D_3, could be made in the skin. Students often ponder the fate of vitamin D_1. It was a short-lived research entity comprising a mixture of vitamins D_2 and D_3, and the term has no value today. Vitamin D_3 is sometimes referred to as cholecalciferol or, more recently, calciol; vitamin D_2 is known as ergocalciferol or ercalciol. The discovery of the hydroxylated versions of vitamin D by Hector F. DeLuca and Egon Kodicek in the 1967 to 1971 period led to a major expansion of our knowledge of a number of biologically active compounds, but calcitriol is the singularly most important version of these. For purposes of discussing the history of foodstuffs, we shall use the term vitamin D to describe all substances that can be activated to produce biological effects on calcium and phosphate metabolism in humans.

History of Vitamin D Deficiency (Rickets)

Though the nutritional entity vitamin D has been known for only 75 years, the deficiency diseases of vitamin D (rickets and its adult-onset counterpart, osteomalacia) were clearly recognized by Daniel Whistler (1645) in the Netherlands and Francis Glisson (1650) in England as early as the mid-seventeenth century.

In reviewing the history of rickets, we must recognize that rickets and osteomalacia are not the only diseases that affect the skeleton. Others include osteoporosis, which results from loss of total bone (i.e., proteinaceous matrix and minerals), and hormonal imbalances (e.g., hyperparathyroidism). Because diagnostic procedures were primitive until the twentieth century, the term "rickets" may often have been applied to other skeletal abnormalities and conditions not caused by vitamin D deficiency. Nevertheless, in many cases there is sufficient detail in the descriptions provided to recognize the condition.

According to strict medical classification, rickets and osteomalacia encompass a group of skeletal malformations resulting from a spectrum of different causes but having the common feature that *the bone matrix is insufficiently mineralized or calcified.* By far the most common cause of rickets is a lack of vitamin D. This deficiency must be the result of inadequate skin synthesis of vitamin D_3 compounded by low dietary intake of vitamin D. The term "rickets" is thought by most to have its origins in the verb in the Dorset dialect *to rucket,* which means to breathe with difficulty. Yet some claim that the term is derived from the Anglo-Saxon word *wrikken,* meaning to twist.

Rickets is characterized by a deformed and misshaped skeleton, particularly bending or bowing of the long bones and enlargement of the epiphyses of the joints of the rib cage, arms, legs, and neck. Victims have painful movements of the rib cage and hence difficulty breathing. In China, medical texts refer to deformities of the rib cage in severe rickets as "chicken breast." Severe rickets is often accompanied by pneumonia. There is currently much research in progress on a second important function of vitamin D, namely to control the differentiation and development of cells of the bone marrow and immune system. Thus with rickets, the defects of the skeleton may be accompanied by reduced ability to fight infections. Rachitic patients have difficulty holding up their heads, which is sometimes depicted in lithographs from the period circa 1650 to 1700 (e.g., Glisson's "De Rachitide," 1650). A more thorough review of the history of rickets can be found in the extraordinarily detailed book of Alfred Hess (1929) entitled *Rickets Including Osteomalacia and Tetany.* Though rickets is rarely life-threatening, it certainly lowers the quality of life for the afflicted individual and probably leads to secondary problems. One of the best documented of these secondary problems is the development of deformities of the pelvis in young females, which can cause difficulties in childbirth. This topic has been given detailed analysis by the University of Toronto historian Edward Shorter (1982) in *A History of Women's Bodies.* Shorter concludes that before 1920, women who had contracted rickets earlier in life had the risk of a "contracted pelvis" that must have caused numerous deaths during their first delivery.

Discovery of Vitamin D

Around the turn of the twentieth century, several physicians noted a seasonal variation in the incidence of rickets and that the disease was associated with lack of exposure to sunlight. In fact, several researchers also noted a higher incidence of rickets in the industrialized cities of northern Europe (which lay under a pall of smoke caused by burning coal in open fires and factories) than in the rural areas around these centers. The Dickensian character Tiny Tim, of the novel *A Christmas Carol,* clearly represents a child who must have been a common sight in the narrow alleyways of the dark cities of the late nineteenth century. In retrospect, it is easy to see how rickets could be prevalent among the occupants of the sweatshops of such dingy cities when their agrarian cousins on a similar diet, but out in the sun 12 hours a day, had no rickets. Sunbaths were recommended by Edwardian physicians as a cure for this condition, but some believed that the accompanying "fresh-air and exercise," rather than sunlight, were the key ingredients in the cure. In 1912, J. Raczynski (1913; described in Hess 1929) performed a definitive experiment by exposing two rachitic puppies to either sunlight or shade for six weeks and showing that the sunlight-exposed animal had a 1.5-fold higher bone mineral content. Nevertheless, controversy persisted as other researchers claimed to show the importance of "country-air and exercise" in the prevention of rickets and still others showed that the onset of rickets could be accelerated by dietary manipulation. Yet it is now clear that a "rachitogenic diet" (a diet that can lead to rickets) is one that contains adequate amounts of all essential nutrients *except* vitamin D, calcium, and phosphate, the raw materials important in bone mineral formation. Diet alone, however, will not cause rickets. Animals deprived of sunlight and fed a rachitogenic diet grow normally in all respects except that, because they lack bone mineral, they develop severe or "florid" rickets. But animals deprived of sunlight and fed a diet inadequate in many of the chief nutrients grow poorly, and the rickets they develop is difficult to discern against a background of other vitamin deficiencies.

By 1919, it was becoming clear that sunlight was the crucial factor in preventing rickets. Kurt Huldschinsky (1919) cured the disease by exposing patients to a mercury-vapor lamp, thereby showing the importance of the ultraviolet (UV) portion of sunlight. In a stroke of genius, he also showed that irradiation of one arm of a rachitic child cured the skeleton throughout the body, *including the other arm.* He invoked the concept that vitamin D must be "a hormone" because it was a chemical that could heal at a distance. Only much later were Adolf Windaus and colleagues (1936) able to show that vitamin D is made in the skin from a precursor, 7-dehydrocholesterol, thereby completing our understanding of this aspect of vitamin D.

Meanwhile, in the 1920s, nutritional biochemists, including Mellanby and McCollum, were busy isolating several essential nutrients in foodstuffs. They too were able to cure rickets by administration of a fat-soluble substance, termed vitamin D by McCollum to distinguish it from vitamin A, which cured xerophthalmia or night blindness (Mellanby 1919; McCollum et al. 1922). In 1928, Windaus received the Nobel Prize principally for his elucidation of the structure of sterols, including vitamin D. Interestingly, Hess and Harry Steenbock separately had been able to produce vitamin D in food by irradiating it with ultraviolet light (Hess and Weinstock 1924; Steenbock and Black 1924). It became clear that the very process occurring in the skin could be mimicked in the test tube by subjecting certain plant oils or even yeast, containing plant sterols, to UV light. Thus vitamin D_2 was born, and with it, food fortification.

In more recent times, DeLuca, the last graduate student of Steenbock at the University of Wisconsin, showed that vitamin D is converted in the liver to a metabolite, 25-hydroxyvitamin D (Blunt, Schnoes, and DeLuca 1968). This is the main transport form of vitamin D in the body, and its blood level reflects the body's supply of vitamin D. Following this discovery, several groups, most notably those of Kodicek at Cambridge, DeLuca at Wisconsin, and Anthony Norman at the University of California, were able to demonstrate and identify the hormonally active form of vitamin D, calcitriol, for the first time (Fraser and Kodicek 1970; Myrtle, Haussler, and Norman 1970; Holick et al. 1971). Also known as 1,25-dihydroxyvitamin D, this hormone is made in the kidney, but it is important to note that its level in the blood is not simply a reflection of the exposure to sunlight or a measure of dietary intake. The human body can store the fat-soluble vitamin D precursor, make just enough calcitriol hormone for its needs, and save the rest of the vitamin D for "hard times." In the case of our ancestors who lived in the higher latitudes of northern Europe and were exposed to sunlight on a seasonal basis, these stores of vitamin D must have been crucial to help them get through each winter without the development of rickets or osteomalacia.

Foodstuffs and Vitamin D

As already pointed out, diet plays a secondary role in maintaining our supply of vitamin D. Nevertheless, diet can assume a critical importance when exposure to sunlight is compromised. Somewhat surprisingly, most foodstuffs are devoid of vitamin D. The only significant sources are animal liver (vitamin D stores of other vertebrates), egg yolks, and fish oils. Milk, generally thought of as a major source of vitamin D, is not rich in the vitamin, and human milk is an extremely poor source of it. It is a well-established observation in contemporary pediatric medicine that most cases of rickets in infants are found in those who are breast-fed, born in the fall, and kept out of the sun during winter months. Of course, the formula-fed infant of today receives milk fortified with vitamin D.

Most grains, meat, vegetables, and fruits are virtually devoid of measurable amounts of vitamin D, although experts in this field are still perplexed by how such creatures as nocturnal bats surviving on a diet of fruit and insects can avoid rickets! It is possible (although unsubstantiated) that exposure of certain foods (e.g., vegetables or fruits) to sun-drying may generate antirachitic activity, presumably because plant ergosterol would be converted into vitamin D_2. Some cultures (e.g., the Chinese) have a tradition of drying vegetables in the sun, which may increase their vitamin D content.

Recent reports indicate that infants fed a so-called macrobiotic diet, consisting of unpolished rice, pulses, and vegetables with a high fiber content along with small additions of seaweeds, fermented foods, nuts, seeds, and fruits, are particularly susceptible to rickets. In one group of Caucasian children in the Netherlands (Dagnelie et al. 1990), 28 percent had physical symptoms of rickets in late summer, and this statistic rose to 55 percent by the following spring. (One might hope that those who extol this sort of diet will modify their teachings so that small amounts of fatty fish might be included, which would supply much-needed vitamin D.)

The association of vitamin D with fish oils, particularly fish-liver oils, is an interesting one recognized well before the formal discovery of vitamin D and predating even the discovery of the importance of sunlight. In 1789, a Manchester physician named Thomas Percival wrote about the medicinal uses of cod-liver oil at the Manchester Infirmary shortly after it had been introduced into British pharmacopoeia. In fact, one might argue that cod-liver oil is a medicine and not a food, but this is a fine point. There is, however, almost universal agreement that it is not a particularly good-tasting substance and hardly a favorite of children. Hess (1929) wrote that cod-liver oil's chief disadvantages lay in taste and odor. Moreover, it was not always completely prophylactic against rickets.

Hess's last comment is a reference to the variable potency of cod-liver oil because it is a natural product and thus subject to seasonal variation dependent upon the diet of the codfish. A more acceptable but less effective source of vitamin D is fish itself, particularly the fatty saltwater fish: herring, mackerel, tuna, halibut, and salmon. These fish have fat stores in the muscle, and because vitamin D is fat-soluble it is found throughout these fat deposits and is not confined to the liver, as in the cod. Fish roe, like eggs, also contain vitamin D. W. F. Loomis (1970), in a review of rickets, speculated that certain social practices, such as the Christian tradition of serving fish on Friday, might be adaptive responses to rickets. Another was June weddings, which tend to bring the first baby in the spring and permit the rapid growth phase of the first six months of life in summer sunshine. By contrast, the fall baby historically lacked vitamin D because of an infancy during the winter months.

Fortification of Food with Vitamin D

With the discovery that irradiation of ergosterol could produce a molecule (later identified as vitamin D_2) with potent antirachitic activity came the realization that such a preparation could be added to foodstuffs rendering low–vitamin D foods useful in the fight against rickets. As noted earlier, the two problems with foods containing vitamin D are that there are too few of them and that even those foods that contain vitamin D vary widely in potency. Steenbock had the idea to fortify staples of the diet such as breakfast cereals, milk, and margarine with vitamin D in the form of irradiated ergosterol, and because this supplement has a narrower range of variability, the potency of such foods could be assured with some degree of confidence. Some U.S. states and Western countries fortify only milk or margarine; others include breakfast cereals as well. Nonetheless, fortifying even these few foods with vitamin D has virtually eradicated the incidence of rickets in the Western world. The fortification of foods with vitamins including vitamin D is arguably one of the most important medical achievements of the twentieth century and certainly a major achievement of the nutritional sciences.

Nowadays, pure crystalline vitamin D_3 is used in food fortification rather than Steenbock's irradiated ergosterol. Nevertheless, Steenbock's "invention" represents one of the earliest examples of a university (Wisconsin-Madison) patenting the application of fundamental scientific research in the biomedical field. The discovery led to the inception of a new university structure, WARF (Wisconsin Alumni Research Foundation), an institution designed to manage patentable research and recycle profits from such discoveries. Aside from serving as a model for many other similar institutions in the United States and around the world, WARF has spawned a number of other products from its profits on vitamin D fortification, including the rodent poison warfarin and most of the new metabolites of vitamin D itself, including calcitriol, identified and synthesized in the laboratory of DeLuca.

Despite the incredible success of food fortification in the eradication of rickets, over the years the process has met some resistance and even outright opposition amid fears that vitamin D in megadoses could cause hypercalcemia and, consequently, kidney damage. These fears are largely groundless because the doses required to produce renal damage are massive and could not be acquired by ingestion of large amounts of foods, even those fortified with vitamin D (cod-liver oil excepted). Yet one of the most notable examples of resistance came in the Province of Quebec, Canada. Health authorities in this province steadfastly resisted the fortification of dairy products with vitamin D until the early 1970s, when finally they bowed to pressure from a group headed by the notable clinical geneticist Charles Scriver to reduce rickets in the French-Canadian population. Following this decision, statistics from one Montreal hospital (Sainte-Justine pour les Enfants) showed a decline in the annual incidence of rickets from 130 per 1,000 to zero in an eight-year span between 1968 and 1976, which coincided with the introduction of provincial legislation making it mandatory for dairies to fortify milk (Delvin et al. 1978). Today, a similar low incidence of rickets can be documented in every children's hospital in North America. Gone too is the once familiar bowleggedness, the signature of rickets, which often remained with the victim for life and was so common in the Great Depression of the 1930s.

With the end of World War II came mandatory rationing and governmental food fortification in Western Europe. But in 1957 politicians in the United Kingdom bowed to political pressure and drastically reduced vitamin D fortification of cereals and powdered milk following an "outbreak" of infantile hypercalcemia. At the time, the outbreak was believed to be caused by overfortification of food with vitamins D and A, although Donald Fraser, a noted Canadian pediatrician who researched the evidence at that time, now feels that this conclusion was probably incorrect (Fraser et al. 1966). The incidence of infantile hypercalcemia today is now no greater in countries that fortify than those that do not. Furthermore, the disease seems to result from an insult to the fetus in utero rather than a problem of the young child overindulging in fortified food, such as infant formula. Nevertheless, the condition results in mental retardation and heart problems that are largely irreversible and thus must be taken seriously.

To this day, the United Kingdom permits fortification of margarine only, probably at the expense of some increased incidence of rickets and osteomalacia in the population. Certainly, blood plasma levels of vitamin D and its metabolites (except calcitriol) are lower, presumably reflecting reduced stores of vitamin D in Britons when compared to a similar population of Americans and Canadians at the same latitude but given fortified food. In summary, it can be stated that the advantages of food fortification with vitamin D far outweigh any disadvantages. The main value of food fortification with vitamin D is to provide a *constant* year-round supply of the essential nutrient in the diet to augment the seasonal production in the skin.

Geographical Aspects of Vitamin D

Synthesis of vitamin D is both season- and latitude-dependent because vitamin D is made in the skin only by exposure to wavelengths in the UV spectrum of sunlight, and these wavelengths are absorbed by the ozone layer of the atmosphere. Only near the equator does the sunlight remain at an angle high enough for UV rays to penetrate the atmosphere on a year-round basis. Michael Holick of Boston City Hospital conducted experiments in which test tubes containing 7-dehydrocholesterol (the skin precursor to vitamin D) were exposed to light at various times of the day at latitudes from Caracas to Edmonton or Glasgow. He concluded (Webb, Kline, and Holick 1988) that in a city such as Boston, vitamin D is synthesized *only* in the months from April to October. Such a result implies that in most of the northern cities of the world, production of vitamin D_3 is seasonal and rickets might result at such latitudes if vitamin D stores are depleted *and* there is no dietary vitamin D.

Historical records also consistently reveal the geographical segregation of rickets to more northerly latitudes. August Hirsch (1883–6, vol. 3), for example, discussed the paucity of data on the geographical distribution of rickets. Theobald Palm, a Western medical missionary to Japan and China, concluded in a valuable paper in 1890 that sunshine is the main etiological factor in rickets. He compiled anecdotal reports suggesting that rickets was rare in southern China but more common in northern regions of the same country. However, reports in the early 1900s suggested a similar incidence of rickets in New Orleans (30° latitude) and New York (40° latitude). Hess (1929) ascribed this similarity to equivalent average annual sunshine exposure (2,519 versus 2,557 hours). It is interesting to note that of the cities cited by Hess for the year 1923, Phoenix, Arizona, has the highest amount of annual sunshine with 3,752 hours (and no rickets in the population), whereas Glasgow (a hotbed of rickets) has the lowest with 1,086 hours. Since UV light penetration is greater at higher altitudes, we would expect the incidence of rickets to be low in mountain cities, and early studies in cities like Denver (5,000 ft. above sea level) bear this out. Even earlier, in 1844, a Swiss physician had pointed out that rickets was more prevalent in the lowlands than the mountains, again presumably reflecting the relative exposure to UV light (Hess 1929: 50). In more recent times, the pollution of major cities has modified local UV exposure and may have increased our predisposition to rickets by reducing skin synthesis of vitamin D. Thus, geography plays a major role in the distribution of rickets, but the relationship is not a simple one directly dependent on degrees of latitude. It is further modified by climate, altitude, and degree of pollution.

The geography of vitamin D and rickets is also modified by diet. It is important to note that many of the peoples who live in northern latitudes depend upon the sea for their survival (e.g., Eskimos, Haida Indians, Greenlanders, Scandinavians). It is tempting to speculate that the natural incidence of rickets in these cultures has been ameliorated by the higher vitamin D content of their diets (e.g., from fish oils). One anecdotal story relating to the higher fat-soluble vitamin content of Arctic meats is the experience of early Arctic explorers. Several were forced to shoot Arctic animals (such as polar bears) and eat almost all edible organs in order to survive. As a result, some contracted hypervitaminosis A, which causes disorientation and brain swelling, probably from ingestion of polar bear liver containing vast stores of vitamins A and D. Eskimos apparently avoid the liver of the polar bear but still get enough vitamins D and A from the rest of their diet.

Social and Ethnic Aspects of Vitamin D

Because vitamin D is produced in the skin by exposure to UV light, social practices relating to exposure of the skin (such as clothing habits or sunbathing) can be of paramount importance to this production. Primitive humans evolved near the equator and are popularly depicted wearing minimal clothing. These considerations, plus the belief that primitive humans must have spent much of their lives outdoors, suggest that their contraction of rickets was unlikely. But as humans increased in numbers and moved into more and more inhospitable climes, the need for clothing would have become greater and the synthesis of vitamin D in the skin would have been compromised. It is possible that sun worship in early cultures reflects a realization of the importance to health of skin exposure to the sun.

Adaptation to sunlight exposure involved the development of melanin pigment in the skin. People exposed to maximal amounts of sunlight at the equator were the darkest, and those at the highest latitudes of Europe were the lightest. Although the subject is somewhat controversial, modern research indicates that skin melanin not only protects against the harmful effects of sunlight (e.g., skin cancer) but reduces the efficiency of the synthesis of vitamin D. Loomis (1970) suggests that summer bronzing in white populations is a seasonal adaptation to UV light exposure, though there is no evidence that vitamin D synthesis is regulated in an individual by such seasonal pigmentation. However, there is also no evidence that excessive exposure to sunlight can cause hypervitaminosis D and toxicity. The interrelationship of skin pigmentation and migration has some relevance to nutrition. Over the course of the past few centuries there has been considerable migration of certain peoples around the world so that cultural groups exist in climates that "their skin was not designed for."

Much has been written about whites developing skin cancer in Arizona and Australia, and considerable evidence is accumulating that indicates rickets and osteomalacia are common among Asian groups in England and Scotland (Felton and Stone 1966; Ford et al. 1973; Dent and Gupta 1975). There is some possibility that the problems of Asians in Britain are exacerbated by a high-phytate, high-phosphate diet (which tends to chelate calcium in the lumen of the intestine) combined with the avoidance of the typical vitamin D–fortified staples that whites consume.

Black children growing up in southern U.S. cities during the last part of the nineteenth century and the first decades of the twentieth century endured rickets almost as a rite of passage. And Rastafarians living outside of the UV climate of the West Indies may also be at risk for rickets. This is because of strict dietary practices that forbid consumption of artificial infant formulas, coupled with reduced opportunities for UV exposure in inner-city apartment complexes and a skin pigment unsuited to their "new" more northerly homes. There is also speculation (Ward et al. 1982) that the vitamin D–rich fish component of the Jamaican Rastafarian diet has been dropped by those living abroad. With the generation of multicultural societies such as currently exist in the United States, Canada, and many former colonial European countries, this potential problem of widespread rickets needs to be better understood and *dietary* solutions need to be formulated.

Clothing must have been developed for both staying warm in cooler climates and combating the harmful effects of UV light in warmer climates. Some cultures, particularly Moslem and Hindu groups, have very strict traditions of purdah, the practice of keeping the female skin out of the gaze of the public and therefore out of the sun. Though this strict policy does not apply to female children below the age of puberty, Saudi Arabian physicians report a higher female to male ratio in rickets patients that they ascribe to the higher UV exposure of the male children. In most cases, however, the practice of purdah cannot be directly blamed for childhood rickets in Saudi Arabia and North Africa, but it can be held responsible for osteomalacia observed in older females in such populations. And because these women with low reserves of vitamin D bear infants, the low UV exposure might be indirectly responsible for rickets. Detailed studies of the etiology of the rickets observed in Moslem groups (Belton 1986; Underwood and Margetts 1987; Elzouki et al. 1989) suggest the existence of maternal vitamin D deficiency, which results from the extra burden placed upon the mother to provide calcium for the skeleton of the growing fetus. Placental and lactational transfer of vitamin D stores from mother to the neonate are thus minimal, and such deficiencies, coupled with inadequate UV exposure, can result in infantile rickets. It is likely that the strict moral standards that prevailed in past centuries in western Europe leading to limited skin exposure also contributed to the well-documented higher incidence of osteomalacia in women.

IV.A.5 ~ Vitamin E

As any nutritional text dated prior to 1970 will indicate, vitamin E has not received much respect from nutritionists. In such texts it is often placed after vitamin K, in the miscellaneous category. This is because it took a good 40 years from its discovery in 1923 (Evans and Bishop 1923) to demonstrate a clear-cut human deficiency disease for vitamin E. Though numerous studies had shown vitamin E to be an essential component of animal diets, deficiency symptoms varied from one species to the next, from reproductive disorders in rats to vascular abnormalities in chickens. Thus, it was not clear that humans had an obligatory requirement for vitamin E. Recent research, however, has shown that this is indeed the case and that vitamin E is just as important to human nutrition as the other vitamins. It is, therefore, pleasing to see that vitamin E is now placed in its proper place in the alphabet of vitamins.

Vitamin E is the nutritional term used to describe two families of four naturally occurring compounds each, the tocopherols and the tocotrienols (Pennock, Hemming, and Kerr 1964). Tocopherols and tocotrienols both contain a chroman ring, which is essential for biological activity, but differ in the degree of saturation of their fatty side chains. They are otherwise interchangeable in their biological role. Each family comprises alpha, beta, gamma, and delta forms, which differ significantly in their potency. Thus, alpha-tocopherol represents the principal source of vitamin E found in the human diet with a small contribution also coming from gamma-tocopherol (Bieri and Evarts 1973). Many texts, including this one, use the terms alpha-tocopherol and vitamin E interchangeably.

Located in the cellular membranes, alpha-tocopherol helps the cell to resist damage from powerful oxidants known as free radicals. These are generated naturally inside the body as by-products of fuel oxidation, and they can be generated artificially by external factors such as radiation, chemotherapy, or pollutants. B. Ames (1983) believes that aerobic respiration using oxygen is the most important of these external factors in generating free radicals and that antioxidants such as vitamin E help to resist free-radical damage. Because of its stabilized chroman ring structure, vitamin E is able to mop up these free radicals and their immediate products, minimizing the damage to the lipids of the membrane and therefore maintaining cell membrane integrity. Simply put, vitamin E stops the fat of the body from turning rancid.

History of the Discovery of Vitamin E

The decade between 1915 and 1925 was one of the most productive in the history of nutrition. The use of semipurified or semisynthetic diets allowed researchers to demonstrate the essential nature of individual components of the diet and, more specifically, to recognize the existence of the vitamins A, B_1, C, and D. Nutritionists (Osbourne and Mendel 1919; Mattill and Conklin 1920) showed that though these diets were able to maintain life, they failed to support reproduction in laboratory animals. Reproductive biologists, thus, realized that the estrous cycle of the female rat or testicular development in the male constituted useful animal models for studying the essential nature of nutritional factors (Long and Evans 1922). Using a basal semipurified diet comprising casein, starch, lard, butter, fats, and brewer's yeast, which would allow rats to grow but not reproduce, groups headed by Herbert M. Evans and L. B. Mendel set about the laborious task of finding a substance that would promote fertility.

Detailed historical accounts of the events surrounding the discovery of vitamin E, its chemistry and biology, have been published by two pioneers in the field, Evans (Evans 1962) and Karl E. Mason, a student of Mendel (Mason 1977). Their recollections are concise, modest accounts of the important milestones in the field, and unlike other accounts of historical events from rival camps, the two actually agree! The reader is referred to the often flowery account of Evans, who describes the identification of a factor in lettuce and wheat germ required for preventing resorption of fetuses in the pregnant rat. He writes:

> Good fairies attended every phase of the advent and early history of vitamin E. We turned our attention at once to the prevention rather than alleviation of these strange resorptions – a prevention which might disclose at once what individual natural foodstuffs carried a missing needed substance. Lettuce, relished by these poor sufferers of our rancid lard diet, was spectacularly successful, and we may have entertained the conviction that vitamin C which was not essential for growth was necessary in pregnancy, had we not quickly shown that not the aqueous, but only the fatty, component of these leaves, the chlorophyll-rich green oil, had worked the good result. Then, to our surprise, wheat was equally remedial, and the concept that vitamin C was involved could not, of course, survive. The good fairies accompanied me to the large Sperry flour mill at a neighboring town, Vallejo, where I found three great streams flowing from the milling of the wheat berry: the first constituted the outer cover or chaff; the second the endosperm, the white so-called flour; and the third which came in flattened flakes, stuck into such units by its oil content – the germ. Night had not fallen that day, before all these components were fed to groups of carefully prepared females – animals which had begun gestation on vitamin E–low diets and were fed both the watery and fatty solutions. Single daily drops of the golden yellow wheat

> germ oil were remedial. That an oil might enrich the embryo's dietary needs for vitamin A and vitamin D, the only fat-soluble vitamins then known, was negated at once when we added the well-known rich source of vitamins A and D, cod liver oil, an addition which did not lessen but increased and made invariable our malady. (Evans 1962: 382)

From the words Evans used to describe his rats, we can clearly discern that he cared about the animals he used in those early studies. The factor initially described as "antisterility factor X" was born (Evans and Bishop 1922). Parallel studies by Mason (1925), working with the male rat, showed that the same factor appeared essential to prevent testicular degeneration in the rat. The name, vitamin E, seems to have been suggested by an opportunist, Barnett Sure, in 1924, based upon the vitamin nomenclature of the time, although the endorsement of this title by Evans helped to gain it widespread use (Evans 1925).

Following the discovery of vitamin E, nutritionists spent the next decade describing symptoms of its deficiency in a variety of animals, *except* humans. Research also focused on its chemical nature. Finally in 1936, Evans, working with Gladys and Oliver Emerson, published the identity of vitamin E from wheat germ oil as an alcohol with the chemical formula ($C_{29}H_{50}O_2$). Evans named this substance "alpha-tocopherol." The origin of this name is described in his personal account:

> I well remember their (the Emersons') plea to me to suggest a proper name for their purified substance when success crowned their efforts. I promptly invited George M. Calhoun, our professor of Greek to luncheon in Berkeley in our small Faculty Club. "Most scientists, medical men especially," said Calhoun, "have been guilty of coining Greek-Latin terms, bastards, of course, and we might have to do this." "What does the substance do?" he asked. "It permits an animal to bear offspring," I replied. "Well, childbirth in Greek is *tocos,*" he said, "and if it confers or brings childbirth, we will next employ the Greek verb *phero.* You have also said that the term must have an ending consonant with its chemical – 'ol', it being an alcohol; your substance is 'tocopherol,' and the pleasant task assigned me quickly solved and not worth the delightful four-course dinner you have arranged." (Evans 1962: 383)

It is, therefore, evident that vitamin E was renamed alpha-tocopherol for the meager price of a four-course meal.

Erhard Fernholz provided the structural formula for alpha-tocopherol in 1938, and it was first synthesized chemically by the brilliant Swiss chemist Paul Karrer working at Hoffmann-LaRoche laboratories in Basel (Karrer et al. 1938).

Vitamin E Deficiency in Humans

During the period 1925 to 1935 there appeared an ever increasing and confusing series of papers in the nutritional literature showing the importance of vitamin E in the prevention of reproductive defects in rats; prevention of embryonic mortality and encephalomalacia in chicks; and prevention of nutritional muscular dystrophy in guinea pigs and rabbits. How could deficiency of a single nutritional factor cause all these different pathological changes in different laboratory animals but have no apparent parallel condition in humans? Even in avian species like the chick and duck the symptoms were not consistent.

Vitamin E deficiency appeared in different sites: muscular dystrophy in ducklings and vascular changes and encephalopathy in chicks. The common thread tying together all these apparently different defects ascribed to vitamin E deficiency was not immediately evident. Although H. S. Olcott and H. A. Mattill (1931) had pointed out the association of antioxidants and vitamin E in lettuce oil, it was not until 1937 after the discovery of alpha-tocopherol that it became clear that alpha-tocopherol was an antioxidant (Olcott and Emerson 1937). It was still later through the work of researchers such as A. L. Tappel and J. G. Bieri in the late 1950s and early 1960s, that the free-radical theory of lipid peroxidation and the function of vitamin E as an antioxidant developed to the point where the conflicting findings could be rationalized using a single mechanism (Tappel 1962).

According to this free-radical theory, membrane lipids in all membranes of the body should be susceptible to oxidative damage, and the exact location of damage observed in different animal species would depend upon variables such as specific membrane lipid composition, vitamin E content, and cellular metabolic rate. Based upon this theory it became easy to rationalize various patterns of damage due to vitamin E deficiency in different animal species. With this new understanding of the nature of vitamin E action came the realization that vitamin E deficiency in humans might show up in different sites (i.e., different membranes) from those showing vitamin E deficiency in animal tissues. Moreover, the recognition that the common feature of all these deficiency symptoms was damage caused by free radicals began a search for human individuals who might generate or be exposed to higher levels of such destructive factors and who might, therefore, develop vitamin E deficiency. These individuals turned out to be prematurely born infants.

Looking back at the extensive literature on vitamin E in humans, it is clear that clues of vitamin E deficiency in pediatric medicine were emerging even in the late 1940s. The advent of modern neonatal units led to the use of respirators in which newborns were kept in an oxygen-rich environment. Premature infants were particularly favored for this treatment, and two conditions suggesting vitamin E deficiency affecting premature infants came to light: hemolytic anemia, in which erythrocyte membranes have an increased tendency to rupture; and retrolental fibroplasia, in which the blood vessels of the developing retina are damaged, leading to scarring and blindness (Farrell 1980). First observed in the 1940s, these conditions were documented and rationalized for the first time with the advent of the free-radical theory.

Free radicals, generated from the oxygen-rich gaseous mix used in such respirators, attacked cellular membranes, in particular those of red blood cells and the cells of the retina. It should be noted that although premature infants are susceptible to damage resulting from vitamin E deficiency, this is due only in part to an increased "insult" from oxidants; it is also partly the result of reduced vitamin E stores and lower vitamin E levels in their blood. Not surprisingly, the severity of retrolental fibroplasia is markedly decreased by pharmacological doses of vitamin E (Hittner et al. 1981). As the assault on cellular membranes in such fast-growing children is diminished and as vitamin E stores are bolstered in the first weeks of life, the risk of vitamin E deficiency decreases substantially. Consequently, vitamin E deficiency is very difficult to demonstrate in healthy children or in adults eating a standard balanced diet.

Toward the end of the 1950s, the Food and Nutrition Board of the National Research Council of the United States funded a long-term, six-year, dietary study of the relationship between blood vitamin E levels and consumption of polyunsaturated fatty acids (PUFA) in a group of male subjects who were given a diet low in vitamin E. The study became known as the Elgin Project, after the hospital in Illinois where it was carried out (Horwitt 1960). Institutionalized subjects were closely monitored for symptoms of vitamin E deficiency while they underwent the increased stress of a diet with a higher PUFA:vitamin E ratio. Not surprisingly, the subjects failed to develop a clear-cut clinical syndrome except that plasma vitamin E levels dropped and red cells showed an increased tendency to hemolysis, but it took two years for these changes to occur.

If vitamin E deficiency does occur in humans beyond the neonatal period, it is usually secondary to another disease state that results in malabsorption of vitamin E from the diet. Since vitamin E is absorbed with the fat in the diet, conditions that result in fat malabsorption, such as chronic cholestasis (liver disease) or cystic fibrosis where there is pancreatic blockage, will result in vitamin E deficiency. Another rare cause of vitamin E deficiency is the genetic absence of beta-lipoprotein, the transporter of vitamin E in the blood, in a condition known as abetalipoproteinemia (Muller, Lloyd, and Bird 1977).

In such individuals with vitamin E supply or transport problems, there is an increased tendency of red cells to hemolyze and also a shortened red cell survival time. More recently, the medical fraternity has begun to recognize muscle and neurological problems that result from human vitamin E deficiency (Sokol 1988). These abnormalities include loss of reflexes and gait disturbances that are accompanied by pathological changes. Autopsies performed on patients with cystic fibrosis show more advanced axonal degeneration than would be expected of normal age-matched individuals (Sung 1964). It would be surprising if humans were spared all of the neurological and muscular defects observed in animals. However, such human vitamin E deficiency is rarely accompanied by the acute muscle, brain, and blood vessel defects observed in laboratory animals fed semisynthetic diets. We should be thankful that it is not.

Dietary Sources of Vitamin E

The substance alpha-tocopherol is present in the diet in a variety of plant oils, including wheat germ oil and the lettuce oil discovered in pioneering work. Soya bean and other plant oils, which became more common dietary components in the latter half of the twentieth century, contain gamma-tocopherol, a less potent version of vitamin E. It is interesting to note that the unsaturated fatty acids, which are present in plant oils and are so prone to free-radical oxidation in our food, are accompanied by the highest concentrations of vitamin E. It is as if nature realized their sensitivity and put in a natural preservative to protect these oils (Bieri, Corash, and Hubbard 1983). Animal fats contain lower amounts of vitamin E, and fish oils have variable amounts depending upon the diet of the fish and the age of the fish oil. Though cod-liver oil has been shown to contain vitamin E, it also contains a high concentration of polyunsaturated fatty acids that can easily become oxidized by free radicals and, consequently, as noted by Evans (1962), be deleterious rather than protective.

One special food associated with vitamin E is wheat germ bread. Sometimes referred to in Europe as Hovis (from the Latin *hominis vis* meaning "the strength of man"), this bread is made with flour containing five times as much of the fatty germ as wholemeal bread. The procedure by which the wheat germ is stabilized involves separating it from the flour, lightly cooking it in steam, and returning it to the flour. This process was jointly patented in the United Kingdom in 1887 by Richard "Stoney" Smith of Stone, Staffordshire, and Macclesfield Miller and Thomas Fitton of the firm S. Fitton and Son. This was about 35 years before the experiments of Evans, which led to the discovery of vitamin E. Although the health-promoting properties of Hovis were clearly recognized in early advertising campaigns, there is no evidence that Hovis was aimed at special groups of people (i.e., those with muscular, reproductive, or vascular problems). With such rich sources of vitamin E as Hovis bread in our normal diet, it is difficult to consume a diet that will result in vitamin E deficiency.

Other Uses of Vitamin E

The history of vitamin E is much shorter than that of the other vitamins, but the absence for so long of a clear-cut human deficiency syndrome allowed for the development of a number of bogus or exaggerated claims for vitamin E, or at least claims that have never been properly substantiated. Most of these have been built upon deficiency symptoms observed in laboratory animals and not in humans. One, based upon findings in the rat, is that vitamin E is a fertility vitamin. As a result, some physicians used the vitamin to treat a number of conditions that produced spontaneous abortions. In a series of poorly controlled, anecdotal studies, Evan Shute (1939) claimed that vitamin E was particularly effective in countering habitual abortion, which is defined as spontaneous abortion before the sixteenth week of gestation during three successive pregnancies. When others tried to confirm these findings, they failed to do so and were left to conclude, as did C. T. Javert, W. F. Finn, and H. J. Stander:

> There is such a maze of literature the proper cognizance cannot be taken of all the pertinent articles. As the reader reviews them in order to develop his own philosophy let him [all obstetricians were male in those days] be reminded of the following important matters:
>
> i. the high percentage of success irrespective of which vitamin, hormone or method is employed;
> ii. the lack of specific information as to the pathogenesis of human spontaneous abortion. (1949: 887)

This skepticism was found to be well grounded; others who have reviewed three decades of experimentation on abortion have also concluded that vitamin E supplementation is ineffective (Marks 1962).

In addition, there have been numerous claims that large doses of vitamin E are beneficial in cardiovascular conditions such as angina, congestive heart failure, and peripheral vascular disease. Current medical opinion is that these claims are unproven. However, this debate was being revisited in the 1990s with the suggestion that the "oxidized" lipoprotein, LDL, may be the chief villain in atherosclerosis, and that its level in the bloodstream inversely correlates with alpha-tocopherol levels. New clinical studies of vitamin E and the risk of coronary heart disease in both male and female health workers have, again, suggested a protective role for the vitamin (Rim et al. 1993; Stampfer et al. 1993). Consequently, long-term supplementation with vitamin E to prevent heart disease is again being discussed.

The association of vitamin E deficiency with nutritional muscular dystrophy in guinea pigs and rabbits led to trials of its use as a supplement in Duchenne's muscular dystrophy (Berneske et al. 1960). Because this condition is a genetically inherited disease with a different etiology than the nutritional version, it is not surprising that vitamin E was ineffective, but this is not to say that vitamin E supplementation cannot help to alleviate some of the consequences of muscular and neurological disease and, therefore, benefit the patient. The recent elucidation of the molecular defect in Lou Gehrig's disease (ALS) as a lack of the enzyme superoxide dismutase (Rosen et al. 1993) has already led to a reevaluation of dietary antioxidant supplementation in this disease because the enzyme works in concert with vitamin E to reduce free radicals inside the cell. It is hoped that the results will be more positive than those reported recently in another neurological condition, Parkinsonism, where alpha-tocopherol supplementation was unsuccessful as an adjunct therapy to the drug deprenyl (Shoulson et al. 1993).

The old adage that if a little is good, a lot must be better, pervades nutritional science. The association of vitamin E with muscle health has led to the use of vitamin supplements in sports (Cureton 1954). Consequently, vitamin E can be considered one of the earliest performance-enhancing drugs, in use long before anabolic steroids and growth hormones. However, a controlled study of Scottish track-and-field athletes in the early 1970s by I. M. Sharman, M. G. Down, and R. N. Sen dispelled the notion that vitamin E improved performance. Presumably the athletes agreed because they moved on to other treatments.

In the 1970s, megadose vitamin therapy came into vogue in North America, and Senator William Proxmire from Wisconsin, who advocated such self-treatments for improved health, subsequently led opposition to legislation that might have blocked such potentially dangerous megadose vitamin products. Simultaneously in vogue was the free-radical theory of lipid peroxidation, which resulted in the idea that the natural aging process is an inability of the organism to keep up with oxidation (Harman 1956).

A possible solution to the problem came from Ames (1983), who suggested that a battery of dietary and endogenously produced antioxidants, headed by vitamin E and also including glutathione, vitamin C, beta-carotene, and possibly uric acid, might help to slow down this process. Ames concluded that the natural aging process results from an inability to completely prevent the harmful effects of oxidation. As a consequence, megadoses of vitamin E have been consumed by thousands of North Americans in the hope that augmenting the antioxidant supply might help defeat free radicals and prevent aging. Although it is difficult to believe that supplemental dietary vitamin E will prevent aging if alpha-tocopherol levels are already adequate in the blood of the majority of adults, the toxicity symptoms (gastrointestinal disturbances) of vitamin E are minor. Thus there seems not much reason to prevent a little self-experimentation, although it is worth noting that this self-experimentation is ably assisted by the pharmaceutical industry.

As the antioxidant properties of vitamin E have become more and more evident, the food and cosmetic industry have found wider and wider uses for it. Vitamin E is a poor antioxidant in vitro and is largely replaced by other substances when a preservative is needed in food. However, the vitamin is now added to a broad range of soaps and shampoos and other cosmetic products in the hope of convincing the buyer that it has special properties in skin and hair. The fact that human vitamin E deficiency is not accompanied by skin and hair problems, or that vitamin E might not even enter the hair or skin when applied via this route, does not seem to be a weighty argument for the consumer. Perhaps the most outrageous claim this contributor has come across in recent years is one stating that a cream containing vitamin E might protect against frostbite. It was applied by a Canadian sled-dog racer to the underside of her dogs' testicles to protect them from the harmful effects of the snow and cold (Sokol 1985).

The past two to three decades have, however, also seen some legitimate uses of vitamin E in medical science. The development of total parenteral feeding solutions in the 1970s included a recognition of the essential nature of vitamin E (Bieri et al. 1983). Long-term artificial feeding solutions are, therefore, supplemented with vitamin E. The widespread use of cancer chemotherapeutic agents such as adriamycin, which generates free radicals to kill cancer cells, can be augmented by vitamin E therapy to help protect surviving normal cells. Tissue transplantation normally involves maintenance of donor organs in oxygenated perfusate prior to surgery, a process that leads to free-radical generation. Use of antioxidants and free-radical scavengers helps improve the survival of such organs, presumably by minimizing the damage caused by free radicals. Children with cholestasis and poor vitamin nutriture receiving liver transplants are given water-soluble vitamin E preparations to help the donated organ survive. Vitamin E can also attenuate the damage caused by free radicals released during myocardial infarctions (Massey and Burton 1989). It appears that uses for vitamin E will continue to proliferate well into the new millennium.

IV.A.6 Vitamin K and Vitamin K–Dependent Proteins

The term "vitamin K" was first introduced by Henrik Dam in 1935, following discovery of a fat-soluble substance that could prevent bleeding (Dam 1935, 1964). During the years 1928 to 1930, Dam conducted studies on the cholesterol metabolism of chicks at the University of Copenhagen. The chicks were being fed an artificial, practically sterol-free diet to which the then known vitamins A and D were added. He observed hemorrhages (bleeding) in different parts of the body in some of the chicks that had been on the diet for more than two or three weeks. In addition, blood that was examined from some of these chicks showed delayed coagulation or clotting (Dam 1964). The low amounts of cholesterol and fat in the diet were ruled out as the causes of the symptom.

Similar observations were made by W. D. McFarlane, W. R. Graham, Jr., and G. E. Hall (1931). W. F. Holst and E. R. Halbrook (1933) observed that the symptoms resembled scurvy, a disease caused by vitamin C deficiency, and could be prevented by addition of fresh cabbage to the diet. These investigators concluded that the protective agent in the cabbage was vitamin C. However, when pure vitamin C became available, it was injected into the chicks and failed to prevent the hemorrhagia (Dam 1964).

Large doses of vitamins A and D (fed in the form of fish-liver oils) and commercial carotene also did not prevent the hemorrhagia (Dam 1935). Cereals and seeds did prevent the symptom, and green leaves and hog liver were found to be potent sources of the antihemorrhagic factor. Research groups led by Dam and H. J. Almquist worked independently to show that the factor was a new fat-soluble vitamin. Dam's report (Dam 1935) was followed in the same year by that of Almquist and E. L. R. Stokstad (1935). The factor was designated vitamin K (Dam 1935, 1964). According to Dam (1964: 10), "The letter K was the first one in the alphabet which had not, with more or less justification, been used to designate other vitamins, and it also happened to be the first letter in the word 'koagulation' according to the Scandinavian and German spelling."

The elucidation of the structure of vitamin K was achieved in a relatively short time because of the number of large research groups involved. Several reviews are available on the isolation and characterization of vitamin K (Doisy, Binkley, and Thayer 1941; Dam 1942, 1964; Almquist 1979). In 1943, Dam received the Nobel Prize for Physiology or Medicine for his discovery of vitamin K. It is interesting to note that Almquist, who published later but in the same year as Dam, did not share the Nobel Prize. Dam did share the prize with E. A. Doisy, who was honored for the isolation, chemical synthesis, and structural identification of one of the forms of vitamin K.

The Structure of Vitamin K

Many compounds, all closely related, are now recognized as having antihemorrhagic activity (Table IV.A.6.1). Common to all is the methylnaphthoquinone nucleus. This nucleus, known as menadione, has not been isolated from natural sources, but it has been synthesized and does possess biological activity. Attached to the methylnaphthoquinone nucleus are carbon chains that vary both in nature and length. Based on the nature of these carbon side chains, the natural K vitamins are subdivided into two groups: phylloquinone (vitamin K_1) and the menaquinones (MK-*n*). Phylloquinone, the plant product, has a 20-carbon side chain with only one double bond. The menaquinones, synthesized by microorganisms, contain side chains with varying numbers of 5-carbon (isoprene) units but always with one double bond per 5-carbon unit. Chain lengths of the known menaquinones vary from 2 to 13 isoprene units. The *n* in MK-*n* refers to the number of 5-carbon units. A menaquinone with 4 isoprene units (20 carbons) in its side chain, for example, would be called menaquinone-4, abbreviated MK-4. Humans convert the synthetic menadione nucleus to menaquinone-4.

Table IV.A.6.1. *Vitamin K analogues*

Analogue	Symbol	Source
Menadione	K_3	Synthetic
Phylloquinone	K_1	Plants, animal tissues
Menaquinones	MK-2 to MK-13	Bacteria, animal tissues

Nutritional Aspects of Vitamin K

Since the human body cannot synthesize the naphthoquinone entity, all the K vitamins in humans, at least the quinone nucleus of these compounds, are of extraneous origin. The K vitamins are synthesized by plants as phylloquinone and by bacteria in the intestines as the menaquinones (Table IV.A.6.1).

Phylloquinone, the form of vitamin K synthesized by plants, is the major dietary form of vitamin K (Booth et al. 1993; Booth, Sadowski, and Pennington 1995; Shearer, Bach, and Kohlmeier 1996). It is found in plants and in the tissues of plant-eating animals (Table IV.A.6.2) and is the form of vitamin K that is added to infant formulas and given to infants at birth.

The best sources of phylloquinone are green leafy vegetables and certain oils, such as soybean, rapeseed, and olive oil (Shearer et al. 1996). The values in

Table IV.A.6.2. *Phylloquinone content of common foods*

Phylloquinone concentration ranges in μg of phylloquinone per 100 g (3.5 oz.) food			
0.1–1.0	1–10	10–100	100–1,000
Avocado (1.0)	Apples (6)	Beans, runner (26)	Broccoli tops (179)
Bananas (0.1)	Aubergines (6)	Beans, French (39)	Brussels sprouts (147)
Beef, steak (0.8)	Baked beans (3)	Beans, broad (19)	Cabbage, green (339)
Bread, white (0.4)	Barley (7)	Cabbage, red (19)	Kale (618)
Chicken, thigh (0.1)	Beef, corned (7)	Cauliflower (13)	Lettuce (129)
Coconut oil (0.5)	Beef, minced (2)	Cockpeas (21)	Parsley (548)
Cod, fresh, fillet (0.1)	Bilberries (4)	Cucumber (21)	Rapeseed oil (123)
Corn flakes (<0.1)	Bran, wheat (10)	Greengages (15)	Soybean oil (173)
Flour, white (0.8)	Bread, whole meal (2)	Mustard greens, cress (88)	Spinach (380)
Grapefruit (<0.1)	Butter (7)	Olive oil, extra virgin (80)	Watercress (315)
Ham, tinned (0.1)	Carrots (6)	Peas (34)	
Maize (0.3)	Cheeses, various (2–6)		
Mangoes (0.5)	Chocolate, plain (2)		
Melon, yellow (0.1)	Corn oil (3)		
Melon, water (0.3)	Courgettes (3)		
Milk, cows (0.6)	Cranberries (2)		
Mushrooms (0.3)	Cream, double (6)		
Oranges (<0.1)	Dates, fresh (6)		
Parsnips (<0.1)	Egg yolk (2)		
Peanuts, roast (0.4)	Figs, fresh (3)		
Pilchards, brine (0.6)	Grapes, black (8)		
Pineapple (0.2)	Grapes, green (9)		
Pork, chop, lean (<0.1)	Leeks (10)		
Potatoes (0.9)	Liver, lamb (7)		
Rice, white (0.1)	Liver, ox (4)		
Rice, brown (0.8)	Nectarines (3)		
Salmon, tin, brine (0.1)	Oats (10)		
Sausage, pork/beef (0.2)	Palm oil (8)		
Spaghetti (0.2)	Peaches, fresh (4)		
Tuna, tin, brine (0.1)	Pears (6)		
Turnips (0.2)	Peppers, green (6)		
Yoghurt (0.8)	Peppers, red (2)		
	Plums, red (8)		
	Raisins (4)		
	Rhubarb (4)		
	Safflower oil (3)		
	Sunflower oil (6)		
	Swede (2)		
	Tomatoes (6)		
	Wheat (8)		

Note: Data are for raw foods except where cooked form is indicated. Numbers in parentheses indicate the micrograms of phylloquinone per 100 g (3.5 oz.) food.

Table IV.A.6.2 represent analyses of a single sample. Phylloquinone concentrations in plants, however, are affected by the stage of maturation and the geographic location of the plant. Further, different parts of the plant may differ in phylloquinone content. Outer leaves of the cabbage, for example, contain three to six times more phylloquinone than inner leaves (Shearer et al. 1980; Ferland and Sadowski 1992a). Although tea leaves and regular ground coffee contain high concentrations of phylloquinone, the brews are not a dietary source of the vitamin (Booth, Madabushi, et al. 1995). The phylloquinone content of oils declines slightly with heat and rapidly on exposure to daylight and fluorescent light when the oils are stored in transparent containers (Ferland and Sadowski 1992b; Shearer et al. 1996).

Recent evidence indicates that the intestinal absorption of phylloquinone from vegetables is poor and is improved by the simultaneous ingestion of fat (Vermeer et al. 1996). Bile acids, secreted into the intestines in response to fat in a meal, are necessary for the absorption of the fat-soluble K vitamins. There is a need for additional studies on the bioavailability of the K vitamins in foods to complement our knowledge of their vitamin K content (Vermeer et al. 1996).

Less is known about the vitamin K content of menaquinones (synthesized by bacteria) in foods. Livers of ruminant species, such as cows, have been found to have nutritionally significant quantities of menaquinones, but the concentrations of menaquinones in other animal organs were very low (Hirauchi et al. 1989; Shearer et al. 1996). Cheeses contained significant quantities of two different menaquinones, but very low quantities of menaquinones were found in milk and yoghurt (Shearer et al. 1996).

A topic currently in dispute is whether the menaquinones produced by bacterial action in the gut are substantially utilized by humans. Concentrations of various menaquinones have been found to be higher than that of phylloquinone in normal human livers (Usui et al. 1989) and, importantly, antibiotics have been known since the late 1940s and early 1950s to sometimes create a vitamin K deficiency. Nonetheless, the degree of importance of menaquinones in human nutrition has not yet been determined (Suttie 1995), and there are data to suggest that the long-chain menaquinones found in human liver are not as effective a form of the vitamin as phylloquinone. Moreover, elimination of foods high in vitamin K from a normal diet can produce signs of vitamin K insufficiency, suggesting that bacterial synthesis of menaquinones only partially satisfies the human vitamin K requirement (Suttie 1995).

Documented cases of vitamin K deficiency in adults have been uncommon. The National Research Council of the National Academy of Sciences recommends a daily dietary allowance (RDA) of approximately 1 microgram (μg) vitamin K per kilogram (kg) of body weight (National Research Council 1989). Thus, the requirement for an individual weighing 150 pounds (68 kg) would be 68 μg phylloquinone. The average vitamin K intake of 10 male college students was determined to be 77 μg/day based on analysis of food composites (Suttie et al. 1988) – an average intake that corresponds to 1.04 μg vitamin K/kg body weight. Foods rich in vitamin K, such as spinach, broccoli, and Brussels sprouts, were not usually consumed in significant amounts by these students. This suggests that daily vitamin K intake may vary considerably depending on whether foods rich in vitamin K are consumed (Suttie et al. 1988). Table IV.A.6.2 makes it clear that 100 grams (g) of spinach (380 μg phylloquinone per 100 g) would contribute much to the recommended daily dietary intake of vitamin K, even if phylloquinone is poorly absorbed from this food.

Vitamin K deficiency can result from inadequate intestinal absorption. Because vitamin K is a fat-soluble vitamin, bile acids and pancreatic juice are needed for its absorption. Thus, causes of poor intestinal absorption can be insufficient production of bile acids, inadequate release of bile acids (for example, obstruction of the bile ducts by gallstones), or pancreatic insufficiency (Report of the Committee on Nutrition 1961; Suttie 1991). Levels of all the K vitamins were reduced in patients with chronic hepatitis and liver cirrhosis (Usui et al. 1989). In addition, secondary vitamin K deficiency has been observed in human subjects taking megadoses of vitamin E (Korsan-Bengtsen, Elmfeldt, and Holm 1974). Vitamin E supplementation is currently on the rise because of its role as an antioxidant. However, the effect of large doses of vitamin E on vitamin K status must always be borne in mind.

An upper limit for vitamin K intake has not been set, but 20 μg/100 kilocalories has been suggested by J. W. Suttie and R. E. Olson (Olson 1989). Menadione, which is not a natural form of vitamin K, can cause severe toxic reactions in infants if administered in large doses. Phylloquinone, however, has been given without adverse effects to infants in a single intramuscular dose that is 100 times their RDA. Adult dietary intakes of 10 to 15 times the RDA also cause no adverse effects (Olson 1989).

Function of Vitamin K

Vitamin K is involved in the synthesis of four clotting factors, one procoagulant protein, two anticoagulant proteins, and two bone proteins. The vitamin K–dependent clotting factors are integral to blood coagulation, such that an untreated vitamin K deficiency results in death due to bleeding. There also must be control of coagulation, and the body, therefore, has anticoagulant systems. Two of the known anticoagulant proteins are vitamin K–dependent.

The vitamin K–dependent bone proteins (in contrast to the vitamin K–dependent clotting proteins) have only recently been discovered, and the physiological role of these proteins in bone has not yet been determined.

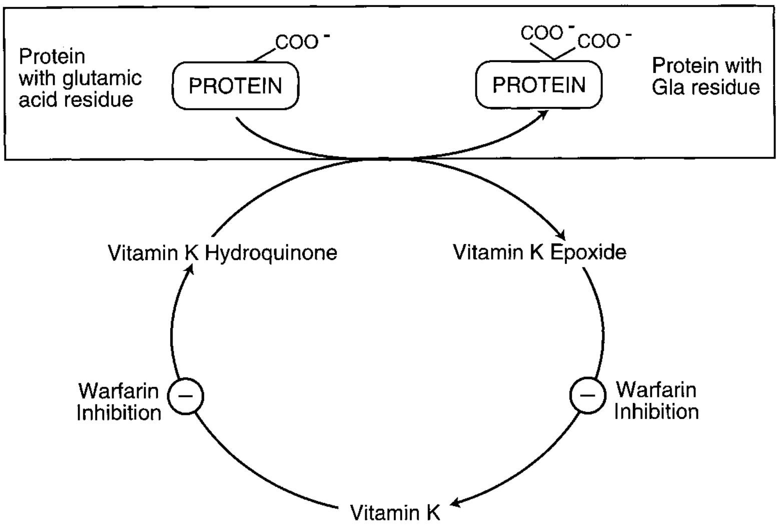

Figure IV.A.6.1. The vitamin K-dependent carboxylase reaction. The vitamin K-dependent carboxylase converts glutamic acid residues of specific proteins to gamma-carboxyglutamic acid (Gla) residues. Vitamin K hydroquinone is simultaneously converted to vitamin K epoxide. The epoxide is reconverted to vitamin K, which is converted to vitamin K hydroquinone, and the cycle repeats. Warfarin inhibits conversion of the epoxide to vitamin K and conversion of vitamin K to vitamin K hydroquinone.

Mechanism of Action of Vitamin K

Vitamin K is a cofactor for an enzyme (vitamin K-dependent carboxylase) that carboxylates specific glutamic acid residues of proteins, converting these amino acid residues to gamma-carboxyglutamic acid residues (Figure IV.A.6.1). This modification occurs after the protein has been synthesized. The gamma-carboxyglutamyl residues are abbreviated Gla.

Although it was established in the early 1950s that vitamin K was necessary for the synthesis of the clotting proteins prothrombin (factor II) and factors VII, IX, and X, the vitamin K-dependent carboxylation reaction was not discovered until 1974. Investigators at that time demonstrated the presence of a new amino acid, gamma-carboxyglutamic acid, in prothrombin (Nelsestuen, Zytkovicz, and Howard 1974; Stenflo et al. 1974). The nature of the carboxylase reaction was soon delineated (Shah and Suttie 1974; Esmon, Sadowski, and Suttie 1975; Suttie 1985). A reduced form of vitamin K (vitamin K hydroquinone) is converted to vitamin K epoxide as the glutamic acid residues of the specific protein are converted to gamma-carboxyglutamic acid residues (Figure IV.A.6.1). At physiological concentrations, vitamin K must be regenerated and reutilized and is recycled. Two reactions take place sequentially to convert vitamin K epoxide to its reduced form (vitamin K hydroquinone) for continued carboxylation (Figure IV.A.6.1). These two reactions are prevented by coumarin anticoagulants, synthetic compounds such as warfarin, which are used medically to counteract excessive clotting.

The vitamin K-dependent (Gla-containing) proteins that have been well characterized include prothrombin and the clotting factors VII, IX, and X (plasma proteins synthesized by the liver); protein Z, a procoagulant plasma protein; protein C and protein S, plasma anticoagulants synthesized by the liver; osteocalcin, also called bone Gla protein; and matrix Gla protein, a bone-matrix protein.

Vitamin K–Dependent Proteins

The clotting proteins. When a cut or injury occurs, platelets (cells in blood) converge on the injury to form a plug, and a clot forms on the platelet plug. This action stops blood loss and prevents the injured person from bleeding to death. A clot is formed by a series of transformations involving more than ten different proteins. In the final stage, fibrinogen, a soluble blood protein, is cleaved by thrombin and converted to fibrin. Fibrin monomers are then cross-linked to form the insoluble or hard clot. A schematic of the clotting cascade is illustrated in Figure IV.A.6.2. Hundreds of papers have been published on the blood clotting cascade; reviews by C. M. Jackson and Y. Nemerson (1980) and by B. Furie and B. C. Furie (1992) provide additional information.

The proteins of the clotting cascade that are vitamin K-dependent are prothrombin (factor II), factor VII, factor IX, and factor X (Figure IV.A.6.2). These proteins, which are central to the blood clotting cascade, are carboxylated after synthesis in a reaction requiring vitamin K (Uotila 1990). The Gla residues make the proteins more negative and endow them with an increased ability to bind positively charged calcium ions. Calcium ions serve as bridges between these proteins and the negatively charged phospholipids of the platelet membrane. The proteins are brought in close proximity to each other on the platelet membrane, augmenting their activation. In the absence of vitamin K, carboxylation of prothrombin and factors VII, IX, and X does not occur. Activation of these factors proceeds so slowly that bleeding may result.

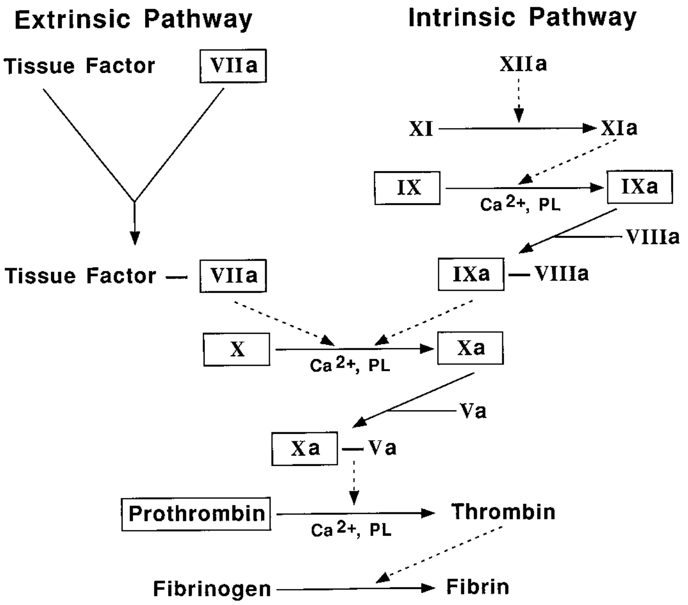

Figure IV.A.6.2. An outline of the clotting sequence. Dashed lines indicate an enzyme action, and solid lines indicate the activation of a protein, formation of a complex, or conversion of one compound to another. The presence of an "a" indicates that a factor has been activated. Vitamin K-dependent factors are located in rectangles. Calcium ions (Ca^{2+}) and phospholipids (PL), supplied by the platelet membrane, are required in those reactions that involve the vitamin K-dependent cofactors.

In response to a vessel injury, platelets aggregate at the injured site and form a platelet plug. The platelet membrane provides a surface on which a clot will subsequently form. Tissue factor (a protein) is also released at the injured site. It combines with activated factor VII. This complex (tissue factor–factor VIIa) activates factor X, which combines with activated factor V. The factor Xa–factor Va complex is able to activate prothrombin (factor II) to produce thrombin, an active enzyme that cleaves fibrinogen molecules to produce fibrin monomers. The fibrin monomers are cross-linked to produce the hard clot. The tissue factor–factor VIIa pathway for activating factor X is called the extrinsic pathway.

Factor X is also activated by a pathway called the intrinsic pathway. All proteins of the pathway are located in plasma. Factor XII, which is perhaps activated by collagen fibers from the injured blood vessel, activates factor XI. Factor XIa activates factor IX, which then combines with activated factor VIII to produce a factor IXa–factor VIIIa complex, which activates factor X.

At the time of identification of vitamin K as the antihemorrhagic factor, prothrombin and fibrinogen were the only proteins in the clotting cascade characterized as involved in the formation of the fibrin clot. The laboratories of Dam (Dam, Schønheyder, and Tage-Hansen 1936; Dam 1964) and A. J. Quick (Quick 1937) independently demonstrated that the activity of prothrombin was decreased in the plasma of chicks fed hemorrhagic diets. The choice of the chick as the experimental animal in these early studies was fortuitous, since chicks develop the symptoms of vitamin K deficiency more readily than other experimental animals (Suttie 1991). Factors VII, IX, and X, the other vitamin K-dependent clotting factors, were not established as essential plasma proteins and vitamin K-dependent proteins until the 1950s.

Human protein Z, another vitamin K-dependent protein, was purified and first described in 1984 (Broze and Miletich 1984). It is synthesized by the liver and promotes the association of thrombin (activated prothrombin) with phospholipid surfaces, a process necessary for clotting. Protein Z deficiency has recently been described as a new type of bleeding tendency (Kemkes-Matthes and Matthes 1995).

The anticoagulants. For several decades prior to the discovery of protein C (Stenflo 1976), the only known vitamin K-dependent plasma proteins were the clotting proteins II, VII, IX, and X. Protein S was subsequently isolated and purified (Di Scipio et al. 1977). Protein C and protein S are now known to be components of a very important anticoagulant system in plasma (Figure IV.A.6.3). Protein C, when activated and bound to protein S, is able to cleave, and thereby inactivate, two of the activated clotting factors, factors Va and VIIIa (Walker 1980; Stenflo 1984; Esmon 1987). The presence of both coagulant and anticoagulant systems in plasma allows for control of clotting.

Hereditary protein C deficiency and protein S deficiency have been discovered (Griffin et al. 1981; Pabinger 1986; Miletich, Sherman, and Broze 1987; Broekmans and Conrad 1988; Bertina 1989; Preissner 1990; Rick 1990). The clinical manifestation of protein S or protein C deficiency is thrombosis (excessive clotting).

The bone proteins. Until the discovery of osteocalcin (bone Gla protein, BGP) in the 1970s, vitamin K was assumed to function only in coagulation. The Gla residues of osteocalcin, a major protein of bone, pro-

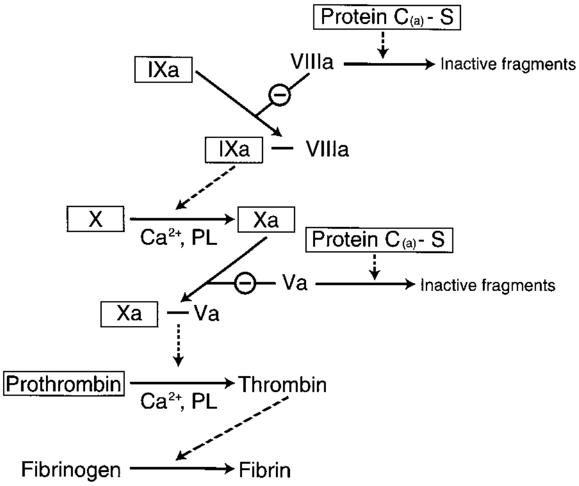

Figure IV.A.6.3. The vitamin K-dependent anticoagulant system. Dashed lines indicate an enzyme action, and solid lines indicate the activation of a protein, formation of a complex, or conversion of one compound to another. The presence of an "a" indicates that a factor has been activated. Vitamin K-dependent factors are located in rectangles. A complex of activated protein C and protein S cleaves activated factor VIII and activated factor V, rendering them inactive. The inactivation of these two factors causes the cessation of blood coagulation, due to decreases in the rates of the two reactions with the encircled negative signs.

vide a point of interaction between the protein and bone mineral (Hauschka, Lian, and Gallop 1975; Poser and Price 1979). Matrix Gla protein was isolated and identified in 1983 (Price, Urist, and Otawara 1983). The synthesis of osteocalcin and matrix Gla protein is regulated by the hormonal form of vitamin D (1,25-dihydroxyvitamin D) (Price 1988). Two vitamins, vitamins K and D, are thus involved in the synthesis of osteocalcin and matrix Gla protein.

A fetal warfarin syndrome, first reported in 1975, has been found in infants born to mothers on warfarin anticoagulant therapy during pregnancy (Becker et al. 1975; Pettifor and Benson 1975; Shaul, Emery, and Hall 1975). Some of the abnormalities identified have been associated with bone formation. Although the functions of osteocalcin and matrix Gla protein are not yet established, defective carboxylation of these two proteins in the presence of warfarin may be a cause of the bone abnormalities associated with fetal warfarin syndrome (Price et al. 1983; Pauli et al. 1987; Price 1988).

In recent years, several studies have implicated vitamin K insufficiency in the pathogenesis of osteoporosis (Binkley and Suttie 1995; Vermeer, Jie, and Knapen 1995; Shearer et al. 1996; Vermeer et al. 1996). Osteoporosis is an age-related disorder characterized by inadequate skeletal strength due to bone loss (decreased bone density) and a predisposition to bone fractures. Peak bone mass is achieved between ages 25 and 35, and bone loss is a natural process that begins thereafter. The highest rate of bone loss for women, however, occurs within the first three to six years after the onset of menopause. Women are at greater risk for osteoporosis than men because of a lower peak bone density and the rapid postmenopausal loss of bone, related, in part, to reduced estrogen levels.

Low concentrations of vitamin K have been found in the blood of patients with bone fractures. When the vitamin K status is insufficient, vitamin K-dependent proteins tend to be undercarboxylated. Osteocalcin is more sensitive to a low vitamin K intake than the coagulation proteins, and, thus, undercarboxylated osteocalcin is the most sensitive known marker of vitamin K insufficiency. Undercarboxylated osteocalcin has been reported to be increased in postmenopausal women and to be highest in those individuals with the lowest hip bone density and greatest hip fracture risk. Vitamin K supplementation has been shown to decrease bone loss, and clinical trials have been initiated to test the effect of long-term vitamin K supplementation on bone mass. Measurements of undercarboxylated osteocalcin suggest that vitamin K insufficiency, formerly characterized by the status of the coagulation system, may be more common than previously thought (Binkley and Suttie 1995; Vermeer et al. 1996).

Other proteins. Gla-containing proteins have also been purified from kidney (Griep and Friedman 1980), urine (Nakagawa et al. 1983), liver mitochondria (Gardemann and Domagk 1983), and human spermatozoa (Soute et al. 1985). The function of these proteins is not presently known.

Abnormal Carboxylation

Hereditary deficiency of vitamin K-dependent clotting proteins (factors II, VII, IX, and X) can result in a rare bleeding disorder that has so far been diagnosed in only seven patients. The first reports of this disorder were in 1966 (Fischer and Zweymuller 1966; McMillan and Roberts 1966), and data (Brenner et al. 1990) suggest that the defect is abnormal carboxylation (due to a defective liver vitamin K-dependent carboxylase enzyme). Deficiencies in the plasma anticoagulants protein C and protein S have also been observed (Brenner et al. 1990).

Hemorrhagic Diseases of Infants

Although vitamin K deficiency symptoms are not very prevalent in adults, hemorrhagic diseases related to vitamin K deficiency are observed in infants worldwide. Three patterns of vitamin K–deficiency hemorrhage – early hemorrhagic disease of the newborn (HDN), classic hemorrhagic disease of the newborn, and late hemorrhagic disease – have been described. The frequency of these diseases, particularly that of late hemorrhagic disease, has increased during the last decade (Lane and Hathaway 1985; Kries, Shearer, and Göbel 1988; Greer 1995).

Early Hemorrhagic Disease

Early hemorrhagic disease of the newborn is characterized by severe, and sometimes life-threatening, hemorrhage at the time of delivery or during the first 24 hours after birth (Lane and Hathaway 1985; Kries et al. 1988). The bleeding varies from skin bruising, cephalohematoma, or umbilical bleeding to widespread and fatal intracranial, intra-abdominal, intrathoracic, and gastrointestinal bleeding (Lane and Hathaway 1985). The disease is often seen in infants whose mothers have taken drugs during pregnancy that affect vitamin K metabolism, such as therapeutic doses of warfarin. Idiopathic cases (no known cause) have also been reported.

Classic HDN

C. W. Townsend (1894) was the first person to use the term "haemorrhagic disease of the newborn." He described 50 infants who began bleeding on the second or third day of life, most commonly from the gastrointestinal tract, and speculated that the disease was of infectious origin. Dam and colleagues (1952) studied 33,000 infants and concluded that low levels of the clotting factor prothrombin in newborns was secondary to a vitamin K deficiency and occurred primarily in breast-fed infants. The researchers showed that this problem could be prevented by administration of vitamin K to mothers prior to delivery and to the infant shortly after delivery.

Normal full-term infants have reduced blood concentrations of the vitamin K–dependent clotting factors II, VII, IX, and X. Further, the levels of these factors decline during the first few days of life. Hemorrhagic disease of the newborn, often called early vitamin K deficiency, occurs from 1 to 7 days after birth. Breast-fed infants are at risk because of the low vitamin K content of breast milk. Bleeding occurs in the gastrointestinal tract, skin, and nose and at circumcision. The disease is prevented by vitamin K prophylaxis at birth (Lane and Hathaway 1985; Kries et al. 1988; Greer 1995), as indicated in 1952 (Dam et al. 1952).

Late Hemorrhagic Disease

Late hemorrhagic disease (late neonatal vitamin K deficiency) strikes at some infants (1 to 12 months of age) who are predominantly breast-fed and who do not receive vitamin K supplementation (Lane and Hathaway 1985; Hanawa et al. 1988; Kries et al. 1988). It is characterized by intracranial, skin, and gastrointestinal bleeding.

That late hemorrhagic disease of the neonate has been observed primarily in breast-fed infants may result from the low vitamin K content of human milk (Lane and Hathaway 1985; Kries et al. 1988; Canfield et al. 1990). However, even if administered at birth, vitamin K may not always prevent deficiency in older infants because of their metabolism rates and consequent elimination of the vitamin. In Japan, from January 1981 to June 1985, 543 cases of vitamin K deficiency were reported in infants over 2 weeks of age (Hanawa et al. 1988). Of these, 427 were diagnosed as having idiopathic vitamin K deficiency, and 387 (90 percent) of this group had been entirely breast-fed (Hanawa et al. 1988). The concentrations of phylloquinone in human milk (mean 2.1 μg/liter) have been found to be significantly lower than those found in cows' milk (mean 4.9 μg/liter) and in unsupplemented infant formulas containing only fat from cows' milk (mean 4.2 μg/liter). Supplemented infant formulas, by contrast, had higher levels of phylloquinone than cows' milk; two of those studied had levels of 75.1 μg/liter and 101.8 μg/liter (Harroon et al. 1982; Kries et al. 1987).

It has been proposed that the late neonatal vitamin K deficiency that occurs in predominantly breast-fed infants may not result solely from lower vitamin K intake but from its combination with other factors, including subclinical liver dysfunction (Hanawa et al. 1988; Kries and Göbel 1988; Matsuda et al. 1989). In fact, I. Matsuda and colleagues (1989) have suggested that the higher content of vitamin K in formulas, unlike the lower content of vitamin K in human milk, can actually mask such defects.

In another study, phylloquinone levels and coagulation factors were measured in healthy term newborns until 4 weeks after birth (Pietersma-de Bruyn et al. 1990). Although breast-fed infants had lower serum phylloquinone levels than formula-fed infants, the levels of the vitamin K–dependent clotting factors II and X were comparable in the two groups. Thus, the authors of this study concluded that breast milk contains sufficient vitamin K for optimal carboxylation of the clotting factors. They have also suggested that the vitamin K supplementation of infant formulas results in higher than normal serum levels of vitamin K in infants without a concomitant rise in the levels of the vitamin K–dependent clotting proteins (Pietersma-de Bruyn et al. 1990).

Vitamin K Prophylaxis

Prophylactic use of vitamin K has been recommended for all newborns by the American Academy of Pediatrics since 1961. Vitamin K prophylaxis is standard for all infants in some geographical regions but is, or has been, "selective" (given only to at-risk infants) in others. However, in some regions where the "selective policy" was in effect, there was a resurgence (in the 1980s and 1990s) of hemorrhagic disease (Tulchinsky et al. 1993; Greer 1995).

The mode of administration (oral versus intramuscular) of vitamin K also became an issue of controversy in the 1990s because of reports from one research group (unconfirmed by two other groups) suggesting an association between intramuscular administration of vitamin K to the neonate and the subsequent development of childhood cancers. But in several countries (for example, Sweden, Australia, and Germany) where use of oral vitamin K prophylaxis (compared with intramuscular) has increased, there has been an increased incidence of late hemorrhagic disease. Oral prophylaxis prevents classic hemorrhagic disease but is less effective in preventing late hemorrhagic disease. Prevention of the latter requires repeated oral doses of vitamin K during the first 2 months of life for exclusively breast-fed infants or other infants at risk (for example, infants with liver disease), all of which presents problems with compliance (Greer 1995; Thorp et al. 1995).

The Vitamin K Ad Hoc Task Force of the American Academy of Pediatrics (1993) has recommended that to prevent hemorrhagic disease, phylloquinone be administered at birth to all newborns as a single, intramuscular dose of 0.5 to 1 milligram. The Task Force has also recommended that research be done to judge the efficacy, safety, and bioavailability of oral formulations of vitamin K. Oral supplements of vitamin K to nursing mothers might become an alternative method of prophylaxis to prevent late hemorrhagic disease (Greer 1995). Physicians could also advise pregnant and nursing mothers to increase their intake of green, leafy vegetables.

The Oral Anticoagulants

The discovery of the first coumarin anticoagulant, dicoumarol, has been interestingly described by K. P. Link (1959). During a blizzard on a Saturday afternoon in February 1933, a Wisconsin farmer appeared at the University of Wisconsin Biochemistry Building with a dead cow, a milk can containing blood without clotting capacity, and about 100 pounds of spoiled sweet clover hay. The farmer's cows were suffering from "sweet clover disease," a malady caused by feeding cattle improperly cured hay made from sweet clover. If the type of hay was not changed and if the cows were not transfused, they developed a prothrombin deficit and bled to death. Link and his colleagues began to work on the isolation and identification of the hemorrhagic agent, and in 1939, it was identified as dicoumarol, a coumarin derivative. As a result of the spoilage, coumarin, a natural component of sweet clover, had been converted to dicoumarol (Link 1959).

Since the discovery of dicoumarol, other coumarin derivatives have been synthesized (Link 1959). The most famous of the coumarin derivatives is warfarin, named for the University of Wisconsin Alumni Research Foundation (WARF), which received a patent for the compound. The coumarin compounds interfere with the metabolism of vitamin K, preventing conversion of vitamin K epoxide to vitamin K and also preventing reduction of vitamin K to vitamin K hydroquinone (Figure IV.A.6.1). This interference causes a buildup of vitamin K epoxide, and when physiological levels of vitamin K are present, the inability of the epoxide to be converted to the vitamin creates a relative vitamin K deficiency. The vitamin K–dependent proteins, including the clotting proteins II, VII, IX, and X, are, therefore, not carboxylated – or only partially carboxylated – and remain inactive (Suttie 1990).

The coumarin compounds, particularly warfarin, have been used as oral anticoagulants in the long-term treatment of patients prone to thrombosis (clot formation). The formation of a clot in a coronary artery narrowed by atherosclerosis is a causative factor in the development of acute myocardial infarction (heart attack), and warfarin is used after acute myocardial infarction to prevent further thrombus (clot) formation and reinfarction.

A recent study of the effect of warfarin on mortality and reinfarction after myocardial infarction concluded that "long-term therapy with warfarin has an important beneficial effect after myocardial infarction" (Smith, Arnesen, and Holme 1990: 147). This study involved 607 patients treated with warfarin and 607 patients treated with a placebo. Compared with the placebo group, warfarin therapy reduced the number of deaths by 24 percent, the number of reinfarctions by 34 percent, and the number of cerebrovascular accidents (strokes) by 55 percent.

In anticoagulant therapy, a dose of the anticoagulant is selected that achieves effective anticoagulation and minimizes bleeding complications (Second Report of the Sixty Plus Reinfarction Study Research Group 1982). The advantage of using warfarin for long-term therapy is that an overdosage is corrected by the administration of a large dose of vitamin K. Large doses of vitamin K are converted to vitamin K hydroquinone by enzymes that are not inhibited by warfarin (Link 1959; Suttie 1990). Correspondingly, persons undergoing warfarin anticoagulant therapy should avoid a diet that is high in vitamin K by limiting, among other things, the intake of green, leafy vegetables (Pedersen et al. 1991).

A Note on Hemophilia

Hemophilia is a bleeding disorder caused by a deficiency in one or, more rarely, two of the clotting proteins (De Angelis et al. 1990). The majority (85 percent) of hemophilia patients are deficient in factor VIII (hemophilia A), with 10 to 12 percent deficient in factor IX (hemophilia B). Rarer forms of the disease result from deficiency in other clotting factors. The hemophilia patient must receive injections of the missing protein in order to maintain proper coagulation. Hemophilia is a genetic disease, most commonly transmitted as a sex-linked recessive trait, and is not related to vitamin K status (Furie and Furie 1988).

IV.B

Minerals

IV.B.1 Calcium

This chapter deals with the history of calcium and its metabolism in adult humans. It should be read in conjunction with Chapter IV.D.4 on osteoporosis, which contains a further discussion of calcium requirements and the effects of a deficiency in adults, and with Chapter IV.A.4 on vitamin D, which deals with the history of rickets, a disease caused in part by a deficiency of calcium resulting from reduced intake or poor absorption.

Historical Aspects

Bone is the main depository of calcium. Fully 99 percent of the body's calcium is in the skeleton, with the rest in extracellular fluid and soft tissues. As early as the sixteenth century, it was recognized by a Dutch physician that the skeleton is not an inactive but a dynamic tissue under hormonal influence and capable of remodeling throughout life (Lutwak, Singer, and Urist 1974). Two specific types of bone cells acted upon in these processes are the osteoblasts (involved in bone formation) and the osteoclasts (involved in bone resorption).

Another important discovery in the history of calcium was made by Sidney Ringer more than 100 years ago. He demonstrated that the contractility of cardiac muscle was stimulated and maintained by the addition of calcium to the perfusion fluid (Ringer 1883). It has also been shown that this important effect of calcium is not limited to cardiac muscle but has a generalized, activating effect in practically all differentiated cells (Opie 1980; Rubin 1982; Campbell 1986). However, in addition to calcium, the presence of specific concentrations of sodium and potassium are needed to achieve this effect (Mines 1911; Lowenstein and Rose 1978).

The state of calcium in the body investigated many decades ago has been subsequently summarized ("The Classic" 1970). The amount of calcium in the body is greater than that of any other positively charged mineral (1,160 grams [g]). Its place of storage is the skeleton, although the small amounts present in the compartments of the extracellular fluid and those of the soft tissues are of great physiological importance because the calcium stored in bone maintains equilibrium with other calcium pools in the body (Rubin 1982).

The interaction and balance of vitamin D, calcitonin, and parathyroid hormone (PTH) are the pillars of normal calcium metabolism, and they play an important role in maintaining a highly controlled calcium homeostasis and normal serum calcium level. This process is based on the direct or indirect action of these substances on the skeleton. Vitamin D is produced by ultraviolet radiation of sunlight on the skin, which yields the vitamin D precursor ergosterol (Hess and Weinstock 1924). The hormones calcitonin and PTH are created, respectively, by the C cells of the thyroid gland and by the parathyroid glands. A deficiency as well as an excessive production and secretion of these three substances can lead to the development of specific disease states.

Vitamin D

Vitamin D, discovered at the beginning of the third decade of the twentieth century, is the substance that acts to prevent rickets. Many of the original reports of the discovery of vitamin D have been republished (Robertson 1969; Pramanik, Gupta, and Agarwal 1971) and are cited here for those who wish to consult them. In addition, the early discovery of the physiological importance of calcium (Ringer 1883) has been redescribed (Fye 1984; Ebashi 1987). The chemical structure of vitamin D was identified by a German chemist, Adolf Windaus, in 1931, and the subsequent commercial production of vitamin D practically eliminated the occurrence of rickets – the vitamin D deficiency disease of children – although treatment with cod-liver oil (rich in vitamin D) also played an important role in the eradication of this disease.

Even though our basic knowledge of vitamin D was obtained between 1919 and 1924, it was not until the 1960s that the vitamin D metabolites were discovered (Lund and DeLuca 1966; Ponchon and DeLuca 1969; Olson, Jr., and DeLuca 1973; DeLuca 1979, 1980, 1988). H. F. DeLuca postulated that vitamin D must be hydroxylated first in the liver and subsequently by 1-alpha-hydroxylation in the kidney to produce the vitamin D hormone 1-alpha-25-dihydroxyvitamin D_3,1,25$(OH)_2D_3$. This is the important vitamin D metabolite that actively affects the absorption of calcium from the intestine. Further studies regarding the mechanism of calcium absorption from the intestine are credited to R. H. Wasserman, who discovered the vitamin D–dependent "calcium binding protein" (CaBP) in the duodenum (Kallfelz, Taylor, and Wasserman 1967; Wasserman, Corradina, and Taylor 1968; Wasserman and Taylor 1968).

Rickets, caused by vitamin D deficiency, was produced experimentally in the 1920s, and much was learned about this illness, which occurs in infancy and childhood at ages of rapid growth (Sherman and Pappenheimer 1921; Steenbock and Black 1924; Pettifor et al. 1978; Pettifor and Ross 1983). Rickets was common in the early part of the twentieth century, and more than 100 years ago it was recognized that a lack of sunlight was responsible, particularly in northern latitudes, where deprivation is most likely to occur. It was also noted that sunlight is curative (Palm 1890; Huldschinsky 1919; Mellanby 1921).

Symptoms of rickets include impaired calcification and excess formation of cartilage in areas of bone growth. The adult form of the disease is called osteomalacia, in which newly formed osteoid does not calcify. This occurs in persons who voluntarily or for other reasons are homebound and therefore not exposed to sunlight.

Several early investigators stated that both rickets and osteomalacia can also be caused by a nutritional deficiency of calcium (McCollum et al. 1921; Theiler 1976; McCollum et al. 1995). Although such a situation would be uncommon, it is possible that the theory was proposed because healing of rickets occurred when a low, insufficient calcium intake of barely more than 100 milligrams (mg)/day was raised to 1,200 mg/day with the simultaneous use of vitamin D. More recent investigators believed it unlikely that vitamin D deficiency alone could produce rickets or osteomalacia but that these diseases occur when there is coexistent calcium deficiency (Pettifor et al. 1981).

Calcitonin

The hormone calcitonin was discovered in 1962 by Harold Copp, who reported that it originates in the parathyroid glands (Copp et al. 1962; Copp 1967, 1969). Calcitonin decreases the calcium level in blood, and this effect was ascribed to decreased bone resorption. The first report of the use of calcitonin in humans came shortly after its discovery (Foster et al. 1966), and further studies revealed that this hormone actually originates in the C cells of the thyroid gland – which, for a while, gave rise to the use of the name "thyrocalcitonin" (Hirsch and Munson 1969). It has been shown experimentally that calcitonin affects not only bone resorption but also bone formation (Baylink, Morey, and Rich 1969).

Because of the ability of calcitonin to cause a decrease in bone resorption, it has been utilized in the treatment of patients with Paget's disease – a deforming and frequently disabling bone disease diagnosed in England more than a century ago (Paget 1877; Bijvoet, Van der Sluys Veer, and Jansen 1968; Shai, Baker, and Wallach 1971; Woodhouse Bordier, et al. 1971). Two available types of calcitonin, primarily salmon calcitonin but also porcine calcitonin, have been joined by human calcitonin. All three types have been (and still are) used in investigative studies of their comparative effectiveness in treating Paget's disease.

Parathyroid Hormone

Parathyroid hormone (PTH), discovered in the early 1920s (Collip 1925), consists of four small pea-sized structures, two of which are located on the upper pole and two at the lower pole of each thyroid lobe. When parathyroid glands, which produce PTH, are functioning normally, the level of secretion depends on the serum calcium level, which in turn depends, in part, on the fraction of the dietary calcium that is absorbed from the intestine and the amount of calcium released from the skeleton by bone resorption. The dietary contribution of calcium to the serum calcium level influences the extent of bone resorption that is induced by PTH to maintain the well-controlled homeostasis of the normal serum calcium level.

The most common clinical aberration of calcium metabolism in hyperparathyroidism is a high level of serum calcium, a low level of serum phosphorus, and frequently, but not invariably, elevated levels of the serum enzyme alkaline phosphatase. There may also be evidence of bone loss on roentgenograms (which can mimic osteopenia) and, more rarely, cystic bone lesions. Kidney stone formation and peptic ulcer of the stomach may also result.

When there is hyperfunction of any of the four parathyroid glands, and excess PTH is secreted, a pathological condition develops that is called primary hyperparathyroidism. This endocrine disorder that affects bone metabolism (primarily the metabolism of calcium and phosphorus) was discovered in the early 1920s in Vienna and discussed in print two years later (Mandl 1926). In 1925, the condition was observed in the United States (Hannon et al. 1930), and shortly after, the first series of patients with hyperparathyroidism in the United States was described (Albright, Aub, and Bauer 1934). A classic study of the parathyroid glands followed in the late 1940s (Albright and Reifenstein 1948).

The symptoms and the treatment of hyperparathyroidism have been extensively discussed in older medical textbooks, which state, as did the classic article by F. Albright, J. C. Aub, and W. Bauer in 1934, that the cause of primary hyperparathyroidism is the enlargement of one or more of the parathyroid glands to form a benign tumor (an adenoma) or a multiple adenomata. However, we now know that the adenoma of a single parathyroid gland or multiple adenomata of the parathyroid glands are the result of hyperfunction of the parathyroid glands – the increased secretion of PTH. The conventional treatment for primary hyperparathyroidism is the surgical removal of the enlarged parathyroid gland or glands.

Reports in the literature also attest to the importance of the role of vitamin D in normal parathyroid function (Mawer et al. 1975). There are also reports of vitamin D deficiency in hyperparathyroidism (Woodhouse, Doyle, and Joplin 1971; Lumb and Stanbury 1974; Mawer et al. 1975; Stanbury 1981), and the use of vitamin D has been recommended for the medical treatment of patients with primary hyperparathyroidism (Woodhouse et al. 1973).

Nutritional Aspects

The nutritional importance of calcium for normal growth and maintenance has been recognized since studies were carried out with experimental animals several decades ago. Those studies that focused on the human calcium requirement, for example, were conducted as early as the 1920s (Sherman 1920), and the importance of calcium in the human metabolism (and its use in therapy) was recognized in the early 1930s (Cantarow 1933). Subsequently, it was shown that a nutritionally high calcium intake resulted in an increased growth rate of children (Stearns, Jeans, and Vandecar 1936; Jeans and Stearns 1938). Textbooks on the importance of calcium began to appear by the late 1930s (Shohl 1939), and the effect of dietary factors on the intestinal absorption of calcium was examined in the early 1940s in a study demonstrating that the presence of dietary protein is necessary for the intestinal absorption of calcium (McCance, Widdowson, and Lehmann 1942).

Early in the 1950s, the interaction in humans of dietary calcium with phosphorus was investigated (Leichsenring et al. 1951), and at about the same time, two studies of the human calcium requirement were carried out in prisons, one in Peru (Hegsted, Moscoso, and Collazos 1952) and one in Scandinavia (Malm 1958). Both of these investigations reported a very low calcium requirement of about 250 mg/day. However, shortly thereafter, it was made clear that a calcium intake of 1,000 mg is necessary to achieve calcium balance (Whedon 1959).

The calcium requirement for skeletal maintenance was investigated at the beginning of the 1970s (Garn 1970), and this study was followed by a determination of the calcium requirement both for middle-aged women (Heaney, Recker, and Saville 1977) and for elderly people (Heaney et al. 1982). In 1984, a strictly controlled metabolic study revealed that 800 mg/day of calcium is insufficient for middle-aged men and that an intake of 1,200 mg is desirable (Spencer, Kramer, Lesniak, et al. 1984). This recommendation was subsequently adopted at a National Institutes of Health Consensus Conference (1995).

As hinted at by the prison studies already mentioned, some investigators believed that humans can adapt to a long-term low calcium intake. Experimentally, however, this was not found to be the case at a calcium intake of 200 mg/day in adults (Spencer and Kramer 1985). It is important to note that bioavailability of calcium for absorption is greatly reduced by substances such as fiber (in large amounts) and phytate in food (Harrison and Mellanby 1934; Mellanby 1949; Ismail-Beigi et al. 1977; Cummings 1978). The negative effect of phytate on calcium has been extensively investigated (Reinhold et al. 1973), but it has also been shown that calcium bioavailability depends on the availability of trace minerals such as copper, iron, and manganese (Strause et al. 1994), and that deficiencies of these trace elements decrease the calcium concentration in bone. The trace element zinc, for example, affects intestinal absorption of calcium in humans (Spencer et al. 1987; Spencer, Norris, and Osis 1992).

The impact of other substances – such as lactose – on the absorption of calcium was reported as early as 1940 (Mills et al. 1940), and 20 years later, a follow-up report was published (Greenwald, Samachson, and Spencer 1963). An extensive review of human calcium requirements was published in the early 1970s (Irwin and Kienholz 1973), and other such surveys have subsequently appeared (Bronner and Peterlik 1995; Bronner and Stein 1995). The suggested recommended dietary allowance (RDA) of calcium in the United States is determined by the Food and Nutrition Board of the National Academy of Science.

Osteoporosis

Osteoporosis is the most common systemic bone disorder in the United States, affecting an estimated 20 million women and perhaps 10 million men. The incidence of osteoporosis is highest for women in the decade after menopause. It occurs much later in men – between the seventh and eighth decades of life. The high incidence of osteoporosis is a major public health problem because of serious complications that may require extensive and costly medical care. The bone loss in women at middle age and older is the result of hormonal deficiency (the loss of estrogen), aging, and other factors that appear to play an important role in causing – or intensifying – the loss of calcium from the skeleton. It has become more and more evident that sufficient calcium intake over the years can play a major role in preventing osteoporosis in later life (Matkovic et al. 1979; Sandler et al. 1985).

The disease develops insidiously over many years, is often asymptomatic, and is frequently discovered accidentally during radiological examination for unrelated medical conditions (Spencer and Kramer 1987). Unfortunately, this means that treatment of osteoporosis is frequently delayed until it is quite advanced, and it may not be detected until complications such as skeletal fractures arise. In the past, physicians assumed that there was no effective treatment available for this disorder. However, in recent years, effective therapeutic modalities have become available for the treatment and even for the prevention of the disease. Among the newer treatment modalities are the biphosphonates (Fogelman et al. 1986; Francis 1995).

When the diagnosis of bone loss is established roentgenographically, osteoporosis is usually advanced, because 30 percent of bone mineral must be lost before the loss will show up on conventional skeletal X rays. The vertebral bodies show poor mineralization and become biconcave; adjacent vertebrae have a "fish-mouth" appearance; and there may be wedging of the involved vertebrae. These changes in bone structure are usually associated with loss of body height, kyphosis, deformity of the chest, and the presence of a "dowager's hump." Routine X rays of the skeleton are not reliable indicators of bone density because of differences in techniques and in subjective interpretations of X-ray findings.

When demineralization of bone is seen on an X ray, this finding does not differentiate between osteoporosis and other demineralizing bone diseases, such as multiple myeloma or hyperparathyroidism. Reliable methods – such as bone density measurements using single and double photon absorptiometry and determining the cortical index – are now available for diagnosing osteoporosis earlier and with more precision than the use of conventional radiographs offers. However, photon absorptiometry (Mazess et al. 1988) is not routinely done because the equipment is not available in all medical centers. Cortical index measurements can be determined by analyzing X rays of the hand and by relating the cortical thickness to the total width of the metacarpal bone.

Another method of determining bone density is radiographic absorptiometry, which utilizes radiographs of the hands and a computer scanner. Newer, sophisticated methods of analyzing bone mass are available in specialized centers. In general, X rays of the thoracic and lumbar spine can indicate the potential existence of postmenopausal osteoporosis. Bone biopsies (needle biopsies) can establish the differential diagnosis of osteoporosis, but this technique is invasive and not acceptable to many patients.

As already noted, a low calcium intake, over prolonged periods of time, results in calcium loss from the skeleton and in a negative calcium balance (Table IV.B.1.1). This condition has an adverse effect on the maintenance of the normal bone structure, and a continued loss of calcium from the skeleton results from bodily efforts to maintain a normal serum calcium level. Moreover, a low calcium intake stimulates the parathyroid glands to excess secretion of PTH, which in turn leads to increased bone resorption in order to maintain the homeostasis of the normal serum calcium level.

Table IV.B.1.1. *Calcium balances of males and females during a low calcium intake*

Number of patients	Type of patient	Study days	Calcium, mg/day			
			Intake	Urine	Stool	Balance
10	Male	36	214	104	196	–86
10	Female	30	192	92	174	–74

The retention of calcium from a high calcium intake, however, is frequently lower for those with osteoporosis than it is for nonosteoporotic subjects or for patients who suffer from other conditions of bone loss, such as hyperparathyroidism or hyperthyroidism. The absorption of calcium from the intestine is decreased in elderly persons, including osteoporotic females. This appears to be caused in part by a relative vitamin D deficiency that occurs with aging (Tsai et al. 1984) but may also result from generalized functional changes of the intestinal mucosa with age, relating to the absorbability of nutrients in general.

Yet even when calcium is administered by the intravenous route (bypassing the intestine), the retention of calcium is low in osteoporotic patients, indicating the inability of the skeleton to accept the added calcium that has entered the circulation directly (Spencer, Hausinger, and Laszlo 1954). Blood levels of the active vitamin D metabolite $1,25(OH)_2D_3$ have been shown to be low in these patients (Tsai et al. 1984). In the differentiation of calcium loss in conditions other than osteoporosis, the determination of urinary hydroxyproline and of free cortisol levels may be helpful.

Although calcium is the major mineral of the bone structure, other minerals – such as phosphorus, magnesium, zinc, and fluoride – are also important because of the interaction of calcium with these elements and their specific functions in the body. Before these interactions are considered, however, the calcium requirement – the amount of calcium needed to maintain a normal calcium status – requires some attention. The data employed in the following discussion were derived from studies carried out under strictly controlled dietary study conditions in the Metabolic Research Unit at the Veterans Administration (VA) Hospital at Hines, Illinois.

The Calcium Requirement

An adequate intake of calcium throughout life has been shown to play an important role in maintaining the normal bone structure and to contribute to the peak bone mass that is achieved at between 25 and 30 years of age (Heaney 1982; Heaney et al. 1982). The bone mass begins to decline after age 35, and this decrease accelerates in females after the menopause. One can safely assume that the adverse and deleterious effects of aging on the bone mass and on the bone structure would be diminished in advancing age if the skeleton could be more robust at the time when the inevitable and accelerated bone loss begins.

In view of these considerations, the questions arise: What should be the daily calcium intake for the elderly? Is the RDA for calcium adequate for this age group (National Research Council 1989)? For calcium, the RDA for young persons up to the age of 24 years is 1,200 mg, but it is reduced to 800 mg/day for all age groups after age 25, including elderly women (National Research Council 1989). It therefore has seemed important to examine whether the 800 mg calcium intake is adequate to maintain a normal calcium balance at middle age (and to prevent excessive calcium and bone loss) and thereby maintain a normal calcium status and a normal skeletal structure in women with advancing age.

Our studies showed that the calcium balance of middle-aged males was only slightly positive, +30 mg/day with an intake of 800 mg calcium (Table IV.B.1.2) – without considering the dermal loss of calcium, which is usually not determined in metabolic balance studies. The latter is stressed because in calcium balance studies, only the urinary and fecal calcium excretions are determined, and the sum of these excretions is related to the calcium intake. A large percentage of these fully ambulatory middle-aged males (34 percent) were in negative calcium balance at the 800 mg/day intake level. Increasing the calcium intake from 800 to 1,200 mg/day resulted in a significant increase of the calcium balance (Spencer, Kramer, Lesniak, et al. 1984). Yet adding another 800 or even 1,100 mg calcium to the 1,200 mg intake did not significantly improve the calcium balance (Table IV.B.1.2). Such a plateau of the calcium balance at the 1,200 mg calcium intake indicates a threshold for the intestinal absorption of calcium at this level (Spencer and Kramer 1987).

Table IV.B.1.2 also shows that urinary calcium was the same whether the calcium intake was 800, 1,200, or 2,000 mg/day. Only when the calcium intake was increased further – to 2,300 mg/day – did urinary calcium increase. This point is emphasized because of the widespread – and unjustified – concern that increasing the calcium intake beyond the 800 mg level may result in kidney stone formation. Such a concern does become important, however, if there is a history of kidney stone formation or even a family history of renal stones, because a certain percentage of kidney stone formers are hyperabsorbers of calcium.

Although these findings came from studies carried out in an all-male VA hospital, there is no reason to assume that they would not also apply to females of similar age (average 54 years) or older. Indeed, in view of the large percentage of the male subjects with negative calcium balances at the 800 mg calcium intake level, and in view of the known calcium loss suffered by middle-aged and older women, it seems clear that the calcium intake of older women should be at least as great as that of considerably younger persons – that is, 1,200 mg/day (National Research Council 1989). Thus, some have recommended that the calcium intake of postmenopausal women should be increased to 1,500 mg/day (Heaney 1982).

Table IV.B.1.2. *Studies of the calcium requirement*

Calcium intake, mg/day	Calcium, mg/day			
	Intake	Urine	Stool	Balance
200	250	85	265	-100
800	820	180	610	+30
1,200	1,250	170	980	+100
2,000	2,060	175	1,750	+135
2,300	2,350	245	1,945	+160

Note: Calcium intake greater than 250 mg was due to the addition of calcium gluconate tablets to the constant low-calcium diet.

It is also important to consider that although calcium intake may be adequate, there are certain factors that influence the utilization of calcium. The following subsections describe the effects of various minerals, nutrients, and drugs – phosphorus, magnesium, fluoride, zinc, strontium, protein, alcohol, and medications – on the metabolism of calcium.

Phosphorus

The mineral phosphorus is present in practically all cells of the body and is closely linked to the metabolism of both calcium and protein. The main storehouse of phosphorus is the skeleton, and the bone crystal hydroxyapatite consists of calcium phosphate. But significant amounts of phosphorus are also contained in the soft tissues. Calcium cannot be retained by itself in bone but is retained together with phosphate. In fact, in calcium balance studies, the retention of calcium improved during high phosphorus intakes (Spencer et al. 1965; Spencer, Kramer, Osis, et al. 1978a).

These observations were made during a high phosphorus intake of 2,000 mg/day, compared with a phosphorus intake of 800 mg/day in the control study. But although the phosphorus intake was increased by a factor of approximately 2.5 (from 800 to 2,000 mg/day) in these investigations, no adverse effect of phosphorus on calcium absorption or calcium balance was observed, regardless of whether the high phosphorus intake was given during a very low calcium intake of 200 mg/day or during a high calcium intake of 2,000 mg/day (Spencer et al. 1965; Spencer, Kramer, Osis, et al. 1978a).

With a high phosphorus intake, fecal calcium was slightly but not significantly increased. Therefore, the intestinal absorption of calcium, determined with tracer doses of ^{47}Ca, was also not decreased (Spencer

Kramer, Osis, et al. 1978a). This result is in contrast to the general unjustified belief that a high phosphorus intake decreases humans' intestinal absorption of calcium. Such an assumption is based primarily on animal studies (Draper, Sie, and Bergan 1972; LaFlamme and Jowsey 1972).

The difference in effect, however, points out the difficulty and unreliability of extrapolating animal data to humans. Very few, if any, strictly controlled dietary studies of the effect of phosphorus on calcium absorption have been carried out in humans, and it is possible that amounts of phosphorus greater than 2,000 mg/day may have adverse effects on calcium absorption. The recently reported beneficial effect of biphosphonates in the treatment of osteoporosis (Watts et al. 1990) may result from the action of phosphate in inhibiting bone resorption by decreasing the activity of the osteoclasts (the bone-reabsorbing cells) (Hodsman 1989). Inorganic phosphate has been reported to have this effect (Yates et al. 1991). The usual dietary phosphorus intake is approximately 1,200 mg/day, most of it from proteins in dairy products and meat.

The main impact of added phosphorus on calcium metabolism is a consistent decrease in urinary calcium, regardless of whether the high phosphorus intake occurs during a low or high calcium intake (Goldsmith et al. 1967; Goldsmith et al. 1969; Spencer, Kramer, Osis, et al. 1978a). The decrease in urinary calcium during a high phosphorus intake is usually believed to reflect decreased calcium absorption. However, as already noted, the intestinal absorption of calcium did not decrease during a high phosphorus intake (Spencer, Kramer, Osis, et al. 1978a). Although there was a slight increase in fecal calcium during the high phosphorus intake in our studies (Spencer et al. 1965; Spencer, Kramer, Osis, et al. 1978a), this increase was not significant.

Several factors other than a decrease in calcium absorption can contribute to the decrease in urinary calcium during a high phosphorus intake; these include decreased bone resorption, increased mineralization, and increased bone formation (Pechet et al. 1967; Flanagan and Nichols 1969). As the intestinal absorption of calcium did not decrease during different high phosphorus intakes up to 2,000 mg/day, the dietary Ca:P ratio does not appear to play an important role in the intestinal absorption of calcium. This viewpoint was also expressed in 1962 by the World Health Organization.

The importance of phosphorus in human health and in calcium metabolism is indicated by the deleterious effects of phosphorus depletion, which is most commonly induced by the use of medications such as aluminum-containing antacids. Even relatively small doses of such antacids induce a considerable loss of calcium (Spencer, Kramer, Norris, et al. 1982). In addition, small doses – as well as larger therapeutic doses (Lotz, Zisman, and Bartter 1968) – induce phosphorus depletion by the complexation of phosphate through aluminum in the intestine. This is evidenced by a very significant increase in fecal phosphorus, which may be as great as the entire dietary phosphorus intake (Table IV.B.1.3).

The loss of phosphorus via the intestine may lead to its removal from bone in order to maintain the phosphorus level in tissues, enzymes, and plasma. The removal of phosphorus from bone appears to be associated with simultaneous removal of calcium from the skeleton, resulting in an increase in urinary calcium and a negative calcium balance. Thus, significant bone loss has been observed in patients who have taken commonly used aluminum-containing antacids for prolonged periods of time.

The prolonged use of intravenous fluids in the absence of food intake may also result in phosphorus depletion, which is associated with clinical symptoms of weakness and fatigue. To our knowledge, no data are available on the relationship of this type of induced phosphorus depletion and calcium metabolism.

Magnesium

Magnesium is an essential nutrient of great importance in controlling normal cardiac rhythm and cardiovascular function. A low magnesium status has been associated with cardiac arrhythmia as well as with cerebrovascular spasm (Altura and Altura 1981). The RDA for magnesium is 300 mg for women and 400 mg for men (National Research Council 1989). Bone is an important repository for magnesium.

Table IV.B.1.3. *Effect of aluminum-containing antacids on the calcium and phosphorus balance*

		Calcium, mg/day				Phosphorus, mg/day			
Patient	Study	Intake	Urine	Stool	Balance	Intake	Urine	Stool	Balance
1	Control	231	89	229	-87	845	533	323	-11
	Maalox[a]	225	123	264	-132	862	138	673	+51
2	Control	254	86	240	-72	933	482	299	+152
	Maalox[b]	279	421	380	-522	873	18	890	-35

[a] Aluminum-magnesium hydroxide, 30 ml three times daily.

[b] Every hour while awake (15 doses = 450 ml per day).

Magnesium balance studies have shown great variability of the magnesium balance in different individuals, regardless of magnesium intake. During a relatively low magnesium intake of about 220 mg/day, the magnesium balance is usually negative. However, equilibrium or even positive magnesium balances have been observed during a low magnesium intake in our studies on male subjects (Spencer, Lesniak, Kramer, et al. 1980).

The intestinal absorption of dietary magnesium is approximately 50 percent of its intake in persons with normal renal function, regardless of calcium intake (Spencer, Schwartz, and Osis 1988). In contrast, patients with chronic renal failure absorb considerably less magnesium, about one-third that of those with normal renal function (Spencer, Lesniak, Gatza, et al. 1980). It appears that magnesium balance depends on both the present and the past magnesium status of the individual. This was demonstrated by increasing the magnesium intake in adequately nourished subjects from a low of 220 to a relatively high 800 mg/day. Such an increase, however, did not improve magnesium balance when compared with intakes of 220 to 300 mg/day. It would appear, therefore, that the diet of these patients prior to the magnesium absorption studies contained an adequate amount of magnesium.

The interaction of magnesium with calcium warrants discussion because magnesium has been reported to have variable effects on the intestinal absorption of calcium. Reports of some animal studies have suggested that magnesium decreases the intestinal absorption of calcium (O'Dell 1960). But other studies have indicated no change in humans (Schwartz et al. 1973), and still others have reported an increase in calcium absorption. Our investigations under controlled dietary conditions have shown that increasing the magnesium intake more than threefold – from 220 to 860 mg/day – had no effect on the intestinal absorption of calcium (Spencer et al. 1994).

Changing the focus to the effect of calcium on magnesium metabolism, we find reports of the intestinal absorption of magnesium being impaired by calcium in animals (Morris and O'Dell 1961). By contrast, however, our studies on humans – employing both magnesium balance studies and tracer studies using radioactive magnesium (Mg^{28}) – have conclusively shown that both intestinal absorption of magnesium and the magnesium balance did not change when the calcium intake was increased from 200 to 800 and even to 2,000 mg/day (Schwartz et al. 1973).

As phosphorus and calcium are closely linked, the effect of phosphorus on the metabolism of magnesium might warrant brief mention. Whereas phosphorus, like calcium, decreased the absorption of magnesium in animals (O'Dell 1960), increased amounts of phosphorus – up to 2,000 mg/day – had little effect on the magnesium balance of humans (Spencer, Lesniak, Kramer, et al. 1980), regardless of whether these studies were carried out during a low or high calcium intake. However, a high magnesium intake led to increased fecal phosphorus excretion and to a less positive or even negative phosphorus balance, probably because of the formation of magnesium-phosphate complexes in the intestine. But despite this effect, the calcium balance was not affected (Spencer et al. 1994). Further studies of the effect of magnesium on phosphorus metabolism in humans are needed. Such studies should seek to determine at which level a high magnesium intake has adverse effects on phosphorus metabolism and, potentially therefore, on calcium metabolism.

Fluoride

Fluoride enters the human food chain because of the fluoride content of water and soil. The skeleton is its major repository in the body. Not only is fluoride beneficial in preventing dental caries in children, but there is evidence that it is also important in maintaining the normal bone structure (Zipkin, Posner, and Eanes 1962). Consequently, fluoride affects the metabolism of calcium. Surveys in the United States and in Finland have demonstrated that the prevalence of osteoporosis is lower in places where the water is naturally high in fluoride content than in areas where this condition does not obtain (Bernstein, Sadowsky, and Hegsted 1966).

Because the main storehouse of fluoride is the skeleton, where it is incorporated in the bone crystal hydroxyapatite (leading to its increased strength) (Zipkin et al. 1962), fluoride has been used for the treatment of osteoporosis since the early 1960s (Rich, Ensinck, and Ivanovich 1964; Spencer et al. 1970). As fluoride may interact with various minerals, such as calcium, phosphorus, and magnesium, we investigated the human metabolism of fluoride during the intake of these inorganic elements. During a fluoride intake as high as 45 mg/day (taken as sodium fluoride), the single effect on calcium metabolism was a decrease in urinary calcium, whereas no change occurred in fecal calcium, the intestinal absorption of calcium, and endogenous fecal calcium (the amount of the absorbed calcium excreted into the intestine) (Spencer et al. 1970). There was also little change in the calcium balance, which depended on the decrease in urinary calcium during the high fluoride intake. Increasing phosphorus intake by a factor of 2.5, from 800 to 2,000 mg/day, had no effect on the fluoride balance, regardless of calcium intake (Spencer et al. 1975). Also, increasing magnesium intake approximately threefold during a high fluoride intake had no effect on the fluoride balance (Spencer, Kramer, Wiatrowski, et al. 1978). Several biochemical and therapeutic aspects of the fluoride metabolism in humans have been summarized (Spencer, Osis, and Lender 1981).

Zinc

The importance of the trace element zinc in human health and nutrition has been emphasized in recent decades. The RDA of zinc is 15 mg/day for men and

12 mg/day for women (National Research Council 1989). Zinc and calcium appear to have the same binding sites in the intestine, and, therefore, the absorption and utilization of one may be inhibited by the other. Animal studies have shown that calcium inhibits the intestinal absorption of zinc (Hoekstra et al. 1956; Luecke et al. 1957), but our studies on humans demonstrated that calcium had no effect on the absorption of zinc (Spencer, Kramer, Norris, et al. 1984). Similarly, phosphorus – used in amounts of up to 2,000 mg/day, alone or combined with the same amount of calcium – did not affect the zinc balance nor the net absorption of zinc (Spencer, Kramer, Norris, et al. 1984). These findings contrasted with those obtained in animal studies, with the different results apparently arising from differences in body weights and differences in the amounts of calcium and phosphorus relative to body weight.

Another question was whether zinc affects the intestinal absorption of calcium. Our calcium absorption studies (using ^{47}Ca as the tracer) have conclusively shown that large doses of zinc (140 mg/day of zinc sulfate) significantly decreased the intestinal absorption of calcium when zinc supplements were given during a low calcium intake of 230 mg/day – but not during a calcium intake of 800 mg/day (Spencer et al. 1987). Further investigations have delineated the dose of zinc and the level of calcium intake at which the decrease of calcium absorption would not occur. Decreasing zinc intake from 140 mg to 100 mg during a low calcium intake of 230 mg/day, and decreasing calcium intake from 800 mg to 500 mg during the high zinc intake of 140 mg/day, in both cases had no adverse effect on the intestinal absorption of calcium (Spencer et al. 1992).

Zinc supplements are freely available "over the counter" and are used in unknown dosages by the public with equally unknown intakes of calcium. This practice is of concern for elderly women who may already have a low calcium status and yet may use large doses of zinc during a low calcium intake. Such a combination would decrease the intestinal absorption of calcium and thereby contribute to further deterioration of the state of calcium metabolism in these individuals.

Strontium

Little attention is being paid to strontium, which, like calcium, is primarily deposited in bone. Our studies have shown that the average dietary intake of strontium is low, at 1.5 to 2.5 mg/day (Warren and Spencer 1972, 1976). In 1950, it was suggested that strontium used in conjunction with calcium would be effective in therapy for osteoporosis and that the retention of both calcium and strontium would be additive (Shorr and Carter 1950). About 30 years later, other investigators again demonstrated the beneficial effect of strontium as a therapeutic agent for osteoporosis (Marie et al. 1985). Moreover, our investigations indicated that large amounts of elemental strontium, such as daily doses of 600 to 900 mg (taken as strontium lactate), were well retained and well tolerated. However, it was found that after discontinuation of strontium supplements, a very high percentage of the retained strontium was excreted in three to four weeks (Warren and Spencer 1976).

It may be speculated that this loss of strontium might not have occurred if calcium intake had been high. Some of our preliminary studies show that the intake of added strontium increases the intestinal absorption of calcium, which could be a significant finding. Further examinations of the effect of strontium on the absorption of calcium are needed because very few substances are known to increase the intestinal absorption of calcium.

Protein

Although proteins are not the same sort of nutrients as minerals, the relationship between proteins and the metabolism of calcium is important because proteins play a major role in the formation of the bone matrix and, conversely, have also been reported to bring about an increase in urinary calcium. However, such findings of calcium loss are primarily based on studies using purified proteins (Walker and Linkswiler 1972; Schuette, Zemel, and Linkswiler 1980). Calcium loss does not occur when complex proteins – which are part of the human diet – are used (Spencer, Kramer, Wiatrowski, et al. 1978; Spencer et al. 1983; Spencer, Kramer, and Osis 1988). The widespread belief that "proteins" generally are a cause of calcium loss frequently stems from reports and statements that do not specify or identify the type of protein used. But in considering the calciuric effect of protein in causing calcium loss, it is important to define the source and type of protein: Are the proteins isolated protein fractions, such as specific amino acids, or are they part of complexes of other nutrients, as is usually the case in the human diet?

Our studies, carried out under strictly controlled dietary conditions, have conclusively shown that a high protein intake (using red meat as its source, in large amounts of up to 550 g of meat per day) did not increase urinary calcium excretion (Spencer, Kramer, Osis, et al. 1978b; Spencer et al. 1983). Such a diet was given daily for as long as four months, and an example of the effect of this type of dietary protein on urinary calcium is shown in Table IV.B.1.4.

Moreover, during this high protein intake, there was no change in fecal calcium, nor in calcium balance, nor in the intestinal absorption of calcium, as determined in ^{47}Ca absorption studies. As already discussed, phosphorus decreases urinary calcium excretion. Dietary protein sources such as meat, milk, and cheese have a high phosphate content, which may explain why urinary calcium does not increase during the intake of these complex proteins. Therefore, the high phosphorus content of complex proteins may prevent and/or counteract any increase in urinary calcium – even with the consumption of red meat, an

Table IV.B.1.4. *Effect of a high-protein diet on calcium metabolism*

Patient	Study	Study days	Calcium, mg/day Intake	Urine	Stool	Balance
1	Control	36	824	111	690	+23
	High protein	36	846	118	683	+45
2	Control	60	824	173	661	−10
	High protein	36	875	157	677	+42

Note: High protein given as red meat; high protein = 2 g/kg body weight compared with 1 gm/kg in the control study.

acid-ash food that would be expected to increase the urinary excretion of calcium (Wachman and Bernstein 1968).

Effects of Excessive Alcohol Consumption

Alcohol cannot be classified as a nutrient. However, chronic alcoholism can lead to bone loss (Feitelberg et al. 1987; Laitinen and Valimaki 1991) and to the development of osteoporosis. The etiology of osteoporosis in this case is multifactorial, but a major cause may well be the poor diet – especially low intakes of calcium, proteins, and vitamin D – associated with prolonged excessive alcohol consumption. Studies have suggested abnormalities in vitamin D metabolism (Gascon-Barre 1985) as well as in the adrenal function (Mendelson, Ogata, and Mello 1971), both of which affect the metabolism of calcium.

Changes in the pancreatic function in chronic alcoholism also lead to a loss of calcium – in this case because of the complexation of calcium with fat in the abdominal cavity – and there may be other factors not yet identified. Table IV.B.1.5 shows the prevalence of osteoporosis in our patients with chronic alcoholism (Spencer et al. 1986). Thirty-one percent were less than 45 years old, and 50 percent of these relatively young patients suffering from chronic alcoholism and osteoporosis were less than 40 years old (Spencer et al. 1986).

Table IV.B.1.5. *Patients with chronic alcoholism and osteoporosis*

Number of patients[a]	Age group, in years	Patients with osteoporosis	Percentage of patients with osteoporosis
5	20–30	–	–
33	31–45	14[b]	31
58	46–62	31	69

[a] All male patients.

[b] Fifty percent of these patients were less than 40 years old.

Table IV.B.1.6. *Effect of corticosteroids on the calcium balance*

Patient	Study	Calcium, mg/day Intake	Urine	Stool	Balance
1	Control	240	185	187	−132
	Corticoids[a]	234	287	177	−230
2	Control	1,955	90	1,733	+132
	Corticoids[b]	1,950	209	1,877	−136

[a] Aristocort, 20 mg/day for 24 days.

[b] Aristocort, 40 mg/day for 60 days.

Effect of Medications

Several medications affect the metabolism of calcium, primarily by increasing urinary calcium and thereby causing calcium loss. The effect of glucocorticoids in causing bone loss and osteoporosis, regardless of gender and age, is well known (Lukert and Adams 1976). Table IV.B.1.6 shows two examples of negative calcium balances during treatment with corticosteroids. These medications increase not only urinary but also fecal calcium, resulting in markedly negative calcium balances. This result occurs during both a low calcium intake of approximately 240 mg/day and an approximate tenfold increase of this amount. The data suggested that the loss of calcium induced by glucocorticoids was dose-dependent.

IV.B.2 Iodine and Iodine-Deficiency Disorders

The term "iodine-deficiency disorders" (IDD) is now used to denote all the effects of iodine deficiency on growth and development (Hetzel 1983). In the past, the term "goiter" was used to describe such effects, but IDD has now been generally adopted in the field of international nutrition and health. In the last 10 years, this reconceptualization has helped to focus more attention on the problem of iodine deficiency. For much of our historical treatment, however, we use the terms "goiter" and "IDD" interchangeably.

Extensive reviews of the global geographic prevalence of goiter have been published. One of these, by F. C. Kelly and W. W. Snedden, appeared as a World Health Organization (WHO) monograph in 1960. A second survey was done more recently by J. Stanbury and B. Hetzel (1980), and the reader is referred to these sources for a closer look at the many countries that still have a significant goiter problem. In general, goiter is associated with elevated areas and regions where there has been leaching of iodine from the soil due to glaciation, snow water, high rainfall, or floods. Thus the great mountain chains of the world, the European Alps, the Himalayas, and the Andes, have become well known as goiter areas, and in fact most mountainous regions throughout the world have iodine-deficient areas.

We now know that in addition to mountainous areas, flooded river valleys, such as those of the Ganges, Brahmaputra, and Irawaddy Rivers in Southeast Asia, have their soils leached of iodine and thus are also severely deficient in the mineral. These inescapable geographical facts mean that vast populations are at risk of iodine-deficiency disorders, and unfortunately it is likely that soil erosion in modern times is acting to increase the iodine-deficient areas of the world. It is, of course, axiomatic that populations totally dependent on food grown in such soil, as in systems of subsistence agriculture, will become iodine deficient.

History of Goiter and Cretinism

Descriptions and speculations about goiter and cretinism (the best-known iodine-deficiency disorders) go back to the ancient world. A historical review provides a fascinating succession of cultural concepts culminating in the twentieth century, when the causative role of iodine deficiency was established and the control of the disorders demonstrated. In the waning years of the twentieth century a global action program was organized in order to eliminate this ancient scourge of humankind by the beginning of the new millennium.

The Ancient Civilizations

An old reference to goiter is attributed to a mythical Chinese cultural hero, Shen-Nung. In his book *Shennung pen-ts'ao ching* (the divine husbandman's classic on materia medica), he is said to mention the seaweed sargassa as an effective remedy for goiter. Goiter is also mentioned in the *Shan Hai Ching* (which probably reached its present form about the second century B.C.), which attributes the disease to the poor quality of water. Other references during the Han dynasty (206 B.C. to A.D. 220) and the Wei dynasty (A.D. 200–264) mention deep mental emotions and "certain conditions of life in the mountain regions" as causes of goiter. The treatment of goiter with sargassa weeds is mentioned by the famous early-fourth-century Chinese medical writer Ge Hong. The Chinese also employed animal thyroid in the treatment of goiter – the use of deer thyroid is mentioned in a sixth-century text. Animal thyroid continued to be used in China and is discussed again by an eminent Chinese physician, Li Shih-chen, in his well-known 1596 herbal *Pen-ts'ao kang-mu* (materia medica arranged according to drug descriptions and technical aspects), in which preparations of pig and deer thyroid are mentioned. The continued use of seaweed and animal thyroid over so many hundreds of years in China suggests that there was certainly some benefit derived from these measures in the treatment of goiter.

Elsewhere in the ancient world there is less mention of the disease. In ancient Hindu literature incantations against goiter may be found in the Veda *Atharva* dating from around 2000 B.C. According to the Ebers papyrus, tumors of the neck were also known in ancient Egypt, where they were treated surgically.

In the famous fourth-century B.C. volume *Airs, Waters, and Places,* attributed to Hippocrates, drinking water was regarded as a cause of goiter. At about the beginning of the Christian era, Aulus Celsus described a fleshy tumor of the neck, which he incised to find that it contained honey-like substances and even small bones and hairs (probably a long-standing goiter). It was subsequently deduced by the Roman physician Galen in the second century A.D. that the glands of the neck, including the thyroid, had the function of secreting a fluid into the larynx and the pharynx. Such views continued to be accepted for many centuries and were held by such famous seventeenth- and eighteenth-century physicians as Marcello Malpighi and Herman Boerhaave.

Medieval Europe

It is of interest to note the attention given to goiter in paintings and sculptures of the Middle Ages. The late Professor F. Merke of Berne unearthed a number of fascinating examples from manuscripts and churches. The earliest depiction of goiter and cretinism is in a book in the Austrian National Library in Vienna – the *Reuner Musterbuch* – dating from 1215. The book was originally from the Cistercian Abbey in Reun near the city of Graz in Styria (Austria), where goiter was highly endemic until recent times. The picture (Figure IV.B.2.1) shows a figure with three large goiters and a stupid facial expression, brandishing a fool's staff in one hand while reaching up with the other toward a toad. This was doubtless a goitrous cretin. It was common to depict a fool grasping a cudgel as shown in this figure. The significance of the toad may be related to the popular use of live or dismembered frogs for the treatment of goiter. As Merke points out, this picture of the Reun cretin predates by some 300 years the recognition of the relationship between goiter and cretinism by Paracelsus (Philippus Aureolus Theophrastus Bombastus von Hohenheim).

According to F. de Quervain and C. Wegelin (1936), the term "cretin" most likely comes from the words "Christianus" or "Crestin" in the southeastern French dialect – referring to a *bon chrétien* because of the innocence of these subjects. These sufferers were in fact given special recognition in the medieval world and often regarded as angels or innocents with magical powers (Merke 1984). Clearly the Church did its best to fit them into the prevailing religious culture.

The Renaissance

Felix Plattner of Basel wrote a classic description of goiter and cretinism following a 1562 visit to the Valais:

> In Bremis, a village of the Valais, as I have seen myself, and in the Valley of Carinthia called Binthzgerthal [today the Pinzgau], it is usual that many infants suffer from innate folly [simplemindedness]. Besides, the head is sometimes misshapen: the tongue is huge and swollen; they are dumb; the throat is often goiterous. Thus, they present an ugly sight; and sitting in the streets and looking into the sun, and putting little sticks in between their fingers [a stick resting between their hands], twisting their bodies in various ways, with their mouths agape they provoke passersby to laughter and astonishment. (Langer 1960: 13–14)

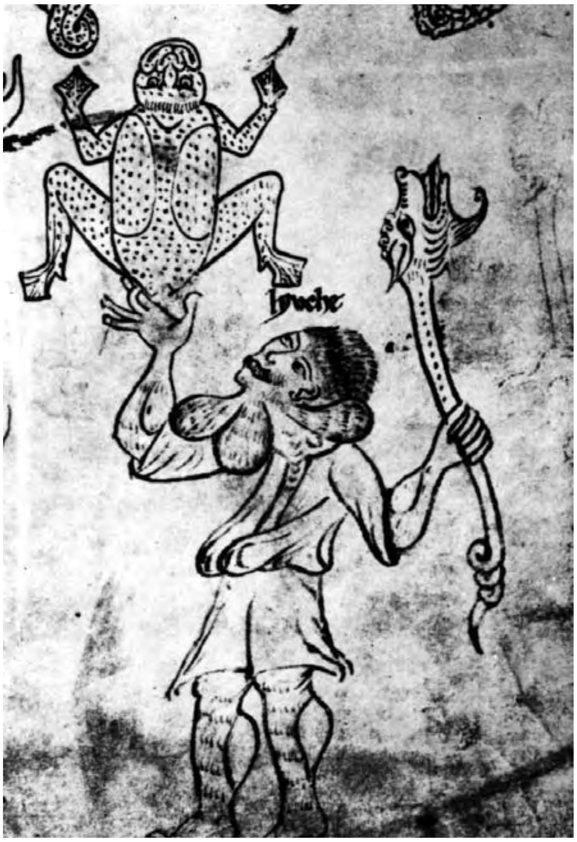

Figure IV.B.2.1. "The Reun cretin" from the Reun Model Book, *Reuner Musterbuch,* produced by the Cistercian Abbey at Reun (near Graz), Austria, and dating from 1215. This model book covers everything that an educated "clericus" of the thirteenth century had to know. The cretin has a large trilobed goiter with the third lobe strung over the left shoulder. His right hand clutches at a frog (possibly for healing), and his left hand holds the "fool's scepter" in order to make the mental deficiency clear. (From Merke 1984, with permission.)

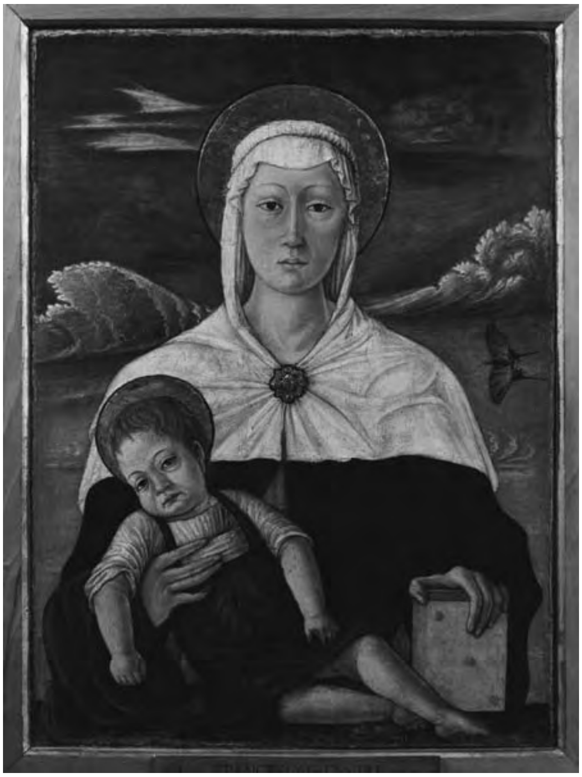

Figure IV.B.2.2. Madonna and child by Francesco di Gentili, fifteenth century. The madonna has a goiter and her child looks hypothyroid. (Pinacoteca, Vatican Museums, Rome; photo, Art Resource, New York.)

A study of goiter in sixteenth-century art was made by H. Hunziger (1915); the disease can be readily observed in the Madonnas of the Renaissance. Works by masters such as Jan van Eyck and Lucas Van der Leyden portray it, as do other paintings in the Sienese and Vatican galleries (Figure IV.B.2.2). All this may indicate that the condition was virtually accepted as normal because it was so common. In a later period goiter is also to be seen in the paintings of Peter Paul Rubens, Rogier van der Weyden, and Albrecht Dürer.

During the Renaissance, goiter was believed to be curable by the touch of a king. According to the king's personal physician, Henry IV of France caused 1,500 goiters to regress by touching the patient and using the formula "Le Roi te touche et Dieu te guerit." The "touch" was also practiced by many English kings; Charles II is alleged to have touched 9,200 persons suffering from the "King's Evil" or scrofula (with which goiter was often confused). According to newspaper reports, on March 20, 1710, Queen Anne revived the ancient custom of curing goiter and scrofula by the laying on of hands. As we pointed out, however, in the sixteenth century Paracelsus had recognized the association of goiter and cretinism and attributed the disease to a deficiency of minerals in drinking water. This reasoning rather neatly contrasts the scientific approach with the magic of the King's Touch!

The Seventeenth Century

The study of human anatomy prospered following the sixteenth-century pioneering work of Andreas Vesalius, Matteo Realdo Colombo, Hieronymus Fabricius ab Aquapendente, and Bartolomeo Eustachi. All of these anatomists noted the thyroid gland, which was called the "glandulus laryngis" by Vesalius. Fabricius recognized the connection between the glandulus laryngis and goiter. But the first clear description of the gland was penned in Latin in 1656 by an Englishman, Thomas Wharton (the translated title is *Adenography, or a Description of the Glands of the Entire Body*). Nonetheless, in the seventeenth century the function of the thyroid was not understood. It was usually regarded as secreting a fluid to "humidify" the walls of the larynx, the pharynx, and the trachea. In fact, the function of the thyroid was not understood until the latter part of the nineteenth century, when it was recognized to have an "internal" secretion in the form of the thyroid hormone, and not an external one.

The Eighteenth Century

In the eighteenth century there was a great escalation in scientific observations and the reporting of such observations. Many of these were collected in Denis Diderot's *Encylopédie* (1751–72), in which the term "cretin" appeared in print for the first time in an article by Diderot's co-editor Jean Le Rond d'Alembert. His definition of a cretin was that of "an imbecile who is deaf, dumb with a goiter hanging down to the waist."

The Nineteenth Century

Interest in and concern about the possibility of the control of goiter accelerated in the early nineteenth century when Napoleon Bonaparte ordered a systematic investigation of the disease. He did so because large numbers of young men from certain regions were being rejected as unfit for military duties. Moreover, Napoleon himself had probably seen something of the problem during his march into Italy through the goiter-infested Valais.

Iodine was isolated from the ashes of the seaweed *Fucus vesicularis* by B. Courtois in France in 1811, and in 1820 Jean François Coindet recommended iodine preparations for the treatment of goiter. However, soon afterward marked opposition developed to its employment because of the occurrence of symptoms of toxicity, which we now know was the result of excessive thyroid secretion.

The iodination of salt was first suggested by Jean Baptiste Boussingault, who resided for many years in Colombia in South America. The people among whom he lived obtained their salt from an abandoned mine and felt that this salt conferred special health benefits. In 1825 Boussingault analyzed the salt and found that it contained large quantities of iodine. In 1833 he suggested that iodized salt be used for the prevention of goiter. Unfortunately, an experiment carried out in France once more obscured the importance of iodine in the etiology of the disease. Goitrous families received salt fortified with 0.1 to 0.5 grams (g) of potassium iodide per kilogram (kg) of salt. But the high dosage produced symptoms of an excess thyroid secretion and consequently the treatment again fell into disrepute.

The Twentieth Century

Present-day practice in the prevention and control of goiter is based on the work of David Marine, who in 1915 declared that "endemic goitre is the easiest known disease to prevent." Marine and his colleague, O. Kimball, carried out the first large-scale trials with iodine in Akron, Ohio, from 1916 to 1920. About 4,500 girls between 11 and 18 years of age took part in the experiment. Roughly half of this group had goiter; the other half had normal thyroid activity. Of the group, 2,190 girls were given a daily dose of 0.2 g of sodium iodide in water for 10 days in the spring and 10 days in the autumn, making a total dose of 4.0 g over the year. The remaining 2,305 girls acted as controls. Two facts stand out from the data generated by this experiment: (1) In the group receiving sodium iodide, of 908 girls with a normal thyroid prior to treatment, only 2 (0.2 percent) developed goiter; however, in the control group, of 1,257 girls with previously normal thyroid, goiter appeared in 347 (27.6 percent); (2) in the group treated for goiter, 773 out of 1,282 girls with the disease (60.4 percent) showed a considerable decrease in the size of the thyroid, whereas in the control group, spontaneous regression of the goiter occurred in only 145 out of 1,048 girls (13.8 percent).

Thus both the prophylactic and the therapeutic effects were impressive. Iodism was very rare (only 11 cases) in spite of the extremely large doses of iodine, and the symptoms disappeared within a few days of stopping the administration of sodium iodide.

Mass prophylaxis of goiter with iodized salt was first introduced in 1924 on a community scale in Michigan (Kimball 1937), where it seems probable that the last glaciation had rendered the soil iodine deficient in that state and throughout much of the Great Lakes region. Goiter surveys of schoolchildren and iodine analyses of their drinking water were carried out in four representative counties, where the average goiter rate among 65,537 children was 38.6 percent. Table salt containing 1 part in 5,000 of potassium iodide was then introduced into the children's diet. By 1929 the average goiter rate had fallen to 9 percent. Moreover a follow-up survey conducted by B. Brush and J. Altland (1952) on 53,785 schoolchildren in the same counties showed a goiter rate of only 1.4 percent. It was also reported that in seven large hospitals in Michigan thyroidectomies accounted for only 1 percent of all operations in 1950 compared with 3.2 percent in 1939. No toxic symptoms of iodide prophylaxis were observed.

The impact of iodized salt on the control of goiter was also vividly demonstrated in Switzerland. As this country is situated in the elevated region of the European Alps, the burden of goiter and cretinism was great throughout the country. In 1923, for example, the Canton of Berne, with a population of about 700,000, had to hospitalize 700 cretins incapable of social life. But with the Cantons' introduction of iodized salt, which proceeded throughout the 1920s, goiter rates fell steeply, and "deaf and dumb institutions" were later closed or used for other purposes.

Observations of Swiss Army recruits revealed definite evidence of this trend of rapid decline throughout the country. Between the years 1925 and 1947, the number of exemptions for military service fell from 31 to less than 1 per thousand. Moreover, following 60 years of the use of iodized salt in Switzerland, a recent review has made clear the benefits it provided in the prevention of all degrees of neurological damage in the Swiss population (Burgi, Supersaxo, and Selz 1990). Indeed, it is now clear that the "spontaneous" disappearance of cretinism throughout Europe was due to a dietary increase in iodine intake. The continued persistence of iodine deficiency and, consequently, goiter and cretinism in Europe is mainly associated with more isolated rural areas that have not undergone the sort of social and economic development that leads to dietary diversification. But even these cases could be completely prevented with the effective distribution of iodized salt.

Goiter and Iodine Deficiency

Iodine deficiency causes depletion of thyroid iodine stores with reduced daily production of the thyroid hormone (T_4). A fall in the blood level of T_4 triggers the secretion of increased amounts of pituitary thyroid stimulating hormone, which increases thyroid activity with hyperplasia of the thyroid. An increased efficiency of the thyroid iodide pump occurs with faster turnover of thyroid iodine, which can be seen in an increased thyroidal uptake of radioactive isotopes ^{131}I and ^{125}I. These features were first demonstrated in the field in the now classic observations of Stanbury and colleagues (1954) in the Andes of Argentina.

Iodine deficiency is revealed by a determination of urine iodine excretion using either 24-hour samples or, more conveniently, casual samples with determination of iodine content per gram of creatinine. Normal iodine intake is 100 to 150 micrograms per day (µg/day), which corresponds to a urinary iodine excretion in this range (Stanbury and Hetzel 1980). In general, in endemic goiter areas the intake is well below 100 µg/day and goiter is usually seen when the level is below 50 μg/day (Pretell et al. 1972). The rate increases as the iodine excretion falls so that goiter may be almost universal at levels below 10 μg/day. The iodine content of drinking water is also low in areas with endemic goiter (Karmarkar et al. 1974).

Goiter, however, can also arise from causes other than iodine deficiency. Foremost among these are a variety of agents known as goitrogens. Recent research (Ermans et al. 1980; Delange, Iteke, and Ermans 1982) has shown that staple foods from the developing world such as cassava, maize, bamboo shoots, sweet potatoes, lima beans, and millets contain cyanogenic glucosides that are capable of liberating large quantities of cyanide by hydrolysis. Not only is the cyanide toxic but the metabolite in the body is predominantly thiocyanate, which is a goitrogen. Fortunately, these glycosides are usually located in the inedible portions of most plants, or if in the edible portion, in such small quantities that they do not cause a major problem. But such is not the case with cassava, which is cultivated extensively in developing countries and represents an essential source of calories for tropical populations of more than 200 million (Delange et al. 1982).

The role of cassava in the etiology of endemic goiter and endemic cretinism was demonstrated by F. Delange and colleagues (1982) in studies conducted in nonmountainous Zaire, and their observations were confirmed by G. Maberly and colleagues (1981) in Sarawak, Malaysia. One major effect of cassava consumption can be to increase iodine loss from the body by increasing urinary excretion.

It is important to note, however, that chronic consumption of large quantities of cassava does not necessarily result in the development of endemic goiter. Such development depends on the balance between the dietary supply of iodine and the thiocyanate (SCN) generated from the cyanide (hydrocyanic acid [HCN]) content of the cassava. The cyanide content of cassava varies with the linamarin content, and this in turn varies with traditional detoxification processes – including soaking in water before consumption, which greatly reduces the HCN content. However, sun-drying of cassava (as in the Ubangi region of Zaire) is not effective in reducing the HCN content, which can, in turn, produce a high prevalence of goiter and endemic cretinism.

A normal or high iodine intake will protect against the goitrogenic effect of the SCN. In fact, a Belgian group has shown that an iodine to SCN (I:SCN) ratio greater than 7 will achieve this protection. Goiter occurs if the ratio is about 3 and will be of high prevalence when the ratio is below 2. At this low ratio endemic cretinism will also be found in the population.

In summary, four factors will determine the SCN ratio: (1) the level of iodine intake in the diet, (2) the HCN content of fresh cassava roots and leaves, (3) the efficiency of the detoxification process used during the preparation of cassava-based foods, and (4) the frequency and quantity of consumption of these foods.

Cretinism and Iodine Deficiency

The gradual disappearance of cretinism in Europe in the early decades of the twentieth century led to the condition being largely forgotten. But in the 1960s endemic cretinism was virtually rediscovered almost simultaneously in a number of the more remote areas of the world, among them New Guinea, Zaire, India, Indonesia, China, and Brazil.

The clinical manifestations of the condition found in these areas have now been reported in considerable detail (Pharoah et al. 1980), and field studies of thyroid gland function and iodine metabolism have also been made in many countries. Evidence of the association of cretinism with severe iodine deficiency and high goiter rates has been uniformly reported.

One noticeable feature of the condition since its rediscovery has been the occurrence of a wide range of defects in individuals. These range from isolated mental deficiency to deaf-mutism of varying degree to a varying severity of paralysis of the arms and legs. But there are also individuals who appear to be normal apart from some coordination defect, all of which indicates that endemic cretinism is part of a spectrum of defects within an iodine-deficient population. And endemic cretinism is, as we shall see, a community or population disease.

It was R. McCarrison, reporting in 1908 from what was then called the North West Frontier of India (including the Karakoram Mountains, which are now in northern Pakistan), who first clearly distinguished two types of endemic cretins – the "nervous" and the "myxedematous" – from a series of 203 patients whom he had studied. In the nervous type, he recognized mental defect, deaf-mutism, and a spastic diplegia (paralysis) with a spastic rigidity, affecting the legs predominantly, that produced a characteristic walk or gait. Squint was also noted. By contrast, the myxedematous type had all the characteristics of severe hypothyroidism: dry swollen skin and tongue, deep hoarse voice, apathy, and mental deficiency. McCarrison regarded this condition as identical with "sporadic cretinism." He found deaf-mutism present in 87 percent of his 203 cases.

These two types of cretinism are also readily seen in China, where the neurological type is the predominant form. In Hetian district in Xinjiang (only some 300 kilometers east of Gilgit, where McCarrison made his original observations in the first decade of the twentieth century), a similar pattern was observed in 1982 (Figure IV.B.2.3) with neurological, hypothyroid, and mixed types present (Hetzel 1989). Later, these observations in China were confirmed by S. Boyages and colleagues (1988).

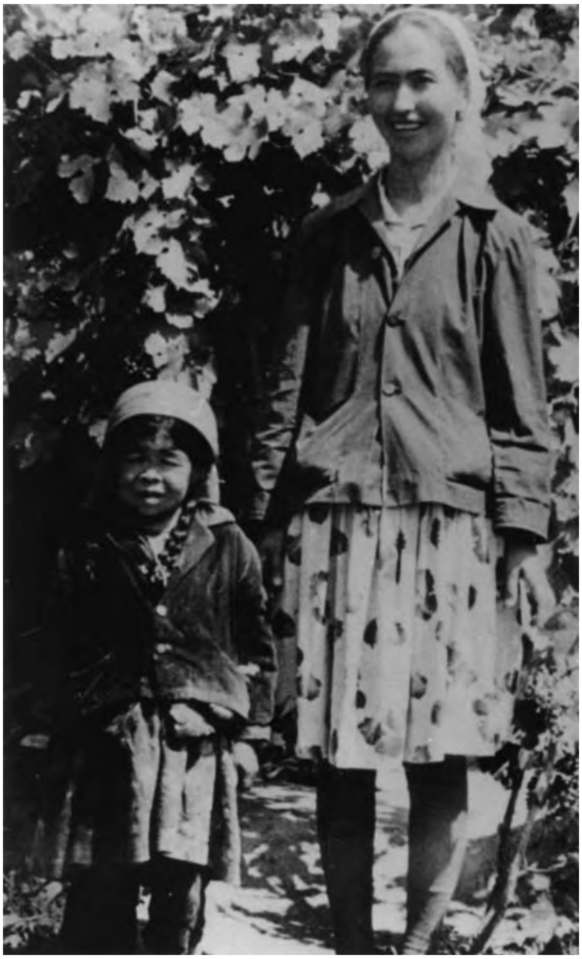

Figure IV.B.2.3. A dwarfed cretin from Xingjiang, China, who is also deaf-mute. This condition is completely preventable. Right: the "barefoot doctor" from her village. Both women are about 35 years of age. (Courtesy of Dr. T. Ma, Tianjin, China.)

It is apparent that these two types of cretinism are distinct conditions. As McCarrison recognized, the features of the myxedematous type are essentially the same as those of sporadic cretinism. However, the myxedematous type is associated with the occurrence of hypothyroidism, which causes endemic cretinism, the latter a result of endemic goiter triggered by severe iodine deficiency in an entire community. By contrast, sporadic cretinism occurs all over the world whether or not iodine deficiency is present. It is usually found with evidence of an absent or misplaced thyroid or with a congenital defect in the biosynthesis of the hormone. To prevent confusion, the term "congenital hypothyroidism" is now generally preferred to sporadic cretinism.

It is now established that endemic cretinism, in its fully developed form characterized by severe mental deficiency, deaf-mutism, and spastic diplegia, is epidemiologically associated with high rates of goiter and severe iodine deficiency (levels of 25 μg/day or less compared to a normal intake of 80–150 μg/day), whereas goiter alone is seen at levels below 50 μg/day (Pharoah et al. 1980; Hetzel and Maberly 1986; Hetzel, Potter, and Dulberg 1990). However, as mentioned previously, the apparent spontaneous disappearance of endemic cretinism in southern Europe raised considerable doubt about its relationship to iodine deficiency (Hetzel 1989).

The hypothesis that there was such a relationship was tested for the first time in a controlled trial beginning in the 1960s. Such testing was made possible by the development of a new method for correction of severe iodine deficiency in Papua New Guinea in the form of the injection of iodized oil (McCullagh 1963; Buttfield et al. 1965; Buttfield and Hetzel 1967). Iodized oil or saline injections were given to alternate families in the Jimi River District in the Western Highlands at the time of the first census (1966). Each child born subsequently was examined for evidence of motor retardation, as assessed by the usual measurements involving sitting, standing, or walking, and for evidence of deafness. Examination was carried out without knowledge as to whether the mother had received iodized oil or saline injections (Pharoah, Buttfield, and Hetzel 1971).

Infants presenting with a full syndrome of hearing and speech abnormalities, together with abnormalities of motor development with or without squint, were classified as suffering from endemic cretinism. By these criteria, there were 7 cretins born to women who had received iodized oil out of a total of 687 children. In 6 of these 7 cases, conception had occurred prior to the iodized oil injections (Figure IV.B.2.4). In the untreated group, there were 25 endemic cretins out of a total of 688 children born since the trial began. In 5 of these 25, conception had occurred prior to saline being given.

It was concluded that an injection of iodized oil given prior to a woman's pregnancy could prevent the occurrence of the neurological syndrome of endemic cretinism in the infant. The occurrence of the syndrome in those who were pregnant at the time of oil injection indicated that the damage probably occurred during the first half of pregnancy (Pharoah et al. 1971).

Subsequent studies in Papua New Guinea have revealed a motor coordination defect in apparently normal children subjected to severe iodine deficiency during pregnancy (Connolly, Pharoah, and Hetzel 1979; Pharoah et al. 1981). There is also evidence of an associated intellectual defect (Pharoah et al. 1984; Fierro-Benitez et al. 1986). Thus it is apparent that the effects of severe iodine deficiency in pregnancy go beyond endemic cretinism to affect children in other unpleasant ways. Such observations have been confirmed in Indonesia and Spain (Bleichrodt et al. 1987) and in China (Boyages et al. 1989).

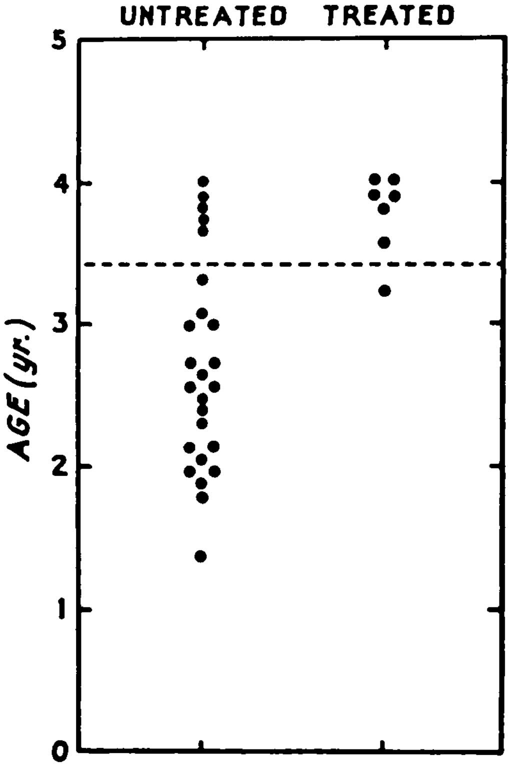

Figure IV.B.2.4. The results of a controlled trial of iodized oil injection in the Jimi River district of the highlands of Papua New Guinea. Alternate mothers were given an injection of iodized oil and saline in September 1966. All newborn children were followed up for the next five years. Each dot represents a cretin child. The figure shows that mothers given iodized oil injections do not have subsequent cretin children, in comparison with the persistence in the untreated group. (From Pharaoh et al. 1971, with permission.)

The importance of the link between iodine deficiency and brain development has led to animal model studies that shed light on the relationship and the mechanisms involved. These studies have revealed reduced brain weight with a reduced number of brain cells during and at the end of pregnancy in iodine-deficient rats, sheep, and marmosets (Hetzel, Chevadev, and Potter 1988). The effect of iodine deficiency is mediated through reduced secretion (by both the maternal and fetal thyroids), which in turn is associated with severe fetal hypothyroidism. To date, the syndrome of neurological cretinism has not been reproduced in an animal species (Hetzel et al. 1988).

The Iodine-Deficiency Disorders

Our concept of the effects of iodine deficiency has undergone a rapid evolution since 1970. Originally the problem was designated as goiter, which (although a fascinating phenomenon for many thyroidologists) cannot by itself justify a high priority for prevention programs in developing countries. As noted in the introduction, the various effects of iodine deficiency at different stages of life are now included in IDD, which has been generally adopted (Hetzel 1983; *Lancet* 1983). These various disorders (listed in Table IV.B.2.1) occur in populations subjected to iodine deficiency, and all can be prevented by correction of the deficiency. We will now review IDD in detail by reference to the four stages of life in which it occurs.

Iodine Deficiency in the Fetus

In iodine-deficient areas there is an increased rate of abortions and stillbirths, which can be reduced by correction of iodine deficiency (McMichael, Potter, and Hetzel 1980). An increased rate of stillbirths has also been observed in iodine-deficient sheep. In iodine-deficient pastures, lamb losses can be reduced by correction of iodine deficiency, and, it has been suggested, the same is true for goats (Hetzel and Maberly 1986). Pregnancy losses have also been produced experimentally with hypothyroidism. Studies in hypothyroid guinea pigs (produced by surgical removal of the thyroid) reveal a three- to fourfold increase in abortions and stillbirths that can be virtually eliminated by replacement therapy with thyroxine during pregnancy (McMichael et al. 1980).

Table IV.B.2.1. *The spectrum of iodine-deficiency disorders (IDD)*

Fetus	Abortions
	Stillbirths
	Congenital anomalies
	Increased perinatal mortality
	Increased infant mortality
	Neurological cretinism
	mental deficiency
	deaf-mutism
	spastic diplegia
	squint
	Myxedematous cretinism
	dwarfism
	mental deficiency
	psychomotor defects
Neonate	Neonatal goiter
	Neonatal hypothyroidism
Child and adolescent	Goiter
	Juvenile hypothyroidism
	Impaired mental function
	Retarded physical development
Adult	Goiter with its complications
	Hypothyroidism
	Impaired mental function
	Iodine-induced hyperthyroidism

In this same vein, data from Zaire and Papua New Guinea indicate an increased perinatal mortality that reflects an increase in stillbirths. There is also increased infant mortality. In Zaire, the results of a controlled trial of iodized oil injections given in the latter half of pregnancy revealed a substantial fall in perinatal and infant mortality with improved birth weight (Thilly 1981). Low birth weight is generally (whatever the cause) associated with a higher rate of congenital anomalies.

Recent evidence indicates that the various effects of iodine deficiency on the fetus (including abortion, stillbirth, congenital anomalies, and the varying manifestations of cretinism) probably arise from the lowered level of thyroid hormone T_4 in the iodine-deficient mother. The more severe the reduction in the level of maternal T_4, the greater the threat to the integrity of the fetus – a proposition supported by animal data on the causes of abortions and stillbirths (Hetzel et al. 1990).

Iodine Deficiency in the Neonate

In former times neonatal goiter was commonly seen in iodine-deficient areas (Hetzel and Maberly 1986). Neonatal hypothyroidism remains a well-recognized cause of mental defect in the Western world. This is because the development of the brain is dependent on an adequate supply of thyroxine. Only about one-third of normal brain development occurs before delivery of the infant; the other two-thirds is completed in the first two years of life. Hence a normal level of thyroxine is extremely important both during and after pregnancy.

In many countries every newborn child is tested for the level of blood thyroxine (usually taken from a prick in the heel at the fourth and fifth days of life). If, after further investigation, the level is found to be low, and a lowered state of thyroid gland function is indicated, then replacement treatment with daily tablets of thyroxine is begun immediately. The results of such a procedure have been evaluated in several countries and deemed to be generally excellent, provided treatment is given early, meaning within the first month of life. In Western countries, the incidence of such an abnormality runs at 1 per 3,500 live births, and results from (1) the absence of the thyroid; (2) an abnormal position of the thyroid (ectopia); or (3) a defect in the "biochemical machinery" required to produce thyroxine (called a biosynthetic defect) (Burrow 1980).

A much higher incidence, however, is found in iodine-deficient environments. Indeed, observations of blood taken from the umbilical vein (in the umbilical cord), just after birth, have revealed a rate of neonatal hypothyroidism of some 10 percent in Zaire and 5 to 10 percent in northern India and Nepal (Kochupillai and Pandav 1987). In the most severely iodine-deficient environments (more than 50 percent have urinary iodine below 25 µg/gram creatinine, which is 25 percent of normal intake), the incidence of neonatal hypothyroidism is 75 to 115 per 1,000 births. By contrast in Delhi, where only mild iodine deficiency is present with a low prevalence of goiter and no cretinism, the incidence drops to 6 per 1,000. But in control areas without goiter the level is only 1 per 1,000.

In India chemical observations have been extended to studies of the Intelligence Quotient (IQ) and hearing ability of schoolchildren. It has been shown that there is a marked reduction in IQ scores in villages with a high rate of (chemical) hypothyroidism in comparison with villages without iodine deficiency. Nerve deafness is also much more common, and there is evidence of lowered growth hormone levels in the blood.

The blood level of thyroxine in the neonate is an important indicator of the severity of iodine deficiency. Monitoring of these levels is now being done in India on samples of cord blood taken by birth attendants and subsequently spread on specially prepared filter paper. The samples are then mailed to a biochemistry laboratory where radioimmunoassay is carried out. This arrangement offers a very convenient and inexpensive method for the assessment of the severity of iodine deficiency provided a suitable functioning laboratory is available. The equipment is complex and costly but automated so that large numbers of samples can be processed. Such laboratories are now being gradually established in India, China, and Indonesia, where there are very large iodine-deficient populations. Data from these laboratories indicate a much greater risk of mental defect in severely iodine-deficient populations than is indicated by the presence of cretinism. Unfortunately, because of a gross inadequacy of manpower and money, it is just not possible to diagnose and treat these infants in most developing-world countries as they are treated in the West. This problem, of course, points up the overwhelming importance of prevention.

Iodine Deficiency in Infancy and Childhood

Iodine deficiency in children is characteristically associated with goiter, the classification of which has now been standardized by the World Health Organization (Dunn et al. 1986). Girls have a higher prevalence than boys and the rate increases with age so that it reaches a maximum with adolescence. Thus observations of goiter rates in schoolchildren between the ages of 8 and 14 provide a convenient indication of the presence of iodine deficiency in a community. The congregation of children in schools is a great advantage in providing access to a population and a place where collection of urine samples for detection of urinary iodine can be conveniently carried out.

As already noted, the prevention and control of goiter in schoolchildren was first demonstrated by Marine and Kimball in Akron, Ohio, in 1917. However, Marine and Kimball (1921) recognized that goiter was only part of IDD. They said:

> The prevention of goitre means vastly more than cervical (neck) deformities. It means in addition, the prevention of those forms of physical and mental degeneration such as cretinism, mutism and idiocy which are dependent on thyroid insufficiency. Further it would prevent the development of thyroid adenomas which are an integral and essential part of endemic goitre in man and due to the same stimulus. (Marine and Kimball 1921: 1070)

Recent studies of schoolchildren living in iodine-deficient areas in a number of countries indicate impaired school performance and lower IQ scores in comparison with matched groups from non-iodine-deficient areas. In Papua New Guinea, for example, children involved in the controlled trial in the Western Highlands have been tested periodically. Differences in bimanual dexterity were revealed by threading beads and putting pegs into a pegboard – differences that correlated with whether or not the mother was severely iodine deficient (Connolly et al. 1979). Indeed, critical studies using a wide range of psychological tests have shown that the mental development of children from iodine-deficient areas lags behind that of children from non-iodine-deficient areas. But the differences in psychomotor development became apparent only after the age of 2½ years (Bleichrodt et al. 1987; Boyages et al. 1989).

Another question has been whether these differences can be affected by correction of the iodine deficiency. In a pioneering study initiated in Ecuador by R. Fierro-Benitez and colleagues (1986), the long-term effects of iodized oil injections have been assessed by comparison of two highland villages. In one of them (Tocachi) such injections were administered. The other (La Esperanza) was used as a control. Particular attention was paid to 128 children aged 8 to 15 whose mothers had received iodized oil prior to the second trimester of pregnancy and, of course, a matched control group of 293 children of similar age. All children were periodically examined from birth at key stages in their development. Women in Tocachi were injected or reinjected in 1970, 1974, and 1978. Assessments in 1973, 1978, and 1981 revealed the following:

> Scholastic achievement was better in the children of treated mothers when measured in terms of school year reached, for age, school dropout rate, failure rate, years repeated and school marks. There was no difference between the two groups by a certain test (Terman-Merrill, Wechsler scale, or Goodenough). Both groups were impaired in school performance – in reading, writing and mathematics, but more notably the children of untreated mothers. (Fierro-Benitez et al. 1986: 195)

The results indicate the significant role of iodine deficiency, but other factors were also important in the school performance of these Ecuadorean children, such as social deprivation and other nutritional difficulties.

In 1982 the results were reported of a controlled trial carried out with oral iodized oil in the small Bolivian Highland village of Tiquipaya, 2,645 meters above sea level (Bautista et al. 1982). Each child in the treatment group received an oral dose of 1.0 milliliter (ml) iodized oil (475 mg iodine), whereas children in the second group received 1.0 ml of a mineral oil containing no iodine but of a similar brown color. Subsequent assessment was double-blind so that the group of the child was not known to the examiners. Interestingly, on follow-up 22 months later, the urinary iodine had increased and goiter size had decreased in both groups. This reflected "contamination" of the village environment with iodine, probably the result of fecal excretion by those who had received the iodized oil injections. There were no differences between the two treatment groups in growth rate or in the performance with the tests. However, improvement in IQ could be demonstrated in all those children, regardless of their group, who showed significant reduction of goiter. This was particularly so in girls. It was concluded that correction of iodine deficiency may improve the mental performance of school-age children, but that a bigger dose should be given.

Such studies are now being conducted in a number of countries. More data are required. However, data generated to date point to significant improvement in the mental performance of schoolchildren by the correction of iodine deficiency.

Iodine Deficiency in the Adult

The common effect of iodine deficiency in adults is goiter, although characteristically there is an absence of classical clinical hypothyroidism in adults with endemic goiter. Nonetheless, laboratory evidence of hypothyroidism with reduced T_4 levels is common, associated with apathy, lethargy, and lack of energy.

Iodine administration in the form of iodized salt, iodized bread, or iodized oil have all been demonstrated to be effective in the prevention of goiter in adults (Hetzel 1989). Iodine administration may also reduce existing goiter, particularly in the case of iodized oil injections. The clearly observed benefits of iodine supplementation promote ready acceptance of such measures by people living in iodine-deficient communities.

Such benefits have been well described by J. Li and X. Wang (1987) for the northeast Chinese village of Jixian. In 1978 Jixian had a population of 1,313 people, of whom 65 percent had goiter and 11.4 percent were cretins. The latter included many severe cases and the village was known locally as "the village of idiots." The economic development of the village was retarded; girls from other villages did not want to marry into and live in that village. The intelligence of the student population was known to be low (children aged 10 had a mental development equivalent to those aged 7).

Iodized salt was introduced in 1978, and by 1982 the goiter rate had dropped to 4 percent. No cretins had been born since 1978. The attitude of the people changed greatly, with their approach to life being much more positive than before iodization. Average income increased from 43 yuan per capita in 1981 to 223 yuan in 1982 and 414 yuan by 1984 – the latter higher than the average per capita income of the district.

Before iodization, no family owned a radio in the village. But after iodization 55 families acquired television sets. Some 44 girls have arrived from other villages to marry boys in Jixian, and 7 men have joined the People's Liberation Army, whereas before men from the village had been rejected because of goiter. Such improvements in the level of living were mainly due to the correction of hypothyroidism by iodized salt.

The Demography of IDD

The prevention and control of IDD must be regarded as an urgent problem for the 1 billion of the world's peoples living in an iodine-deficient environment (Table IV.B.2.2). Of these, 350 million live in China and 200 million in India (*World Health Organization Report* 1990) (Map IV.B.2.1).

These populations are at risk of developing one or more of the iodine-deficiency conditions that can retard physical, social, and economic growth and development. Indeed, more than 5 million of the world's people are estimated to be suffering from mental retardation as gross cretins. But in addition, three to five times this number suffer from lesser degrees of mental defect because their mothers were iodine-deficient during pregnancy (WHO 1990).

Table IV.B.2.2. *Estimated prevalence of iodine-deficiency disorders in developing countries, by region and numbers of persons at risk (in millions)*

	At risk	Goiter	Overt cretinism
Africa	227	39	0.5
Latin America	60	30	0.3
Southeast Asia	280	100	4.0
Asia (other countries including China)	400	30	0.9
Eastern Mediterranean	33	12	–
Total	1,000	211	5.7

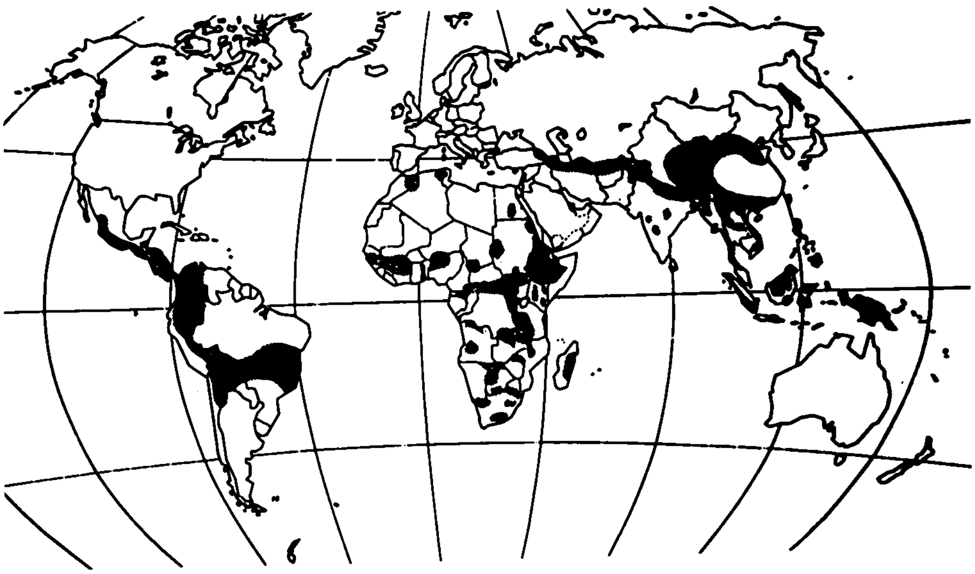
Iodine Technology for Prevention

Iodized Salt

Iodized salt has been the major preventive method used against iodine deficiency since the 1920s. However, there are serious difficulties in the production and quality maintenance of iodized salt for the millions that are iodine deficient. In Asia, the cost of iodized salt production and distribution at present is of the order of 3 to 5 cents per person per year. This



Map IV.B.2.1. The distribution of iodine-deficiency disorders in developing countries. Large populations in Asia provide two-thirds of the one billion at risk due to iodine deficiency of the soil. (From Hetzel 1989 and WHO 1990, with permission.)

must be considered cheap in relation to the benefits produced but there remain logistical problems of getting the salt to the iodine-deficient subjects. In addition, there may be problems with the iodine content – the salt may be left uncovered or exposed to heat, which leads to loss of iodine by volatilization.

Finally, there is the difficulty of getting people to consume the salt. Although the addition of iodine makes no difference to the taste of salt, the introduction of a new variety of the mineral to an area where it has been available, and its source familiar, is likely to be resisted. In the Chinese provinces of Xinjiang and Inner Mongolia, for example, the strong preference of the people for desert salt (of very low iodine content) led to a mass iodized oil injection program to prevent cretinism (Ma et al. 1982).

Iodized Oil by Injection

The value of iodized oil injection in the prevention of endemic goiter and endemic cretinism was first established in New Guinea with trials involving the use of saline injection as a control. Experience in South America and elsewhere has confirmed this value (Hetzel et al. 1980), and, in fact, the quantitative correction of severe iodine deficiency for a period of over four years by a single intramuscular injection (2 to 4 ml) has been demonstrated (Buttfield and Hetzel 1967). Iodized oil can be administered through local health services, where they exist, or by special teams. In New Guinea, public health teams carried out the injection of a population in excess of 100,000, along with the injection of triple antigen. In Nepal 4 million injections have now been given. In Indonesia some 1 million injections were given between 1974 and 1978, together with the massive distribution of iodized salt (Djokomoeljanto, Tarwotjo, and Maspaitella 1983). A further 4.9 million injections have been given by specially trained paramedical personnel in the period 1979 to 1983. In Xinjiang in China, 707,000 injections were given by "barefoot doctors" between 1978 and 1981, and a further 300,000 to 400,000 injections were being given in 1982 (Ma et al. 1982). Iodized oil is singularly appropriate for the isolated village community so characteristic of mountainous endemic goiter areas. Iodized walnut oil and iodized soybean oil are more recently developed preparations and have been used on a wide scale in China since 1980. As with iodized salt, the striking regression of goiter following iodized oil injection ensures general acceptance of the measure (Figure IV.B.2.5).

In at-risk areas the oil should be administered to all females up to the age of 45 years, and to all males up to the age of 15 years and perhaps beyond. A repeat of the injection would be required in three to five years depending on dose and age. With children the need for a repeat injection is greater than with adults, and

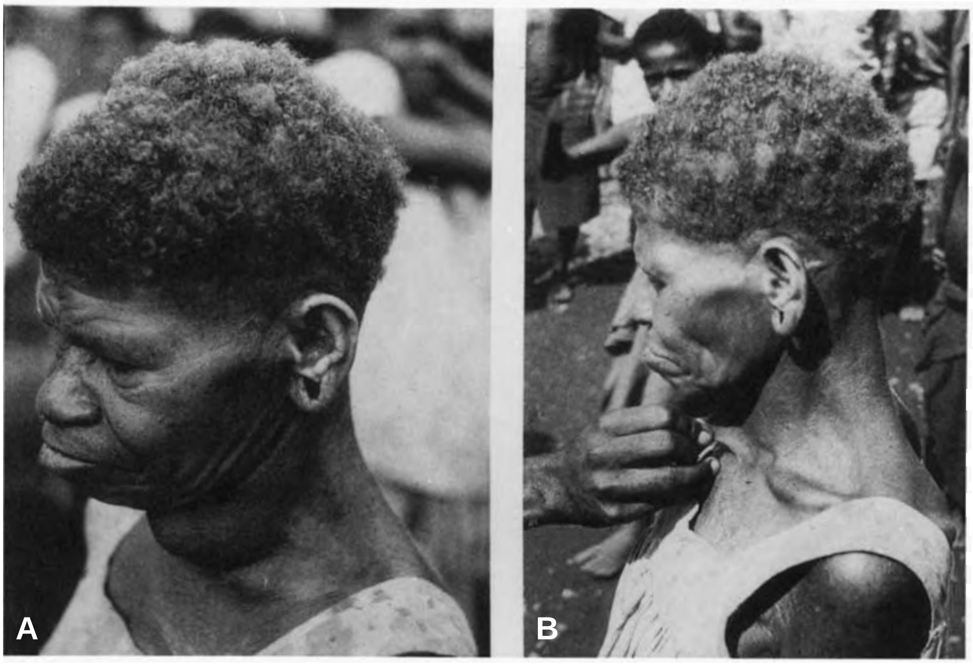


Figure IV.B.2.5. Nodular goiter in a New Guinean (A) before and (B) three months after injection of iodized oil. The photos demonstrate the subsidence of goiter following the injection of iodized oil. (From Butterfield and Hetzel 1967, with permission.)

the dose should be repeated in three years if severe iodine deficiency persists (Stanbury et al. 1974).

Disadvantages of injections are the immediate discomfort produced and the infrequent development of abscesses at the site of injection. Sensitivity phenomena have not been reported (Hetzel et al. 1980), but a potential difficulty is disease transmission through syringes (hepatitis B or HIV infection). A major problem with injections is their cost, although the expense has been reduced with mass packaging to an order of magnitude similar to the costs of iodized salt, especially when the population to be injected is restricted to women of reproductive age and to children, and a primary health-care team is available (Hetzel 1983; SEARO/WHO 1985; Dunn et al. 1986).

Iodized Oil by Mouth

The effectiveness of a single oral administration of iodized oil for one to two years has been demonstrated in South America and in Burma. But recent studies in India and China reveal that oral iodized oil lasts only half as long as a similar dose given by injection (Dunn 1987b). However, oral administration avoids the hazard of transmitting hepatitis B or HIV infection through contaminated syringes. Moreover, oral administration of iodized oil to children could be carried out through baby health centers and schools. A 1 ml dose (480 mg) covers a period of 12 months at present.

Less Common Prevention Technologies

The use of other methods of iodization such as iodized bread and iodized water has not proceeded to the mass population level but may be indicated in special situations.

Iodized Bread

Iodized bread has been used in Holland and in Australia, and detailed observations are available from the Australian island of Tasmania. Since 1949 the Tasmanian population has received iodine dietary supplements in the form of weekly tablets of potassium iodide (10 mg) given to infants, children, and pregnant women through baby health clinics, schools, and antenatal clinics whenever possible. The prevalence of endemic goiter fell progressively during the next 16 years but was not eliminated. The failure to eliminate the disease completely was traced to a lack of cooperation by a number of schools in the distribution of the iodide tablets. The distribution through the child health centers to infants and preschool children was also ineffective because of the children's irregular attendance.

For this reason a decision was made to change the method of prophylaxis from iodide tablets to iodized bread. The use of potassium iodate up to 20 parts per million (ppm) as a bread improver was authorized by the National Health and Medical Research Council of Australia in May 1963, and the necessary legislation was passed by the Tasmanian Parliament in October 1964.

The effects of bread iodization were measured by a series of surveys of palpable goiter rates in schoolchildren. A definite decrease in the visible goiter rate was apparent by 1969. Yet studies of urinary iodide excretion and plasma inorganic iodide in May 1967 revealed no excessive intake of iodide. Correction of iodine deficiency was confirmed by evidence of a fall of 24-hour radioiodine uptake levels in hospital subjects as well as normal plasma inorganic iodine concentration and urine iodine excretion (Stewart et al. 1971).

Thus bread iodization was effective in correcting iodine deficiency in Tasmania in the 1960s. However, today there is a greater diversity of sources for dietary iodine. It is readily available from milk due to the use of iodophors in the dairy industry, and it is also available from ice cream due to the use of alginate as a thickener.

Iodized Water

Reduction in goiter rate from 61 percent to 30 percent with 79 percent of goiters showing visible reduction has been demonstrated following water iodization in Sarawak (Maberly, Eastman, and Corcoran 1981). Similar results have been obtained with preliminary studies in Thailand by Romsai Suwanik and his group at the Siriraj Hospital, Bangkok, and in Sicily (Hetzel 1989). Iodized water may be a more convenient preventive measure than iodized salt and there may be less likelihood of iodine-induced thyrotoxicosis. Certainly this method is appropriate at the village level if a specific source of drinking water can be identified.

The Hazards of Iodization

A mild increase in incidence of thyrotoxicosis has been described following iodized salt programs in Europe and South America and following the introduction of iodized bread in Holland and Tasmania. A few cases have been noted following iodized oil administration in South America. That no cases have yet been described in New Guinea, India, or Zaire is probably due to the scattered nature of the population in small villages and limited opportunities for observation. In Tasmania it was apparent that a rise in incidence of thyrotoxicosis accompanied a rise in iodine intake from below normal to normal levels due to iodized bread, which was finally introduced in April 1966 (Stewart et al. 1971). The condition can be readily controlled with antithyroid drugs or radio-iodine. Nonetheless, in general, iodization should be minimized for those over the age of 40 because of the risk of thyrotoxicosis (Stanbury et al. 1974; Hetzel 1983).

International Action Toward Elimination

Since 1978, there has been increasing concern about a lag in the application of our new knowledge of the iodine-deficiency disorders and their prevention

(Stanbury and Hetzel 1980; Hetzel 1983). A symposium at the Fourth Asian Congress of Nutrition in Bangkok in 1983 brought the problem to the attention of the international nutrition community with the preparation of a comprehensive report on the "Prevention and Control of Iodine Deficiency Disorders for the United Nations System" (*Lancet* 1983).

This report, which was subsequently published (Hetzel 1988b), indicated the need for the establishment of an expert group of scientists and other health professionals committed to bridging the wide gap between research and action. At a WHO/UNICEF Intercountry Meeting in March 1985, in Delhi, a group of 12 such experts agreed to found the International Council for Control of Iodine Deficiency Disorders (ICCIDD). In 1986 an International Board was established and the ICCIDD was formally inaugurated at Kathmandu, Nepal (*Lancet* 1986a).

The ICCIDD has welcomed as members all who have concern for and expertise in IDD and IDD control (*Lancet* 1986a). The main role of the ICCIDD is to make such expertise available to international agencies and national governments who have responsibility for the control of IDD, and so bridge the great gap between available knowledge and its application. At the inaugural meeting in Kathmandu, Nepal, a global review of the IDD problem took place along with an appraisal of current expertise in iodine technology and IDD control programs. This meeting led to the first ICCIDD monograph (*Lancet* 1986b; Hetzel, Dunn, and Stanbury 1987).

The ICCIDD is now a global, multidisciplinary group, consisting of some 300 members from 70 countries, and has a quarterly newsletter and a secretariat in Adelaide, Australia. Support since 1985 has been received from UNICEF (New York) and the Australian government and since 1991 from the Canadian government.

Since 1987, the ICCIDD has become fully active in facilitating interagency cooperation in the prevention and control of IDD by holding a series of interagency meetings and establishing regional interagency working groups (particularly involving WHO and UNICEF, but also some of the bilaterals). A Global Action Plan has now been endorsed by the UN agencies to take account of these developments. The purpose of the Global Action Plan is to provide global and regional support for the establishment and monitoring of effective national IDD control programs. It includes activities at the national, regional, and global levels.

At the national level, such activities include initial assessments, national seminars, communication packages, intersectoral planning with a National IDD Control Commission, evaluation, and monitoring with laboratory services. In Indonesia and China, International Working Groups have now been established by ICCIDD in collaboration with WHO and UNICEF.

At the regional level, the development of a series of regional IDD working groups provides for the necessary close working relationship between ICCIDD, WHO, and UNICEF. The IDD Task Force for Africa has been particularly successful in developing a coordinated strategy involving both multilateral and bilateral agencies.

At the global level, major functions include advocacy and the provision of public information, as well as the maintenance of a global monitoring system.

In view of the progress already achieved and the promising potential of current and planned national prevention and control programs, the goal of eliminating IDD as a major public health problem by the year 2000 was reaffirmed by the 1990 World Health Assembly (*World Health Organization Report* 1990). An escalation of funding now became an essential step in the achievement of this goal.

In September 1990, the World Summit for Children held at the United Nations in New York was attended by 71 heads of state and 80 other government representatives. The World Summit signed a Declaration and approved a Plan of Action that included the elimination of IDD as a public health problem by the year 2000.

This summit was followed in October 1991 by a conference entitled "Ending Hidden Hunger," which was a policy and promotional meeting on micronutrients including iodine, vitamin A, and iron. It was attended by multidisciplinary delegations from 55 countries with major IDD problems. These delegates were nominated by heads of state in response to an invitation by the director general of the World Health Organization, H. Nakajima, and the executive director of UNICEF, James Grant. At this meeting there was a firm commitment to the goal of eliminating IDD and vitamin A deficiency and reducing iron deficiency by one-third of 1990 levels. These various developments encourage the hope that very significant progress would be made toward the elimination of IDD during the last decade of the twentieth century with great benefits to the quality of life of the many millions affected (Hetzel 1989).

IV.B.3 ∽ Iron

Iron has played a critical role in the evolution of life. The ancient Greeks, believing iron to be a special gift sent to earth by one of the gods, named it *sideros,* or star (Liebel, Greenfield, and Pollitt 1979). As the second most common metal, iron accounts for 5 percent of the earth's crust; it is also found in both sea- and freshwater (Bernat 1983). Scientists believe that the earth's atmosphere was originally a reducing one with very low oxygen pressure. As a result, large amounts of reduced iron would have been available for living organisms (Bothwell et al. 1979). Iron is an essential element for all organisms, with the possible exception of some *Lactobacillus* (Griffiths 1987; Payne 1988). In animals, the processes of DNA replication, RNA synthesis, and oxygen and electron transport require iron. Today most iron in the environment exists in an oxidized state and is less available to organisms. However, the problems of extracting insoluble iron have been overcome during evolution. A variety of sophisticated mechanisms have evolved that are specific to different kingdoms and/or different species (e.g., mechanisms plants use to be able to live in acidic or iron-poor environments) (Bothwell et al. 1979). Such mechanisms in animals include iron complexing agents, which transport iron and deliver it to cells, and low-molecular-weight compounds, such as fructose and amino acids, that reduce iron into a soluble form (Griffiths 1987; Simmons 1989: 14).

Metabolic processes within humans involve the presence of free radicals, that is, substances that are reactive because of instability in the arrangement of electrons (Wadsworth 1991). Iron may be present as a free radical. Such instability makes iron highly likely to donate or accept electrons. As a result, iron is versatile and able to serve a number of functions within cells. These functions include acting as a catalyst in electron transport processes and serving as a transporter of oxygen. Iron is a key component of hemoglobin, the oxygen carrier found in red blood cells. It is involved in many other extracellular processes as well (Woods, DeMarco, and Friedland 1990). Iron also is required for collagen synthesis, the production of antibodies, removal of fats from the blood, conversion of carotene to vitamin A, detoxification of drugs in the liver, and the conversion of fuel nutrients to energy (Long and Shannon 1983). In addition to its importance in the maintenance of normal metabolic processes, iron involvement in pathological change and initiation of disease is a critical facet of host defense.

Iron occurs in the human body in two states: circulating in blood and in storage. The absolute amount of iron in the body is actually quite small, despite its critical importance in metabolism. A healthy adult has an average of between 4 and 5 grams (g) of iron with a range of 3 to 6 g (Bernat 1983). Approximately 30 percent of all iron in the body is in storage. Most iron utilized in the body is needed by bone marrow to make new red blood cells. After a life span of about 120 days, red blood cells are destroyed and the released hemoglobin is broken down. Liberated iron from the hemoglobin is stored in macrophages in the liver, spleen, and kidney for future use.

Most iron in a healthy person (2.5 to 3 g) is found in red blood cells in the form of hemoglobin (Moore 1973; McLaren, Muir, and Kellermeyer 1983). Small amounts of iron, approximately 0.13 g, occur in myoglobin, a protein in muscle tissues. Only 0.008 g of iron is located in heme tissue enzymes, 0.5 g is in nonheme enzymes, and about 0.004 g is bound to the iron-binding protein transferrin found in blood (Arthur and Isbister 1987).

Between 0.7 and 1.5 g of iron is found in storage (Bezkorovainy 1989). It occurs in either a diffuse soluble form as ferritin, an intracellular protein, or as hemosiderin, an insoluble aggregate form of ferritin (Bezkorovainy 1989). Ferritin is formed when apoferritin (an iron-free protein) combines with freed iron from the breakdown of hemoglobin in senescent red blood cells (Simmons 1989: 14). Basically, ferritin is an apoprotein shell enclosing a core of iron that consists of 24 subunits of either the H or the L type (Worwood 1989). The two types of subunits are of slightly different size and electrical charge. Different organs have various percentages of one or the other type of subunits. For instance, H subunits are predominantly found in ferritin located in the heart and L subunits are predominantly found in ferritin located in the liver. It has been suggested that those organs that have a high iron content, such as the liver and spleen, have a predominance of the L subunits, whereas those with less iron, such as heart, intestine, pancreas, and placenta, have more of the H subunits (Bezkorovainy 1989: 53). Therefore, the L subunit dominated ferritin is thought to be concerned primarily with long-term iron storage whereas the H-dominated ferritin is concerned primarily with preventing iron overload (Bezkorovainy 1989: 53). Although the majority of ferritin is located in the organs that make up the reticuloendothelial system, a small amount exists in plasma. Most ferritin molecules contain only 2,000 atoms of iron (Fairbanks and Beutler 1988). However, up to 4,500 atoms of iron can be incorporated into the ferritin internal cavity. Iron atoms enter the ferritin protein coat through tiny channels or pores, which are formed by the positioning of subunits (Fairbanks and Beutler 1988; Worwood 1980: 204; Worwood 1989). Hemosiderin represents the end point of the intracellular storage iron pathway. Hemosiderin granules are actually denatured, partly degraded, aggregated molecules of ferritin (Bezkorovainy 1989).

Balance is the crucial feature of human iron metabolism. Too much iron is toxic and too little can produce severe anemia (Arthur and Isbister 1987). In fact, much of the toxicity of iron appears to be related to its propensity to form unstable intermediates with unpaired electrons or free radicals (Griffiths 1987). Lethal accumulations of iron can occur in most organs of the body but the liver, spleen, pituitary, and heart are particularly vulnerable to excess iron (Weinberg 1984; Stevens et al. 1988; Cook 1990; Kent, Weinberg, and Stuart-Macadam 1990, 1994). The immune system can also be compromised by excess iron. For this reason it is extremely important that iron be chelated (bound) to prevent uncontrolled free-radical reactions. In normal animals and humans, iron is almost always bound to proteins, leaving only an extremely low concentration of free iron; in fact, in most biological systems iron is bound to complexing agents. Over 99 percent of iron in plasma is chelated to transferrin to prevent uncontrolled free-radical reactions (Griffiths 1987). However, in individuals with hyperferremia (iron overload), as much as 35 percent of iron may not be transferrin-bound, causing iron to accumulate in the liver, spleen, and heart (Weinberg 1989: 10).

By contrast, insufficient iron can produce severe anemia that impairs the quality of life and may eventually lead to cardiac and respiratory failure (Weinberg 1989). The body maintains an equilibrium in part through the transfer of circulating iron to storage, as well as through the conversion of free iron to bound iron. The key to body iron supplies is recycling; only a very small amount is absorbed from food or lost through excretion (sweat, feces, urine, or menstruation). Iron is conserved in a nearly closed system. Each iron atom cycles repeatedly from plasma and extracellular fluid to the bone marrow, where it is incorporated into hemoglobin, and then to the blood, where it circulates for approximately 120 days within erythrocytes (red blood cells). Afterward, iron is released to plasma. This is accomplished by phagocytes (cells that engulf and then consume debris and foreign matter) of the liver or spleen (the reticuloendothelial system[1]) that digest hemoglobin and destroy old erythrocytes. The process releases iron to plasma, which continues the cycle (Fairbanks and Beutler 1988: 195). Within each cycle, small amounts of iron are transferred to storage sites, and small amounts of storage iron are released to plasma. In addition, small amounts are absorbed by the intestinal tract from ingested food containing iron and small amounts are lost through sweat, urine, feces, or blood (Fairbanks and Beutler 1988: 195). Consequently, little dietary iron is needed to replace iron loss.

Iron Requirements in Humans

Because most needed iron is recycled, humans actually require very small quantities to maintain health. For example, healthy 70-kilogram (kg) adult males lose approximately 1 milligram (mg) of iron daily through excretion by the skin and the gastrointestinal and urinary tracts (Bothwell et al. 1989).[2] Required replacements are 1 mg daily. Children lose only about 0.5 mg daily but their required replacement is approximately 1 mg daily to compensate for the needs of growth. Early estimates of iron loss among women of reproductive age were high, an average of 2 to 3 mg per day, resulting in an equal replacement requirement (Hoffbrand and Lewis 1981; Arthur and Isbister 1987). However, more recent and systematic studies call such estimates into question. A Swedish study showed that the average woman loses between

0.6 and 0.7 mg through menstruation; 95 percent of women lose an average of *less* than 1.4 mg per day (Fairbanks and Beutler 1988: 205). Scientists are beginning to recommend that average menstruating women absorb only 1.4 mg iron daily to replace losses (Monsen 1988: 786).

Absorption of iron occurs mainly in the duodenum and jejunum, although all parts of the small intestine and even the colon may be involved. Little is known about the precise mechanisms by which the body's need for iron is communicated to the mucosal cell of the intestine (Cook 1990). But however it is achieved, the body is able to adapt to a wide range of iron requirements and intakes by modifying the rate of gastrointestinal absorption. Absorption of iron varies according to health, physiological status, iron stores, age, and sex. Studies have shown that the absorption of iron from an adequate diet might range from a fraction of a milligram to 3 or 4 mg a day, depending on body iron content. For example, hyperferremia, or iron overload, is associated with decreased iron absorption from dietary sources. Blood loss and true iron deficiency result in increased iron absorption. Absorption also varies according to the iron source. Iron-deficient males absorb 20 percent more nonheme iron and 21 percent more heme iron than iron-replete males (Cook 1990: 304). The same adaptability applies to iron loss. Normal males lose about 0.9 mg of iron per day. In contrast, hypoferremic males lose only about 0.5 mg per day and hyperferremic males lose about 2.0 mg per day (Finch 1989).

According to James Cook (1990), the three major determinants of body iron in healthy individuals are physiological iron demands, dietary supply of available iron, and adaptation. It is the dietary supply of available iron that is most often focused upon by the medical profession and nutritionists. Dietary iron supply is actually determined by three main factors: total iron intake, content of heme iron, and bioavailability of nonheme iron (Cook 1990). However, actual absorption of iron is a function of the adaptability of iron metabolism and an individual's iron status. Dietary iron comes in two forms – heme and nonheme. The largest percentage of dietary iron is inorganic, or nonheme, which is absorbed primarily in the duodenum. Its absorption is influenced by the presence of inhibitors and enhancers found in ingested foods. The most important inhibitors include tannin (found in tea), coffee, phytates in bran, calcium phosphate, egg yolk, polyphenols, and certain forms of dietary fiber. Although bran and phytate in the diet do inhibit iron absorption, there is speculation that high bran and phytate intake may induce changes in the intestines or its microflora over a prolonged period and reduce the inhibitory effect of these substances (Cook 1990). Enhancers include meat and organic acids such as citric acid, lactic acid, alcohol, certain spices and condiments in curry powder, and ascorbic acid (Bothwell et al. 1989).

Unlike nonheme iron, heme iron is absorbed directly into the intestinal cell as an intact porphyrin complex and is unaffected by other components of the diet. Heme iron usually accounts for only 10 to 15 percent of the total daily intake of iron; however, the absorption of heme iron is relatively high and it can account for as much as 25 percent of the iron absorbed from the daily diet (Hallberg 1980: 118).

Most Westerners, who ingest some kind of meat almost daily, easily obtain sufficient amounts of iron to replace daily losses. In fact, in some cases, dietary consumption is four to seven times greater than the amount of iron needed. They also consume iron through fortified foods, such as most wheat products or wine and cider, which can add 2 to 16 mg or more per liter (Fairbanks and Beutler 1988). A study of military personnel showed that 20 to 30 mg of iron per day was ingested, in part because food was cooked in iron containers (Fairbanks and Beutler 1988: 194–5).

Several factors make it difficult to quantify the bioavailability of iron in the body. Uncertainties concerning the nature of the interactions that occur between enhancers and inhibitors make it difficult to determine the true bioavailability of iron from various foods or diets. Compounding the problem are misconceptions that result from not considering a food source within its natural context. Often quoted is the belief that milk is a poor source of iron. Although this is true for humans drinking bovine milk, it is not true for human infants drinking human breast milk. There is a very high bioavailability of iron in human breast milk for human infants. As much as 40 percent of iron in human milk is absorbed by human infants, whereas less than half that amount is absorbed from bovine milk (Pochedly and May 1987). Iron availability of milk is species-specific, and calves absorb significantly more from bovine milk than they would from human milk (Picciano and Guthrie 1976).

Not only is Western dietary intake of iron high; the Recommended Dietary Allowance (RDA) of the United States Food and Nutrition Board is high: 18 mg per day for premenopausal women and 10 mg per day for men and older women (Eaton, Shostak, and Konner 1988). This high RDA leads to perceived high levels of iron deficiency in populations throughout the world. Medical and government policy has traditionally encouraged more iron consumption over less. Accordingly, iron supplements are routinely administered to pregnant women and infants. Iron supplementation on a massive scale has been carried out in the United States since the 1940s when the Food and Nutrition Board of the National Academy of Science endorsed fortification of wheat flour with iron as well as vitamins. It is now standard practice to fortify a broad range of foods, including many of the items available on the shelves of supermarkets around the world. In fact, the only infant formula available to disadvantaged women participating in the American WIC (Women, Infants, and Children) program is one fortified by iron; non-iron-fortified formula is prohibited (Kent et al. 1990). Yet iron is naturally found in almost all foods.

Particularly rich sources of iron include organ meats, red meat, blackstrap molasses, cocoa, oysters, clams, and dried beans (Long and Shannon 1983). Water also can contain iron; that from wells and boreholes can have more than 5 mg of iron per liter (Fairbanks and Beutler 1988: 195). This is in addition to the large amount of iron that can be absorbed by food cooked in iron containers. Even if iron were nonexistent in a person's diet, which is very unlikely, it would take years to produce true dietary iron deficiency without concomitant blood loss that depletes body iron stores: "[I]ron deficiency is almost never due to dietary deficiency in an adult in our community. A diagnosis of dietary iron deficiency in an adult male or postmenopausal female usually means that the site of blood loss has been missed" (Arthur and Isbister 1987: 173). In fact, occult gastrointestinal blood loss has been detected in nearly 50 percent of infants misclassified as dietary-induced iron deficient (Fairbanks and Beutler 1988: 195). In addition, many cases of the anemia of infection/inflammation caused by chronic diseases have been mistaken for iron-deficiency anemia.

Measurement of Iron in Humans

Several blood indices are used to measure iron but only the most common ones are briefly described here (Table IV.B.3.1). One of the most reliable methods is bone marrow aspiration and biopsy, which permits a direct measurement of the body's iron stores as indicated by the amount of ferritin and hemosiderin present. However, because of the discomfort to the subject, the possibility of introducing infection, and the costs involved, the procedure is usually conducted only when other, less invasive measurements indicate a need for a highly accurate assessment.

In past studies hemoglobin and hematocrit (a measurement of the packed cell volume) were employed to ascertain iron sufficiency. The widespread use of automated electronic blood cell counters, such as the Coulter counter, makes hemoglobin/hematocrit values easily obtainable and therefore frequently used indices to assess iron adequacy. In addition, the relative ease of determining these indices make them popular measurements in situations where automated machines do not exist. Unfortunately, a number of variables interact with and influence these indices, making them poor measures of iron status. Hemoglobin/hematocrit measurements can be unreliable because they are affected by cultural factors, such as smoking, and environmental factors, such as altitude, and the iron content of drinking water and soil (Kent et al. 1990).

Serum iron is also not a very reliable measure of iron status. It, like hemoglobin and hematocrit, is influenced by a number of factors, including a woman's menstrual cycle, the presence of infection, and the time of day blood is drawn (there is a diurnal cycle wherein serum iron values are as much as 30 percent higher in the morning than in late evening [Fairbanks and Beutler 1988: 200]). Transferrin is another component of blood measured to investigate the iron status of a person. Transferrin is a plasma iron-binding protein. One molecule has two iron-binding sites, each of which can bind one atom of ferric iron at each receptor site (Noyes 1985). Although originally thought to be similar, the two iron-binding sites more recently have been recognized as not chemically or physically equivalent for reasons not well understood (Bezkorovainy 1989). The primary function of transferrin is to transport iron from the intestinal tract, spleen, and liver to sites such as the bone marrow for hemoglobin synthesis, to macrophages for storage, to the placenta for fetal needs, or to other cells for iron-containing enzymes (Fairbanks and Beutler 1988: 200).

Most transferrin, between 70 and 90 percent, is transported to bone marrow (Fairbanks and Beutler 1988: 200). Total iron-binding capacity (TIBC) is the capacity of transferrin to bind iron, and it represents the highest amount of iron that the plasma (i.e., serum) can bind (Bezkorovainy 1980: 10; Fielding 1980: 15). In humans, only about one-third of the transferrin iron-binding sites are occupied by iron; the rest are free (Bezkorovainy 1989b). Transferrin saturation, the amount of transferrin that is saturated with iron (calculated by dividing serum iron value by the

Table IV.B.3.1. *Normal hematological values for the more common iron indexes (norms vary slightly according to measurement instrument and source)*

	Hemoglobin (g/dl)	Hematocrit (%)	Transferrin saturation (%)	Serum ferritin (μg/l)	Serum iron (μmol/1)	Transferrin (g/dl)	Red blood cell (μl)	Vitamin B_{12} (pg/l)	Serum folate (ng/ml)	Red cell folate (ng/ml)
Adults										
Males	14–18.2	40–54	16–50	12–250	12.6–27	1.9–4.3	4.4–6.0	200–1,100	3–14	160–600

Children[a]	11–14.8	33–14.8	16–50	7–140	10.0–27	1.9–4.3	3.4–5.6	200–1,100	3–14	160–600

[a] Values for children are age-dependent.

total iron-binding capacity), is usually considered a better assessment of iron metabolism than is transferrin, serum iron, or total iron-binding capacity alone. Nevertheless, transferrin saturation values are affected by chronic disease and inflammation, in addition to insufficient diet, blood loss, and various types of iron overload. Therefore, by themselves, these measurements are not reliable in determining the etiology of an anemia or iron overload. Furthermore, "transferrin measurements are relatively insensitive, as the degree of change with variation in iron stores is small relative to assay variability. Serum ferritin measurement is a key indicator of iron stores" (Cook and Skikne 1989: 350). In fact, and contrary to conventional practices, physicians are now suggesting different methods to measure iron status: "Traditional tests of serum iron and TIBC may be useful but currently are not recommended for indirect measurement of iron stores [i.e., measurement in the absence of a bone marrow biopsy]" (Beissner and Trowbridge 1986: 88–90). More recently, it has been noted that "a wide range of values for transferrin saturation and total iron-binding capacity is consistent with either iron deficiency anemia or anemia of chronic disease. . . . The two disorders can be distinguished by the serum ferritin level, iron stain of a bone marrow specimen for hemosiderin, or both" (Farley and Foland 1990: 92).

Red blood cell counts are routinely calculated by most automated blood cell counters. Red blood cells are often malformed with reduced life spans in various types of anemia and are associated with ineffective erythropoiesis (or red cell production) (Jacobs and Worwood 1982: 175). However, red blood cells usually have a normal life span in most iron overload disorders without severe liver disease (McLaren et al. 1983). At one time it was thought that red blood cell size might be useful in distinguishing iron deficiency from the anemia of chronic disease. But recent studies have disproved this proposition (e.g., Thompson et al. 1988; Osborne et al. 1989).

Mean corpuscular volume (MCV) reflects the capacity of the cell. A decreased cell size can signify a hemoglobin synthesis disorder, but a smaller size is also associated with both iron-deficiency anemia and anemia of chronic disease/inflammation and other iron disorders, such as thalassemia and sideroblastic anemia. Moreover, elevated MCV can result from a variety of disorders other than infection, including idiopathic ones. Although widely used because it is measured as part of the automated complete blood cell count, the main disadvantage of MCV is that it does "not distinguish true iron deficiency from secondary iron-deficient erythropoiesis due to inflammatory or neoplastic disease" (Cook and Skikne 1989: 351). As a result, a number of researchers contend that MCV can provide only a crude measure of iron status (Labbe and Finch 1980: 52).

Storage iron is held within the ferritin molecule. Experiments show that serum ferritin is the most noninvasive diagnostic indicator of iron status. The reliability of serum ferritin surpasses that of free erythrocyte protoporphyrin, which in the past was thought by some to be more diagnostic in discriminating the etiology of anemia (Zanella et al. 1989). Serum ferritin is a particularly sensitive measurement because it reflects changes in iron stores before they are completely exhausted or, in the case of overload, increased (e.g., Finch and Huebers 1982; Cook and Skikne 1989). There are now numerous studies that show that serum ferritin is a reliable measure of iron stores, second only to actual bone marrow aspirations (e.g., Thompson 1988; Burns et al. 1990; Guyatt et al. 1990).

These hematological measurements together present a reliable view of the iron status of an individual. However, when all are not available, serum ferritin, in conjunction with a measure of the amount of circulating iron, is minimally necessary for reliable interpretations.

Iron and Infection

One of the most exciting frontiers in iron studies concerns the body's efforts to diminish iron content in response to disease. Hypoferremia (or low circulating-iron level) is associated with an array of chronic diseases and inflammatory responses, including neoplasia (cancer), bacterial and parasitic infections, and rheumatoid arthritis (Kent 1992). The associated anemia of chronic disease is characterized by subnormal hemoglobin, subnormal serum iron, subnormal transferrin saturation levels, and normal to elevated serum ferritin levels (Table IV.B.3.2).

Hypoferremia in reaction to chronic diseases and inflammations has been noted in experimental animals as well as in humans. Studies show that within 24 hours after exposure to pathogenic microbes, serum iron levels fall and a resistance to otherwise lethal doses of a variety of pathogens is produced (Payne 1988). There is even a slight drop in

Table IV.B.3.2. *Comparison of laboratory values of anemia of dietary iron deficiency and anemia of chronic disease*

Anemia	Hemoglobin	Serum iron	Transferrin saturation	Serum ferritin	ESR
Iron deficiency	Decreased	Decreased	Decreased	Decreased	Normal
Chronic disease	Decreased	Decreased	Decreased	Normal–Raised	Raised

hemoglobin levels after smallpox revaccination, which is thought to represent a rather innocuous procedure (Reizenstein 1983).

The body reduces iron levels by preventing macrophages from releasing the metal from storage to transferrin and by reducing intestinal iron absorption. Transferrin saturation levels drop concomitantly as iron is sequestered in macrophage storage. Serum ferritin levels increase, serving as an indirect measure of body iron stores. The reduction of available iron affects microorganisms and rapidly multiplying neoplastic (cancer) cells because they require iron for proliferation. However, they either cannot store the element in a nontoxic form, as is the case for a number of pathogens, or they require larger amounts of iron for rapid proliferation than they possess, as is the case for neoplastic cells. Microorganisms requiring host iron include bacteria, fungi, protozoan parasites, and neoplastic cells.

Microinvaders acquire iron from their hosts in several ways. Perhaps most intriguing is acquisition through the production of small iron-binding compounds called siderophores. These iron chelators, or "iron scavengers," seek out iron in the host and donate it to the microorganism that produced them. In addition, some siderophores may serve as iron donors for another strain or species (Bezkorovainy 1980: 305–6). Siderophores compete with the host for the iron-binding proteins. The body responds by producing fever, which reduces the ability of some bacteria to produce siderophores (Lee 1983; Weinberg 1984). That is, fever serves as a countermeasure to microorganism proliferation by inhibiting their ability to extract iron from the host. The resulting hypoferremia prevents pathogens from obtaining sufficient quantities of growth-essential iron; they therefore fail to multiply or multiply with considerable difficulty (Kochan 1973: 22). Studies have documented that "a single episode of fever and/or inflammation in man appears to restrict the release of iron from effete red blood cells by the reticuloendothelial system, leading to a decrease in serum iron concentration and to stimulation of the production of ferritin [to store iron] for a prolonged period" (Elin, Wolff, and Finch 1977: 152).

It has long been recognized that an important deterrent to pathogens in infants is provided by lactoferrin, an iron-binding protein that occurs in breast milk. Lactoferrin binds free iron and thereby deprives microorganisms of necessary iron; it also has a propensity to interact with or complement specific antibodies (Bullen, Rogers, and Griffiths 1974). When iron-binding proteins become saturated with iron there is an increase in the amount of free iron (i.e., nonbound iron that is more accessible to pathogens). Both in vitro and in vivo experiments have shown that the bacteriostatic properties of lactoferrin, for example, are abolished when iron-binding proteins are saturated with iron, making the body more vulnerable to microorganism invasion (Pearson and Robinson 1976).

Understanding hypoferremia as a defense against disease allows us to understand the geographical distribution of anemia. George Wadsworth (1975), for example, noted that levels of hemoglobin in women living in temperate climates usually exceed 10 g per 100 milliliters (ml), whereas usual levels in women living in tropical climates may be only 8 g per 100 ml. The etiology of hypoferremia provides a clue for this otherwise puzzling observation. Parasitic and bacterial infections are endemic in tropical environments (e.g., Goodner 1933). The higher prevalence of infection has been related to the increased total complexity and diversity of the tropical ecological system (Dunn 1968). Hypoferremia is produced by the body in an attempt to ward off the numerous pathogenic insults associated with tropical environments. However, in these cases, and particularly when exacerbated by blood loss and nutrient malabsorption that often accompany protozoan and bacterial infections, hypoferremia might develop to such a severe state that it becomes a problem in and of itself (Stuart-Macadam 1988; Kent and Weinberg 1989; Kent et al. 1990: 67).

The role of hypoferremia as a nonspecific body defense against disease is not completely accepted, although microbiologists in particular have long recognized the role of iron in host defense. As early as 1868 Armand Trousseau noted that iron supplementation reactivated quiescent pulmonary tuberculosis (Weinberg 1984; Keusch and Farthing 1986). Research in 1944 showed that iron-binding proteins in egg whites and serum were involved in the inhibition of Shigella dysentery (Schade and Caroline 1944). Starving humans who are susceptible to some diseases are immune to others in which microorganisms must exact iron from their hosts to obtain the amount needed to proliferate. For example, refeeding programs in Niger reactivated malaria infections (Murray et al. 1976). Similar refeeding programs in Somalia resulted in a recrudescence of a number of different infections, including parasitic and bacillary dysentery, acute infectious hepatitis, brucellosis, tuberculosis, and others (Murray et al. 1976; Murray and Murray 1977). Moreover, a study of two groups of Kenyan Turkana pastoralists indicated lower iron levels enhanced host immunity. One group drank primarily milk; the other group drank milk and consumed over 150 g of fish per day, ingesting almost a third more iron than the non-fish-eating group. Those who ate fish were not anemic but were plagued by malaria, brucellosis, molluscum contagiosum, common warts, diarrhea, and *Entamoeba histolytica.* The non-fish-eating Turkana were slightly anemic but had significantly lower incidences of these diseases (Murray, Murray, and Murray 1980).[3]

There is now a body of literature based on in vivo and in vitro experiments that demonstrates the role of iron in disease (e.g., Weinberg 1966, 1974, 1977, 1984, 1990; Bullen et al. 1974; Masawe, Muindi, and Sway 1974; Strauss 1978; Oppenheimer et al. 1986; Bullen and Griffiths 1987; Crosa 1987; Griffiths and Bullen 1987; Kluger and Bullen 1987; Selby and Friedman 1988; Stevens et al. 1988; Kent et al. 1990, 1994). Even so, a large percentage of the public and even those in the health-care community are not aware that in certain circumstances diminished iron is not a pathological disease state but a physiological defense.[4] They are unaware that the current focus on iron fortification of food and on iron supplementation preparation is misdirected and potentially counterproductive to the body's attempt to ward off illness.

Supplying iron-fortified foods or vitamins to developing countries and disadvantaged minorities in Western nations without ascertaining the prevalence of dietary-induced, versus disease-induced, anemia may be harming the very people the food is intended to help. The practice of indiscriminate food fortification is putting these populations at risk for contracting a variety of diseases, including cancer (Finch 1989). Studies show that the high iron content of most Western diets particularly affects men and postmenopausal women, who, as a result, suffer more from certain types of neoplasia and from myocardial infarction. In fact, recent treatment uses iron chelators to bind iron at the location of inflammation, such as at the joints in rheumatoid arthritis, where it is thought iron causes tissue damage, among other problems (Biemond et al. 1988). In addition, drugs such as aspirin prevent heart attacks, at least in part, by causing chronic intestinal bleeding, which reduces iron levels (Sullivan 1989; also see Arthur and Isbister 1987 for discussion of aspirin and other anti-inflammatory drugs that can cause occult blood loss).

Iron and Heart Disease

Despite extensive epidemiological studies to identify risk factors for coronary disease, many unanswered questions remain. Individuals who have multiple risk factors often never develop cardiac events whereas others who would seem to be low risk experience cardiovascular problems (Sullivan 1989). Therefore, other possible factors, such as iron levels, should be examined for a contributory role in causing heart disease.

Some studies suggest a link between cardiac diseases and iron levels (Sullivan 1989; Salonen et al. 1992). Excess iron, as occurs in beta-thalassemia and chronic iron overload, has been associated with ischemic heart disease and heart attacks (Leon et al. 1979). Men, with more iron than premenopausal women who regularly lose iron through menstruation, also have more heart disease (Weinberg 1983; Sullivan 1989). Postmenopausal women, who have more iron than premenopausal women, have a higher risk of heart disease, although, of course, they constitute an older group. But women taking oral contraceptives, which reduces the amount of menstrual bleeding, are also more prone to heart disease (Sullivan 1983; Frassinelli-Gunderson, Margen, and Brown 1985; Colditz et al. 1987).

Not all cardiologists agree that the association between iron and cardiac disease is causal. However, J. L. Sullivan (1989) and others (Salonen et al. 1992) have suggested that high serum ferritin values, which measure the amount of iron in storage, are a powerful predictor for heart disease. Common iron chelators used clinically to reduce heart attacks, such as deferoxamine and aspirin, cause increased bleeding times and occult blood loss. Moderate to heavy fish consumption causes occult bleeding, thereby reducing iron levels and the risk of heart disease (Kromhout, Bosschieter, and Coulander 1985; Herold and Kinsella 1986; Houwelingen et al. 1987). The consequent reduction in iron levels among consumers of fish and iron chelators or drugs that promote bleeding could be responsible for the reduction of heart disease. This is in contrast to persons who consume large amounts of red meat that contain heme iron, which is more readily absorbed than nonheme iron found in vegetables. Another interesting association between available iron and heart attacks is based on the circadian rhythm of the body. Serum iron levels have diurnal patterns with an increase in the early morning. Heart attacks also occur three times more frequently during this time of day (Sullivan 1989: 1184).

Iron and Parasites

Parasites are a serious threat to the health of rural communities in the tropics; over 90 percent of this population are infected with at least one and often several nematode species, including hookworm, roundworm, and whipworm (Behnke 1987). There are basically three ways in which parasites can cause anemia. One is the anemia of chronic disease discussed earlier. A second way is by competing for the same nutrients as the host, including iron. A third way is by causing actual blood loss. Hookworm (*Necator* sp.), in particular, can cause heavy blood loss and, as a result, anemia. Hookworm infestations have been found in 12 percent to 95 percent of study populations throughout the tropical regions of the world – from the Amazon rain forest to Southeast Asia (Florentino and Guirriec 1984: 65). Malaria parasites are also dependent on iron from their hosts. The distribution of the sickle trait and heterozygous forms of thalassemia, which cause anemia, provide some protection against the malaria parasite.

Iron and Cancer

Another exciting path iron studies are exploring concerns the examination of the role of iron in neoplastic disease. Neoplastic cells require more iron than normal cells because of their rapid proliferation. In an attempt to accommodate their increased need for iron, these cells extract iron from their host. In reaction, the body attempts to prevent their proliferation by producing hypoferremia. Anemia is a commonly associated condition of neoplasia of various types (Miller et al. 1990). The type of anemia that usually occurs with neoplasia is that of chronic disease/inflammation as indicated by elevated serum ferritin levels. For example, patients with acute leukemia, Hodgkin's disease, multiple myeloma, and other malignancies have elevated to highly elevated serum ferritin concentrations that tend to become greater as the disease progresses (Bezkorovainy 1980; Worwood 1980).

Males with higher iron stores than premenopausal women have a significantly increased risk of cancer of the colon, bladder, esophagus, and lung. Women with higher levels of iron because they are postmenopausal or are hyperferremic also have a greater risk of cancer (Selby and Friedman 1988; Stevens et al. 1988). Very high serum ferritin levels are associated with other types of neoplasia, including malignant histiocytosis, primary hepatocellular carcinoma (liver cancer), and multiple malignancies (Hann et al. 1989; Ya-You et al. 1989). Other studies show that serum ferritin levels are significantly different in patients with benign and malignant effusions (abnormal fluid accumulations). Of the patients with benign nonneoplastic effusions, 96 percent had serum ferritin levels below 1,000 nanograms (ng) per ml; very high serum ferritin levels of over 3,000 ng per ml were encountered only in patients with malignancies (Yinnon et al. 1988).

Even more indicative is a study of patients afflicted with malignant histiocytosis and virus-associated hemophagocytic syndrome. At the onset of their disease these patients were anemic while having levels of serum ferritin above 1,000 ng per ml. As the disease progressed, serum ferritin levels increased to greater than 12,000 ng per ml (Esumi et al. 1988). Patients were given either chemotherapy or prednisone, depending on their disease. All patients with consistently high serum ferritin levels died within three months of treatment, whereas all patients with serum ferritin values less than 1,000 ng per ml lived beyond three months and are alive today with normal serum ferritin levels (Esumi et al. 1988). The more severe the disease, the higher the ferritin levels. We interpret these dramatic findings as the body's failed attempt to thwart disease by sequestering as much iron as possible. As the threat of disease decreased, serum ferritin levels began to drop. Noriko Esumi and colleagues (1988: 2071) conclude that "serum ferritin level in histiocytic proliferative disorders is a useful indicator of disease activity in both neoplastic and reactive conditions rather than only a marker of malignant process."

The popular belief that non-Western groups have a lower incidence of cancer because they have healthier diets than Westerners may be correct for reasons other than those usually proposed. As noted earlier, Westerners tend to have high iron levels because of a generally high-iron diet, ubiquitous fortification of cereal products, and the widespread practice of taking vitamins fortified with iron. High iron levels have been implicated in increasing one's vulnerability to neoplasia. It might be that in an attempt to improve our diets to reduce morbidity through the ingestion of excess iron, we actually worsen our diets and encourage high levels of morbidity.

Hyperferremia: Causes and Problems

In addition to high serum ferritin values and high concentrations of iron in the liver and spleen, increased concentrations of iron and ferritin occur in the bile of hyperferremic individuals. Bile iron is increased in patients with idiopathic hemochromatosis to as much as twice that of normal individuals; bile ferritin is increased to as much as five times that of normal individuals (Hultcrantz et al. 1989).

There are basically two types of hyperferremia – acquired and inherited (Table IV.B.3.3). Inherited hyperferremia is usually termed hereditary (or idiopathic) hemochromatosis. This disorder is autosomal (involving a nonsex chromosome) recessive, the responsible gene being located on the short arm of chromosome 6 (Edwards et al. 1988: 1355). Although the full manifestation of the disease occurs only in affected homozygotes, a small proportion of heterozygotes have been found to exhibit minor abnormalities in laboratory tests that measure the body's iron burden (Edwards et al. 1988). The incidence of hemochromatosis in a presumably healthy population of 11,065 European-Americans (with transferrin saturation values of above 62 percent) was 5 people per 1,000; the amount of iron loading in the liver and consequent organ damage varied widely (Edwards et al. 1988). Studies conducted in Scotland and France yielded a lower number of affected individuals, although the incidence was still substantial, ranging from 1 in 400 to 1 in 517 persons (McLaren et al. 1983: 223).

Table IV.B.3.3. *Types of disorders associated with iron overload*

Primary iron overload
Hereditary (idiopathic) hemochromatosis

Secondary iron overload
Hereditary transferrin deficiency
Thalassemia syndromes
African siderosis (African hemosiderosis; also Bantu siderosis)
Kaschin-Beck disease
Transfusional hemosiderosis
Alcoholic cirrhosis with hemosiderosis
Porphyria cutanea tarda
Acquired hemolytic anemia
Ineffective erythropoiesis (red blood cell production)
Pyridoxine-responsive anemia

Source: Adapted from McLaren, Nuir, and Kellermeyer (1983: 206).

Thalassemia syndromes (i.e., thalassemia major, intermedia, minor, and minima) are inherited disorders in which intestinal iron absorption is increased due to the hemolytic anemia and ineffective erythropoiesis (i.e., production of red blood cells). The condition is complicated by transfusion therapy (McLaren et al. 1983: 216). The result is hyperferremia. Occasionally a complete absence of serum transferrin (termed atransferrinemia) occurs in which marrow is without iron but heavy iron deposits are found in the heart, pancreas, liver, and mucous glands (McLaren et al. 1983). The cause is linked to the homozygous expression of an autosomal recessive gene. Heterozygous expression of this recessive gene can also result in anemia.

More unusual is hereditary hypochromic anemia, which is a sex-linked recessive disorder that is variable in its manifestation. A poorly understood disorder, porphyria cutanea tarda, results from a defect in the heme synthetic pathway. This condition is often found in combination with hepatic siderosis (iron storage), possibly from increased dietary iron absorption or heterozygosity for idiopathic hemochromatosis (McLaren et al. 1983: 226).

Acquired hyperferremia results from a number of causes. Three of the most common disorders that produce acquired hyperferremia are transfusional iron overload (also called transfusional hemosiderosis), alcoholism and cirrhosis with hemosiderosis, and African siderosis (or Bantu siderosis). Iron overload can be a by-product of prolonged intravenous iron administration or repetitive transfusions. As a common complication of maintenance dialysis, for example, hyperferremia requires regular phlebotomy (bloodletting) to correct the situation (McCarthy et al. 1989).

Alcohol abuse stimulates absorption of dietary iron and reduces the ability of intestinal epithelial cells to prevent excessive transport of iron into the blood (Mazzanti et al. 1987). Hyperferremia can even occur in individuals who have not yet developed liver damage (Rodriguez et al. 1986).

In most parts of sub-Saharan Africa, African or Bantu siderosis results from brewing beer in iron containers and cooking food in cast-iron pots. Large deposits of iron occur in the liver, spleen, and to a lesser extent, in the macrophages of the bone marrow. One study indicated that the average rural southern African male ingests between 50 and 100 mg of iron daily in beer alone (Bothwell et al. 1965: 893)! In a variety of studies of Africans who died from accidental deaths and other causes in South Africa, between 40 and 89 percent of the subjects exhibited varying degrees of iron overload (Bothwell and Bradlow 1960). The condition is detectable as early as late adolescence and becomes most severe between the ages of 40 and 60 years. In another study 75 percent of the males autopsied manifested siderosis compared with 25 percent of the women (Bothwell and Isaacson 1962: 524). The lower incidence of siderosis among women is due to a combination of greater iron loss through menstruation and the cultural practice of women drinking less beer and therefore ingesting less iron.

In the past 25 years the frequency of siderosis has dropped. This decline is particularly notable among urban Africans who do not drink as much of the traditional home-brewed beer as the rural population but still ingest large amounts of alcohol in different forms (MacPhail et al. 1979). A study conducted in the mid-1980s in Zimbabwe revealed that 12 percent of the men tested had an elevated serum ferritin level and a transferrin saturation of over 70 percent (Gordeuk, Boyd, and Brittenham 1986). However, although the frequency of siderosis in various areas of Africa has been declining over the past 25 to 30 years, it remains a serious health problem among a large percentage of rural populations.

Because hyperferremia results in the accumulation of iron in various organs, particularly the liver, spleen, heart, and pancreas, it can lead to severe cirrhosis, heart failure, and diabetes mellitus. Although the precise mechanism(s) involved is not well understood, it appears that tissue damage occurs in the liver and other organs as a result of the toxicity of excess iron. Cirrhosis occurs even in hyperferremic patients who do not drink any alcohol, although the combination of alcohol consumption and hyperferremia exacerbates the cirrhosis (McLaren et al. 1983: 240). In addition, different etiologies of iron overload appear to have slightly different manifestations. For example, the ratio of liver iron to marrow iron was much greater in patients with hereditary hemochromatosis than in those with African siderosis (McLaren et al. 1983: 236).

Hyperferremic individuals are plagued by problems other than those associated with the toxicity of excess iron. For reasons detailed earlier, they also suffer from an increased susceptibility to bacterial and parasitic microorganisms and neoplastic diseases (cancer). For example, one study demonstrated an increased risk of contracting *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* bacteremia in dialysis patients with iron overload (Boelaert et al. 1987). Similar studies revealed an increased risk and virulence from several iron-sensitive microorganisms, including *Listeria monocytogenes, Brucella spp.,* and *Vibrio vulnificus.*

Problems Associated with Insufficient Iron

As in the case of hyperferremia, there are two basic categories of hypoferremia (or low circulating-iron levels) based on their etiology. Most common are the acquired anemias, including iron deficiency, drug-induced anemia, and anemia of chronic disease/inflammation. Less common are hereditary anemias, such as sickle-cell anemia and congenital sideroblastic anemia. Some, such as sickle-cell anemia, are classified in a clinical setting by the morphological shape of the hemoglobin (Table IV.B.3.4).

Macrocytic anemia can be induced by diet, resulting from malabsorption, or it can be caused by an inherited disorder. Because Vitamin B_{12} (cobalamin) and folic acid (folate) are required for normal red blood cell nuclear growth and synthesis, deficiencies of these nutrients can cause anemia (Simmons 1989: 12–14). Vitamin B_{12} deficiency from dietary causes is very rare and occurs only in strict vegetarians who exclude all meat, eggs, and milk. However, this deficiency can also arise from a number of disorders, including impaired absorption of B_{12} or folate such as in pernicious anemia; malabsorption that can result from certain drugs, such as those used to treat sprue and celiac diseases, and gastrectomy; competition from parasites such as the fish tapeworm; hereditary impairment of absorption capabilities; increased requirements of the vitamin due to pregnancy, tumors, and hyperthyroidism; or impaired utilization of the vitamin, as in red cell enzymopathy, abnormal binding proteins, absence of transport protein, or nitrous oxide administration (Simmons 1989: 40).

Folate deficiencies can result from the following: a lack of green vegetables in a diet; alcoholism; impaired absorption due to sprue and celiac diseases; drugs used to treat malignant diseases; malaria and bacterial infections; increased requirements stemming from pregnancy; conditions such as hyperthyroidism; or impaired utilization as occurs with drugs like phenytoin (Simmons 1989: 40–1).

Table IV.B.3.4. *Morphological classification of anemia*

Morphology	Anemia
Macrocytic	Nonmegaloblastic
	Liver disease
	Reticulocytosis
	Megaloblastic
	Vitamin B_{12} deficiency
	Pernicious anemia
	Folate deficiency
	Myelodysplastic syndrome
Hypochromic microcytic	Iron deficiency
	Anemia of chronic disease/inflammation
	Thalassemia
	Hereditary/acquired sideroblastic anemia
	Lead poisoning
Normochromic normocytic	Decreased reticulocytosis
	Renal failure
	Endocrinopathies
	Anemia of chronic disease/inflammation
	Aplasia (idiopathic or secondary)
	Myelophthisis
	Increased reticulocytosis
	Spherocytic (congenital and acquired)
	Nonspherocytic
	Sickle-cell anemia

Two types of hypochromic microcytic anemia are most prevalent. One is caused by blood loss that is not counterbalanced by a sufficient dietary intake. The second, less common cause results from unmet nutritional demands even without blood loss. In men, bleeding from the gastrointestinal tract is the most frequent cause, and although this condition may occur in women as well, menorrhagia (excessive menstrual flow) is more often responsible. The other principal cause of this variety of anemia is chronic disease, in which iron deficiency appears to form a nonspecific defense mechanism against disease.

Less common is sideroblastic anemia, which can be acquired or congenital. Acquired sideroblastic anemia can be drug- or toxin-induced from cancer chemotherapy, antituberculous drugs, and ethanol, or it can be idiopathic, such as preleukemic or dysmyelopoietic syndromes (Beissner and Trowbridge 1986). Patients with sideroblastic anemia tend to accumulate excess iron in the tissues and therefore are vulnerable to many of the problems associated with iron overload. Lead poisoning can also cause hypochromic microcytic anemia.

Some anemias are associated with specific geographical regions. For example, thalassemias are a varied group of inherited disorders characterized by one or more defects in the synthesis of the normal alpha or beta globin chains of hemoglobin. They can occur in homozygous or heterozygous states and include thalassemia major, thalassemia intermedia, thalassemia minor, and thalassemia minima (Simmons 1989: 55). The geographical distribution of thalassemia is primarily in the Mediterranean region, although it is also found in Southeast Asia, the Middle East, and the Orient and among immigrants from those areas. There is much variation in the clinical manifestations of these genetic disorders. The defect in hemoglobin chains causes a reduction in hemoglobin in afflicted individuals. Ironically, and as discussed earlier, thalassemia can also result in iron overload of some organs because intestinal iron absorption is increased due to the hemolytic anemia and ineffective production of red blood cells. In the heterozygous form, however, thalassemia has been postulated to be a deterrent to malaria infections, perhaps by causing a reduction in the amount of circulating iron.

A normocytic normochromic anemia that involves the premature destruction of red blood cells is sickle-cell anemia, an inherited autosomal dominant disorder. Sickle-cell anemia is lethal in the homozygous form, but it can also become symptomatic in heterozygotes in situations of oxygen deprivation such as at high altitudes. Geographically, sickle-cell anemia is most common in equatorial Africa but is also found to a lesser extent in the Mediterranean region and India. This distribution has been attributed to the improved immunity individuals who are heterozygous for the sickle-cell trait have from malaria parasites (e.g., *Plasmodium falciparum*). Approximately 8.5 percent of

American blacks are heterozygous for the sickle-cell trait and are relatively symptom-free; in contrast, homozygous individuals suffer from hemoglobin levels between 5 and 9 g per decaliter (dl), leg ulcers, hematuria, and other afflictions (Simmons 1989: 68–70).

Common autosomal dominant normocytic normochromic anemias that represent a defect in the red cell membrane include hereditary spherocytosis, found primarily in people of northern European descent, and hereditary elliptocytosis, found worldwide (Simmons 1989: 62–4). Spherocytic (congenital and acquired) anemia involves a deficiency in the Glucose-6-phosphate dehydrogenase enzyme (abbreviated G6PD) that is sex-linked with full expression in affected males and partial expression in females (Simmons 1989: 65). Its geographic distribution is worldwide, with the highest frequency in African populations, although it is also found in Italian, Greek, Asian, and Jewish populations.

Congenital nonspherocytic hemolytic anemia results from deficiency in several red cell enzymes, including glucose 6-phosphate dehydrogenase (G6PD). This condition is found in Asian, European, and Mediterranean populations, as well as in other populations to a lesser extent (Simmons 1989). This anemia is also caused by ingestion or contact with the fava bean by Mediterranean peoples (even from just inhaling the pollen of the bean among some sensitive males, usually under the age of 12). It can also be triggered by the use of antimalarial and other drugs in African and Mediterranean populations. A third cause can result from infection with viral or bacterial pathogens worldwide in persons with G6PD deficiency – pathogens include *Escherichia coli, Salmonella, Streptococcus, Rickettsiae,* viral hepatitis, pneumococcal pneumonia, malaria, and rheumatoid arthritis (Simmons 1989: 65).

A variety of anemias are associated with immunological disorders, including transfusion reactions, ABO or Rh blood-group incompatibility between fetus and mother, and autoimmune hemolytic anemia, a condition in which antibodies or lymphocytes attack cells of the person who produced them. The most common type of autoimmune hemolytic anemia is termed warm-antibody because the autoantibody reacts most efficiently with red cells at 37° Celsius (C) and occurs especially in systemic lupus erythematosus and lymphomas. Less common is cold-antibody type, in which the antibodies are optimally reactive at temperatures less than 37° C, including cold hemagglutinin disease and paroxysmal cold hemoglobinuria (Simmons 1989: 78–81).

Conclusions and Future Directions for Research

As we learn more about iron, we learn more of its multifaceted interrelationship with health and disease in a variety of conditions and situations. It is also apparent that this interrelationship is a complex one. For example, lowered iron levels do not necessarily mean higher morbidity, nor is anemia primarily a nutritional disorder. We predict that future studies of iron will concentrate on its role in health, especially during the periods of rapid growth that occur in childhood and pregnancy, and in response to chronic infection, inflammation, and malignancy.

Further elucidation of iron as a cause of, and as a defense against, disease should reduce morbidity levels all over the world. Therefore, we have much to gain through multidisciplinary research that investigates all aspects of iron. Presented here is an overview of the fascinating picture of iron, a picture only now coming into focus.

Susan Kent
Patricia Stuart-Macadam

We are most grateful to Drs. Gene Weinberg, Steven Kent, and Roy Stuart for the valuable comments on a draft of this chapter. Any inadequacies, however, are solely our responsibility.

Notes

1. The reticuloendothelial system is also called the monocyte-macrophage system.
2. This excretion can be broken down into the following: gastrointestinal loss, of which blood comprises 0.35 mg. mucosal 0.10 mg, and biliary 0.20 mg; urinary loss of 0.08 mg; and skin loss of 0.20 mg (Fairbanks and Beutler 1988: 205).
3. Eugene Weinberg (1966, 1974, 1977, 1978, 1981, 1984, 1990) has numerous publications outlining the exact techniques microorganisms use to extract iron from hosts and the techniques hosts have developed to thwart them.
4. For example, most physicians routinely prescribe oral iron for their pregnant patients; others recommend iron supplements to patients with lowered hemoglobin levels without examining serum ferritin levels. We need to reassess the currently popular practice of indiscriminate iron fortification of foods and infant formula.

IV.B.4 Magnesium

> *It's astonishing how much you may see,*
> *in a thicker fog than that, if you only*
> *take the trouble to look for it.*
> Charles Dickens, *Christmas Stories*

Magnesium is one of the most plentiful elements in nature and the fourth most abundant metal in living organisms. It is extremely important in both plant and animal metabolism. Photosynthesis does not proceed when the magnesium atom is removed from the chlorophyll molecule. Magnesium also plays a key role in many enzyme reactions that are critical to cellular metabolism and is one of the main determinants of biological excitation (Aikawa 1981).

Despite its ubiquitous distribution and the multiplicity of its actions, magnesium has long been considered as a microelement with a vague physiological role, and not until the early 1930s was it recognized as an essential nutrient. Magnesium deficiency in humans was only described in 1951, and according to several experts, it continues to be diagnosed less frequently than it should be (Whang 1987).

There are many explanations for the reluctance to allow magnesium deficiency a place in medicine; among them are the difficulties in measuring magnesium, which have restrained the accumulation of knowledge. Moreover, the essentially intracellular location of the magnesium ion has discouraged the detection of its deficit. Lastly, because magnesium is so widely distributed in foods, its dietary intake has been assumed to be sufficient to meet the body's requirements.

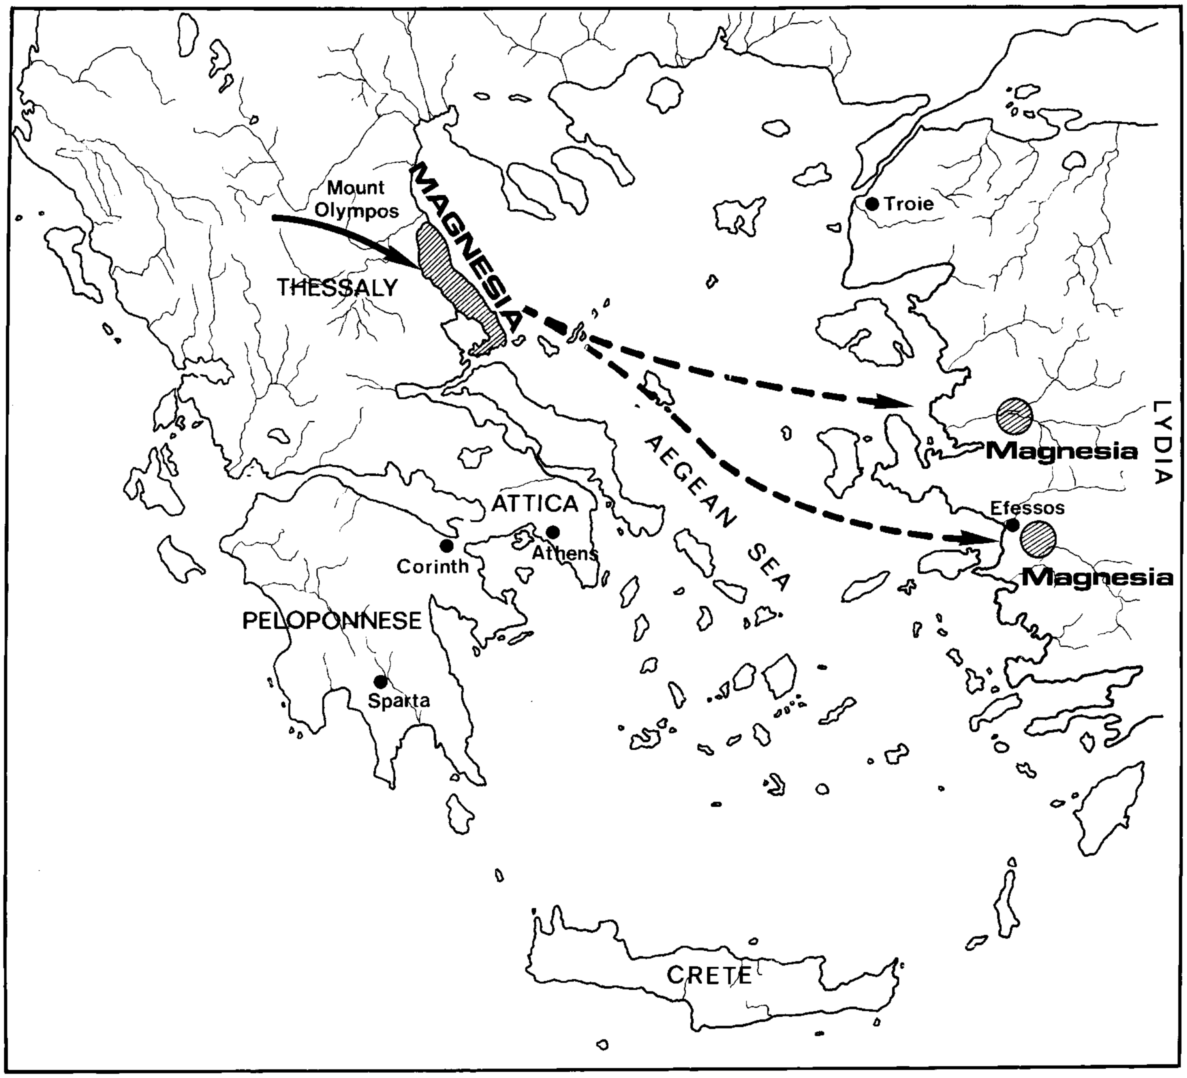
Actually, pure magnesium deficiency is quite rare. Marginal deficiency of magnesium, however, is believed to occur fairly often in the general population. Moreover, in most diseases causing magnesium deficiency, significant nutritional factors exist.

A Note on Etymology

The word "magnesium" originates from the Greek word *Magnesia.* Magnesia is the eastern peninsular region of Thessaly in central Greece. It was named after the *Magnetes,* a prehistoric Macedonian people, by whom Magnesia was first inhabited in the twelfth century B.C. The *Magnetes* are mentioned by Homer, and the port of Magnesia in the Pagassitic Gulf was the place whence the Argonauts sailed on their way to Colchide. Magnesia was also the name of three different overseas colonies established by the *Magnetes* during the eleventh century B.C.: one in central Crete, and two in the inland of Asia Minor (Map IV.B.4.1).

Magnetes lithos and *Magnesia lithos,* which both mean "stone of Magnesia," were the names given by the ancient Greeks to minerals obtained from the earth of either the metropolitan Magnesia or its Asian colonies. *Magnetes lithos* or *magnetes* (magnet) was the term used for lodestone (native iron oxide that attracts iron). Hippocrates, however, the fifth-century B.C. father of medicine, referred to *Magnesia lithos* as a cathartic (purgative). He recommended (as translated by Paul Potter) that "if the cavity does not have a spontaneous movement, you must clean it out by giving spurge-flax, Cnidian berry, hippopheos, or magnetic stone" (Hippocrates 1988). ("Stone of Magnesia" or "Magnesian stone" would be a more appropriate translation than "magnetic stone.") Presumably, the stone mentioned by Hippocrates was native magnesium carbonate (magnesite), the white and light powder that was later called *magnesia alba* and is still used as an aperient and antacid.

Magnesia alba was prepared from the mother liquors obtained in the manufactures of niter by M. B. Valentini of Giessen, in 1707, but it was confused with "calcareous earth" until 1755, when J. Black of Edin-



Map IV.B.4.1. Magnesia and its colonies in Asia Minor. The migration of *Magnetes* during the twelfth and eleventh centuries B.C.

burgh distinguished chemical differences between magnesia and lime. In 1807, Sir Humphrey Davy, conducting his studies on earth compounds in London, succeeded in isolating a number of alkali-earth metals that he named barium, strontium, calcium, and magnium after their oxides baryta, strontia, chalk, and magnesia. Before long, "magnesium" replaced magnium as the name of the element derived from magnesia (Durlach 1988b).

Recognition of Magnesium Deficiency

The Early Years

It was near the end of the nineteenth century when the nutritional significance of minerals was first recognized. That not only organic substances but also nonorganic elements contained in food are necessary for life became evident in about 1870, when the German biologist J. Forster demonstrated the lethal effect in dogs of a diet deprived of inorganic salts (Forster 1873). A few years later, J. Gaube du Gers in France reported that mice fed a diet consisting of magnesium-free bread and distilled water were rendered progressively sterile. Impressed by this finding, he hastened to conclude that magnesium is "the metal of vital activity for what is most precious in life: reproduction and sensation" (Gaube 1895).

By 1900, on the American side of the Atlantic, J. Loeb accomplished his original experiments on the physiology of neuromuscular contractions and was able to state that biological excitation "depends upon the various ions, especially the metal ions (sodium, calcium, potassium, and magnesium) existing in definite proportions in the tissue" (Loeb 1900) (Table IV.B.4.1). About the same time, it was discovered that the magnesium atom occupies the central position in the chlorophyll molecule (Willstatter and Stoll 1913). Thus the most fundamental role of magnesium in nature was discovered, for which a 1915 Nobel Prize was awarded.

As postulated by Jerry Aikawa in recent years, life on earth would not be possible without magnesium, since photosynthesis is absolutely dependent on this element and the photosynthetic process is indispensable for the enrichment of the environment with oxygen (Aikawa 1981). An understanding, however, of the myriad roles of magnesium in biology had to await a method suitable for its measurement in biological materials. The first such method was a gravimetric technique involving the precipitation of magnesium ammonium phosphate. It was introduced by L. B. Mendel and S. R. Benedict in 1909 and was subsequently superseded by its modification to a colorimetric procedure (Alcock 1969).

In the following years, a large number of chemical approaches, including adsorption of titan yellow dye by magnesium hydroxide in the presence of a stabilizer, titrimetric, or colorimetric methods measuring various magnesium-dye complexes, and fluorometric techniques (Table IV.B.4.2), were used for the determination of magnesium in plasma or serum, urine, or fecal samples. The multiplicity of methods is indicative of the lack of satisfaction among investigators with any one of them.

An impressive step forward in the understanding of the role of magnesium metabolism in health and disease was made by the availability of atomic absorption spectrophotometry. This simple, precise method permits multiple determinations of minute amounts of magnesium in small samples of biological fluids and tissues, in a matter of minutes. The theoretical basis of flame spectrophotometry lies in the discovery made by the famous German physicist Gustav Kirchhoff in 1860, that both emission and absorption of light of a specific wavelength are characteristic of a given element. Emission spectrophotometry was first used to measure serum magnesium by V. Kapuscinski and his co-workers in 1952. The quantitative measurement of atomic absorption was conceived by A. Walsh in 1955. J. Alan applied this technique to the measurement of magnesium in plants in 1958, and two years later, atomic absorption spectrophotometry was used for the determination of serum magnesium by J. Willis (Alcock 1969).

Alkaline phosphatase was the first enzyme shown to be activated by magnesium. The discovery was made by H. Erdtmann in 1927. Since then, as many as 300 enzymes have been known to be activated by this cation in vitro, including all those utilizing adenosine triphosphate or catalyzing the transfer of phosphate. Because magnesium is the second most plentiful intracellular cation, it has been postulated that its function also extends to all these enzymes in vivo. By inference, the predominant view has been that magnesium is required for most of the major metabolic pathways in the cell, including membrane transport, protein, nucleic acid, fat and coenzyme synthesis, glucose utilization, and oxidative phosphorylation (Wacker 1969).

Introducing the Concept

The credit for introducing the concept of magnesium deficiency belongs to Jehan Leroy. He showed for the first time that the metal is essential for mammalian metabolisms when he found that white mice fed a diet deficient in magnesium failed to grow (Leroy 1926). However, the most distinctive manifestation of magnesium deficiency was recognized in 1932, when the group led by E. McCollum reported the development of hyperemia and progressive neuromuscular irritability, culminating in generalized and sometimes fatal seizures, in weanling rats fed a diet containing 0.045 millimoles (mmol) per kilogram (kg) of the element (Kruse, Orent, and McCollum 1932).

It should be noted that flaccid paralysis as a pharmacological effect of intravenous magnesium sulfate has been described by French authors since 1869 (Jolyet and Cahours 1869). A distinction, however, should be made between pharmacological properties of a substance and manifestations of its metabolic effect. The fact that a generalized convulsion can be controlled by massive parenteral magnesium administration, for instance, does not necessarily mean that the symptom is due to deficiency of this ion.

During the 1950s and 1960s, the early experiments of McCollum and his colleagues were confirmed and extended by many research groups. Experimental magnesium deficiency produced in rats, dogs, cocks, and other animal species was found to be associated with multiple pathological lesions, including nephrocalcinosis, myocardial necrosis, and calcium deposition in the aorta and the coronary and peripheral vessels; and to be accompanied by other metabolic changes, such as hypercalcemia, azotemia, and tissue potassium depletion.

About the time that McCollum published his original findings on experimental magnesium deficiency, a form of spontaneously occurring hypomagnesemic tetany was observed in adult lactating cattle and sheep. The disease, characterized by neuromuscular irritability, tetany, and convulsions, was termed "grass tetany" because the symptoms developed in the affected animals when they were first allowed to graze on fresh green grass in the spring (Sjollema 1932). Grass tetany has since been reported in many parts of the world, including the United States, many European countries, New Zealand, Australia, and Japan. Although there have been numerous investigations, the etiology of the disease is not clear.

Plasma magnesium is usually low in those afflicted, but grass tetany has also been observed in animals with decreased cerebrospinal magnesium levels whose serum magnesium was normal. The diet of the animals, when they are confined indoors during the winter, consists of silage, grains, and grain mash, which are deficient in magnesium, but symptoms of deficiency do not arise until shortly – sometimes within two days – after the animals are turned out on spring grass. It is of interest that the magnesium content of grasses and grazing vegetation in grass tetany–prone areas has been found to be decreased when compared with the vegetation of non-prone areas (Kubota 1981).

In 1959, a second form of hypomagnesemic tetany of ruminants was recognized when R. Smith reported a gradual development of hypomagnesemia in association with progressive irritability and tetany in calves fed for a long time on a pure milk diet. Magnesium supplementation was found to prevent the disease (Smith 1959). It should be noted that cow's milk contains magnesium in fair amounts, but its high phosphate and calcium content can adversely interfere with magnesium absorption.

Magnesium Deficiency in Humans

As early as 1932, B. Sjollema and L. Seekles, by extrapolating data from veterinary medicine, postulated that human cases of tetany may be related to hypomagnesemia. In 1934, A. B. Hirschfelder and V. G. Haury described seven patients with hypomagnesemia associated with muscular twitching or convulsions and concluded that a clinical syndrome did indeed exist involving low magnesium (hypomagnesemia) accompanied by twitching or by convulsions. One more case of hypomagnesemic tetany was reported by J. F. Miller in 1944. The patient was a 6-year-old boy with associated osteochondrosis of the capital epiphysis of the femurs. Soon after World War II inanition was recognized as a cause of hypomagnesemia, but clinical manifestations were not mentioned (Flink 1980).

The broad spectrum of full-blown manifestations of the magnesium deficiency syndrome was recognized in the early 1950s, when Edmund B. Flink described the amazing case of a woman who, having been on almost continuous intravenous fluid therapy for several months, developed striking neurological symptoms and signs, including almost every form of involuntary movement (Table IV.B.4.3). When first seen by Flink in July 1951 at Minnesota University Hospital, the patient was cachectic, dehydrated, and semicomatose and had severe hyponatremia, hypokalemia, hypophosphatemia, and hypochloremic alkalosis. With the appropriate replacement treatment, serum electrolytes returned to normal within a few days. However, on the sixth day of treatment, the patient began having repeated convulsions associated with gross tremor and myoclonic jerks of extremities, jaw, and tongue, facial

Table IV.B.4.3. *Causes of human magnesium deficiency and year of their first description*

Causes	Year
Inadequate intake	
Starvation	1949
Prolonged fluid therapy without magnesium	1951
Chronic alcoholism	1954
Protein–caloric malnutrition	1960
Defective absorption	
Prolonged diarrhea – any cause	1957
Malabsorption	1960
Increased urinary losses	
Diuretic-induced	1952
Renal diseases	1958
Drug–induced tubular dysfunction	1969

grimacing, choreiform and athetoid movements, and inability to talk or swallow.

These symptoms continued until the eleventh day, when a blood sample was taken for the determination of serum magnesium level. As stated quite emphatically by Flink, "serum magnesium level was obtained for no better reason than that magnesium and phosphate interact and are important intracellular elements" (Flink 1985). Serum magnesium was determined by the titan yellow method and was found to be very low. This finding prompted the intramuscular administration of magnesium sulfate in the daily dose of 2.0 mg. The response was so dramatic that it was characterized by Flink as "unforgettable" (Flink 1985). Tremor decreased after the first dose, and within 24 hours the patient was oriented and able to speak and eat (Fraser and Flink 1951).

One year later, similar symptoms in a patient with alcoholic cirrhosis stimulated the start of clinical and laboratory research on magnesium metabolism in alcoholism by Flink and his colleagues. Much of the knowledge of normal human magnesium metabolism and its alteration in disease originated from these early studies (Wacker and Parisi 1968).

Initially, the discovery of hypomagnesemia in patients with chronic alcoholism and delirium tremens, together with the response of some of these patients to parenteral administration of magnesium, led to the hypothesis that symptoms of alcohol withdrawal were due to magnesium deficiency. However, it was soon realized that many alcoholic patients with near normal serum magnesium levels also had symptoms, whereas others with very low levels did not. It was, therefore, suggested that serum magnesium might not reflect magnesium status, and balance studies were undertaken to elucidate this issue further. It is now quite clear that the main cause of magnesium depletion in alcoholism is inadequate magnesium intake. These early balance studies established the concept of tissue magnesium depletion in the presence of normal serum magnesium levels and revealed increased urinary losses as a possible mechanism of magnesium deficiency. Thus, a significant amount of parenterally administered magnesium was found to be retained by alcoholic patients, indicating tissue magnesium depletion, whereas acute administration of large doses of alcohol was shown to result in increased renal magnesium excretion (Flink et al. 1954). Urinary excretion of magnesium after a load dose has been subsequently established as a feasible test in clinical practice for the evaluation of magnesium status.

That magnesium depletion is likely to occur as a result of drug treatment was first recognized in 1952, when H. E. Martin, J. Mehl, and M. Wertman reported a fall in serum magnesium in association with increased magnesium excretion in 10 patients with congestive heart failure treated with ammonium chloride and mercurial diuretics. Since that time, other diuretics, such as thiazides and loop diuretics; antibiotics, including aminoglucosides, tircacillin, carbenicillin, and amphotericin B; and also cisplatin and cyclosporin have been added to the list of iatrogenic causes of magnesium depletion (Whang 1987).

Intestinal disorders were recognized quite early as a common cause of clinical magnesium deficiency. During the late 1950s and the early 1960s, ulcerative colitis and regional enteritis, along with almost every cause of persistent diarrhea, including chronic laxative abuse, and also intestinal malabsorption due to chronic pancreatitis, short bowel syndrome, gluten enteropathy and tropical sprue, have been reported fairly often in association with symptomatic hypomagnesemia (Table IV.B.4.3).

Data from patients with malabsorption have confirmed previous observations in patients with primary hyperparathyroidism, indicating a relationship between magnesium metabolism and calcium metabolism. Hyperparathyroidism has been recognized as a cause of hypomagnesemia since 1956 (Harman 1956). Although some patients have been found to develop symptoms while hypercalcemic, in most cases hypomagnesemia has accompanied the fall in serum calcium levels after the removal of a parathyroid adenoma and has been attributed to the absorption of magnesium by the "hungry" bones of osteitis fibrosa cystica (Barnes, Krane, and Cope 1957). Since that time, it has been realized that hypercalcemia from any cause, including metastatic osteolysis and multiple myeloma, can be associated with symptomatic hypomagnesemia, because hypercalcemia causes increased excretion of magnesium in the urine (Eliel et al. 1968).

That the two major intracellular cations, potassium and magnesium, behave similarly was originally noted in the course of diabetic ketoacidosis (Martin and Wertman 1947). Similarities between the two ions were further emphasized by the observation that serum potassium and magnesium are both low in cases of primary aldosteronism (Mader and Iseri 1955). Moreover, cardiac arrhythmias, such as ventricular extrasystoles, ventricular tachycardia, and ventricular fibrillation, similar to those induced by hypokalemia, have been described in various clinical disorders known to result in depletion of magnesium. As a matter of fact, the demonstration that in hypertensive patients treated with diuretics, potassium supplementation alone has little effect on ventricular extrasystoles unless magnesium supplementation is added to the regimen has aroused clinical interest in magnesium deficiency significantly over recent years (Hollifield 1984).

Controversial Issues

A Puzzling Syndrome

During the 1960s, human magnesium deficiency was established as a clinical entity beyond any doubt. However, conflicting reports in the literature may have created the view for many that clinical magnesium deficiency is a puzzling syndrome comprising almost every symptom and sign. Such confusion also results partly from the previously mentioned difficulties in assessing magnesium status along with superimposed nonspecific manifestations related to primary illness or other concomitant metabolic abnormalities.

Thus, in addition to the generally accepted signs and symptoms of neuromuscular hyperactivity and disturbance of cardiac rhythm (Table IV.B.4.4), a great variety of manifestations, ranging from difficulty in learning to multiple phlebothromboses, have been proposed as components of the clinical picture of magnesium deficiency (Table IV.B.4.5). Moreover, the observation that even severe magnesium deficiency may have no symptoms or signs has added significantly to the confusion (Martin, Mehl, and Wertman 1952).

The term "spasmophilia" was first introduced by the French physician Nicolas Corvisart in 1852. In 1874, Wilhelm Erb attributed spasmophilia to neuromuscular hyperexcitability, and since then the term has been used to denote "a condition in which the motor nerves show abnormal sensitivity to mechanical or electric stimulations and the patient shows a tendency to spasm, tetany and convulsions" (Dorland 1943).

In 1959, Jean Durlach described a syndrome that he called "hypomagnesemic constitutional spasmophilia." The syndrome, which was considered to be "the nervous form of primary chronic magnesium deficiency in adults," comprised a long list of nonspecific neuromuscular, psychological, cardiovascular, and gastrointestinal manifestations, such as anxiety, excessive emotivity, globus hystericus, dyspnea *sine materia,* dizziness, insomnia, headaches, myalgias, cramps, tremors, tetanic attacks, palpitations, Raynaud's syndrome, biliary dyskinesia, epigastric cramps, and syncope. Symptoms were ameliorated by oral administration of magnesium salts. Low erythrocyte magnesium, a positive Chvostek's sign, and abnormal electromyographic, electroencephalographic, and electronystagmographic tracings were reported as characteristic of the syndrome (Durlach and Lebrun 1959).

Table IV.B.4.4. *Generally accepted symptoms and signs of magnesium deficiency*

Neuromuscular manifestations
Muscular twitching and tremor
Myoclonic jerks
Convulsions
Ataxia and nystagmus
Irritability and restlessness
Dysphagia
Dysarthria
Chvostek's sign (and rarely Trousseau's sign)
Tetany (rarely)
Apathy
Coma

Cardiac manifestations
Premature ventricular contractions
Atrial fibrillation
Torsades de pointes
Ventricular fibrillation
Sudden death

Metabolic effects
Refractory hypokalemia
Hypocalcemia

Table IV.B.4.5. *Additional symptoms and signs attributed to magnesium deficiency by some authors*

Neuromuscular and psychologic manifestations
Anxiety
Depression, hysteria, hypochondria (neurotic triad)
Intellectual and affective retardation
Learning deficiencies
Headaches
Dizziness
Insomnia
Sight weakness
Startle response and noise sensitivity
Neck and back pains
Acroparesthesia
Raynaud's syndrome
"Spasmophilia"

Cardiac manifestations
Coronary artery spasm
Greater size of myocardial infarction

Miscellaneous
Hair and ungueal brittleness
Dysplasia of teeth enamel
Opacification of lens
Ostomalacia
Gastritis, visceral spasm, or dyskinesia ("visceral spasmophilia")
Mitral valve prolapse

Source: Data from Durlach (1988a).

In the years that followed, the compass of clinical magnesium deficiency was broadened to encompass such divergent manifestations as phlebothrombosis, allergic disorders, intellectual retardation, sight weakness, hepatic dysfunction, cases of dysmenorrhea, spontaneous abortion, and mitral valve prolapse. This broadening of the spectrum of clinical manifestations of magnesium deficiency was based on a great number of cases studied by Durlach and other investigators in continental Europe.

The fact that publication of such cases in English has been rare is indicative of the reluctance of American and British experts to accept the existence of a syndrome such as "idiopathic spasmophilic diathesis" due to magnesium deficiency. However, an incident investigated by the U.S. Food and Drug Administration (FDA) in 1980 and a recent double-blind trial performed in Southampton imply that the idea of the involvement of magnesium deficiency in bizarre clinical syndromes should not be totally rejected.

The incident investigated by the FDA was as follows: 11 high school football players with diet histories suggesting low calcium and magnesium intake were given a phosphate-free, soluble calcium preparation because of leg cramps. They were then subjected to the noise and physical contact of a football game. Over a short period, 8 of them developed serious neuromuscular dysfunction manifested by ataxia, slurred speech, hyperventilation, muscle spasm, and tonicoclonic seizures. All of them recovered without specific treatment, and none developed neurologic sequelae. About 10 years later, W. F. Langley and D. Mann noticed the similarity of this syndrome with grass tetany in animals and postulated that central nervous system magnesium deficiency was responsible for its occurrence. The condition was thought to be brought on by a sudden rise in serum calcium and was termed "reactive symptomatic magnesium deficiency" (Langley and Mann 1991).

The randomized double-blind, placebo-controlled trial in Southampton concerned the effect of intramuscular administration of magnesium sulfate on the symptoms of chronic fatigue syndrome (Cox, Campbell, and Dowson 1991). As stated by the authors, the study was undertaken because many of the symptoms of the chronic fatigue syndrome – anorexia, nausea, learning disability, personality changes, tiredness, and myalgia – are similar to those of magnesium deficiency, and because in a pilot study they found that patients with the syndrome had low red blood cell magnesium concentrations. Within six weeks, red cell magnesium had returned to normal in all patients treated with magnesium. In addition, magnesium administration resulted in improvement in energy, pain perception, emotional reactions, sleep patterns, sense of social isolation, and physical mobility, as scored with the use of the Nottingham health profile. The authors confessed, however, that their trial was small and that there was only 6 weeks of follow-up and, therefore, the results were hardly conclusive (Cox, Campbell, and Dawson 1991).

The "Water Story"

In 1957, J. Kobayashi reported a geographical relationship between stroke-associated mortality and river water acidity in Japan (Kobayashi 1957). This was the beginning of what was later called the "water story." Following the publication of the Japanese data, H. A. Schroeder (1960) investigated the relationship between mortality from different diseases and mineral content of drinking water in the United States, and concluded that the important determinant was water hardness rather than water acidity. Drinking soft water, he suggested, may promote the prevalence of cardiovascular disease, whereas hard water may exert a protective action. Since then, associations between hardness of drinking water and mortality from cardiovascular disease have been reported in England and Wales, in Sweden, and in Ontario – the softer the water the higher the mortality from cardiovascular disease.

Ten years after the original report of Kobayashi, T. Crawford and M. D. Crawford (1967) compared cardiac lesions found in medicolegal necropsies in cases of sudden death in two areas: Glasgow, a notable soft-water area with a high cardiovascular disease mortality; and London, a city with very hard water and a considerably lower mortality from cardiovascular causes. They realized that despite the large difference in mortality, the incidence of coronary atherosclerosis was similar in both places. This finding was subsequently interpreted to mean that the excess mortality in the soft-water area might correspond to sudden deaths due to fatal ventricular arrhythmias. Moreover, chemical analysis of the coronary arteries revealed very low values for calcium and magnesium in the soft-water area, suggesting that the mineral content of the arteries was related to the mineral content of the drinking water.

On the basis of the evidence just mentioned, a "cardiac water factor" has been postulated to exist. Presumably, such a factor would be either something beneficial in hard water or something harmful in soft water. Since the bulk of water hardness is made up of calcium and magnesium, these two ions have been the more likely candidates for the "cardiac water factor." Magnesium is a much more abundant intracellular ion than calcium. Furthermore, a considerably greater proportion of the daily magnesium intake, as compared with the daily calcium intake, comes from drinking water. Coupled with the arrhythmogenic potential of magnesium depletion, these facts have led to the hypothesis that magnesium is the cardioprotective factor contained in hard water.

In support of this hypothesis, T. W. Anderson and colleagues (1975) found that magnesium concentrations in myocardial samples obtained from accident victims were significantly lower in five soft-water cities of Ontario than in three hard-water cities of the same province. However, a similar report in England at about the same time (Chipperfield et al. 1976) found a significant difference in mean myocardial magnesium concentration between heart muscle samples obtained from noncardiac deaths in two cities with different water hardness, but the difference was "in the wrong direction." This discrepancy led Anderson and colleagues to conclude that if there was any sort of 'water factor' in Britain, it probably involved something beside magnesium (Anderson et al. 1980).

In the meantime, other simple correlation or multivariate statistical studies, including analysis of the data of the World Health Organization myocardial infarction registry network, have failed to discover a causal relationship between water hardness and heart disease mortality. Schroeder's report has been criticized as misleadingly simplistic, because it was based on correlations between just one index of environmental exposure and a set of death rates (Hammer and Heyden 1980). In addition, the demonstration that only a small proportion of the daily mineral element intake comes from drinking water has cast doubt on the possible physiological significance of water hardness.

Advocates of the "water factor," however, have adopted a somewhat different approach that emphasizes not water hardness but the interrelationship of individual elements contained in drinking water, along with the intake of these elements as they are ingested with food (Marier 1981). In this context, of particular interest are the observations of H. Karppanen in Finland, a country with a very high prevalence of cardiovascular disease. Mortality from ischemic heart disease in Finland shows a peculiar geographic distribution: Starting from the eastern areas, where it is extremely high, it decreases continuously toward the western and southwestern part of the country. These regional differences in mortality correlate with differences in the content of exchangeable magnesium in the arable soils: Magnesium concentration in the soil of eastern areas is only about one-third of that of the southwestern areas. Soil is the primary source of magnesium. Low magnesium concentration in soil is, therefore, expected to result in a low magnesium concentration in drinking water, and also in a low magnesium content of the cereal crops, which are a major food source of magnesium.

In addition to these observations, Karppanen has reported a strong positive correlation between the death rate from ischemic heart disease and the estimated average calcium-to-magnesium ratio of the diet in various Organization for Economic Cooperation and Development (OECD) countries. According to Karppanen, this correlation suggests that what really matters in the "water story" is the ratio of calcium-to-magnesium intake rather than the sum or the absolute amount of each of these elements (Karppanen 1981).

Nutrient or Drug?

Magnesium was known as a drug long before it was recognized as a nutrient. Thus, even in the nineteenth century, parenteral magnesium sulfate was used in the management of eclamptic convulsions and also as an ancillary anesthetic agent. In cardiology, magnesium was first introduced in 1935, when L. Zwillinger reported a beneficial effect of intravenous magnesium sulfate on paroxysmal tachycardia and extrasystolic arrhythmia in patients treated with digitalis. Since then, parenteral magnesium salts have been repeatedly used as an antiarrhythmic agent. Intravenous magnesium has also been recognized as a potent vasodilator agent, useful in the treatment of heart failure and angina pectoris.

During the past five years, several randomized clinical trials have examined the effects of intravenous magnesium in acute myocardial infarction. Collectively, these trials strongly suggest that magnesium therapy may result in decreased mortality as well as the frequency of postinfarction arrhythmias. A larger trial with a planned sample size of 2,500 patients was started in 1987 (Woods 1991).

In all these studies and in many of the cases of treatment of cardiac arrhythmias, the beneficial effect of intravenous magnesium has been related to pharmacological action rather than to repletion of a deficit. In fact, when magnesium is given intravenously, serum magnesium levels are usually raised well above normal values. However, hypomagnesemia is an established cause of cardiac arrhythmias, and magnesium deficiency has been shown to be associated with sudden cardiac death and increased mortality in the acute stage of myocardial infarction (Dyckner 1980). Moreover, low levels of magnesium have been found in myocardial tissue obtained at necropsy from patients with acute myocardial infarction. Consequently, under conditions of magnesium deficiency, a supplement of magnesium is expected to have the same favorable effect on cardiac arrhythmias, and possibly the same protective action against myocardial ischemia, as the administration of magnesium salts in pharmacological doses.

On the basis of the evidence just mentioned, it is clear that the characterization of magnesium as a drug or as a nutrient depends on the distinction between pharmacological action and replenishment of deficient stores (Charbon 1989). When there is a proven magnesium deficiency, magnesium acts as a nutrient. The patient is then expected to be completely cured as soon as the deficit is corrected. However, parenteral magnesium salts may be given as a drug. In this case, though, their potency and duration of action will depend on magnesium concentration in plasma, and their effect will be the same in each case of repeated administration.

Adequacy of Intake

Estimates of the daily requirements of magnesium have been largely based on the original calculations published in 1942 by J. Duckworth and G. Warnock, who calculated the magnesium requirements by analyzing the available data from balance determinations done in the 1930s. Currently, the Recommended Dietary Allowance (RDA) proposed by the Food and Nutrition Board of the National Research Institute of the United States is 350 mg per day for men and 300 mg per day for women, providing about 4.5 to 5.0 milligrams (mg) per kilogram of body weight per day (Munro 1980). RDA is increased to 450 mg per day during pregnancy and lactation and to 400 mg per day during adolescence in males. For infants and children the corresponding values are 100 and 200 mg per day.

Magnesium is so plentiful in both plant and animal foods that the recommended daily intake is readily obtained in ordinary diet. Common dietary sources include unprocessed cereal, nuts, legumes, vegetables, seafood, dairy products, meats, and drinking water.

However, Mildred Seelig (1964) in the United States and Durlach (1988a) in France have suggested that magnesium intake in developed countries may be insufficient to meet daily needs. Since then this concern has been shared by many nutritionists.

The shortage of magnesium in contemporary diets has been attributed to the increased reliance of people in most Western countries on highly purified foods, such as sugar, starch, soft drinks, and distilled alcohol, that contain very little magnesium. Agricultural techniques of accelerated growth, resulting in decreased magnesium fixation by plants, and the use of magnesium-poor soil fertilizers, and also of pesticides that inhibit magnesium absorption, are considered as additional causes of decreased magnesium content in food items currently available for civilian consumption in industrialized countries. In fact, analysis of sample meals in the United States, Canada, and several European countries has revealed that the contemporary magnesium intake ranges from minimal adequacy to as low as 50 percent of the RDA (Table IV.B.4.6). This observation seems to hold particularly true for special population groups, such as pregnant women, teenage girls, or elderly people, because of increased needs, limited nutritional intake, or the age-associated decline in intestinal magnesium absorption (Mountokalakis 1987). In view of these considerations, Seelig has suggested that the recommendations for daily magnesium intake should be revised upward to as much as 7 to 10 mg/kg body weight.

Other experts opposed to this view have argued that since the RDA includes a generous margin of safety above the current estimates of the minimal daily requirements, the expression of adequacy of magnesium intake as a proportion of the RDA may be misleading. As a matter of fact, metabolic studies have indicated that a positive magnesium balance can be maintained at intakes as low as 60 percent of the currently proposed RDA. The answer to these arguments has been that because RDA is calculated by analyzing the results of metabolic studies conducted under conditions of relative serenity, it does not take into account possible changes of magnesium requirements related to the stresses of everyday life. The advocates of the "magnesium malnutrition" hypothesis emphasize that although the reported suboptimal intakes do not necessarily lead to overt clinical magnesium deficiency, they may represent a "long-term marginal magnesium insufficiency" with the potential risk of increased vulnerability to several disease processes (Marier 1982). The present uncertainty about evaluating the clinical status of magnesium impedes any attempt to clarify this issue further.

Table IV.B.4.6. *Magnesium intake in the modern-day world*

Locality and special group range)	Year	Population studied	Intake as percentage of RDA (average o
		Healthy adults

Epilogue

The story of magnesium is a story of discovery and also a story of neglect. Over the past few decades, enthusiasm about magnesium has repeatedly turned to indifference. Since 1971, when the First International Symposium on Magnesium Deficit in Human Pathology was held at Vittel (France), five international congresses and several American and European meetings on magnesium have taken place, and three journals exclusively devoted to magnesium have been published. Yet despite all this worldwide research activity, the practicing physician has relatively little interest in magnesium, and hypomagnesemia is currently the most underdiagnosed electrolyte deficiency (Whang 1987). Moreover, essential data for diagnosis and physiopathology are still lacking.

No doubt magnesium is an important intracellular element with a key role in many metabolic functions. The irony is that this multifaceted role of magnesium in the organism has been the main obstacle in understanding its fundamental function. A characteristic example is the physiological interrelationships of magnesium and hormones. Companion to both calcium and potassium, magnesium has long been assumed to interact with the hormones involved in the homeostasis of these two ions. The evidence, however, now shows that neither parathyroid hormone nor aldosterone exerts an overriding control on magnesium metabolism. Yet the facts that magnesium and calcium are mutually influenced and that hypomagnesemia can cause loss of intracellular potassium, in spite of a normal plasma potassium, are not in question.

Some 30 years ago, magnesium was hardly mentioned in the medical textbooks. Since then, much more information has been acquired. Although most of the current textbooks contain adequate data on the subject, they repeatedly state that magnesium is found in so many foods that, ordinarily, magnesium deficiency is rare in healthy people. It should be noted, however, that although magnesium is well conserved by both the kidneys and the bowel when the supply is limited, it is poorly stored so that a regular intake is needed to avoid deficiency. It is, therefore, natural to assume that a marginal deficiency state may be not uncommon. And once it was realized that magnesium has important cardiovascular effects, emphasis shifted from a focus on overt clinical magnesium deficiency to interest in the concept of marginal magnesium deficiency as a risk factor for cardiovascular disease. The importance of this concept is underscored by the characterization of magnesium as "nature's physiological calcium blocker" (Iseri and French 1984).

Because most of the body's magnesium is intracellular, the challenge for the future is to develop a feasible test in clinical medicine that will give meaningful information on the overall intracellular magnesium status. The question of intracellular magnesium is, without doubt, the most difficult to resolve. It is, however, the clarification of this issue that will enable us to understand better the relationship of magnesium to health and disease and to ascertain the magnitude of the segment of the population that may be deficient in this important nutrient.

IV.B.5 Phosphorus

Phosphorus (abbreviated as P) is a highly toxic element, which, when it occurs in the form of a phosphate salt, becomes a nutrient essential for human health. Phosphates are found in practically every type of food and, consequently, are plentiful in the typical diet. Inorganic phosphates (abbreviated as P_i) are absorbed from food as electrically charged salt anions. The organic phosphates (P_o) that exist in cells and extracellular compartments of foods are primarily converted to P_i through digestive processes prior to absorption. A few organic phosphates are apparently absorbed as part of small fat-soluble organic molecules, such as the phosphates of phospholipids. The concentration of P_o molecules, however, is not under homeostatic control, in contrast to the concentration of P_i, which is regulated along with calcium (Ca) in blood and extracellular fluids.

The close association between calcium and P_i in the extracellular body fluids and in bone tissue requires joint consideration of dietary calcium and dietary phosphates for an understanding of their physiological linkages and the important relationship between low calcium intakes and high phosphate intakes. This relationship potentially contributes to altered calcium homeostasis and the loss of bone mass.

Several aspects of P_i are reviewed here in an attempt to place these essential chemical anions in the perspective of their utilization in human health and disease. The physiological functions of P are reviewed first, and a number of general references have also been included in the bibliography for the interested reader.

Physiological Functions of Phosphates

The regulation of P_i in the blood is maintained by a complex homeostatic system that also controls the blood concentration of Ca. P_i ions can follow several potential metabolic pathways after entry into cells.

One immediate use of P_i ions is to phosphorylate glucose through enzymatic steps via kinases. They are also used in the phosphorylation of several other molecules; for example, creatine phosphate serves as an energy reserve in skeletal muscle tissue, and adenosine triphosphate is the primary donor of energy from its high-energy bonds within cells. In addition, several types of phospholipids and nucleic acids incorporate P_i within their molecular structures.

Cellular uses of P in intermediary metabolism are very extensive. Practically all energetic steps utilize high-energy phosphate bonds (adenosine triphosphate, or ATP) for the synthesis of organic molecules: to drive transport systems across cell membranes, to make muscles contract, to allow nerves to conduct impulses and transfer information, to convey genetic information, and to provide skeletal support and protection. In addition, phosphates circulating in blood have buffering activity. Clearly, P_i ions have multiple uses both within and without cells. Mineralized bone serves as an important store of P_i ions that can be retrieved through the action of parathyroid hormone (PTH) on bone cells. Because of the large reservoir of P_i ions, hypophosphatemia and P deficiency are rare events in adults without other major complications.

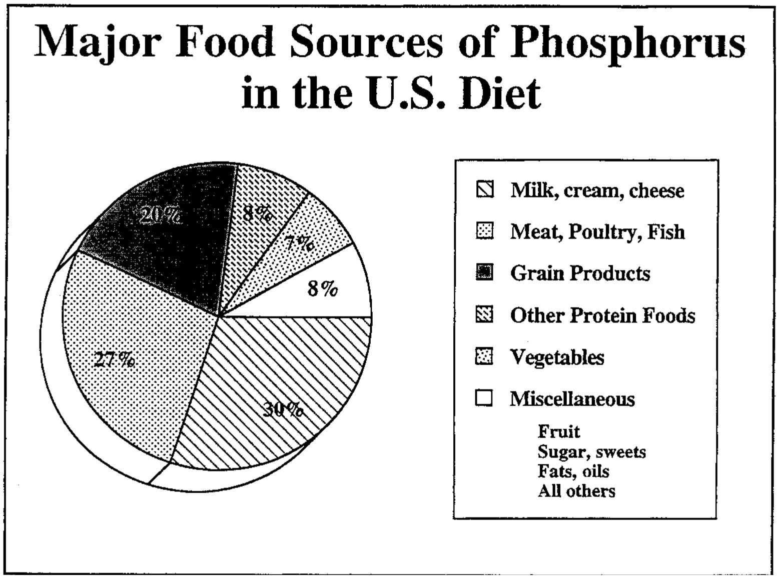
Phosphates in Foods

In terms of dietary sufficiency, P does not present a problem for human health because of the abundance of molecules containing this element in the food supply. Rather, the potential health problem is dietary Ca insufficiency in relation to excess intake of phosphates over periods of years, or even decades. Phosphorus deficiency, a rare clinical disorder, occurs almost exclusively because of a pathological change in the handling of phosphates, rather than because of a dietary inadequacy. The reason for these encompassing statements is that almost all foods contain phosphate groups in both organic (P_0) and inorganic (P_i) forms, and many of the foods – especially animal products – commonly consumed by all populations of the world are rich in P.

The approximate percentage distribution of foods (by food group) that provide dietary P in the United States is as follows: Milk and dairy products – 30 percent; meat, poultry, and fish – 27 percent; cereal grains and grain products – 20 percent; legumes, nuts, and seeds – 8 percent; vegetables – 7 percent; and other (miscellaneous) foods, including fruits – 8 percent (Figure IV.B.5.1). Although accurate data are lacking, it is presumed that these percentages are similar for the nations of the European Union, along with other Western countries. For populations that consume few dairy foods (or none), the percentage of dietary P contributed by grains, legumes, vegetables, and fruits would be greatly increased, depending on the food traditionally available. Vegetarians of all types, but especially "vegans" (strict vegetarians), have lower P intakes than do omnivores who consume several servings a day of dairy foods and meats. But, even though P intakes by vegans could be insufficient, deficiency symptoms are very unlikely.

As Figure IV.B.5.1 illustrates, P is widely found in foods in their natural unprocessed condition, and available food composition tables report the amounts of P measured in natural foods without any phosphate additives. Unfortunately, no food tables exist for the P content of processed foods. This lack is a serious hindrance to the accurate estimation of total phosphorus consumption from all foods, processed and unprocessed.

Figure IV.B.5.1. Approximate percentage contributions of the major food groups to the consumption of phosphorus. (Note: Phosphate additives are not included in these estimates.) (From USDA, CSFII 1994; adapted from Anderson and Garner 1996.)



Plant Foods

Although cereal grains and most vegetables yield good amounts of phosphates, these are nonetheless typically smaller amounts than those provided by animal foods. Moreover, except for highly processed wheat flours and polished rice, cereal grains have much of their P_o bound in phytates that are not completely digested within the gastrointestinal (GI) tract, and therefore, the total amount of P in grains is not available for absorption. Legumes and foods made from them, including soy flour and peanuts, are good sources of P, but this is not the case for most other plant foods, save for nuts such as almonds. Fruits, fruit juices, and vegetable oils contain negligible amounts of P. Table IV.B.5.1 lists the amounts of P (as a combination of both P_i and P_o) and calcium in commonly consumed foods.

Cereal grains contain significant amounts of the polyphosphate phytic acid (inositol hexaphosphate) in the bran and other parts. Each phytate molecule contains 6 P_o groups that become P_i groups when phytates are digested within the lumen of the GI tract by phosphatase enzymes. Food composition tables should be consulted for the phosphorus (combined P_o and P_i) content of specific foods.

Table IV.B.5.1. *Content of phosphorus and calcium in commonly consumed food in mg per serving*

Food Item	Serving size (1)	Phosphorus, mg	Calcium, mg	Calcium: phosphorus ratio
Yoghurt, plain	cup	326	415	1:0.8
Milk, 3.5%	cup	228	291	1:0.8
Milk, skim	cup	247	302	1:0.8
Cheese, Amer.	1 oz	211	174	1:1.2
Mozzarella, skim	1 oz	149	207	1:0.7

Broccoli	0.5 cup	50	47	1:1.1
Corn, kernel	0.5 cup	39	2	1:19.5

Source: Hands, FOOD Finder: Food Sources of Vitamins and Minerals (1990).

Animal Foods

Animal foods are rich in P, with eggs, meats, fish, crustaceans, mollusks, poultry, and dairy products containing large amounts of this element. Liver, cheeses, and eggs (yolks) are highest in phosphorus, followed by meats, fish, and poultry, and then by milks (of any fat content). (See Table IV.B.5.1 for a listing of the P content of commonly consumed foods.) Mixed dishes that feature cheese or milk also have large amounts of P.

Food Additives

Phosphates (both P_i and P_o) are increasingly found in the food supplies of economically developed nations because of their widespread use as chemical additives in food applications. The food and beverage industries add a significant amount of phosphates to many foods and to cola-type beverages. Phosphate additives represent a diverse group of molecules, practically all of which are readily solubilized within the stomach or upper small intestine and are thereby highly bioavailable. Processed foods currently consumed by North Americans often have a significantly increased phosphorus content because of the intentional addition of one or more of these phosphate salts (Calvo 1993; Calvo and Park 1996). Phosphate additives have several functions in foods, notably as acids, buffers, anticaking agents, emulsifiers, and sequestrants (Dziezak 1990), and individuals who consume many processed foods (especially those with cheese in them) are estimated to have an increased daily phosphorus intake of 10 to 15 percent.

Supplements

Because practically all foods naturally contain phosphorus, and many processed foods have phosphates added to them, no need for supplementation exists in healthy individuals with normal renal function. Except for very rare clinical cases of renal phosphate wasting condition, or phosphate deficiency in newborns or premature babies, it is difficult to conceive of a situation requiring phosphate supplements.

Phosphate Additives – Recent Changes

The use of phosphate additives in food processing has accelerated since 1950, and in fact, for the first time in history, humankind faces an excess of phosphorus in the food supply because of the intentional addition of an estimated 40 to 50 different phosphate salts (Calvo and Park 1996). This, in turn, has introduced the possibility of an adverse effect of total phosphate consumption (from foods, beverages, and additives) on bone health, much as excess sodium intake from sodium-processed foods has contributed to the high prevalence of hypertension in the United States and other nations.

An interesting aspect of this increased intake of P is that it is not included in national survey estimates of total P consumption, meaning that the true intake of phosphorus in the United States is substantially underestimated (Oenning, Vogel, and Calvo 1988; Calvo and Park 1996). A study by M. S. Calvo and Y. K. Park (1996) shows a trend of increasing availability of phosphate additives in the food supply from specific items, such as frozen pizza, frozen processed poultry, and frozen prepared foods. Particularly worrisome is the increased availability of frozen processed poultry products in the marketplace over the last few years. (Frozen-food manufacturers, especially, utilize phosphate additives because of the phosphates' stability when the foods are thawed or heated.) Fast-food entrees also often contain phosphate additives, but little or none of the phosphate-additive content of these foods is included in estimates of phosphorus consumption (Calvo and Park 1996).

Dietary Intakes of Phosphates

Current dietary patterns in the United States suggest that, on the average, American women are consuming too little Ca in relation to P. In every age category over 11 years, the calcium intakes of females are so low that the median Ca:P ratio falls to 0.6, and approximately 10 percent of the female population has a ratio of 0.4 or less. This low ratio contributes to a persistent elevation (above baseline) of the parathyroid hormone (PTH), the major regulatory hormone affecting Ca and P metabolism.

Figure IV.B.5.2a illustrates the patterns of P and Ca consumption of females in the United States (USDA 1994). These median (50th percentile) intakes are compared to the Recommended Dietary Allowances (RDAs) (National Research Council 1989). Figure IV.B.5.2b shows the Ca:P ratio from the diet of females across the life cycle. The Ca:P ratio of 1:1 is illustrated as a line to demonstrate that this idealized ratio is not met from foods by females (or males) except during the first few months of life when breast milk is consumed.

Requirements and Allowances of Phosphorus

P is an essential nutrient because it is needed for both organic molecules and the mineralized tissues – bones and teeth. Indeed, it has been speculated that calcium-phosphate salts were the substratum for the synthetic steps that resulted in the origin of life in the liquid medium during the early history of the planet Earth.

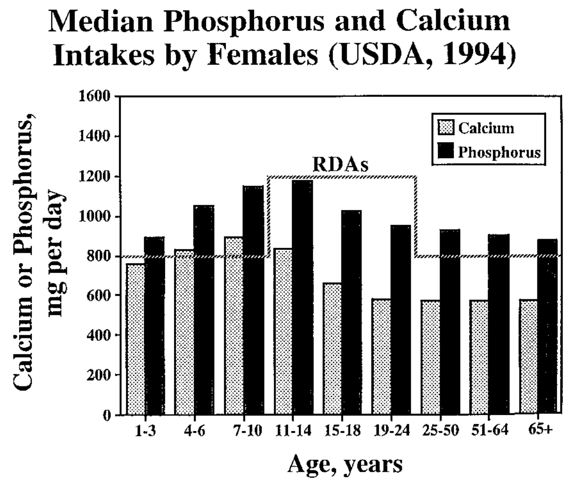

Figure IV.B.5.2a. Median phosphorus and calcium consumption (50th percentile) of females in the United States in comparison to the 1989 Recommended Dietary Allowances (RDAs) for both phosphorus and calcium. (From USDA 1994.)

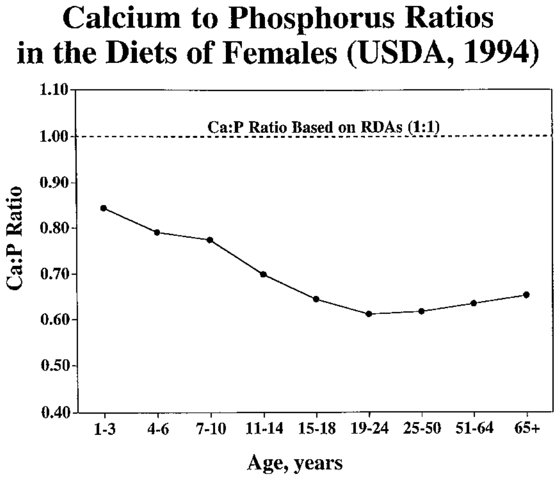

Figure IV.B.5.2b. The dietary calcium to phosphorus (Ca:P) ratio of females across the life cycle, calculated from the data in Figure IV.B.5.2a. The RDAs of calcium and phosphorus generate a 1:1 ratio (dotted line), but this ratio is not achieved except during the first few months of life by infants fed breast milk. (From USDA 1994.)

Phosphorus Requirements

The amounts of P needed in the diet each day depend on several variables, such as stage of development in the life cycle, gender, body size, and physical exertion. Mean requirements of dietary P are not precisely known for either sex during adulthood, but daily U.S. intakes (roughly between the 10th and 90th percentiles) of P fall in a range of approximately 1,600 to 2,400 milligrams (mg) per day for males and 1,200 to 1,600 mg for females, according to data generated by the U.S. Department of Agriculture's Continuing Survey of Food Intakes by Individuals (CSFII) (USDA 1994; Calvo and Park 1996).

Requirements of P may be as low as 600 to 800 mg a day for females and 800 to 1,000 mg for males, but these are educated guesses only, which assume adequate consumption patterns of calcium. Excess P_i that is absorbed is excreted by individuals with healthy kidneys in practically a 1:1 ratio to intake. In late life and in individuals who have declining renal function, some phosphate ions may be harbored (not truly stored) in mineralized atheromatous deposits within the arteries and in the skin. P balance-assessment methods have been historically helpful in arriving at estimates of P requirements, but they typically have low precision of measurements in feces; therefore, they are not very reliable.

Phosphorus Allowances

Recommended Dietary Allowances have long been established for phosphorus as well as for calcium, and age- and gender-specific recommendations have been kept identical for both of these minerals across the life cycle since the first edition of the RDAs in the early 1940s. These identical values presume a 1:1 ratio of dietary intake of calcium and total phosphorus (P_i and P_o combined), but actual dietary intakes almost never achieve such a ratio except in the early months or years of life. When the typical intake ratio declines to approximately 0.5:1, the homeostatic regulation of serum calcium becomes so significantly challenged that skeletal mass may be lost in order to maintain the blood calcium concentration at a set level.

The Calcium:Phosphorus Ratio and Relationship

The problem with excessive dietary P intakes (or even just adequate intakes) is the imbalance between calcium and phosphorus that can result from typically low dietary calcium consumption patterns (see Figure IV.B.5.2b). Because practically all foods contain phosphates, but only a few have much calcium, eating behaviors that exclude calcium-rich foods (mainly milk and related dairy foods) may contribute to a condition known as nutritional secondary hyperparathyroidism – and one that can be exacerbated in individuals who consume diets rich in phosphate additives and cola drinks with phosphoric acid (Calvo 1993). The high intake of total P is not in itself so much of a problem as are the behaviors that lead to the avoidance of calcium-rich foods. This is because the latter lowers the Ca:P ratio and causes the development of a persistent elevation of PTH (Calvo, Kumar, and Heath 1990). A diet containing adequate amounts of Ca can overcome these adverse effects of P (Barger-Lux and Heaney 1993).

Because long-term prospective human studies of high-P diets have not been published, data from short-term and cross-sectional investigations must be used to assess the adverse effects of persistent low-Ca, high-P intakes on bone status. Unfortunately, only a few researchers have examined this issue of the dietary Ca:P ratio. One four-week investigation of young women consuming a Ca:P ratio of 0.25:1 revealed the undesirable persistent rise in PTH (Calvo et al. 1990). Another study of cross-sectional data from healthy, young-adult females indicated that too much P relative to calcium in the usual diet has a negative effect on the mineral content and density of bone (Metz, Anderson, and Gallagher 1993).

The mean Ca:P ratio of U.S. adults approximates 0.5:1 (Calvo 1993), and in fact, healthy ratios of intakes of the two elements range from 0.70 to 0.75 when the recommended number of servings from all food groups (based on the Basic Food Guide or Food Pyramid) are consumed each day. In other words, it is very difficult in the United States to achieve a ratio of 1:1, the ratio recommended in the RDAs (National Research Council 1989), without taking Ca supplements. Nonetheless, a healthy eating pattern should include a ratio within the range of 0.7:1 to 1:1. Intake ratios at or below 0.5:1 are of concern because of the likelihood of persistently elevated PTH concentrations and the potential loss of bone mass, which could lead to fragility fractures.

Digestion of Phosphates from Foods

Phosphates in foods exist mainly as organic molecules that must be digested in order to release inorganic phosphate into fluids of the intestinal lumen. P_i anions freed up by digestive enzymes are then ready for absorption; little likelihood exists for their resynthesis or precipitation because of the lower pH level (~6.0 to 7.0) of the upper half of the small intestine.

The common types of enzymes of the gut that break the bonds of phosphate-containing molecules are secreted almost entirely by the exocrine pancreas. These enzymes include phospholipases, phosphatase, and nucleotidase – as these names imply, the enzymes have specific target molecules that contain phosphates. Once these P_i molecules are solubilized in the lumen, all are equal in the sense that the absorbing mechanisms of the small intestine do not discriminate based on the molecule of origin.

Phytates, which occur in large amounts in cereal grains, are rather poorly digested by humans. The reason is that phytase enzymes are not made in the human body, and only the phytase enzymes present in the bran and other parts of the grain can accomplish this chemical digestion.

Intestinal Absorption of Phosphates

Inorganic phosphate anions are efficiently absorbed across the small intestine, primarily in cotransport with cations, in order to maintain the electrical neutrality of cells. The efficiency of absorption (net) of P_i ranges between 60 and 70 percent in adults, almost twice the efficiency (net) of calcium from the diet (that is, 28 to 30 percent) (Anderson 1991). For example, for every 1,000 moles of P_i, approximately 700 are absorbed (net), compared to only 300 (net) from 1,000 of Ca in the diet. Therefore, the excretory mechanisms have to work more efficiently to eliminate the extra P_i absorbed following meals. In children, the net absorption efficiencies may be as high as 90 percent for P_i and 50 percent for Ca. Several factors have adverse effects on P_i absorption, but these typically have little overall influence on P_i utilization, homeostasis, or metabolism. A few factors may enhance P_i absorption, but these, too, have little significance for the overall economy of P_i in the body (Allen and Wood 1994). A high P intake has been reported to have little effect on calcium absorption (Spencer et al. 1978).

The absorption efficiency of P_i declines later in life so that the net absorption of phosphorus from foods is somewhat reduced; probably this occurs in a similar fashion as calcium absorptive efficiency is lowered with age, especially after age 65 in females.

P_i ions are absorbed across all three segments of the small intestine, but the rapid entry into the bloodstream of radioactively labeled phosphates suggests that duodenal absorption occurs both very efficiently and at a high transfer rate. Therefore, the bulk of the absorbed P_i ions are transported across this segment, lesser amounts across the jejunum, and still lesser amounts across the ileum. If the hormonal form of vitamin D – calcitriol or 1,25-dihydroxyvitamin D – is elevated, P_i absorption can be even further enhanced in all segments of the small intestine.

Regulation of Blood Phosphate (P_i) Concentration

The homeostatic regulation of P_i in blood is primarily controlled by PTH, but several other hormones also exert influences on it. The major sites of regulation are the kidneys and the gut. PTH acts on the renal tubules to inhibit P_i reabsorption, while at the same time enhancing Ca reabsorption. The response of the kidneys to the action of PTH is the primary route of loss of P_i from the body. A secondary route is the small intestine, through which intestinal secretions from glands within the serosa of the intestinal lining remove P_i from the bloodstream to the gut lumen. This route of loss of P_i ions is called endogenous fecal excretion, and the quantity of P_i lost by this route may be almost as great as renal losses over a 24-hour period.

Absorption of an excess of P_i tends to lower the blood Ca ion concentration, which then triggers the secretion of PTH from the parathyroid glands. The role of circulating P_i in the secretion of PTH has been investigated in animal models and in human subjects to establish the connection with high dietary phosphorus intake. As mentioned, the absorption of P_i ions is rapid following a meal, much more so than for calcium ions. When an excess of P_i ions exists in the blood, the P_i concentration increases; this change, in turn, drives down the Ca ion concentration through a mechanism involving ionic binding between the two ions.

The net reduction in the concentration of Ca ions then stimulates the secretion of PTH. In turn, PTH enables the transfer of residual circulating Ca and P_i ions into the bone fluid compartment and into other extravascular compartments of the body. (Some investigators suggest that calcitonin, another calcium-regulating hormone, is involved in the movement of these ions into bone and, hence, in the conservation of calcium after a meal.) The persistently elevated PTH, however, tends to undo calcium conservation in the skeleton because this hormone continuously stimulates the reverse transfer of Ca and P_i ions from bone to blood (Calvo et al. 1990). The net result is that the skeleton loses bone mineral when PTH is elevated, even within the normal range of blood concentration, over extended periods of time. (The actual site of loss of this Ca is the gut, which has a poorly regulated secretion of Ca ions through intestinal glands.) PTH also has other roles in the kidney that, in effect, contribute to Ca retention by the body and to the elimination of P_i via urinary excretion.

PTH is considered the major hormone regulating P_i homeostasis because of its powerful roles in enhancing renal and, possibly, intestinal P_i losses while, at the same time, conserving calcium ions. When PTH is elevated, renal P_i reabsorption is largely inhibited, and similarly, the secretion of P_i ions by intestinal mechanisms is enhanced (although an understanding of this route of P_i loss is less established). PTH also acts on bone tissue to increase the transfer of calcium ions from the bone fluid compartment (BFC) and from the resorption of mineralized bone tissue to the blood plasma to restore the calcium ion concentration. By these same actions of PTH, P_i ions are also indirectly transferred from the BFC and bone to the blood.

Phosphate Balance

P balance means that intake of P from foods equals losses in urine and feces (and other sources, such as sweat and skin, which are seldom measured). In effect, P_i ions that are absorbed are accounted for by losses from the body. Under balance conditions, no net gain or loss of P_i ions occurs. This zero-balance state probably only exists during the adult years from roughly 20 to 60. During growth, and during pregnancy and lactation, positive balance states tend to predominate, whereas in late life, phosphate retention may increase and become a major health problem for individuals with declining renal function. Phosphate retention (positive P balance) results from the declining effectiveness of PTH in enhancing renal excretion of P_i ions with decreasing renal function.

A schematic diagram of the P balance of an adult male is shown in Figure IV.B.5.3. An adult male would typically consume 1,200 to 1,400 mg of P a day, whereas an adult female would consume 900 to 1,000 mg per day (USDA 1994; Calvo and Park 1996).

These estimated intakes of P by gender, however, do not include phosphate additives in foods.

Positive P balance (both P_o and P_i), or the net gain of this element by the body, is difficult to measure, but numerous balance studies suggest that P homeostasis (that is, zero balance) is typically maintained even when Ca balance may be significantly negative. Radioisotopic and stable nuclide studies have greatly advanced our knowledge about the fluxes of P_i and Ca ions across the gut and renal tubules in animal models and, to a lesser extent, in human subjects. Balance studies without the use of stable or radioactive nuclides are notoriously fraught with potential errors of collection and measurement, and these difficulties make such studies generally unreliable in the precise quantitative sense.

The uptake of P_i ions by cells requires carrier mechanisms or cotransport systems because of the electrical charge and water-solubility properties of these anions. P_i ions typically cotransport with glucose in postprandial periods, but their charge must be neutralized by cations, typically not calcium ions. Also, after meals, P_i ions enter the bone fluid compartment, but in this case, typically with calcium ions. Calcitonin has been considered primarily responsible for the uptake by bone tissue of these two ionic species following food ingestion and the intestinal absorption of the ions (Talmage, Cooper, and Toverud 1983). After entry into cells, the P_i ions in the cytosol are almost immediately used to phosphorylate glucose or other molecules, and a small fraction of the ions are stored as organic molecules or inorganic salts within cellular organelles.

Some P_i ions that enter bone may enter bone cells, especially osteoblasts or lining cells, whereas other ions bypass the cells and go directly to the BFC, an extension of the blood/extracellular-fluid continuum. In the BFC, P_i ions in solution increase the P_i concentration (activity) that permits these ions to combine with Ca ions in excess of their solubility product constant (Ksp) and form mineral salts (precipitate) in bone extracellular tissue. The formation of hydroxyapatite crystals (mineralization) is essential for structural support and protection of internal organs from environmental trauma. P_i ions are, therefore, essential for the formation of the endoskeletons typical of most vertebrates except cartilaginous fish.

Approximately 60 to 70 percent of P_i ions are cleared by the kidneys in healthy individuals. If PTH is elevated, P_i excretion is enhanced even more, so that P_i losses are further increased. Under the same conditions of elevated PTH, the secretion of P_i by the gut is also increased. The endogenous fecal secretion of phosphates is the second major route of loss that the body uses to maintain P_i ion homeostasis.

Persistently Elevated Parathyroid Hormone

Of the many diseases that have significant alterations in P homeostasis, only two are reviewed in any depth here. The first is persistently elevated PTH in response to a low Ca:P dietary intake pattern, whereas the second is renal secondary hyperparathyroidism resulting from chronic renal failure. Previously, the former was often referred to – perhaps erroneously in the case of humans (in contrast to animals) – as nutritional secondary hyperparathyroidism. In the context of human disease, the term "hyperparathyroidism" is inappropri-

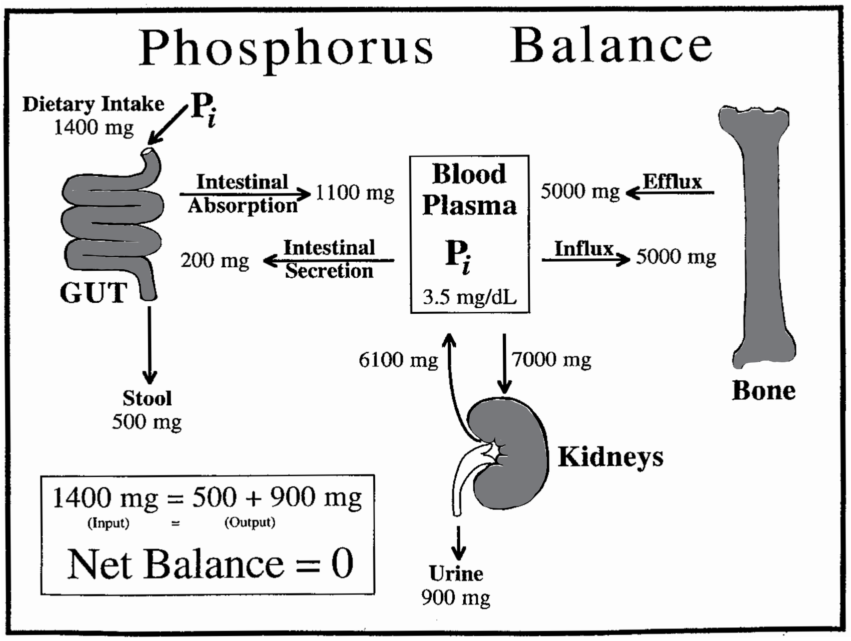

Figure IV.B.5.3. Schematic diagram of phosphorus balance of an adult male. (Adapted from various sources.)

ate because the PTH levels that result from a low Ca:P ratio typically remain within the normal range of blood concentration, although usually at the high end of the range. As mentioned, a persistently elevated PTH, even if it remains within the normal range, contributes to increased bone turnover that can result in a reduction of bone mass and density (Calvo et al. 1990). If this condition continues for a year or longer, it could contribute to fragility fractures because of the thinning of trabecular plates at bone sites, such as the vertebrae, wrist, and proximal femur. On the basis of obtaining a benefit from a PTH value at the lower end of the range, individuals with a low Ca:P ratio would be advised to increase their calcium intake from foods first and from supplements second. An adequate calcium intake is known to reduce serum PTH concentration (Krall and Dawson-Hughes 1994).

Figure IV.B.5.4 diagrams the mechanism through which a low dietary Ca:P ratio contributes to the development of a persistently elevated PTH concentration. Figure IV.B.5.5 illustrates the potential changes in bone mass and mineralization of the skeleton in individuals who typically consume diets with low Ca:P ratios compared to those who have normal intake ratios. The persistently elevated PTH is responsible for the limited bone mineralization and the loss of bone mass (Anderson 1996).

Renal Secondary Hyperparathyroidism

Renal secondary hyperparathyroidism results from a severe increase in PTH that occurs because the kidneys can no longer filter and secrete sufficient amounts of P_i ions each day. As the blood concentration of P_i increases, the serum PTH also rises in an attempt to correct the error (increase of serum P_i). The action of PTH on bone tissue then predominates, and the rate of bone turnover continues to increase, unless corrected by renal dialysis or kidney transplantation. Without correction, the net result is a

continuing increase in the serum P_i concentration and a rapid thinning of bone tissue at practically every site in the body. If severe enough, this condition can result in fractures at almost any skeletal location. Oral phosphate binders, such as aluminum or magnesium hydroxides, are usually administered to patients to reduce the amount of P_i absorbed by the small intestine and to enhance calcium absorption, but this strategy typically is not sufficient to stem the gradual increase in serum PTH as the disease progresses.

Potential Adverse Effects

"Over-the-counter" antacids contain mineral salts, which bind phosphate ions that are released from foods or secreted into the gut lumen by glands of the GI tract. If excessive amounts of these antacid drugs (also taken as nutrient supplements when containing calcium and/or magnesium) are ingested, individuals may be at increased risk of lowering their serum phosphate concentration to the point of serious deficiency. It is fortunate that the use of mineral antacids containing calcium, magnesium, aluminum, or some combination has declined greatly of late in the United States because of the availability of more effective antacid drugs that previously could only be obtained by prescription.

Summary

Phosphorus has important roles in human health. Phosphates participate in diverse functions in the body, both intracellularly and extracellularly as P_i and P_o groups. These anions are especially important in energetic reactions within cells, in nucleic acids, and in other structural molecules and the extracellular tissues of bones and teeth. Dietary deficiency of this element is highly unlikely during practically the entire life cycle.

High intakes of P are common because of the natural widespread availability of phosphates in foods. Moreover, processed foods are likely to contain phosphate additives that contribute to a potentially excessive consumption of phosphorus by individuals in the United States and, most likely, in all economically developed nations throughout the world. When a chronic pattern of low Ca consumption is coupled with high dietary intakes of P (both P_o and P_i), PTH becomes persistently elevated. The potential outcome is low bone mass and an increased risk of skeletal fractures, especially late in life. This adverse relationship between a high dietary P intake and bone loss strongly suggests that the consumption of adequate amounts of Ca are essential for the development and maintenance of bone mass throughout life.

IV.B.6 Potassium

Potassium (K) is found in virtually all aerobic cells and is essential to life. It is the third most abundant element in the human body (after calcium and phosphorus) and the eighth most abundant element in the earth's crust, with a mass percent of 1.8, which means that every 100 grams (g) of the earth's crust contains 1.8 g of potassium. Potassium is a very reactive alkali metal with an atomic number of 19 and an atomic weight of 39.098 atomic mass units (amu). Its outer "4s" electron is not bound very tightly to the atom, which is therefore easily ionized to K^+ (Dean 1985), and potassium reacts readily with chlorine to form the salt potassium chloride. Potassium chloride is a white crystalline solid at room temperature with alternating potassium ions and chloride ions on the lattice sites. Potassium is found primarily in seawater and in natural brines in the form of chloride salt. The minerals mica and feldspar also contain significant quantities of potassium (Dean 1985).

The Discovery of Elemental Potassium

Potassium was first isolated in 1807 by Humphry Davy (1778–1829), who electrolyzed "potash" with a newly invented battery designed to contain a series of voltaic cells, with electrodes made out of zinc and copper plates dipped in a solution of nitrous acid and alum. In Davy's time, the term "potash" referred to any number of different compounds, including "vitriol of potash" (potassium sulfate), "caustic potash" (potassium hydroxide), and "muriate of potash" (potassium chloride as well as potassium carbonate), the last of which was formed by leaching ashes from a wood fire and evaporating the solution to near dryness in an iron pot. Today, potash is usually potassium carbonate, although potassium chloride is still called potash by fertilizer manufacturers (Kent 1983: 262). The potash Davy used was potassium hydroxide that he had dried and melted. He wrote of his experiment:

> A small piece of pure potash, which had been exposed for a few seconds to the atmosphere, so as to give conducting power to the surface, was placed upon an insulated disc of platina, connected with the negative side of a battery of the power 250 of 6 and 4, in a state of intense activity; and a platina wire communicating with the positive side, was brought in contact with the upper surface of the alkali. The whole apparatus was in the open atmosphere. Under these circumstances a vivid action was soon observed to take place. The potash began to fuse at both its points of electrization. There was a violent effervescence at the upper surface; at the lower, or negative surface, there was no liberation of elastic fluid; but small globules having a high metallic lustre, and being precisely similar in visible characters to quicksilver formed, and others remained and were merely tarnished, and finally covered with a white film which formed on their surfaces. These globules, numerous experiments soon shewed to be the substance I was in search of, and a peculiar inflammable principle the basis of potash. (Davy 1839–40, 5: 60)

The next day, Davy isolated sodium metal by electrolyzing soda ash (sodium hydroxide) in much the same way. In the history of chemistry, isolating potassium and sodium was no mean accomplishment. It had been suspected by several people, but especially by Antoine Lavoisier (1743–94), that potash was a compound and that the "basis of potash" was, indeed, a metal (Partington 1962, 3: 485). Davy's experiments confirmed this suspicion. Several years earlier, in 1801, Carl Friedrich Kielmeyer, also suspecting that potash was an oxide of some metal, had attempted to electrolyze potash using a voltaic pile but was unsuccessful (Partington 1964, 4: 45). Thus, the credit for discovering the two most important alkali metals clearly goes to Humphry Davy.

Between 1808 and 1809, the French chemists Louis Thenard (1777–1857) and Joseph Gay-Lussac (1778–1850) found that only small quantities of potassium and sodium could be derived by the electrolysis of fused alkali hydroxides and went on to develop a much improved method for producing larger quantities of both (Partington 1964, 4: 94). Thenard and Gay-Lussac reacted the fused alkali with red-hot iron turnings in an iron gun barrel lined with clay and sand and collected the condensed metal vapor in a receiver attached to the gun barrel. An explosion using this dangerous device nearly blinded Gay-Lussac.

A variation that further improved the method for producing potassium used potassium carbonate as the source of potassium and carbon instead of iron as the reducing agent to produce elemental potassium and carbon dioxide as the reaction products. In 1827, Frederich Wohler (1800–82) first employed potassium produced by this technique to isolate metallic aluminum in more or less pure form. He reacted anhydrous aluminum chloride with potassium metal as the reducing agent and obtained enough aluminum metal to measure its properties (Ihde 1964: 467). Today, metallic potassium is usually produced by reacting molten sodium with molten potassium chloride and condensing the gaseous potassium formed by this reaction. There are very few industrial uses for elemental potassium, although many of its compounds are widely utilized throughout industry and agriculture. For example, potassium nitrate is commonly employed as a fertilizer in the tobacco industry where chloride-containing fertilizers are undesirable.

Potassium in Living Organisms

Despite all of potassium's various functions, its principal function in living organisms is in the transportation of ions across cell membranes. In most animal cells, the internal concentration of potassium ions is between 20 and 30 times higher than the external concentration of potassium ions found in the extracellular fluids. Most cells also have considerably different internal concentrations of sodium ions than are found externally. Neither the reason for the existence of these ionic gradients across the cell membrane nor, for that matter, potassium's principal role in cell metabolism was understood until comparatively recently, and many of potassium's functions in living organisms are still being investigated. It can be said with certainty, however, that moving sodium ions and potassium ions across membranes is an important activity in most organisms, and that if this activity stops, the organism dies.

The Sodium-Potassium-ATPase Pump

The significant step toward understanding potassium's role in animal cells was taken in 1957. In that year, the Danish biochemist Jens Skou, who later won the 1997 Nobel Prize in chemistry, found an enzyme in crab nerve cells that hydrolyzed adenosine triphosphate (ATP) into adenosine diphosphate (ADP) and any one of several phosphorus-containing anions, such as dihydrogen phosphate, in the presence of magnesium ions only if both sodium ions (Na^+) and potassium ions (K^+) were present (Skou 1965: 6). Magnesium ions are always required for enzymes (called ATPases) to catalyze the hydrolysis of ATP.

The unusual property of this enzyme was that neither K^+ nor Na^+ alone had any significant effect on its activity. A short time later, Skou proposed that this Na^+-K^+-ATPase complex was part of a transmembrane pump that pumped Na^+ and K^+ into and out of cells, and that the energy needed for this process was supplied by the hydrolysis of ATP. Many different kinds of animal tissues were soon found to exhibit similar Na^+-K^+-ATPase activity, and it was shown that this enzyme was, indeed, a protein that resided in a cell's membrane, with its sodium ion receptor facing the interior of the cell (or the cytoplasm), and its potassium ion receptor facing the external environment. The Na^+-K^+-ATPase pumped sodium ions out of the cell and potassium ions into the cell, accompanied by the hydrolysis of ATP. Brain, nerve, and muscle cells – and the electric organ of the electric eel – were discovered to be particularly rich in K^+-Na^+-ATPase activity (Lehninger 1970: 617).

"Membrane transport" – the pumping of ions across cell membranes – is such an important part of a cell's total activity that it is estimated that more than one-third of the ATP consumed by a resting animal is expended transporting ions across membranes (Stryer 1988: 950). The Na^+-K^+ pump, in particular, maintains proper electrochemical potentials across cell membranes and maintains the proper concentrations of Na^+ and K^+, both internally and externally. Because these concentrations are usually far from the equilibrium concentrations, the ions must be pumped against their respective concentration gradients. The sodium-ion and potassium-ion concentration gradients in most animal cells control cell volume, drive the transport of sugars and amino acids across cell membranes, and control the electrical excitability of both nerve and muscle cells.

In the most ubiquitous transport systems in animal cells, the Na^+-K^+ pump removes 3 sodium ions from the interior of the cell and pumps in 2 potassium ions from the cell's surroundings, using the transmembrane Na^+-K^+-ATPase to facilitate the transport of the ions. One molecule of ATP is hydrolyzed to supply the necessary free energy. This process is shown schematically in Figure IV.B.6.1. Typically, the internal concentration of potassium ions is approximately 20 times greater than the external concentration of potassium ions. This concentration gradient is maintained also by the free energy supplied by the hydrolysis of ATP and the transmembrane enzyme pump. The ATP supplies energy to the enzyme by phosphorylating it in the presence of sodium ions and magnesium ions. The phosphorylated enzyme is then dephosphorylated in the presence of potassium ions to regenerate the original enzyme and form a phosphorus-containing ion, such as hydrogen phosphate. The energy stored in the ATP is transferred to the enzyme via the phosphate group bonding to it. The enzyme uses this energy to move ions against their gradients and then gets rid of the phosphate group via hydrolysis.

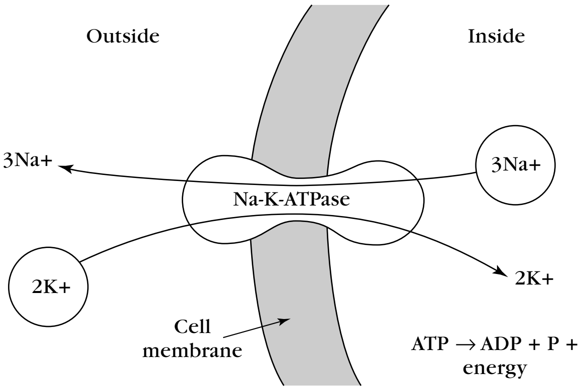

Figure IV.B.6.1. The Na^+-K^+-ATPase transmembrane pump pumping Na^+ ions out of the cell and K^+ ions into the cell.

Potassium in the Nerves and the Nervous System

Potassium ions and sodium ions are found in the nerve cells of virtually all animals and play a vital role in the transmission of nerve impulses. These ions regulate the nerve's transmembrane potential, and it is the transmembrane potential difference between the interior and exterior of a nerve cell that causes the transmission of nerve impulses along the nerve (Atkins 1994: 334). Many K^+-Na^+ pumps are distributed throughout the nervous system. When a nerve is resting, there is a high internal potassium ion concentration and a high external sodium ion concentration. When the cell experiences a pulse, the nerve cell membrane's structure alters, becoming permeable to sodium ions. Because the membrane is now more permeable to sodium ions, the ions rapidly flow into the interior of the cell and reduce the size of the sodium ion concentration gradient so that it becomes smaller than it was when the nerve was resting. In other words, the Na^+ ions and K^+ ions exchange places. Because the membrane's potential arises primarily from the difference in concentration on either side of the membrane, the voltage across the membrane drops. This change in voltage triggers the adjacent part of the cell wall to alter its structure. The pulses of collapsing potential pass along the nerve. Behind each pulse, the Na^+-K^+ pump restores the proper internal sodium ion concentration by pumping out sodium ions and pumping in potassium ions.

Potassium in Muscle Tissue

Generally speaking, muscle tissue can be divided into two classes, smooth and striated. Striated muscle is under voluntary control and has a striated or striped appearance under a light microscope. Striated muscle found in vertebrates contains 2 protein filaments that interact with each other. One of the filaments contains myosin and the other contains 3 proteins – actin, tropomyosin, and troponin. Striated muscle contraction is regulated primarily by calcium ions (Ca^{++}), and the calcium ion concentration is itself regulated by a Ca^{++}-ATPase pump, very similar in kind and function to the Na^+-K^+-ATPase pumps found in other kinds of cells. In mammalian striated muscle, however, fatigue is associated with a loss of intercellular K^+ and a gain in intercellular Cl^-, Na^+, and H_2O, and it may indeed be the case that, in humans, fatigue is related to these changes in the potassium ion concentration gradient across muscle cells. Lowering the internal potassium ion concentration and raising the external potassium ion concentration depolarizes the cell membrane. The rapid recovery of muscle function following brief rest periods is caused by a reestablishment of the proper potassium ion concentrations and a restoration of the resting potential of the muscle cell's membrane.

Smooth muscle, such as that found in the heart or veins, is not subject to voluntary control. The contraction of smooth muscle is controlled by the degree of phosphorylation of its light chains. Phosphorylation leads to contraction and dephosphorylation leads to relaxation. In smooth muscle, Na^+-K^+ pumps and active transport are directly involved with contraction and relaxation. For example, in vascular smooth muscle, the function of the Na^+-K^+-ATPase pump is to transport 2 potassium ions into the cell for every 3 sodium ions it takes out. The energy for this transport is supplied by phosphorylation. As in striated muscles, extracellular calcium ions also play an important role in cell function, but in smooth muscles this role is primarily to regulate the K^+-Na^+ equilibria extant in the cell (O'Donnell and Owen 1994).

The importance of the Na^+-K^+ pump in smooth muscle function has some intriguing consequences. It is entirely possible – and evidence is mounting that it is more than just possible – that a principal underlying cause of hypertension in humans is an inhibitor of Na^+-K^+-ATPase activity or an impaired Na^+-K^+ pump (Blaustein et al. 1986; O'Donnell and Owen 1994: 687). It is also well known that a certain class of compounds, called cardiotonic steroids, specifically inhibit the Na^+-K^+ pump. These steroids prevent the dephosphorylation of Na^+-K^+-ATPase. As a consequence, these compounds are very important in the treatment of heart disease.

For example, digitalis (an extract from purple foxglove leaves that contains a mixture of cardiac steroids), which is perhaps the best-known remedy for congestive heart failure and has been widely used for centuries, increases the force of heart muscle contraction by inhibiting the Na^+-K^+-ATPase pump (Voet and Voet 1990: 496). This increases the sodium ion concentration inside the cell, thereby causing a reduction in the concentration gradient across the membrane, because the internal sodium ion concentration becomes closer to the external sodium ion concentration. Reducing the sodium ion concentration gradient reduces the extrusion of calcium ions via the Na^+-Ca^{++} exchanger, which increases the internal calcium ion concentration. A high intracellular calcium ion concentration causes the heart muscle to contract (Stryer 1988: 955). Ion exchangers, such as the Na^+-Ca^{++} exchanger, are conduits – or ports – that allow ions to diffuse in and out of a cell via concentration gradients rather than through active transport, and they are not fueled by ATP.

The medicinal effects of digitalis were known long before the compounds themselves were identified and long before the Na^+-K^+-ATPase pump was discovered. In the 1770s, a woman in Shropshire, England, using extracts from some 20 different herbs, prepared a cocktail that had a remarkable effect on curing congestive heart failure or "dropsy," as it was called. Many people suspected that this woman was a witch because of the curative power of her concoctions. A physician by the name of William Withering heard about the woman's remarkable medicine and, after considerable effort, found that foxglove was the significant herb in the cocktail. He published his findings in 1785 in his classic work, *An Account of the Foxglove and Some of its Medical Properties.* A line from this paper is worth noting: "It [the foxglove] has a power over the motion of the heart to a degree yet unobserved in any other medicine, and this power may be converted to salutary ends" (Estes and White 1965: 110).

Potassium in Protein Synthesis

Protein synthesis on ribosomes requires a high potassium concentration for maximum efficiency. Ribosomes are cellular bodies that serve as the sites for protein synthesis and can be thought of as the cell's protein factories because protein assembly from amino acids, controlled by RNA, takes place on the ribosome's surface (Lehninger 1970: 616).

Potassium in Glycolysis

Potassium is necessary for glycolysis, which is a form of fermentation that ultimately converts glucose ($C_6H_{12}O_6$) into pyruvate (C_3COCOO^-) with the associated production of ATP. Glycolysis can be thought of as a fundamental aspect of the generation of metabolic energy that occurs in virtually all living organisms, including humans. Glycolysis requires potassium ions for maximum activity of one of the enzyme catalysts, pyruvate kinase, which is involved in the process (Stryer 1988: 350). If there is sufficient oxygen present, the pyruvate enters the mitochondria where it is completely oxidized to CO_2 and H_2O. If there is insufficient oxygen present, as is often the case in muscle contraction, pyruvate is converted to lactic acid. In yeast, which is an anaerobic organism, pyruvate is converted to ethanol and carbon dioxide.

In 1897 and 1898, the German chemist Eduard Buchner discovered that when yeast cells were crushed with sand and diatomaceous earth *(kieselguhr),* the cell-free liquid extract was able to ferment sucrose into alcohol and carbon dioxide. Buchner's results showed, for the first time, that fermentation could occur outside a living cell, and his fermentation experiments contributed greatly to the overthrow of the "vital force" theory then prevalent in the biological sciences, and started the field of modern biochemistry. Even Louis Pasteur thought that fermentation could occur only in living cells. Buchner was awarded the Nobel Prize in chemistry for this work in 1907 (Partington 1964, 4: 309).

Renal Control of Potassium

In humans, the kidneys are responsible for most potassium excretion, although fecal matter does contain about 10 percent of the potassium ingested (Stanton and Giesbisch 1990). However, renal malfunction as a result of disease or trauma often will prevent the proper elimination of potassium from the body. For example, because maintenance of the proper potassium ion balance is vital, the secretion of potassium ions by the distal tubule is one of the kidney's most important functions, and it is the distal tubule that, more or less, regulates the quantity of potassium ions eliminated in the urine. More than 75 percent of the filtered potassium is reabsorbed in the proximal tubule, and this percentage remains nearly constant no matter how much is filtered. About 50 percent of the urinary potassium is secreted into the urine by the distal tubules in normally functioning kidneys. If this secretion is prevented – as, for example, in polycystic kidneys – dangerous levels of potassium ions can accumulate and cause heart failure. Na^+-K^+-ATPase pumps, H^+-K^+-ATPase pumps, and K^+- Cl^--Na^+ cotransport have all been found to control potassium in tissues within the kidneys.

Difficulties with potassium elimination are also encountered if the production of a hormone in the adrenal gland, aldosterone, is inhibited. Aldosterone catalyzes the elimination of potassium ions so that lowering the concentration of this enzyme reduces the rate of potassium ion elimination and can increase potassium ion concentrations in the blood to dangerous levels.

Potassium and Health

Potassium is essential for human life. A normal adult male, weighing 70 kilograms (kg), contains approximately 135 g of the mineral in his body. About 98 percent of this potassium is found in his cells and the other 2 percent in extracellular fluids (Macrae, Robinson, and Sadler 1993, 6: 3668). Potassium deficiency is called hypokalemia and – because potassium is present in most foods – when it occurs, it is often in areas where people exist on subsistence or starvation diets. Severe diarrhea, diabetes, and prolonged use of cortisone can also cause hypokalemia.

For living cells to function properly it is essential they maintain a correct balance between internal potassium ion concentrations and external potassium ion concentrations. There are many factors that influence this balance, in addition to the various pumps and transport systems already described. For example, there must be a normal water balance in the organism, because if the amount of K^+ inside a cell remains fixed and the amount of water increases, the potassium ion concentration will decrease proportionately, or if the amount of water decreases, the potassium ion concentration will increase. A potassium deficiency resulting from urine loss often occurs during the treatment of heart disease because the medication used prevents sodium and water retention. To reduce this deficiency, foods high in potassium are often prescribed.

Recently, a possible connection between potassium and hypertension has been discovered (Brancati 1996). It was found that African-Americans, a particularly high-risk group for hypertension and acute myocardial infarction, benefited greatly from a diet rich in potassium. Indeed, in a double-blind test, all of the subjects who received potassium supplements reduced their blood pressure – regardless of age, gender, body weight, or alcohol consumption. It was not clear why potassium was especially beneficial for African-Americans. It may be that their diets are particularly low in potassium, but it is more likely the case that, for some reason, African-Americans are especially sensitive to potassium. This finding is certainly also consistent with the mechanism of the Na^+-K^+-ATPase pump discussed earlier.

Potassium and Diet

Potassium is one of the most important elements in the human diet. According to the National Academy of Sciences, a healthy adult should consume between 1,875 milligrams (mg) and 5,625 mg of this mineral daily (National Academy of Sciences 1980: 173). It is probable that the diets of our hunter–gatherer ancestors contained some 2 mg of potassium for every calorie consumed. It is also known that people who consume more than 4 g of potassium each day have a much lower incidence of disease.

Unfortunately, a modern diet typically contains only 0.5 mg of potassium for every calorie consumed, although it is the case that practically all successful dietary weight-loss programs, dietary cholesterol-lowering programs, and dietary blood-pressure–lowering programs contain foods that are high in potassium. Some of these are oranges, tomatoes, peas, spinach, bananas, cantaloupe, and fish (Pennington 1985). Foods that are very high in potassium content, with the exception of potatoes, are relatively low in energy content, which makes them especially healthful for normal adults.

Summary

Potassium is a relatively abundant alkali metal that comprises a significant fraction of the earth's crust. Its salts and oxides are widely used in industry and agriculture. Potassium's role in membrane transport and other metabolic processes make it vital to virtually every living organism. Recently, antibiotics using potassium ions have been discovered, and it is beginning to appear that eating foods rich in potassium or taking potassium supplements can reduce hypertension in humans. Most foods contain some potassium, and the maintenance of good health in normal adults seems to require a diet that contains 4 g of potassium per day.

IV.B.7 ~ Sodium and Hypertension

Historically, dietary salt (sodium chloride) has been obtained by numerous methods, including solar evaporation of seawater, the boiling down of water from brine springs, and the mining of "rock" salt (Brisay and Evans 1975). In fact, R. P. Multhauf (1978) has pointed out that "salt-making" in history could be regarded as a quasi-agricultural occupation, as seen in frequent references to the annual production as a "harvest." Such an occupation was seasonal, beginning with the advent of warm weather or the spring high tide and ceasing with the onset of autumnal rains. Multhauf has argued further that the quest for salt led to the development of major trade routes in the ancient world. The historian Herodotus, for example, described caravans heading for the salt oases of Libya, and great caravan routes also stretched across the Sahara, as salt from the desert was an important commodity exchanged for West African gold and slaves. Similarly huge salt deposits were mined in northern India before the time of Alexander the Great, and in the pre-Columbian Americas, the Maya and Aztecs traded salt that was employed in food, in medicines, and as an accessory in religious rituals. In China, evidence of salt mining dates from as early as 2000 B.C.

Homer termed salt "divine," and Plato referred to it as "a substance dear to the gods." Aristotle wrote that many regarded a brine or salt spring as a gift from the gods. In the Bible (Num. 18:19), it is written: "This is a perpetual covenant of salt before the Lord with you and your descendants also." In the Orient, salt was regarded as the symbol of a bond between parties eating together. In Iran, "unfaithful to salt" referred to ungrateful or disloyal individuals. The English word "salary" is derived from *salarium,* the Latin word for salt, which was the pay of Roman soldiers. Moreover, Roman sausages were called *salsus* because so much salt was used to make them (Abrams 1983).

The preservative properties of salt have maintained the essentiality of the mineral throughout history. It helped meat last over long journeys, including those of marching armies and the migrations of peoples. Salt's power to preserve meat led to the so-called invention of salted herring in fourteenth-century Europe, which has been called "a new era in the history of European salt production" (Multhauf 1978: 9). The technique of pickling preserves food by extracting water from animal tissues, making the dehydrated meat or fish resistant to bacterial attack (Bloch 1976).

During the eighteenth century, other industrial uses began to be found for salt. The invention in 1792 of a way to make sodium carbonate began the carbonated-water industry, and by 1850, 15 percent of the salt of France was going into soda. Since that time, nondietary uses of salt have far outweighed its employment for culinary purposes (Multhauf 1978).

Historically, governments appreciated the importance of salt and have taxed it since ancient times (Multhauf 1978). During the nineteenth century in the United States, a salt tax helped build the Erie Canal, and during the twentieth century in India, Mahatma Gandhi revolted against a salt tax, leading to the famous "March to the Sea." Such has been the importance of salt that one historian has written: "Clearly, anyone who can control the salt supply of a community has powers of life and death. The control of water, being more ubiquitous than salt, is not so simple to put into effect" (Bloch 1976: 337).

Salt and Sodium: Essential to Life

Salt in the Body

In 1684, Robert Boyle became the first to demonstrate scientifically that the "salty taste" in blood, sweat, and tears was actually caused by the presence of salt. After he removed the organic matter from whole blood by ignition, a fixed salt remained, which he found to be virtually identical to marine salt. About a century later (1776), H. M. Rouelle showed that a large proportion of the inorganic materials in blood serum could be isolated in the form of cubic crystals of "sea salt." Later still, in the nineteenth century, J. J. Berzelius and A. J. G. Marcet revealed that sodium chloride was the principal inorganic constituent of other body fluids (both those that occasionally collected in the abdominal cavity, around the lungs or heart, or in a cyst or a blister and those that permanently surrounded the brain and spinal cord) and was present in much the same concentration as in blood serum (Kaufman 1980). In the same century (1807), Sir Humphry Davy discovered both sodium and potassium by passing an electrical current through moist caustic potash or caustic soda. More recently, biomedical researchers have defined sodium as the principal cation of the circulating blood and tissue fluids of animals (Denton 1982).

Sodium is the sixth most common element on earth. Sodium chloride (what we commonly call salt) is the chemical combination of ions of sodium (Na^+, molecular weight 23) and chlorine (Cl^-, molecular weight 35.5) – the latter element, in its pure form, is a deadly greenish-yellow gas that reacts with water to form hydrochloric acid. Forty percent of the weight of common salt is made up of sodium; the remainder is chloride. Pure sodium is never found in nature. When freed from common table salt by electrolysis, sodium is a soft metal, lighter than water, and so reactive with oxygen in the air that it must be specially stored in air-free containers to prevent it from exploding. Sodium also reacts violently with water, as the two together form sodium hydroxide, in the process liberating hydrogen gas, which, in turn, bursts into flame from the heat of the reaction.

Nonetheless, even though a reactive element, sodium is essential to animal and human life. Indeed, life could be defined as the sum of the chemical processes that take place in the solution of salts between and within cells. In humans, the nutrients required to fuel life processes are first chewed and mixed with salt solutions produced by the salivary glands, then dissolved in salt and enzyme solutions from the stomach and pancreas, absorbed as salt solutions from the intestines, and delivered to the cells dissolved in a salt solution that ultimately depends on the ingestion of critical amounts of sodium and water. Excreted body fluids – blood, sweat, and tears – and feces are made up of these salts, and sodium salts are their key ingredient.

The Physical Need for Salt

In the nineteenth century, G. Bunge made the observation that carnivores never sought out salt, but herbivores did. His observation seemed to fit into common knowledge – hunters as well as husbandrymen knew that herbivores came to salt licks – but Bunge suggested something new: that salt was a necessity for life. In his travels he observed in numerous places that carnivores never ate salt but herbivores seemed to have a vital need for a supplement of it. He noted that herbivores excreted 3 to 4 times as much potassium as carnivores and theorized that the much higher potassium content of the vegetarian diet displaced sodium from body salts, causing an increase in the amount excreted in the urine. Therefore he reasoned that continuous consumption of a purely vegetarian diet with large amounts of potassium would make a large intake of sodium necessary for the maintenance of sodium balance (Bunge 1902).

Decades later, anthropologist Alfred Kroeber took issue with this notion of a biologically driven hunger for salt. He observed the Native Americans living along the Pacific coast of the United States and noted that salt was consumed in the south but not in the north. He saw no relationship among such factors as dietary salt use, the relative prevalence of seafood or meat in the diets, and the various climatic conditions, writing: "It must be concluded that whatever underlying urge there may be in physiology as influenced by diet and climate, the specific determinant of salt use or nonuse in most instances is social custom, in other words, culture" (Kroeber 1942: 2). H. Kaunitz found similar situations in areas of Australia, South Africa, and South America and suggested that salt craving might arise from "emotional" rather than innate needs (Kaunitz 1956).

J. Schulkin (1991) has recently noted that among psychologists in the 1930s, it was widely believed that "learning" – not biologically driven physical need – was responsible for the ingestion of minerals. However, C. P. Richter (following American physiologist Walter Cannon's theory of *The Wisdom of the Body* [1932]) took a minority view that "learning" might not be the primary driver, and in 1936, he provided the first experimental evidence for a salt appetite. He removed the adrenal glands from experimental rats, thus depriving them of the sodium-retaining hormone aldosterone – a situation that would prove fatal in the absence of dietary sodium – and the amount of sodium ingested by the adrenalectomized rats increased dramatically. In 1939, he hypothesized that the drive for sodium was innate, and in 1941, he "discovered" that hormonal signals generate sodium hunger. Moreover, in 1956, he showed that during reproduction periods, the ingestion of salt by female rats rose markedly (Schulkin 1991).

One of the key experimental laboratories in the study of sodium metabolism has been the Howard

Florey Institute in Melbourne, Australia, where investigators, under the leadership of Derek Denton (1982), have conducted many experiments. In one of the most notable, researchers trained sheep to press a lever to get salt water to drink. The sheep were then depleted of salt by saliva drainage. When finally given access to the lever for salt water, the sheep within 30 minutes consumed the precise amount of sodium that they had lost. Their "wisdom of the body" was such that, even if the sheep were given salt solutions of varying concentrations, they still consumed the amount required to replace the deficit.

The work of Denton and others strongly supported the view that there is an innate hunger for salt and that the brain controls this behavior (Schulkin 1991). But although there are a number of minerals that are "essential" nutrients, only sodium seems to command a "built-in" hunger; there is no "innate" craving for magnesium or potassium, to choose two examples. On the other hand, it is likely that, in the past, the hunger for sodium abetted the intake of other essential minerals, which would usually have been found in the same "salt-licks" as sodium. Sodium hunger does not *require* "learning," although significant "learning" does interact with innate mechanisms to help guide sodium-hunger behavior (Schulkin 1991). The following is a summary of Schulkin's ideas of the steps involved in the innate sodium-hunger pathway:

1. An animal is "sodium-hungry." (This would result from either a reduction in salt intake or excessive excretion of sodium from nonrenal sources, such as intestines or sweat glands.)
2. A "representation" of salty taste is activated in the brain.
3. The representation serves to guide the animal's behavior in its search for salt – including its location, identification, and ingestion of the mineral.
4. Innate mechanisms are responsible for the sodium-hungry animal:
   a. Ingesting the salt immediately upon its first exposure (no "learning" is required for this), and
   b. Noting the significance of salt when not sodium-hungry.
5. Thus, in terms of b, there is a hedonic shift in the perception of salt that emerges in the salt-hungry animal.
6. The result is a motivated behavior with appetite (physiologic need) and consummatory phases (behavioral want) in search of salt.

Sodium Physiology

Sodium is vital in maintaining the pressure and volume of the blood and the extracellular fluid. A major purpose of the blood is to carry intracellular fluids, bringing nutrients to the cells and removing metabolic products from them. As blood flows through the capillaries, water – containing nutrients – passes from the capillaries into the extracellular spaces to bathe the cells with nutrients and pick up cellular metabolic products (mostly waste), which are then swept by water movement back into the veins and carried to the kidney, liver, and lungs for metabolism or excretion. Sodium is also important in the transmission of nerve impulses, helps to metabolize carbohydrates and proteins, and has independent interactions with other ions – such as those of potassium, calcium, and chlorine – to maintain the "sea within" us. But most importantly, from a medical viewpoint, sodium is a vital factor in the regulation of blood pressure.

Sodium is measured in units of moles or grams. For nutritional purposes, grams are used, usually milligrams (1 gram [g] = 1,000 milligrams [mg]); for clinical purposes (to measure concentration), millimoles per liter are used (1 mole = 1,000 millimoles or mmols). One mole equals the molecular weight of the element. As the atomic weight of sodium is 23, 1 mole of sodium is equal to 23 grams of sodium (23,000 mg), and 2,300 mg of sodium is the same as 100 mmols of sodium.

Until the late 1940s, the measurement of sodium in both biological fluids and diets was a mostly laborious process that required the skills of a quantitative analytical chemist using 13 different steps – including, among others, "ashing," extracting, evaporating, precipitating, washing, and weighing sodium yields on a microbalance – to determine the quantity in a single sample (Butler and Tuthill 1931). But in 1945, a revolution in the analytic accuracy and speed of sodium measurement was begun with the first report of the use of the flame photometric method. In 1945, this technique still required precipitation of plasma before analysis, but by 1947, only dilution of plasma was required (Overman and Davis 1947), and by 1949, instruments were available that could provide very accurate results within 5 minutes using either plasma or urine. By 1953, these devices were in wide use (Barnes et al. 1945; Mosher et al. 1949; Wallace et al. 1951).

The body has built-in "set points" designed to maintain sodium in homeostasis. When it takes in less salt than is lost in the urine, sweat, and stool, the concentration of sodium in the blood falls. When the blood sodium falls below an inherited "set point" (about 140 mmol per liter of serum), an area of the brain that is bathed by blood senses the decreased sodium concentration and activates hormonal defenses to maintain a constant concentration of the mineral. If the concentration of sodium continues to diminish, the kidneys will adjust by accelerating the excretion of water, so that the blood's sodium concentration is maintained at the vital level. If the sodium supply is not replenished, there is a gradual desiccation of the body and, finally, death. In other words, a lack of sufficient sodium causes the organism literally to die of thirst.

By contrast, if blood sodium increases above the set-point level, a secretion of antidiuretic hormone (ADH) is released by the pituitary gland, and thirst mechanisms are activated to find and ingest water until the sodium concentration is reduced. At the same time, ADH causes the kidneys to excrete less water in an attempt to keep the body's sodium at the correct concentration. If, however, the water supply is not replenished, more sodium will be excreted, and eventually, these water losses will lead to death.

The overriding mechanism that regulates total body sodium (and blood pressure) has been termed the "renal-fluid volume mechanism for pressure control" by A. C. Guyton and colleagues (1995). An analysis of the factors controlling blood pressure has shown that it can only be raised by one of two mechanisms: increasing the intake of dietary salt or limiting the kidney's ability to excrete sodium.

Sodium and Human Evolution

The body's need for sodium may also have played a role in genetic variability within the human species. During the 1980s, theories were proposed that suggested such a role in two diseases related to salt metabolism: cystic fibrosis and hypertension.

Cystic fibrosis (CF) is a recessive genetic condition related to sodium metabolism, in which, it was hypothesized, the carrier state had been protective of fluid and electrolyte loss during epidemics of diarrhea in human history. CF carriers, notably children before the age of reproduction, were thought to have protective mechanisms that diminished the loss of water during episodes of infectious diarrhea. Thus, individuals who were genetically enabled to control water and salt losses were more likely to survive to reproductive age. Indeed, the heterozygote carrier has been shown to have less sodium loss in feces than the homozygote noncarrier (Gabrial et al. 1994).

A more controversial evolutionary hypothesis is that one form of hypertension (high blood pressure) – "salt-sensitive" hypertension, which has a high frequency among African-Americans – may result, in part, from genetic adaptation to the African environment and its diseases of the past. More specifically, it has been suggested that – both during the trans-Atlantic slave trade and during the period of slavery itself – individuals able to conserve sodium would have been more likely to survive the dehydrating diseases aboard ship, as well as the debilitation of hard physical labor. If so, then this past experience might be partially responsible for today's prevalence of "salt-sensitive" high blood pressure among black people in the Western Hemisphere (Wilson and Grim 1991; Curtin 1992; Grim and Wilson 1993).

Salt Deficiency

When humans go without salt in the diet, or lose it because of illness, the major symptoms are apathy, weakness, fainting, anorexia, low blood pressure, and, finally, circulatory collapse, shock, and death. Sir William Osler (1978: 121–2), observing dehydrated cholera patients in the late nineteenth century, provided a classic description of the condition:

> [P]rofuse liquid evacuations succeed each other rapidly . . . there is a sense of exhaustion and collapse . . . thirst becomes extreme, the tongue white: cramps of great severity occur in the legs and feet. Within a few hours vomiting sets in and becomes incessant. The patient rapidly sinks into a condition of collapse, the features are shrunken, the skin of an ashy gray hue, the eyeballs sink in the sockets, the nose is pinched, the cheeks are hollow, the voice becomes husky, the extremities are cyanosed, and the skin is shriveled, wrinkled and covered with a clammy perspiration. . . . The pulse becomes extremely feeble and flickering, and the patient gradually passes into a condition of coma.

Many cholera patients in the past could have been saved with rehydration therapy, and it is a central tenet in modern medical treatment that lost body fluids should be replaced with others of the same composition. Replacing a salt loss by giving water or a water loss by giving salt can be fatal. Although a history of the illness and an examination of the patient can provide clues to the type of loss, the best method is to test the blood and urine chemically – a method that only became possible in the 1930s, with the most useful test that which determined the amount of chloride in urine. Accomplished by simply mixing 10 drops of urine with one drop of an indicator and then adding silver nitrate, a drop at a time, until the end point was reached, this was called the "Fantus test" after Dr. Bernard Fantus at the University of Chicago.

This test proved so useful in treating salt- and water-depleted British soldiers in India and Southeast Asia during the mid–1930s that Dr. H. L. Marriott, in his classic text on fluid replacement therapy, stated: "It is my belief that the means of performing this simple test should be available in all ward test rooms and in every doctor's bag" (Marriott 1950: 56).

Most early studies of sodium depletion in humans were prompted by diseases. One was Addison's disease (in which the adrenal gland that makes the sodium-retaining hormone for the body stops working), and another was diabetes (in which a high level of blood glucose forces the excretion of large amounts of water by the kidneys). Such studies were also conducted in cases of extreme depletion brought on by starvation or acute diarrhea. In the 1930s, however, R. A. McCance (1935–6) published his report of a series of experiments that established a baseline on the clinical nature and physiology of sodium depletion in humans.

To induce salt depletion, McCance (1935–6) employed a sodium-free diet combined with sweating. (Because laboratory animals do not sweat, he used humans as his test subjects.) There was no "research-quality" kitchen available, the food was prepared in the McCance home, and the subjects of the experiment – all volunteers – slept and ate there. The diet consisted of sodium-free "casein" bread, synthetic salt-free milk, sodium-free butter, thrice-boiled vegetables, jam, fruit, homemade sodium-free shortbread, and coffee. During recovery periods, the volunteers ate weighed quantities of high-sodium foods (such as anchovies and bacon) and small, weighed amounts of sodium chloride. Sweating was induced by placing the subjects in a full-length radiant heat bath – for two hours with the heat on and then 10 minutes with the heat off. Their sweat was collected in rubber sheets, and a final washing of each subject with distilled water ensured that even small amounts of lost sodium would be accounted for. The subjects' average sweat loss was 2 liters, and they commented that the washing procedure was "not uncomfortable" after 2 hours in the hot bath (McCance 1935–6).

By reducing sodium in the diet, along with inducing sodium losses through sweating, McCance and his colleagues found that only a week was required to make healthy subjects seriously sodium depleted. They maintained 4 volunteers in this condition for an additional 3 to 4 days, so that the total period of deprivation lasted about 11 days.

Detailed measurements of intake (food and water) and output (sweat, urine, and feces) recorded that the subjects lost 22.5 g of sodium and 27.2 g of chloride – or about 50 g of salt. Their body weights dropped by about 1 kilogram (kg) per day, and sodium excretion averaged 3,400 mg of sodium per day for the first 4 days. Weights then stabilized, but sodium loss continued.

As the deficiency progressed, the volunteers all experienced feelings of physical fatigue, anorexia, nausea, difficulty in urinating, and extremely weak pulses. Muscle spasms and cramps – especially cramps in the fingers – were common. The subjects' faces became drawn and "ill-looking," and they slowed mentally, becoming dull and apathetic. McCance was struck by the similarity of a number of these symptoms to those of Addison's disease, but the symptoms and signs all rapidly cleared up when the volunteers resumed consumption of sodium (McCance 1935–6).

Both before and during World War II, as many in the Allied armed forces were severely disabled by heat- and water-related illnesses, there was intense interest in understanding the mechanics of water and salt metabolism and the effects of heat on the human body. Research was even undertaken to see how long a man could survive on a raft in the ocean, or in the desert, so that restrictions could be placed on certain military activities (such as limiting the duration of searches for lost aviators, who, after the specified survival time had passed, might reasonably be presumed dead). Other studies examined the conditions that servicemen could be forced to work under and defined safe limits. For example, after 5 hours of marching in the heat, with full packs and no water, even well-conditioned marines could not continue (Ladell 1949).

During and after World War II, there was also interest in the effects of diarrhea. J. L. Gamble (1945) showed that intestinal secretions contained more sodium than chloride, and D. A. K. Black (1946) reported a series of experiments on 10 men with blood pressures averaging 94 mm Hg SBP/59 mm Hg DBP, who were victims of tropical sprue (a disease characterized by chronic diarrhea). The patients were bedridden, listless, and incapable of exertion. But these symptoms disappeared – and blood pressure rose to normal – with sodium supplementation (Black 1946).

Excess Sodium

Humans, as noted, have evolved complex "redundant systems" to regulate sodium and other essential minerals. For marine animals, deriving sodium from the sea was a relatively easy matter. As evolution progressed, however, satisfaction of sodium needs became a more complicated task. Land dwellers had first to locate sources of sodium, then ingest the mineral, and, further, conserve it within their bodies. To achieve this, physiological and behavioral mechanisms evolved that were designed primarily to protect against a life-threatening deficit of sodium, such as can occur with vomiting, sweating, diarrhea, or kidney malfunction.

But although the body's systems are reasonably effective against sodium deficit, evolution did not do as well in protecting humans against an excessive intake of the mineral. There are two different kinds of excessive sodium intake: (1) acute ingestion of salt without water, or of very salty water (such as seawater or other briny water); and (2) chronic ingestion of toxic levels of sodium in the food supply.

It seems likely that the former was never a major problem in the history of humankind and probably occurred only when people felt forced to drink seawater or the water from salt springs or salt lakes. Chronic ingestion of excess salt in food, however, is both a recent and a very real problem. Until the past few centuries, salt intake was primarily determined by the amount a person chose to add to food ("active intake"). Increasingly, however, as foods were preserved in salt, and especially today with foods processed with salt, the great majority of salt intake has become "passive," meaning that food processors and manufacturers – not consumers – decide the quantity of salt to be included in the foods they produce.

Indeed, it has been estimated that in prehistoric times, the daily human intake of sodium was about 690 mg, with 148 mg derived from vegetables and 542 mg from meat (Eaton and Konner 1985). By contrast, today the U.S. Food and Drug Administration (FDA) recommends keeping dietary intake to

2,400 mg of sodium per day (the amount contained in 6 g – or about 1 teaspoon – of table salt). This is roughly the same amount accepted by an advocacy group that promotes a low-salt diet, Consensus Action on Salt and Hypertension (CASH). Needless to say, even such a "low-salt" diet still delivers 3.5 times the amount of sodium provided by the meat and vegetables of the Paleolithic diet.

Although there is also concern over high salt intake by children, food processors only relatively recently halted their practice of adding sodium to baby food. (Presumably, the mineral was meant to improve the food's flavor for parents.) This change for the better followed the observation by L. K. Dahl, M. Heine, G. Leitl, and L. Tassinari (1970) that young rats with a high sodium intake became hypertensive and remained so for the rest of their lives. But despite this discovery, the average sodium intake by two-year-olds in the United States remains higher than the amount recommended by the FDA and by CASH (Berenson et al. 1981).

Moreover, the average intake throughout much of the industrialized world today is about 10 g of table salt (3,900 mg of sodium) per person per day (James, Ralph, and Sanchez-Castillo 1987; USDA/USDHHS 1995). But only about 10 percent of the sodium consumed occurs naturally in foods; another 15 percent is added by consumers ("active intake"), and the remaining 75 percent is added to food by manufacturers and processors. Therefore, based upon the average industrial diet, only 390 mg of sodium is naturally occurring, 585 mg is added by the consumer, and a substantial 2,925 mg is derived ("passive intake") from sodium added during processing (James et al. 1987).

Obviously, then, a low-salt diet like that of our ancient ancestors seems an impossible goal; increasingly, the population is at the mercy of the food industry. Yet, that industry gains several advantages by using excessive salt in food processing. Salt, added to food, improves flavor and palatability, especially for those who have become addicted to its taste. Salt increases the "shelf-life" of food (although, with today's effective packaging and refrigeration technology, there is little need for the presence of near-toxic levels of sodium in the food supply), and salt adds very inexpensive weight to the final product (by helping to retain water), thereby increasing profit margins. Finally, increased salt consumption stimulates thirst and thus increases consumption of the beverages sold by many of the major food companies (McGregor 1997).

History of Hypertension

"Blood pressure" refers to the force exerted against the walls of the arteries as blood is pumped throughout the body by the heart. This pressure can be measured, and abnormally high levels indicate a condition of "high blood pressure," or hypertension, which is classified into two types. *Secondary* hypertension is that resulting from a known cause, such as a disease of the kidneys, whereas *essential* or *primary* hypertension arises with no evident cause. More than 90 percent of hypertension cases fall into the latter category (Wilson and Grim 1993).

Salt consumption was linked with blood pressure long ago – as early as the second century B.C. in ancient China. In the *Huang-ti nei-ching* ("The Inner Classic of the Yellow Emperor"), it was written that "if too much salt is used for food, the pulse hardens" (Swales 1975: 1).

In 1836, Richard Bright reported on the kidneys and hearts of 100 patients who had died of kidney problems. He noted that, in most instances, when the kidney was small and shrunken, the heart was often markedly enlarged – an indication of high blood pressure (Bright 1836). In the late nineteenth century, R. Tigerstedt and T. G. Bergman (1898) coined the term "renin" in their report that saline extracts from kidney tissue raised blood pressure. A few years later, French researchers L. Ambard and E. Beaujard noted that blood pressure was lowered by the dietary restriction of sodium chloride and raised by its addition or increase; they believed, however, that chloride was the culprit because they were unable to measure sodium content (Ambard and Beaujard 1904).

Many attempts to induce high blood pressure in experimental animals followed but proved inconclusive. In 1934, however, Harry Goldblatt noted that when he placed an adjustable clamp so that it partially blocked the renal artery of a dog, the animal developed a rapid increase in blood pressure that was sustained so long as the clamp remained in place. Research to determine the mechanism causing this high blood pressure began, and by 1940, two teams of investigators (Eduardo Braun-Menendez and colleagues in Buenos Aires and Irving Page and O. M. Helmer in Indianapolis) succeeded in isolating a material that caused vasoconstriction. Both groups reported that there was a substance – coming from the kidneys – that, when mixed with blood, generated a potent vasoconstricting and blood-pressure–raising substance. The South American group called this "hypertensin" and the U.S. group "angiotonin," but eventually the two were determined to be the same chemical, which was named "angiotensin."

Within a few years, W. Kempner (1944) reported that a low-sodium diet decreased blood pressure and heart size even in cases of malignant hypertension. The following year, he described the effects of a low-sodium diet on 65 patients who were hypertensive but showed no evidence of renal disease. After an average of only 48 days on a rice–fruit diet, the average blood-pressure readings decreased from a systolic blood pressure (SBP) of 197 mm Hg and a diastolic blood pressure (DBP) of 115 mm Hg to an SBP of 151 mm Hg and a DBP of 97 mm Hg. In those patients who experienced a decrease in blood pressure, the response was obvious within the first 7 to 10 days on the low-sodium diet, and Kempner observed that the maximum decrease in blood pressure was first attained after only 10 days.

Most early blood-pressure studies were on whites, yet the prevalence of high blood pressure in blacks is much greater and, as mentioned, is thought to result, at least in part, from salt intake. The first report of an association between salt intake and blood pressure in African-Americans was by A. Grollman and colleagues (1945), who studied patients given less than 1 gram (<1,000 mg) of sodium chloride in their daily diets. In the case of two black women, blood pressure declined to normal, promptly rose when salt intake was increased, and then fell again when the low-sodium diet was resumed.

Five years later, V. P. Dole and colleagues (1950) reported the results of a series of studies to evaluate the sodium content of Kempner's rice–fruit diet and its effect on blood pressure and heart size. They confirmed all of Kempner's observations and, further, documented that the effect of the diet was related to its low sodium content and not low chloride (Dole et al. 1950).

The introduction of diuretics, which act to excrete sodium and water via the kidneys, came in the late 1950s, and these were quickly shown to lower blood pressure significantly (Freis et al. 1958). In the 1970s, however, a series of observations made by a research group in Indianapolis (which included Clarence E. Grim, co-author of this chapter) once again focused attention on the relationship between dietary sodium and blood pressure. This culminated in several reports indicating that even a normotensive individual would experience an increase in blood pressure if enough salt was consumed (Murray et al. 1978; Luft et al. 1979). In addition, ethnic differences in sodium metabolism and blood-pressure responses were documented in normotensive subjects; such evidence demonstrated, for the first time, that blacks were more sensitive to salt than whites. These studies also demonstrated the enormous capacity of human kidneys to excrete sodium, which was proof of Guyton's hypothesis that excess salt will always increase blood pressure (Guyton et al. 1995).

Current Thinking on Sodium and Hypertension

Cardiovascular disease is now a major cause of death in all countries of the world, and high blood pressure is the most common (although treatable) precursor of heart disease. Unfortunately, as pointed out in a recent review by J. P. Midgley, A. G. Matthew, C. M. T. Greenwood, and A. G. Logan (1996), most sodium-reduction trials in hypertensive subjects have not yet produced definitive evidence that reducing sodium intake improves long-term health (but see also Staessen et al. 1997). Indeed, some have argued (based on a single observational study) that reducing salt intake may do more harm than good (Alderman et al. 1995).

Nonetheless, high dietary salt intake has been reported to be associated with other adverse medical outcomes, including death from stroke, enlargement of the heart (a precursor to congestive heart failure), and even asthma mortality (Antonios and McGregor 1995). Moreover, recent population-based studies seem to confirm that the major cause of high blood pressure is an excessive dietary intake of sodium. Using a standardized protocol in a 52-center worldwide study, INTERSALT showed a positive, significant, linear relationship between salt intake and blood pressure. The statistical relationship suggested that each 100 mmol of sodium intake was responsible for a 2 mm Hg increase in systolic blood pressure. In addition, the INTERSALT findings suggest a powerful effect of dietary sodium intake on the rise in blood pressure with age. It has also been argued that a reduction in the average intake of sodium in Britain – from 150 mmol to 100 mmol per day – could reduce strokes and heart attacks in that nation by 22 percent and 16 percent, respectively, and would have a greater impact than that of all of the drugs used to treat high blood pressure (McGregor and Sever 1996).

For the majority of hypertensive persons, it seems well established that lifestyle improvements, such as lowering dietary sodium intake while increasing dietary potassium intake, reducing body weight, and increasing exercise, can lower blood pressure. Although such efforts would likely lower a person's blood pressure by "only" 5 mm Hg, it is important to consider the societal health benefits of such a downward shift across the entire population. From a population-wide perspective, this could dramatically reduce the prevalence of hypertension and cardiovascular disease.

It has been estimated that it costs $1,000 per year to treat each hypertensive person (Elliott 1996). If lifestyle changes could lower the average blood pressure by only 5 mm Hg, then 21.4 million persons would no longer require treatment. This would save the United States about $21 billion a year in the cost of health care for hypertension alone, not to mention the costs saved by the reduction of strokes by about 40 percent and cardiovascular disease by about 25 percent. The potential economic advantage of implementing low-cost lifestyle changes to lower blood pressure across society should be obvious. Indeed, it is clear that most countries of the world will not be able to afford expensive medical therapies to control high blood pressure and should be implementing public-health strategies to lower blood pressure and the devastating consequences of hypertension for a country's workforce.

IV.B.8. ~ Other Trace Elements

Beginning early in the twentieth century, scientists were able to qualitatively detect small amounts of several elements in living organisms. In reports, these elements were often described as being present in "traces" or "trace amounts," and within a short time, they became known as the trace elements. Today, trace elements are understood to be those elements of the periodic table that occur in the body in micrograms per gram (µg/g) of body weight or less. They may be essential – that is, they may be indispensable for growth, health, and completion of the life cycle – or they may be nonessential: fortuitous reminders of our geochemical origins or indicators of environmental exposure. Some of the nonessential trace elements can be beneficial to health through pharmacologic action, but all are toxic when consumed in excess.

An essential element is defined by many in the scientific community as an element whose dietary deficiency consistently results in a suboptimal function that is preventable or reversible by physiological amounts of the element. However, other experts accept an element as essential only if it has a defined biochemical function. Thus, there is no universally accepted list of trace elements that are considered essential.

The essential trace elements are usually required by humans in amounts indicated by milligrams per day (mg/d). In 1980, the term "ultratrace element" began to appear in the literature; this was defined as an element with a daily dietary requirement of some 50 nanograms per gram (ng/g) for animals (Nielsen 1980). For humans, however, the term often is used to indicate elements with an established, estimated, or suspected requirement of less than 1.0 mg/d (generally indicated as micrograms per day, or µg/d) (Nielsen 1994b).

At present, both signs of deficiency and defined biochemical functions in humans are known for only 7 trace and ultratrace elements. The trace elements are copper, iron, and zinc, and the ultratrace elements are cobalt (in the form of cobalamin), iodine, molybdenum, and selenium. Although essential functions have been identified for manganese, unequivocal signs of its deficiency in humans have not been described. Conversely, such signs have been described for chromium and boron, but their specific biochemical functions have not been conclusively defined. Based on animal experiments, and discovery of their essential functions in lower forms of life, 4 other trace or ultratrace elements are probably essential to humans: arsenic, nickel, silicon, and vanadium. In addition, 2 elements with beneficial pharmacological properties are fluorine (anticariogenic) and lithium (antimanic). Since 1970, reports have appeared suggesting that other elements, including aluminum, bromine, cadmium, germanium, lead, rubidium, strontium, and tin, may be essential. However, weak, limited, or controversial data have prevented general acceptance of the essentiality of these elements.

The essential trace elements iron and zinc and the essential ultratrace element iodine are discussed in separate chapters and thus are not addressed here.

Arsenic

History of Oral Intake

Since ancient times, arsenicals have been characterized by actions both benevolent and malevolent. Very early, it was found that some arsenic compounds were convenient scentless and tasteless instruments for homicidal purposes, and until the nineteenth century, arsenic reigned as the king of poisons; indeed even today, the term "arsenic" is primarily thought of as synonymous with poison. Nonetheless, this bad reputation did not prevent it from becoming an important pharmaceutical agent. According to a review by H. A. Schroeder and J. J. Balassa (1966), the medicinal virtues of arsenicals were acclaimed by Hippocrates (460 to 357 B.C.), Aristotle (384 to 322 B.C.), Theophrastus (370 to 288 B.C.), and Pliny the Elder (A.D. 23 to 70).

Beginning in 1905, various arsenicals were developed for pharmacological purposes, and by 1937, they numbered 8,000. Arsenicals were considered at various times to be specific remedies in the treatment of anorexia, other nutritional disturbances, neuralgia, rheumatism, asthma, chorea, malaria, tuberculosis, diabetes, skin diseases, and numerous hematologic abnormalities. Today, however, either the use of arsenic for these disorders has fallen into disrepute or more effective alternatives have taken its place.

Discovery of Nutritional Importance

Reports describing attempts to produce a nutritional arsenic deficiency first appeared in the 1930s. E. Hove, C. A. Elvehjem, and E. B. Hart (1938) found that a milk diet fortified with iron, copper, and manganese, furnishing as little arsenic as 2 μg/day, did not significantly affect growth, hemoglobin concentration, and red blood cell number or fragility in rats. However, an arsenic supplement of 5 μg/day delayed the rate of fall of hemoglobin concentration in rats fed whole milk without mineral supplementation. J. T. Skinner and J. S. McHargue (1946) also found that arsenic supplementation increased hemoglobin concentrations in rats fed a skim milk and sucrose diet adequately supplemented with iron and copper.

H. A. Schroeder and J. J. Balassa (1966) found that rats and mice grew and developed normally when fed diets containing as little arsenic as 0.053 μg/g; additional arsenic in their drinking water improved the appearance of their skin and hair. Perhaps the first findings accepted as evidence for the possible nutritional essentiality of arsenic appeared in 1975 and 1976, when apparent deficiency signs were described for rats, goats, and pigs (Nielsen and Uthus 1984; Anke 1986; Uthus 1994). Subsequently, deficiency signs were reported for chickens and hamsters (Uthus 1994).

Dietary Importance

In goats, pigs, and rats, the most consistent signs of arsenic deprivation were depressed growth and abnormal reproduction characterized by impaired fertility and elevated perinatal mortality (Nielsen and Uthus 1984; Anke 1986). Arsenic deprivation also caused myocardial damage and death during lactation in goats. Some biochemical changes found with arsenic deprivation include depressed plasma triglycerides and taurine concentrations, liver polyamine concentration, liver glutathione S-transferase activity, liver S-adenosylmethionine concentration, and specific activity of S-adenosylmethionine decarboxylase (Uthus 1994). The large number of responses to arsenic deprivation – reported for a variety of animal species by more than one research group – strongly suggests that arsenic is a nutritionally important ultratrace element for higher animals.

Although a biochemical function has not been defined for arsenic, its actions in vitro and the findings from animal deprivation studies indicate a function that affects the formation and utilization of labile methyl groups arising from methionine. Through this effect on methyl group metabolism, arsenic possibly affects the methylation of important molecules, such as DNA. If so, suboptimal methyl metabolism caused by lack of arsenic could be of concern; for example, hypomethylation of DNA can lead to some forms of cancer. It has also been suggested that arsenic plays an important role in human health because of findings that injuries of the central nervous system, vascular diseases, and cancers correlated with markedly depressed serum arsenic concentrations (Mayer et al. 1993). Because arsenic is most likely an essential nutrient, the belief that any form of it is unnecessary, toxic, or carcinogenic must be discarded.

Boron

History of Oral Intake

The recognition that the presence of boron in foods can be both beneficial and detrimental apparently dates from the 1870s. At that time, it was discovered that borax and boric acid could be used to preserve foods, and for the next 50 years or so, borate addition was considered one of the best methods of preserving or extending the palatability of foods such as fish, shellfish, meat, sausage, bacon, ham, cream, butter, and margarine (Gordon 1987). During World War I, the use of boron as a preservative played a vital role in preventing food crises. In other words, in the last decades of the nineteenth century and the first decades of the twentieth century, boron was considered beneficial, and prevailing medical opinion held that boron was innocuous because, despite its widespread use, no deaths had been blamed on it.

As early as 1902, however, some German and American scientists had begun to question this orthodox view. Foremost among the works that changed perceptions about boron was a report by H. W. Wiley (1904), which stated that consumption of boric acid in doses greater than 0.5 g/day for 50 days resulted in disturbances in appetite, digestion, and health in human volunteers. Following this change in perception, the opinion that boron posed a risk to health started to gain momentum, and by the mid–1920s, many countries began legislating against the addition of borates to food. Only during World War II were the new restrictions eased, as shortages made food preservation a major concern in many countries (Gordon 1987). After the war, restrictions were gradually reimposed and by the middle of the 1950s, the use of boron as a food preservative was virtually forbidden throughout the world. At this time, boron also began to receive attention from toxicologists. Because of some accidental poisonings and inappropriate uses in the medical profession, between 1950 and 1980 boric acid and borates were seen as only important to human health from a toxicological point of view.

Discovery of Nutritional Importance

During the 1920s, K. Warington (1923) and A. L. Sommer and C. B. Lipman (1926) showed that boron was an essential nutrient for plants, and in subsequent decades, other investigators attempted – unsuccessfully – to demonstrate that it was essential for higher animals as well (Hove, Elvehjem, and Hart 1939; Orent-Keiles 1941; Teresi et al. 1944). It was reported in 1945 that high dietary boron (100 to 1,000 μg/g) enhanced survival and increased body fat and liver glycogen in potassium-deficient rats (Skinner and McHargue 1945), although further experiments, using a different diet with an unknown basal boron content and with different amounts of boron supplementation, failed to confirm these findings (Follis 1947). The inability in these early studies to produce a boron deficiency in animals apparently resulted in generations of students of biochemistry and nutrition learning that boron was a unique element because it was essential for plants but not for higher animals, including humans.

In the early 1980s, however, this dogma began to change. C. D. Hunt and F. H. Nielsen (1981) reported that boron deprivation depressed the growth of chicks, with the effect seemingly more marked when dietary cholecalciferol was marginally deficient. Moreover, morphological examination of the tibias of chicks indicated that an interaction between boron and cholecalciferol affected bone formation. In the years since this report, circumstantial evidence has accumulated to suggest strongly that boron is an essential nutrient for higher animals and humans.

Dietary Importance

Listing the signs of boron deficiency for animals is difficult because of the large number reported and because most studies of this deficiency in animals have used stressors to enhance the response to changes in dietary boron. However, although the nature and severity of the changes varied with dietary composition, many of the findings indicated that boron deprivation impairs calcium metabolism, brain function, and energy metabolism (Hunt 1994; Nielsen 1994a; Nielsen 1997). They also suggest that boron deprivation impairs immune function and exacerbates adjuvant-induced arthritis in rats.

Humans as well as animals respond to changes in dietary intake of boron (Nielsen 1994a; Penland 1994; Nielsen 1997). Among the effects of boron deprivation in men over the age of 45, postmenopausal women, and postmenopausal women on estrogen therapy were the following: an effect on macromineral and electrolyte metabolism evidenced by decreased serum 25-hydroxycholecalciferol and increased calcitonin (when dietary magnesium and copper were low); an effect on energy substrate metabolism suggested by increased serum glucose and decreased serum triglycerides; an effect on nitrogen metabolism indicated by increased blood urea nitrogen and serum creatinine and decreased urinary hydroxyproline excretion; an effect on oxidative metabolism indicated by decreased erythrocyte superoxide dismutase and serum ceruloplasmin; and an effect on erythropoiesis and hematopoiesis suggested by decreased blood hemoglobin and mean corpuscular hemoglobin content combined with increased hematocrit, platelet number, and erythrocyte number.

Boron depletion also depressed the elevation in serum 17-beta-estradiol and plasma copper caused by estrogen ingestion, altered electroencephalograms so that they suggested diminished behavioral activation (for example, more drowsiness) and mental alertness, and impaired psychomotor skills and the cognitive processes of attention and memory.

Although a defined biochemical function is not yet known for boron, accumulated knowledge about its nutritional effects and metabolism has resulted in the recognition that boron may be of practical nutritional importance. However, no clinical disorder can be conclusively attributed to suboptimal boron nutriture. Because boron affects the macromineral metabolism, it seems likely that an inadequate boron intake may contribute to some disorders associated with suboptimal calcium metabolism, such as osteoporosis.

Chromium

Discovery of Nutritional Importance

By 1948, chromium had been recognized as a consistent component of plant and animal tissue. The first suggestion that chromium might have biologic activity appeared in 1954 (Curran 1954), when it was found that chromium enhanced the synthesis of cholesterol and fatty acids from acetate by rat liver. In 1959, trivalent chromium was identified as the active component of the "glucose tolerance factor," which alleviated the impaired glucose tolerance in rats fed certain diets apparently inadequate in chromium (Schwarz and Mertz 1959). Between 1964 and 1968, the first reports appeared indicating that chromium could affect glucose tolerance in humans (Mertz 1993).

Subsequently, it was found that chromium supplementation also decreased serum cholesterol concentrations and normalized exaggerated insulin responses to glucose loads. Despite these suggestive findings, chromium did not receive much attention as a possible essential element for humans until 1977, when apparent chromium deficiency signs were found in a patient receiving total parenteral nutrition (Jeejeebhoy et al. 1977). Shortly thereafter, other patients receiving total parenteral nutrition were found to exhibit abnormalities of glucose metabolism that were responsive to chromium supplementation.

Dietary Importance

In 1959, it was reported that chromium-deficient rats exhibited a glucose intolerance similar to that of clinical diabetes mellitus (Schwarz and Mertz 1959). Since that time, several other deficiency signs have been described for animals, including impaired growth, elevated serum cholesterol and triglyceride concentrations, increased incidence of aortic plaques, corneal lesions, and decreased fertility and sperm count (Anderson 1988). Many of these signs were made more evident by using nutritional, metabolic, physiological, or hormonal stressors.

Signs of apparent chromium deficiency have been found in three women receiving long-term total parenteral nutrition containing low amounts of chromium. One subject, who had received total parenteral nutrition for 3.5 years, exhibited impaired glucose tolerance and glucose use, weight loss, neuropathy, elevated free fatty acid concentrations, depressed respiratory exchange ratio, and abnormalities in nitrogen metabolism (Jeejeebhoy et al. 1977). These abnormalities were alleviated by chromium supplementation. Another subject, who had received total parenteral nutrition for 5 months, developed severe glucose intolerance, weight loss, and a metabolic encephalopathy-like confusional state. All of these abnormalities were reversed by chromium supplementation (Freund, Atamian, and Fischer 1979). Chromium supplementation also reversed the development of unexplained high blood and urine glucose in a third patient who had followed a total parenteral nutrition regimen of several months' duration (Brown et al. 1986).

Although these three descriptions of human chromium deficiency are somewhat dissimilar, in all cases the apparently chromium-deficient subjects exhibited impaired glucose tolerance, or high blood glucose with glucose spilling into the urine, and a refractoriness to insulin. In addition, since 1966, a large number of reports from numerous research groups have described beneficial effects from chromium supplements in subjects with degrees of glucose intolerance ranging from low blood sugar to insulin-dependent diabetes. Most recent are reports that relatively high chromium supplementation (200 to 1000 µg/day of chromium picolinate) decreased blood glucose and glycated hemoglobin in 162 Beijing, China, residents with high blood glucose (Anderson et al. 1997); such supplementation also decreased blood glucose, C-peptide, and insulin concentrations in gestational diabetic women undergoing a glucose tolerance test (Jovanovic-Peterson, Gutierrez, and Peterson 1996). Thus, there is a growing body of evidence suggesting that chromium supplements may be a viable treatment option for some people with diabetes resulting from inadequate synthesis of insulin or insulin resistance. In other words, chromium is potentiating the action of low amounts of insulin or improving its efficiency so that the need for exogenous sources is reduced or eliminated. Beneficial effects of chromium supplementation on blood lipid profiles also have been reported.

Even though a biochemical function has not been defined for chromium, it most likely is an essential element. Even the skeptics of chromium essentiality agree that chromium can be beneficial because of its positive effects on glucose and lipid metabolism in some individuals. This is apparently the reason that in 1980 an Estimated Safe and Adequate Daily Dietary Intake (ESADDI) was established for chromium (National Research Council 1980). For children over age 7 and adults, this amount is 50 to 200 µg/day. There is some evidence that an intake of chromium of less than 20 µg/day is inadequate, and dietary surveys indicate that a significant number of people consume less than this amount. Thus, it seems possible that inadequate chromium status may be partially responsible for some cases of impaired glucose tolerance, high blood glucose, low blood glucose, refractoriness to insulin, and, ultimately, diabetes. Furthermore, because impaired tissue responsiveness to insulin is a possible risk factor for cardiovascular disease, and because chromium deprivation has unfavorable effects on cholesterol and lipid metabolism, inadequate chromium status may increase susceptibility to ischemic heart disease.

Copper

Discovery of Nutritional Importance

The presence of copper in plant and animal tissues was recognized early in the nineteenth century, but this was thought to be the result of accidental contamination. The first indication that the mineral was associated with specific biochemical substances occurred when it was found in blood proteins in snails (Harless 1847). Copper was also found in the tail-feather pigment of the turaco (Church 1869) and was shown to be a constituent of octopus hemocyanin (Fredericq 1878). The discovery of reproducible amounts of copper in the human brain (Bodansky 1921) stimulated acceptance of the fact that it was definitely a physiological constituent of biological material.

Its universal distribution in plants prompted the hypothesis that copper was a catalyst participating in life processes (Fleurent and Lévi 1920; Guérithault and Maquenne 1920), and soon afterward, McHargue (1925, 1926) produced evidence suggesting that the element was beneficial in the diet of rats. Conclusive evidence that copper is an essential nutrient, however, came from studies of hemoglobin regeneration in anemic rats. In 1928, it was demonstrated that copper supplementation prevented both anemia and growth-stunting in young rats on milk-only diets (Hart et al. 1928), and subsequently, anemia caused by copper deprivation was shown to occur in chickens, cows, dogs, goats, pigs, sheep, rabbits, and humans.

Shortly after the initial discovery that rats required the mineral, certain naturally occurring copper-deficiency disorders were identified in cattle (salt-sickness in Florida and *lecksucht* in the Netherlands) and sheep (enzootic neonatal ataxia in Western Australia) (Neal, Becker, and Shealy 1931; Sjollema 1933; Bennetts and Chapman 1937). In addition to poor growth and anemia, copper deficiency was characterized by defects in pigmentation, keratinization of wool, bone formation, reproduction, myelination of the spinal cord, cardiac function, and connective tissue formation.

During the 1960s and 1970s, the first descriptions of copper deficiency in humans began to appear.

Deficiency symptoms were described for premature babies (Al-Rashid and Spangler 1971; Ashkenazi et al. 1973) and for young Peruvian and Chilean children with severe malnutrition and chronic diarrhea (Cordano, Baertl, and Graham 1964; Graham and Cordano 1969). Anemia, neutropenia, and osteoporosis were the main characteristics of the deficiency. The discovery of a genetic disease (Menkes disease) with characteristics of copper deficiency also showed that low copper status could adversely affect humans (Danks et al. 1972a, 1972b). Since 1984, reports have appeared describing signs of copper deficiency in adults brought on by depletion–repletion experiments (Klevay and Medeiros 1996).

Dietary Importance

Recent studies, mostly with rodents, have shown that copper deficiency results in a large number of defects associated with the cardiovascular system, including abnormal electrocardiograms, connective tissue abnormalities in blood vessels, enlarged hearts, altered fatty acid profiles, glucose intolerance, abnormal blood pressure, elevated blood cholesterol, pleural effusion, and ventricular aneurysms (Klevay and Medeiros 1996).

The importance of copper for malnourished children and premature infants has been described. Subsequent to its discovery, an ESADDI of 2 to 3 mg for adults was established (National Research Council 1980); some years later, this was changed to 1.5 to 3.0 mg (National Research Council 1989). Human depletion–repletion studies in adults have indicated that copper intakes of 0.65 to 1.02 mg/day are insufficient. Some subjects fed diets containing this amount exhibited changes in serum cholesterol, heart rhythm, and oxidative metabolism – measured by erythrocyte superoxide dismutase activity, serum ceruloplasmin, and mononucleated white cell cytochrome c oxidase (Klevay and Medeiros 1996). Such changes suggest that a low copper status can increase the risk for ischemic heart disease (Klevay 1990), a suggestion in urgent need of confirmation because pooled data from surveys in Belgium, Canada, the United Kingdom, and the United States have revealed that approximately one-third of 849 diets supplied copper in quantities of less than 1.0 mg/day (Klevay et al. 1993).

Fluorine

Discovery of Nutritional Importance

Fluorine first attracted nutritional attention in the 1930s, when unsuccessful attempts were made to show that low fluoride intakes produced any kind of pathology in rats and when fluoride was identified as the factor causing a mottled condition of tooth enamel known as "Colorado brown stain" and other such descriptive names (Whitford 1990). It was also noted at that time that fewer dental caries occurred in those individuals with mottled enamel, and subsequently it was discovered that fluoride intakes could be achieved that brought about caries reduction without mottling. As a consequence, water fluoridation was begun as a public health measure in 1945.

In the 1960s, an association was made between high fluoride intake and a reduced incidence of osteoporosis (Messer 1984). However, although the use of pharmacologic amounts of fluoride to prevent bone loss is still being investigated, its usefulness in this regard seems limited. Another round of fluoride confusion came in the early 1970s, when scientists suggested that fluoride was necessary for hematopoiesis, fertility, and growth in mice and rats (Messer 1984). It turned out, however, that this assertion was based on experiments in which animals were not fed optimal diets, and it was later concluded that the effects of fluoride were only achieved through pharmacologic mechanisms.

Dietary Importance

At present, there is no substantive evidence that fluoride is an essential nutrient. The major known biological action of fluoride is its ability to protect against pathological demineralization of calcified tissues, which is not an essential function in the true sense, but a beneficial action delivered through pharmacological mechanisms. Nonetheless, because fluoride was recognized as having beneficial properties through oral intake, ESADDIs for various times in the life cycle were established; for adults, this amount is 1.5 to 4.0 mg (National Research Council 1989).

Manganese

Discovery of Nutritional Importance

Between 1913 and 1921, manganese was found to be a constant component of plant and animal tissues, and in 1923, it was shown to be required by plants and microorganisms (McHargue 1923). Attempts to demonstrate that manganese was required by laboratory animals were unsuccessful, however, because the purified diets employed were so deficient in other essential nutrients that even the addition of manganese did not result in normal growth and survival. In 1931, it was found that manganese was essential for the growth of mice and also for normal ovarian activity in both mice and rats; it was vital to preventing testicular degeneration in rats as well (Kemmerer, Elvehjem, and Hart 1931; Orent and McCollum 1931; Waddell, Steenbock, and Hart 1931). Five years later, researchers learned that perosis ("slipped tendon") and nutritional chondrodystrophy in poultry were caused by inadequate manganese intake (Wilgus, Norris, and Heuser 1936, 1937; Lyons and Insko 1937). The identification of a specific biochemical function for manganese remained elusive for many years, but finally, in 1962, the mineral was found to have a specific role in the synthesis of the mucopolysaccharides of cartilage (Leach and Muenster 1962). The first report of a possible case of human manganese deficiency appeared in 1972 (Doisy 1972).

Dietary Importance

Manganese deficiency symptoms have been induced in many species of animals. They include impaired growth, skeletal abnormalities, disturbed or depressed reproductive function, ataxia of the newborn, and defects in lipid and carbohydrate metabolism (Freeland-Graves and Llanes 1994; Finley and Johnson 1996). Establishing the signs of manganese deficiency in humans, however, has been difficult.

The first possible description of manganese deficiency in humans was that of a man who had been fed a semipurified diet for an extended period of time (Doisy 1972). He developed weight loss, depressed growth of hair and nails, dermatitis, and low blood cholesterol. Moreover, his black hair developed a reddish tinge, and his clotting protein response to vitamin K supplementation was abnormal. Subsequent to the appearance of these signs, it was realized that manganese had been left out of his diet, and the subject responded to a mixed hospital diet containing manganese. Unfortunately, no supplementation with manganese alone was tried, and thus, although this case is often cited as an example of human manganese deficiency, the experimental design does not permit this to be stated conclusively.

Another report indicated that men fed only 0.11 mg/day of manganese for 35 days exhibited decreased cholesterol concentrations in serum, a fleeting dermatitis, and increased calcium, phosphorus, and alkaline phosphatase in blood (Friedman et al. 1987). Short-term manganese supplementation for 10 days, however, failed to reverse these changes, and consequently, whether the observed changes were caused by manganese deprivation can be questioned. Probably the most convincing report of a human manganese deficiency is that concerning a girl, age 4 years, who had been maintained on total parenteral nutrition that was low in manganese since she was 9 days old. She developed short stature, brittle bones, and low serum manganese; manganese supplementation improved bone density and longitudinal growth (Norose 1992). In addition to the symptoms just discussed, a low manganese status has been associated with osteoporosis and epilepsy; that is, patients with these conditions often have low serum or plasma manganese concentrations (Freeland-Graves and Turnlund 1996). Although such limited findings have made it difficult to establish the nutritional importance of manganese, most scientists do not doubt that it is essential for humans.

Molybdenum

Discovery of Nutritional Importance

From the toxicological point of view, molybdenum became important when it was discovered that the drastic scouring disease of cattle, "teart," was caused by ingestion of excessive molybdenum, high amounts of which were present in herbage growing in the affected areas (Ferguson, Lewis, and Watson 1938). From a nutritional viewpoint, in 1930 molybdenum was reported to be essential for the growth of *Azotobacter,* a nonpathogenic bacterium found in soil and water (Bortels 1930).

Subsequently, it was discovered that molybdenum was needed by nearly all nitrogen-fixing organisms, and by 1939, the mineral was known to be both required by higher plants (independent of its role in nitrogen fixation) and consistently present in animal tissues (ter Meulen 1932; Arnon and Stout 1939). However, an early attempt to show that molybdenum was required by laboratory animals was unsuccessful (Teresi, Elvehjem, and Hart 1942), and later attempts to produce symptomatic molybdenum deficiency in rats and chicks were only successful when the diets contained massive amounts of tungsten, an antagonist of molybdenum metabolism (Higgins, Richert, and Westerfeld 1956). In 1981, the first report appeared of a human molybdenum deficiency caused by a dietary lack (Abumrad et al. 1981).

Dietary Importance

There are very few descriptions of molybdenum deficiency signs in humans (Rajagopalan 1988). In one study, four young men exhibited no clinical signs after consuming a diet with a molybdenum content of only 22 μg/day for 102 days (Turnlund et al. 1995). However, the low amount of the mineral resulted in decreased urinary excretion of uric acid and an increased urinary xanthine excretion after the administration of a load of adenosine monophosphate. These findings indicated that xanthine oxidase (a molydoenzyme) activity was decreased.

The most convincing case of molybdenum deficiency was found in a patient receiving prolonged parenteral nutrition therapy (Abumrad et al. 1981). The patient's symptoms (which were exacerbated by methionine administration) included high blood methionine and oxypurine concentrations, low blood uric acid concentration, and low urinary excretion of uric acid and sulfate. The patient suffered mental disturbances that progressed to coma, but supplementation with ammonium molybdate improved the clinical condition, reversed the sulfur-handling defect, and normalized uric acid production.

A human genetic disorder caused by a lack of functioning molybdenum as part of the enzyme sulfite oxidase has been identified (Rajagopalan 1988). This genetic disease is characterized by severe brain damage, mental retardation, and dislocation of ocular lenses, and results in increased urinary output of sulfite, S-sulfocysteine, and thiosulfate, and a marked decrease in sulfate output.

Although molybdenum deficiency has not been recognized as a nutritional problem, it cannot be ignored because there may be unrecognized situations in which molybdenum nutriture plays an important role. For example, the molybdenum hydroxylases apparently are as important as the microsomal monooxygenase system in the metabolism of drugs and compounds foreign to the body (Beedham 1985). Perhaps low molybdenum hydroxylase activity (caused by molybdenum deficiency) would have undesirable consequences when a person is stressed by high intakes of xenobiotics. An ESADDI has been established for molybdenum; for adults it is 75 to 250 μg (National Research Council 1989).

Nickel

Discovery of Nutritional Importance

The earliest study of the biologic action of nickel appeared in 1826, when signs of oral nickel toxicity were described in rabbits and dogs (Nriagu 1980). The first reports on the presence of the mineral in plant and animal tissues appeared in 1925 (Berg 1925; Bertrand and Mâcheboeuf 1925), and although it was suggested that nickel was nutritionally essential in 1936 (Bertrand and Nakamura 1936), the first direct evidence for its essentiality for higher animals appeared in 1970 (Nielsen and Sauberlich 1970). By 1984, extensive signs of nickel deprivation had been reported for 6 animal species – chickens, cattle, goats, pigs, rats, and sheep (Nielsen 1984). Unfortunately, many of these symptoms may have been manifestations of pharmacologic actions of nickel; that is, high dietary nickel used in some experiments may have alleviated an abnormality caused by something other than a nutritional deficiency of nickel (for example, many diets used in the experiments were apparently low in iron) (Nielsen 1985).

Studies of nickel since 1984 probably give a more accurate picture of its nutritional role in higher animals. Support for the essentiality of the mineral has come from the identification of nickel enzymes in lower forms of life; the first to be identified was jackbean urease in 1975 (Dixon et al. 1975). Since then, nickel has been found to be an essential component of urease from bacteria, mycoplasma, fungi, yeast, algae, higher plants, and invertebrates (Mobley, Island, and Hausinger 1995). Nickel also has been identified as an essential component of three redox enzymes in bacteria involved in hydrogen oxidation, methane biogenesis, and acetate formation; these enzymes are hydrogenase, methylcoenzyme M reductase, and carbon monoxide dehydrogenase (Lancaster 1988). A nickel deficiency in humans has not been reported.

Dietary Importance

Recent studies (Nielsen 1995) suggest that nickel deprivation in goats and rats results in depressed growth, reproductive performance, and plasma glucose and alters the distribution of other elements in the body, including calcium, iron, and zinc. As with other ultratrace elements, the nature and severity of the signs of nickel deprivation are affected by the composition of the diet. For example, both vitamin B_{12} (Nielsen et al. 1989) and folic acid (Uthus and Poellot 1996) affect the response to nickel deprivation. This correlation, in turn, has resulted in the hypotheses that vitamin B_{12} is necessary for the optimal expression of the biological role of nickel and that nickel has an essential function closely related to vitamin B_{12} metabolism.

The recent discoveries of nickel essentiality and its defined biochemical functions in various microorganisms, plants, and animals indicate that it is also an essential nutrient for humans. Nonetheless, until more is known about its physiological function, it is inappropriate to specify that certain disorders might be wholly, or even partially, attributable to abnormal nickel nutrition or metabolism. But because the nickel content in some human diets can be lower than that which induces changes in animals, it may well turn out that nickel will be found to be an element of concern in human nutrition.

Selenium

Discovery of Nutritional Importance

From the biological point of view, the early history of selenium focused on its toxicological properties. The first report appeared about 1295 in the writings of Marco Polo (Trelease and Beath 1949). He described a poisonous plant (most likely seleniferous) growing in the mountains of western China, which, when eaten by beasts of burden, caused their hoofs to drop off – a phenomenon known to occur in cattle and horses that consume plants containing toxic amounts of selenium. The first scientific description of selenium toxicity, however, appeared only in 1842 (Moxon and Rhian 1943), and the element received little further attention until 1935. At that time, selenium poisoning (caused by the consumption of grains and forages high in this element) was found responsible for two diseases of livestock – known as "blind staggers" and "alkali disease" – that occurred in the northern plains of the United States (Franke and Painter 1935). This discovery stimulated investigation of the distribution of selenium in rocks, soils, plants, and animals.

In 1957, selenium came under consideration as an essential nutrient when it was found that it prevented liver necrosis in vitamin E deficient rats (Schwarz and Foltz 1957) and exudative diathesis in vitamin E deficient chicks (Patterson, Milstrey, and Stokstad 1957; Schwarz et al. 1957). The following year it was reported that muscular dystrophy, which occurred in lambs and calves in certain areas of the world, was caused by selenium deficiency (Muth et al. 1958; Proctor, Hogue, and Warner 1958). Subsequently, researchers identified areas of the world that were home to naturally occurring selenium deficiency, which impaired the growth, health, and fertility of animals living in them. Identification of a biochemical function for selenium in mammals came in 1973, when the element was shown to be a constituent of the enzyme glutathione peroxidase (Rotruck et al. 1973). Reports first appeared in 1979 indicating that a naturally occurring clinical condition – Keshan disease – was partially attributable to low selenium intake (Keshan Disease Research Group 1979).

Dietary Importance

All known pathologies of selenium deficiency in animals can be alleviated by luxuriant intakes of vitamin E. Thus, the nutritional importance of selenium is most evident in vitamin E deficient animals. A variety of pathological changes attributable to combined deficiencies of selenium and vitamin E have been described for several animal species. These changes result in dysfunctions of the brain, the cardiovascular system, the liver, the muscles, and the fetus. Many of the pathological conditions caused by the combined deficiencies can be modified by other dietary factors, including the intake of polyunsaturated fatty acids, sulfur amino acids, and synthetic antioxidants (Combs and Combs 1984).

Evidence that selenium can be of practical nutritional importance came from studies of the relationship between selenium and Keshan disease, an endemic cardiomyopathy affecting children and young women that occurs in an area running from northeastern to southwestern China (Levander and Burk 1994). The primary pathological changes in Keshan disease include heart enlargement with multiple focal degenerative necrosis and fibrous replacement of the myocardium. Selenium supplementation was found effective in preventing Keshan disease, the incidence of which varied with several other factors, and it has been suggested that low vitamin E status or oxidant stress caused by viral or bacterial infection may be contributory factors. Other reports of selenium deficiency came from studies of patients on long-term total parenteral nutrition. The signs of deficiency in these patients included bilateral muscular discomfort and a dilated cardiomyopathy that histopathologically resembled Keshan disease (Levander and Burk 1994).

Finally, it was found that a luxuriant intake of selenium achieved by supplementation (200 μg/day) was effective in preventing the occurrence of some forms of cancer (Clark et al. 1996). Because the preceding discovery indicated that those individuals who are selenium deficient can be considered at risk for developing pathology, people should achieve an intake meeting the Recommended Dietary Allowance of 70 and 55 μg/day for adult men and women, respectively (National Research Council 1989).

Silicon

Discovery of Nutritional Importance

Silicon has long been thought important in maintaining health in humans. Before much was known about it in biology, one of the luminaries of medical science, Louis Pasteur, predicted that silicon would prove to be an important therapeutic substance for many diseases (Becker et al. 1983), and at the beginning of the twentieth century, numerous French and German reports suggested that the prediction of Pasteur would become fact. These reports described therapeutic successes in treating numerous diseases – including atherosclerosis, hypertension, and dermatitis – with sodium silicate, with simple organic silicon compounds, and with tea made from the silicon-rich horsetail plant. However, by 1930, these "therapeutic successes" had come to be viewed as failures, and in the face of inadequate evidence for silicon's biological activity, the mineral faded into medical obscurity.

During the next four decades, silicon – as consumed in the diet – was generally considered a biologically inert, harmless, nonessential element for living organisms, except for some lower forms of life (diatoms, radiolarians, and sponges) in which silica meets a structural need (Carlisle 1984). But then, in 1972, it was reported that silicon was essential for bone formation (Carlisle 1972), and at about the same time, other studies appeared suggesting, as had those of the early twentieth century, that inadequate dietary silicon may contribute to some cases of atherosclerosis, hypertension, some bone disorders, and the aging process. However, these studies have generally been ignored because a specific biochemical role for silicon, which could explain the mechanism behind such occurrences, has not been identified.

Dietary Importance

Most of the signs of silicon deficiency in animals indicate aberrant metabolism of connective tissue and bone. Illustrative are chicks on a silicon-deficient diet that exhibit structural abnormalities of the skull, depressed collagen content in bone, and long-bone abnormalities characterized by small, poorly formed joints and defective endochondral bone growth (Carlisle 1984). Silicon deprivation can also affect the response to other dietary manipulations. Thus, although rats fed a diet low in calcium and high in aluminum accumulated high amounts of aluminum in the brain, it was found that relatively high silicon supplements prevented such accumulation (Carlisle and Curran 1987).

Similarly, whereas high dietary aluminum depressed brain zinc concentrations in thyroidectomized rats fed low dietary silicon, relatively high silicon supplements prevented the depression (Carlisle, Curran, and Duong 1991). This effect, however, was not seen in nonthyroidectomized rats. Other biochemical actions indicating that silicon is an essential element include its consistent presence in collagen; and in bone tissue culture it is needed for maximal bone prolylhydroxylase activity (Carlisle, Berger, and Alpenfels 1981). Silicon deficiency decreases ornithine aminotransferase (an enzyme in the collagen formation pathway) in rats (Seaborn and Nielsen 1996). Thus, ample evidence exists to suggest that silicon is an essential nutrient for higher animals, including humans.

Findings from animals indicating that silicon nutriture affects macromolecules – such as glycosaminoglycans, collagen, and elastin – suggest that silicon is needed for healthy bones, brains, and blood vessels (Seaborn and Nielsen 1993). Although more needs to be known about the physiological or biochemical function and requirement for silicon, speculation has materialized on the possible involvement of silicon deprivation in the occurrence of several human disorders, including atherosclerosis, osteoarthritis, osteoporosis, hypertension, and Alzheimer's disease. Such speculation indicates the need for more work to clarify the consequences of silicon deficiency in humans.

Vanadium

Discovery of Nutritional Importance

A report on the toxicity of vanadium was published in 1876 (Priestley and Gamgee 1876) but apparently failed to stimulate interest in the mineral's biological actions. Consequently, the subject lay dormant until the turn of the twentieth century, when various French physicians used vanadium as a panacea for a number of human disorders. Shortly thereafter, a classic paper on the pharmacological and toxicological actions of vanadium appeared (Jackson 1912) – at about the time that extremely high vanadium concentrations were found in the blood of ascidian worms (Henze 1911, 1912). The hypothesis that vanadium has a physiological role in higher animals has had a long, yet muddled, history. In 1949, O. Rygh reported that vanadium might be needed by animals because it markedly stimulated the mineralization of bones and teeth and prevented caries formation in rats and guinea pigs. In 1950, D. Bertrand wrote that "we are completely ignorant of the physiological role of vanadium in animals, where its presence is constant." In 1963, H. A. Schroeder, J. J. Balassa, and I. H. Tipton indicated that although vanadium behaves like an essential trace metal, final proof of its essentiality for mammals was still lacking. But in 1974, L. L. Hopkins, Jr., and H. E. Mohr stated: "[W]e are secure in the concept that vanadium is an essential nutrient." Subsequent reviews, however, have presented a convincing argument that the evidence for the nutritional essentiality of vanadium was inconclusive (Nielsen 1984, 1985). That is, much of the evidence for essentiality may have been the result of high vanadium supplements (10 to 100 times the amount normally found in natural diets) inducing pharmacologic changes in animals fed imbalanced diets. The most substantive evidence for vanadium essentiality has appeared only since 1987.

Dietary Importance

Signs of apparent vanadium deprivation have been described in goats (Anke et al. 1989) and rats (Uthus and Nielsen 1990; Nielsen, Poellot, and Uthus 1997). For goats, such signs include depressed milk production and skeletal deformations of the forelegs, including thickening of the forefoot tarsal joints. Vanadium-deprived rats exhibit altered thyroid hormone metabolism, especially if stressed with high or low iodine intakes. Supporting the suggestion that vanadium is an essential element for higher animals are the findings of functional roles for vanadium in lower forms of life. Algae, lichens, fungi, and bacteria all have enzymes that require vanadium for activity. These enzymes include haloperoxidases, which catalyze the oxidation of halide ions by hydrogen peroxide, thus facilitating the formation of a carbon-hydrogen bond (Vilter 1995).

Numerous biochemical and physiological functions for vanadium have been suggested on the basis of its in-vitro actions on cells and pharmacologic actions in animals; these actions (Willsky 1990) include insulin-mimetic properties, numerous stimulatory effects on cell proliferation and differentiation, effects of cell phosphorylation-dephosphorylation, effects on glucose and ion transport across the plasma membrane, and effects on oxidation-reduction processes.

Based on circumstantial evidence from animal deprivation studies and the functional roles of vanadium in lower forms of life, it seems quite possible that the mineral may be found essential for some enzyme reaction important to human health, perhaps one that is involved in thyroid metabolism. However, until a biochemical function is definitively identified for vanadium, its nutritional importance will be uncertain. Knowledge of a biochemical function is also needed in order to disentangle the element's pharmacologic actions from its nutritional actions. Yet, because vanadium is so pharmacologically active, a beneficial pharmaceutical role for this element may be found.

Summary

Trace elements were known to be present in biological materials more than 100 years ago, and several were found to be essential for plant and animal life more than 60 years ago. Studies of the pharmacological and beneficial properties of various trace elements, which were being done in the nineteenth century, continue today. However, except for iron, iodine, and cobalt (as cobalamin), the possibility that some trace elements are of practical nutritional importance did not receive much attention until about 30 years ago. At that time, excitement abounded about trace elements, and the new knowledge of them was considered a breakthrough toward better health.

One trace element after another was identified as essential, or at least suggested to be essential, and new functions were being found for those already established as essential. As these new essential elements or new functions were identified, hopes were raised that trace element nutriture would help to unravel the causes of some diseases, especially those that are chronic and associated with aging. Unfortunately, this has not occurred, but research does continue to show that some trace elements are more important than is currently acknowledged. The history of investigations into the trace elements iron, iodine, zinc, and selenium indicates a likelihood that several more elements – especially boron, copper, and chromium – will be found to be of nutritional (and clinical) importance for human health and longevity.

IV.B.9 ~ Zinc

In 1869, J. Raulin showed for the first time that zinc is a growth factor for *Aspergillus niger.* Then, in 1926, it was discovered that zinc is essential for higher plants (Sommer and Lipman 1926). The importance of zinc in the growth and development of rats was demonstrated in 1934 (Todd, Elvehjem, and Hart 1934), and in 1955, H. F. Tucker and W. D. Salmon related a disease in swine called parakeratosis to a deficiency of zinc. Shortly thereafter, zinc was shown to be a growth factor for chickens (O'Dell, Newberne, and Savage 1958).

The manifestations of zinc deficiency in animals include growth failure, loss of hair, thickening and hyperkeratinization of the epidermis, and testicular atrophy. Zinc deficiency in breeding hens results in decreased hatchability and gross anomalies in embryonic skeletal development.

Although the importance of zinc for animals was established 60 years ago, it has only been during the past 30 years that zinc deficiency in humans has been recognized. In 1974, the Food and Nutrition Board of the National Research Council of the National Academy of Sciences made a landmark decision in establishing a recommended dietary allowance (RDA) for zinc.

Discovery of Zinc Deficiency in Humans

Studies in Iran

In 1958, this author joined the staff of Dr. Hobart A. Reimann, Chief of Medicine at the Nemazee Hospital of Pahlevi University in Shiraz, Iran. In the fall of that year, Dr. James A. Halsted of the Saadi Hospital of Pahlevi University invited me to discuss a patient who had severe anemia.

The patient was a 21-year-old male, who appeared to be only a 10-year-old boy. In addition to severe growth retardation and anemia, he had hypogonadism, hepatosplenomegaly, rough and dry skin, mental lethargy, and geophagia. His intake of animal protein had been negligible. He ate only wheat flour and unleavened bread and consumed nearly 0.5 kilograms (kg) of clay daily (the habit of geophagia in the villages around Shiraz is fairly common). Ten more cases that were similar arrived at the hospital for my care within a short period of time.

We documented the existence of iron-deficiency anemia in the patients, but there was no evidence of blood loss. We considered three possible mechanisms of iron deficiency: (1) The availability of iron in the high-cereal, protein-containing diet was most probably very low due to high phytate levels in the bread, which bind iron; (2) that geophagia further decreased iron absorption (as Minnich and colleagues [1968] observed later); and (3) that an excessive loss of iron by sweating in the hot summers of Iran may have contributed significantly to negative iron balance.

After administration of ferrous sulfate (1 gram per day) orally and a nutritious hospital diet containing adequate animal protein, the anemia was corrected, hepatosplenomegaly improved, subjects grew pubic hair, and genitalia size increased (Prasad, Halsted, and Nadimi 1961). Liver function tests were unremarkable except for the serum alkaline phosphatase activity, which increased after treatment. Retrospectively, two explanations seem plausible: (1) Ordinary pharmaceutical preparations of iron might have contained appreciable quantities of zinc as a contaminant, and (2) animal protein in the diet most likely supplied available zinc, thus inducing the activity of alkaline phosphatase, a known zinc metalloenzyme.

It was difficult to account for all of the clinical features solely by tissue iron deficiency because growth retardation and testicular atrophy are not normally found in iron-deficient experimental animals. Moreover, since this syndrome was fairly prevalent in the villages near Shiraz, the rare syndrome of hypopituitarism as an explanation for growth retardation and hypogonadism was considered to be very unlikely.

We explored the possibility that zinc deficiency may have been present concomitantly with iron deficiency in these patients (Prasad et al. 1961). Because heavy metals may form insoluble complexes with phosphate, we speculated that some factors responsible for decreased availability of iron in these patients with geophagia may also have decreased the availability of zinc. B. L. O'Dell and J. E. Savage (1960) observed that the phytate (inositol hexaphosphate) present in cereal grains markedly impaired the absorption of zinc. Changes in the activity of alkaline phosphatase as observed in our patients had also been noticed after the zinc supplementation of deficient animals. Thus, it seemed that the dwarfism, testicular atrophy, retardation of skeletal maturation, and changes in serum alkaline phosphatase activity of our subjects might be explained by zinc deficiency.

I. I. Lemann (1910) had previously reported a similar clinical syndrome in patients who had hookworm infection in the United States, but this was not related to a nutritional deficiency. Similar cases from Turkey were reported by F. Reimann (1955), but without detailed descriptions. He considered a genetic defect to be a possible explanation for certain aspects of the clinical syndrome.

Studies in Egypt

In October 1960, Dr. William J. Darby invited me to meet with him at the U.S. Naval Medical Research Unit in Cairo, Egypt, where I shared with him my speculation that zinc deficiency in the Middle East was prevalent and was responsible for widespread growth retardation and male hypogonadism. The next day, Professor Darby and I went to nearby villages to assess if, indeed, growth-retarded adolescents were clinically recognizable. We were accompanied by an Egyptian male nurse who spoke both English and Arabic.

Because of the striking clinical similarities between Iranian and Egyptian dwarfs, I was able to recognize several subjects who looked like 8- or 10-year-old boys, but whose chronological ages, on questioning, appeared to be 18 to 20 years. This assured me that, indeed, growth retardation and male hypogonadism were also prevalent in Egyptian villages. Following this experience, Professor Darby approved plans to investigate zinc metabolism in growth-retarded subjects.

The clinical features of Egyptian growth-retarded subjects were remarkably similar to those of the Iranians, except that the Iranian dwarfs had more pronounced hepatosplenomegaly, a history of geophagia, and no hookworm infection. The Egyptian subjects, by contrast, had both schistosomiasis and hookworm infestations but no history of geophagia.

A detailed investigation of the Egyptian cases was carried out with associates A. Miale, Z. Farid, H. H. Sandstead, and A. Schulert. The dietary history of the Egyptian subjects was similar to that of the Iranians. The consumption of animal protein was negligible, with the diet consisting mainly of bread and beans *(Vicia fava)*.

Zinc concentrations in plasma, hair, and red cells were decreased, and ^{65}Zn studies showed that the plasma zinc turnover was greater, the 24 h exchangeable pool was smaller, and the excretion of ^{65}Zn in stool and urine was less in the growth-retarded subjects in comparison to controls (Prasad, Miale, and Farid 1963). These studies established for the first time that zinc deficiency occurs in humans, without advanced cirrhosis. Liver function tests and biopsies revealed no evidence of cirrhosis in our subjects (Prasad et al. 1963b). Furthermore, in contrast to cirrhosis patients, who excreted abnormally high quantities of zinc in the urine, our patients excreted less zinc in urine than did control subjects. We also ruled out other chronic diseases that might have affected the serum zinc concentrations.

Serum iron was decreased, unsaturated iron binding capacity was increased, serum copper was slightly increased, and serum magnesium was normal in our subjects. Hair analysis for manganese, cobalt, molybdenum, and other elements revealed no difference when compared to the normal subjects. We found no evidence for deficiency of serum B_{12}, ascorbic acid, vitamin A, carotene, or folic acid.

Iranian physicians had commonly believed that growth retardation and sexual hypofunction were the results of visceral leishmaniasis and geophagia. We, however, found no evidence of leishmaniasis in Iran. The role of geophagia was unclear, although we suspected that excess phosphate in the clay prevented absorption of both iron and zinc. The predominantly wheat diet in the Middle East, now known to contain high quantities of phytate and fiber, most probably reduced the availability of zinc.

In Egypt the cause of dwarfism was commonly considered to be schistosomiasis, and in China investigators had also implicated schistosomiasis as a causative factor for growth retardation. Yet, because the Iranian subjects exhibited dwarfism but did not have schistosomiasis or hookworm infections, the question arose as to whether schistosomiasis was the fundamental cause of dwarfism in Egypt. We initiated an investigation to find the answer (Prasad, Schulert, and Miale 1963; Prasad 1966).

It was known that schistosomiasis or hookworm infection was nonexistent in the oasis villages of Kharga, located 500 kilometers (km) southwest of Cairo, although the people of Kharga are culturally and nutritionally similar to those in the delta region. Hence, we conducted a field study in Kharga on 16 patients with hypogonadism and dwarfism. Their anemia was mild, and none had either schistosomiasis or hookworm disease. Concentrations of iron and zinc in the serum were subnormal.

Because red blood cells are rich in both iron and zinc, blood loss due to hookworm and schistosomiasis in the delta villages contributed significantly to both iron and zinc deficiencies. But in Kharga, parasitic infections were not present, and the artesian spring, the principal source of water for the Kharga villages, revealed iron and zinc concentrations of 3,170 and 18 micrograms per liter (µg/l), respectively.

In Cairo, by contrast, the iron and zinc concentrations of drinking water were 70 and 400 μg/l, respectively. Thus, although the foods consumed by the subjects in both the delta region and the oasis villages were similar, those in the latter probably derived a significant amount of iron but no zinc from their water source. Consequently, a better iron status for individuals in Kharga villages, in comparison to those in delta villages, was due to higher iron intake from water and lack of blood loss due to parasites.

Although dwarfism and hypogonadism had previously been attributed to schistosomiasis in Egypt and China, our demonstration of the existence of such patients in Iran and Kharga, where schistosomiasis was absent, showed that this parasitic infection was not necessarily responsible for these clinical features.

We were, however, unable to account for the hepatosplenomegaly on the basis of liver disease. This left three possibilities: anemia, zinc deficiency, or a combination of the two. In each case, the size of the liver and spleen decreased significantly after zinc supplementation, suggesting that zinc deficiency may have played an as-yet undefined role in hepatosplenomegaly.

In the Middle East, we examined only male subjects, as females refused to participate. But later studies from Iran by J. A. Halsted and co-workers (1972) demonstrated that zinc deficiency was probably prevalent in females manifesting growth retardation.

Our further investigations in Egypt showed that the rate of growth was greater in patients who received supplemental zinc as compared with those given iron, or those with only an adequate animal protein diet (Prasad 1966; Sandstead et al. 1967). Pubic hair appeared in all subjects within 7 to 12 weeks after zinc supplementation was initiated. Genital size became normal, and secondary sexual characteristics developed within 12 to 24 weeks in all zinc supplemented patients. No such changes were observed in a comparable length of time in the iron-supplemented group or in the group on an animal protein diet alone. Thus, our studies demonstrated that both growth retardation and gonadal hypofunction in these subjects were related to zinc deficiency. The anemia was due to iron deficiency and responded to oral iron treatment.

Chronology of Other Observations

By using the dithizone technique, R. E. Lutz (1926) assayed zinc in various tissues and concluded that the body of a 70 kg man contained 2.2 grams (g) of zinc, a figure remarkably close to that which is accepted today. R. A. McCance and E. M. Widdowson (1942) were the first to report on the absorption and excretion of zinc, and showed that the principal route of zinc excretion was in the feces, with only a small amount lost in urine.

I. Vikbladh (1950) measured serum zinc concentration by dithizone technique and reported that the level was 19.7 ± 0.24 micromoles per liter (μmol/l), a value in general agreement with those reported by using modern methods. Vikbladh (1951) also observed that the serum zinc concentration was decreased in many chronic diseases, including liver disease. B. L. Vallee and colleagues (1956) reported that the serum zinc concentration decreased in patients with cirrhosis and suggested that the hypozincemia of these subjects was conditioned by hyperzincuria.

Our studies in the early 1960s demonstrated for the first time the effects of zinc deficiency on human growth and gonadal development (Prasad, Miale, Farid et al. 1963a, 1963b; Prasad, Schulert, Miale et al. 1963; Sandstead et al. 1967), and that this deficiency may have various causes in different populations. It is now evident that nutritional, as well as conditioned, zinc deficiency may complicate many disease states in human subjects.

In 1968, R. A. MacMahon, M. L. Parker, and M. McKinnon (1968) first observed zinc deficiency in a patient who had steatorrhea. Subsequently, zinc deficiency was discovered to be common in patients with malabsorption syndromes (McClain, Adams, and Shedlofsky 1988).

V. Caggiano and co-workers (1969) were the first to report a case of zinc deficiency in the United States. The patient was Puerto Rican with dwarfism, hypogonadism, hypogammaglobulinemia, giardiasis, strongyloidiasis, and schistosomiasis. Zinc supplementation resulted in improved growth and development.

In 1972, a number of Denver children from middle-class families were reported to exhibit evidence of symptomatic nutritional zinc deficiency (Hambidge et al. 1972). They consumed a predominantly cereal protein diet low in available zinc. Growth retardation, poor appetite, and impaired taste acuity were all related to a deficiency of zinc in the children, and they were corrected with supplementation. Symptomatic zinc deficiency in United States infants was also reported later by K. M. Hambidge, C. E. Casey, and N. J. Krebs (1983). In addition, our own recent studies in the United States have shown that zinc deficiency in the well-to-do elderly may be fairly prevalent (Prasad et al. 1993). Clearly, then, a substantial portion of the U.S. population may be at risk of zinc deficiency.

Meanwhile, Halsted and colleagues (1972) published a study involving a group of 15 men who were rejected at the Iranian army induction center because of "malnutrition." Two women were also included in their study. All were 19 or 20 years old, with clinical features similar to those reported earlier by A. S. Prasad and colleagues (Prasad et al. 1961, 1963a, 1963b). They were studied for 6 to 12 months. One group was given a well-balanced diet, containing ample animal protein plus a placebo capsule. A second group was given the same diet, plus a capsule of zinc sulfate containing 27 mg zinc. A third group received the diet for a year, with zinc supplementation during the last six months.

The zinc-supplemented subjects grew considerably faster and showed evidence of earlier onset of sexual function (as defined by nocturnal emission in males and menarche in females) than those receiving the well-balanced diet alone (Halsted et al. 1972).

A clinical picture, similar to those reported by our studies involving zinc-deficient dwarfs, has been observed in many developing countries. Therefore, it must be the case that various levels of zinc deficiency prevail in countries where diets depend too heavily on cereals.

P. M. Barnes and E. J. Moynahan (1973) studied a 2-year-old girl with severe acrodermatitis enteropathica, who was receiving diiodohydroxyquinoline and a lactose-deficient synthetic diet. The response to this therapy was not satisfactory. It was noted that the concentration of zinc in the patient's serum was profoundly decreased, and oral zinc sulfate was administered. The skin lesions and gastrointestinal symptoms cleared completely, and the girl was discharged from the hospital. When zinc was inadvertently omitted from the child's regimen, she suffered a relapse; however, she promptly responded to oral zinc again.

In the original report, the authors attributed the girl's zinc deficiency to the synthetic diet, but it soon became clear that zinc was fundamental in the pathogenesis of acrodermatitis enteropathica – a rare inherited disorder – and the clinical improvement reflected improvement in zinc status. This interesting observation was quickly confirmed in other patients throughout the world. The underlying pathogenesis of zinc deficiency in these patients is most likely dietary malabsorption of zinc, the mechanism of which remains to be determined.

R. G. Kay and C. Tasman-Jones (1975) reported the occurrence of severe zinc deficiency in subjects receiving total parenteral nutrition for prolonged periods without zinc. T. Arakawa, T. Tamura, and Y. Igarashi (1976) and A. Okada and co-workers (1976) announced similar findings in this circumstance. These observations have been documented by several investigators, and in the United States, zinc is routinely included in total parenteral fluids for subjects who are likely to receive such therapy for extended periods.

W. G. Klingberg, Prasad, and D. Oberleas (1976) were the first to report severe parakeratosis, alopecia, and retardation of growth and gonadal development in an adolescent with Wilson's disease who received penicillamine therapy. Zinc supplementation completely reversed these clinical manifestations.

Recent literature suggests that several findings in patients with sickle cell anemia, such as growth retardation, male hypogonadism, abnormal dark adaptation, and abnormal cell-mediated immunity, are related to a deficiency of zinc (Prasad et al. 1975, 1981; Warth et al. 1981; Prasad and Cossack 1984; Prasad et al. 1988). Hyperzincuria due to renal tubular dysfunction has been noted in such subjects, and this may be a contributing factor in the pathogenesis of zinc deficiency. Hypogeusia, decreased serum testosterone level, and hyperprolactinemia due to zinc deficiency have been observed in male patients with chronic renal disease (Mahajan et al. 1979, 1980, 1982, 1985). Zinc supplementation has corrected the abnormalities that have been associated with these disparate circumstances.

During the past three decades, a spectrum of clinical deficiency of zinc in human subjects has been recognized. If the deficiency is severe, it may be life-threatening. The symptoms developed by severely zinc-deficient subjects include bullous-pustular dermatitis, diarrhea, alopecia, mental disturbances, and intercurrent infections due to cell-mediated immune disorders. These manifestations are seen in patients with acrodermatitis enteropathica, following total parenteral nutrition (without zinc), and after penicillamine therapy.

Growth retardation, male hypogonadism, skin changes, poor appetite, mental lethargy, abnormal adaptation to darkness, and delayed wound healing are some of the indicators of moderate zinc deficiency in human subjects. Causes of moderate zinc deficiency that have been well documented include nutritional factors, malabsorption, sickle cell disease, chronic renal disease, and other debilitating conditions.

The beneficial effect of zinc in healing wounds of patients with zinc deficiency was first reported by W. J. Pories and W. H. Strain (1966). The symptom of abnormalities of taste was first related to a deficiency of zinc in humans by R. I. Henkin and D. F. Bradley (1969), and such abnormalities, which are reversible by zinc supplementation, have been observed in patients with chronic renal disease (Mahajan et al. 1980).

Marginal Deficiency of Zinc

Although the importance of zinc to human health has now been elucidated and its deficiency recognized in several clinical conditions, it was only recently that an experimental human model was established to permit a study of the specific effects of a mild zinc deficiency (Prasad, Rabbani, and Abbasi 1978; Abbasi et al. 1980; Rabbani et al. 1987; Prasad et al. 1988).

We did this by developing a semisynthetic soy-protein-based diet that supplies 3 to 5 milligrams of zinc per day (mg zinc/d) (Rabbani et al. 1987). All other nutrients in the diet are consistent with the RDA (1974, 1989). Male volunteers, ages 20 to 45 years, were first given a hospital diet containing animal protein for 4 to 8 weeks, which averaged 12 mg zinc/d. After that, the subjects received the experimental diet containing 3 to 5 mg zinc/d, which continued for 28 weeks. Following this period, the volunteers received a daily 27 mg zinc supplement for 12 weeks while still consuming the experimental diet. Throughout the study, all nutrients, including protein, amino acids, vitamins, and minerals (both macro- and microelements), were kept constant, except zinc, which was varied as outlined above. By this technique, we were able to induce a specific zinc deficiency in men.

Our dietary manipulation created a negative zinc balance of approximately 1 mg per day, and we calculated that in a six-month period a total of about 180 mg of negative zinc balance was achieved. A 70 kg adult male contains approximately 2,300 mg of zinc, and, therefore, a loss of 180 mg of zinc would seem to be only 8 percent of the total body zinc. But this is not necessarily the case. Approximately 28 percent of the zinc in the human body resides in bone, 62 percent in muscle, 1.8 percent in the liver, and 0.1 percent in the plasma pool. Only 10 percent of the total body zinc pool exchanges with an isotopic dose within a week's time (Prasad et al. 1963a; Foster et al. 1979).

In an adult animal model, zinc concentrations in muscle and bone do not change as a result of mild or marginal zinc deficiency. In cases of mild or marginal zinc deficiency, one cannot expect a uniform distribution of the deficit over the entire body pool, and most likely the compartments with high turnover rates (liver and peripheral blood cells, such as lymphocytes, granulocytes, and platelets) suffer a disproportionate deficit. Thus, if one were to consider that only 200 to 400 mg zinc, which is represented by liver zinc and the mobile exchangeable pool, is the critical pool, a negative balance of 180 mg from this pool may be a considerable fraction.

Our studies in this model have indicated that a mild or marginal deficiency of zinc in humans is characterized by neurosensory changes, oligospermia, decreased serum testosterone concentration, hyperammonemia, decreased lean body mass, decreased serum thymulin activity, decreased IL-2 production by peripheral blood mononuclear cells, decreased NK cell activity, and alterations in T-cell subpopulations. All of these manifestations can be corrected by zinc supplementation.

When zinc deficiency was very mild (5.0 mg zinc intake during the 20- to 24-week zinc-restricted period), the plasma zinc concentration remained more or less within the normal range, whereas the zinc concentration of lymphocytes and granulocytes declined (Meftah et al. 1991). Within 8 weeks of zinc restriction, the activity of lymphocyte ecto 5′nucleotidase (5′NT), serum thymulin activity, and IL-2 production by peripheral blood mononuclear cells decreased, and the intestinal absorption of ^{70}Zn increased significantly, suggesting that lymphocytes, thymus, and intestinal cells are very sensitive to zinc restriction (Meftah et al. 1991; Lee et al. 1993; Prasad et al. unpublished observation).

Biochemical Advances in Zinc Metabolism

D. Keilin and J. Mann (1940) were the first to demonstrate that carbonic anhydrase was a zinc metalloenzyme. Over the next 20 years, only five additional zinc metalloenzymes were identified, but in the last 30 years the total number has greatly increased. If related enzymes for different species are included, more than 200 zinc metalloenzymes are now known to exist (Chesters 1982; Galdes and Vallee 1983).

I. Lieberman and co-workers (1963) have shown that several enzymes necessary for nucleic acid synthesis in microorganisms require zinc. It is now well known that zinc is needed for DNA polymerase 1 (in *Escherichia coli*), bacterial RNApolymerase (in *E. coli*), and reverse transcriptase (in avian myeloblastosis virus) (Wu and Wu 1983).

Until 1965, there was no evidence that zinc-dependent enzymes were adversely affected as a result of zinc deficiency. Our investigations then demonstrated that the activity of various zinc-dependent enzymes was reduced in the testes, bones, esophagus, and kidneys of zinc-deficient rats in contrast to their pair-fed controls, and that this reduction of activity correlated with the decreased zinc content of the tissues (Prasad, Oberleas, Wolf et al. 1967).

Several studies have shown that zinc deficiency in animals impairs the incorporation of labeled thymidine into DNA. This effect has been detected within a few days of the institution of a zinc deficient diet in experimental animals, suggesting that dietary zinc deficiency may result in an immediate impairment of DNA synthesis. Prasad and Oberleas (1974) provided evidence that this early reduction in DNA synthesis was due to an adverse effect of zinc restriction on the activity of deoxythymidine kinase. These results were confirmed by I. E. Dreosti and L. S. Hurley (1975), who showed that the activity of deoxythymidine kinase in 12-day-old fetuses taken from females exposed to a dietary zinc deficiency during pregnancy was significantly lower than in ad-libitum-fed and restricted-fed controls.

Zinc and Immunity

P. J. Fraker, S. Hass, and R. W. Luecke (1977) revealed that severely and marginally zinc-deficient young adult-A/Jax mice have abnormal T-helper cell function. In addition, it is now known that other T-lymphocyte-mediated functions are found to be adversely affected by zinc deficiency. By using the young adult mouse as a model, it was demonstrated that a moderate period of suboptimal zinc administration causes thymic atrophy, lymphopenia, and alterations in the proportions of the various subsets of lymphocytes and mononuclear phagocytes (Fraker et al. 1986). As a result, antibody-mediated responses to both T-cell-dependent and T-cell-independent antigens are significantly reduced. Cytolytic T-cell responses, NK-cell activity, and delayed-type-hypersensitivity (DTH) reactions are also depressed.

In humans, patients with acrodermatitis enteropathica (a genetic disorder of zinc absorption) exhibit atrophic thymus, lymphopenia, anergic DTH responses, and reduced NK-cell activity (Fraker et al. 1986). Impaired DTH responses, correctable with zinc supplementation, were reported in zinc-deficient sickle cell anemia patients (Ballester and Prasad 1983), as were decreased NK-cell activity, decreased IL-2 activity, decreased serum thymulin activity, and alterations in lymphocyte subpopulations (Prasad et al. 1988).

Metallothionein

Metallothionein (MT) was discovered in 1957. M. Margoshes and Vallee (1957) identified a cadmium-binding protein in equine kidney cortex responsible for the natural accumulation of cadmium in the tissues. Metal and sulfur content are extremely high in MTs. In human cells, expression of the ISO-MT genes appears to be regulated differentially by cadmium, zinc, and glucocorticoids, and ISO-MT genes are indications for tissue-specific expression (Kagi and Schaffer 1988). A number of studies have led to the identification of various DNA segments serving as promoter sites in the 5′region of various MT genes in induction by metal ions and hormones. In the mouse MT-1 gene, the functional metal responsive promoter is composed of a set of four closely related metal-regulatory elements, each made up of eight nucleotides and localized near the TATA box.

Zinc may be the regulator of the mRNA strands responsible for de novo synthesis of MT in intestinal cells (Cousins 1979). It has been suggested that MT programs the fluctuating levels of zinc in and out of intestinal cells and plays an important role in regulating the absorption and/or excretion of not only zinc but also cadmium and copper.

Zinc and Gene Expression

The importance of zinc in DNA-binding proteins as regulators of gene expression has been recently recognized (Brown, Sander, and Argos 1985; Miller, Mclachlan, and Klug 1985; Klug and Rhodes 1987). The first zinc-finger protein to be recognized was transcription factor-IIIA of xenopus Laevis, which contained tandem repeats of segments with 30 amino acid residues, including pairs of histidines and cysteines (Miller et al. 1985). The presence of zinc in these proteins is essential for site-specific binding to DNA and gene expression. The zinc ion apparently serves as a strut that stabilizes folding of the domain into a finger-loop, which is then capable of site-specific binding to double-stranded DNA. The zinc-finger loop proteins provide one of the fundamental mechanisms for regulating gene expression of many proteins. In humans, the steroid hormones (and related compounds, such as thyroid hormones, cholecalciferol, and retinoic acid) enter cells by facilitated diffusion and combine with respective receptors (which contain the DNA-binding domain of the zinc-finger loops) either before or after entering the nucleus. Complexing of a hormone by its specific receptor evidently initiates a conformation change that exposes the zinc-finger loops, so that they bind to high-affinity sites on DNA and regulate gene expression (Hollenberg et al. 1985; Hughes et al. 1988; Sunderman and Barber 1988).

Interaction of Zinc with Other Elements

Zinc blocks the absorption of dietary copper, and also copper in the endogenous secretions (Brewer et al. 1988). Earlier, Prasad, Brewer, Schoomaker et al. (1978) observed that when subjects with sickle cell anemia were treated with 150 mg zinc/d in divided doses in order to reduce the number of irreversible sickle cells in the peripheral blood, they showed a decrease in the concentration of serum copper and ceruloplasmin. This observation led us to consider treatment of Wilson's disease patients with zinc. Our studies showed that zinc therapy in Wilson's disease patients leads to a negative copper balance, most likely by induction of MT synthesis in the intestines, whereby copper is sequestered and ultimately excreted in the feces (Brewer et al. 1983, 1987). According to our experience, zinc is an effective copper removal agent, is well tolerated, and prevents accumulation of copper in the liver (Brewer et al. 1983, 1987, 1988).

IV.C

Proteins, Fats, and Essential Fatty Acids

IV.C.1 ~ Essential Fatty Acids

The history of the scientific documentation of the need for fat in the diet began with the early nineteenth-century work of Michel Eugene Chevreul (Mayer and Hanson 1960). He showed that lard contained a solid fat, which he termed stearine, and a liquid fat he called elaine (later shown to be the isomer of oleine), and in 1823, this work was published in a treatise, *Chemical Investigations of Fats of Animal Origin.* Chevreul also crystallized potassium stearate, naming it "mother-of-pearl" and calling its acidified product "margarine" (from the Greek word for mother-of-pearl). In addition, Chevreul isolated various acids from fats and distinguished them on the basis of their melting points.

Meanwhile in 1822, Edmund Davy had reported that iodine would react with fats, and by the end of the century, work by L. H. Mills and Baron Hubl led to the procedure devised by J. J. A. Wijs in 1898 for determining a fat's "iodine value" or "iodine number" – a measure of the extent to which a fat is unsaturated, based on its uptake of iodine. Highly saturated coconut oil, for example, has an iodine number of 8 to 10, whereas that of highly unsaturated linseed oil ranges from 170 to 202.

Phospholipids were described in 1846 by N. T. Gobley, who found that egg yolk had a substance that contained nitrogen and phosphorus in addition to glycerol and fatty acids. He named it lecithin. The nitrogenous base was shown to be choline by A. Strecker in 1868, and J. W. L. Thudichem described kephalin in 1884 (Mayer and Hanson 1960).

These early advances in chemistry and methodology were necessary before the major leap to studying the fats in nutrition could be taken. Indeed, advances in chemistry and technology have preceded key discoveries in the study of essential fatty acids and their functions throughout its history.

The Concept of Essential Fatty Acids

During the late 1920s, several groups of investigators explored questions of the nutritional value of fat that went beyond the knowledge that dietary fats provided energy and contained vitamins A and D. Among them were Herbert M. Evans and George O. Burr, who experimented with diets that were sufficiently purified to exclude fat. In three published papers (1927a; 1927b; 1928), they described a previously unknown deficiency disease that resulted from an absence of dietary fats and suggested the existence of a new vitamin, "vitamine F." Shortly after this, at Yale University, Ava Josephine McAmis, William E. Anderson, and Lafayette B. Mendel determined that a nonsaponifiable fraction of cod liver oil delivered vitamin A – but no fat – to experimental rats, and that slightly better growth was achieved when about 20 milligrams (mg) of peanut oil was fed to the rats along with the cod liver oil fraction. Animals receiving the most peanut oil grew best. The researchers wrote, with exemplary caution, that "whether this apparent beneficial effect of a small amount of fat is due to its content of vitamin A or other vitamins, or to its acting as a vehicle for the fat-soluble vitamins, or whether fat per se is essential, is not conclusively demonstrated" (McAmis, Anderson, and Mendel 1929: 262).

At the same time, George and Mildred Burr, at the University of Minnesota, published their results from feeding a very low fat diet to rats (1929). They concluded that there was, indeed, a requirement for fat in the diet and also believed that they had discovered a new deficiency disease curable by the feeding of small amounts of unsaturated fats or pure "linolic *[sic]*" acid. The following year, they coined the term "essential fatty acids" (1930).

The symptoms observed in rats that were considered indicative of dietary insufficiency included late failure of growth, kidney lesions, abnormal water consumption (because of excessive extradermal water loss), scaly skin, and necrotic tails. However, the concept of the essentiality of fatty acids was not immediately accepted. Critics pointed out that the skin lesions of rats, for example, were also seen with some B-vitamin deficiencies and thus not specific to fat deficiency. In addition, there was confusion surrounding the nature of the "fat-free" diets fed to rats because those consuming cornstarch managed some growth, whereas those on sucrose did not.

These questions were explained by the studies of Evans and Samuel Lepkovsky (at the University of California, Berkeley), who, first of all, showed that there was enough fat in cornstarch to support some growth in rats (1932a). They determined further that, if saturated fat (in this case, coconut oil) rather than carbohydrate was fed to the rats, deficiency symptoms became evident even more rapidly (1932b). In still another experiment (1932c), they isolated the fatty acid methyl esters from carcasses of rats that had been on either the fat-free or the supplemented diets, fed the esters to other rats, and discovered that the iodine numbers of fatty acids from fat-free–fed animals were higher than those from rats fed supplemented diets, thus showing that the degree of unsaturation is not a criterion of fatty acid essentiality.

The fat from the rats fed fat-free diets contained more unsaturated fatty acids than that from other rats at weaning, but the unsaturated fatty acids present did not relieve the deficiency symptoms, which was the first indication of the biosynthesis of eicosatrienoic acid. This phenomenon was later observed by Raymond Reiser and colleagues (1951) and finally explained by A. J. Fulco and J. F. Mead (1959). In the meantime, Evans, Lepkovsky, and E. A. Murphy had added both failure of reproduction and lactation in female rats (1934a, 1934b) and sterility in male rats (1934c) to the list of deficiency symptoms.

Requirement for Essential Fatty Acids

The reports of skin lesions in rats fed fat-free diets caused pediatrician Arild E. Hansen (1933) to suspect that infants suffering from eczema had an unsatisfied fat requirement. Hansen treated the condition with various oils, and shortly thereafter, Theodore Cornbleet reported the highly successful treatment of eczema by dietary supplementation with corn oil (1935). He also noted that this supplementation brought relief to his patients with asthma.

Later, in collaboration with Hilda F. Wiese and others at the University of Texas School of Medicine in Galveston, Hansen studied essential fatty acid requirements using dogs as the experimental model (Hansen and Wiese 1951). As their methods for quantifying fatty acids progressed from fractionation of methyl esters to spectrophotometric analysis of the alkali-conjugated fatty acids (Wiese and Hansen 1953), Hansen and Wiese were able to determine serum levels of unsaturated fatty acids in both poorly nourished (Hansen and Wiese 1954) and healthy (Wiese, Gibbs, and Hansen 1954) children. This work resulted in hard evidence of a deficiency of essential fatty acids that could occur in infants; it also resulted in recommendations for dietary intake of linoleic acid based upon the serum levels of di-, tri-, and tetraenoic acids of infants fed formulas containing different sources of fat (Wiese, Hansen, and Adams 1958). The researchers concluded that the dietary linoleate needed to provide optimum serum concentrations of polyunsaturated fatty acids was about 4 percent of the total calories. This advance in understanding the biochemistry of fatty acids in serum led to the use of biochemical criteria for defining nutrient deficiency.

Interrelationships among Fatty Acids

The alkaline isomerization method for analyzing specific fatty acids had led to the deduction that arachidonic (tetraenoic) acid was formed from dietary linoleic acid and that pentaenoic and hexaenoic acids were formed from dietary linolenic acid (Rieckehoff, Holman, and Burr 1949; Widmer and Holman 1950). Moreover, studies by Ralph Holman and his group at the Hormel Institute, University of Minnesota, also determined that linoleic and linolenic acids were not interconvertible. These findings were confirmed by the use of radioisotopically labeled fatty acids (Steinberg et al. 1956), and radioisotope tracer methods were used to define the source of Evans and Lepkovsky's (1932c) noncurative polyunsaturated fatty acid. A trienoic acid was identified by Fulco and Mead (1959) as 5,8,11-eicosatrienoic acid, which they found was derived from oleic acid.

During the 1960s, gas-liquid chromatography became the method of choice for the identification and quantification of fatty acids. A series of dose-response studies using single pure unsaturated fatty acids was conducted by Holman and his associates (Holman 1964), who developed interaction relationships which showed that the ratio of triene (eicosatrienoic acid) to tetraene (arachidonic acid) was proportional to the linoleate concentration in the diet of rats. They also determined that the diene and triene fatty acids were competitive with each other in conversions to longer-chain metabolites. For instance, 0.1 percent of energy as linolenate inhibited metabolism of linoleate by 50 percent, whereas it required 3.2 percent of linoleate to inhibit linolenate conversion by 50 percent. Interpretation of their many experiments led to the presentation of the sequence of chain elongation and desaturation of linoleic acid as 18:2 to 18:3 or 20:3; 18:3 to 20:3 to 20:4 or 22:3; 20:4 to 22:4 to 24:4 or 22:5. In the absence of linoleate and linolenate, the conversion of endogenous oleate (18:1) to 20:3 and 22:3 becomes dominant.

Nomenclature for Essential Fatty Acids

In studies prior to those of Holman and others in the 1960s, the original common names of the fatty acids were used. However, as the complexities of their double-bond configurations began to define their places in metabolism, it became necessary to establish simple and clear nomenclature. Diene, triene, monoene, and saturated, along with chain length, were no longer sufficient to describe physiologically important activities of the compounds. The locations of the double bonds were clarified, but the delta notation for the position of the double bonds was confusing when applied to chain elongation and desaturation. Holman (1964) used nomenclature based on the position of the double bond in relation to the nth (or omega) carbon. The linoleic acid family began with a double bond at the n minus 6 position; therefore, it was called the omega 6 family. The naturally occurring polyunsaturated fatty acids have methyl interrupted, rather than conjugated spacing; so linoleate is 18:2 omega 6,9. In the same pattern, linolenic acid is 18:3 omega 3,6,9. The importance of the specificity of desaturases was yet to be explained.

Importance of Human Requirements

Even though it had become accepted that linoleate was an essential nutrient, recommendations for dietary consumption were considered only for infants. Hansen, the pediatrician, agreed with Holman, the biochemist, that 0.5 to 1 percent of energy was enough, based upon keeping the triene–tetraene ratio below 0.4 (Holman 1973). By this time, the feeding of a fat-deficient diet to human subjects was not acceptable, so human studies were conducted using supplements; and, of course, diagnosis of malnourished infants also yielded findings.

The definitive proof of essential fatty acid requirement, however, came with the advent of intravenous feeding and its ability to provide total nutritional support (made possible by the method of implantation of a catheter in the superior vena cava, allowing infusion of hyperosmolar fluid) for long periods of time (Dudrick et al. 1968). Early formulas used glucose-protein hydrolysate fluid with electrolytes, minerals, and vitamins added, and reports of essential fatty acid deficiency symptoms in infants began to appear (Hallberg, Schuberth, and Wretlind 1966). Fatty acid analyses were made when a case came to the attention of the Hormel Institute group, which reported that after 100 days of total parenteral nutrition, the infant had a triene–tetraene ratio of 18 and extreme scaliness of skin (Paulsrud et al. 1972).

The first efforts to add lipids to intravenous formulas were unsuccessful. An emulsion containing cottonseed oil proved unacceptable because of toxic reactions, and that experience delayed general use of lipid emulsions (Alexander and Ziene 1961). Indeed, as late as 1973, the U.S. Food and Drug Administration had not approved the addition of fat preparations to parenteral formulas, and reports continued of essential fatty acid deficiency in infants (White et al. 1973). A 10 percent soybean oil emulsion, which employed a nontoxic emulsifying agent, egg phospholipid, and a smaller fat particle (0.5 microns in diameter), finally proved to be acceptable (Bivins et al. 1980).

Infants were not the only ones at risk for essential fatty acid deficiency from total parenteral nutrition. Adults with lesions of the gastrointestinal tract were reported to have biochemically defined linoleate deficiency (Wapnick, Norden, and Venturas 1974). Fourteen patients had triene–tetraene ratios with an average of greater than 2. Adults who had sufficient stores of adipose tissue fat were not believed to be at risk of essential fatty acid deficiency until the use of total parenteral nutrition (TPN) showed that this was not necessarily the case. When glucose and amino acids were infused continuously, lipolysis of adipose tissue fat was suppressed, and biochemical evidence of deficiency was present even if some fat was provided by oral nutrition in combination with parenteral feeding (Stein et al. 1980). By the mid–1970s, however, intravenous fat emulsions had become generally available, and it was accepted that a sufficient supply of linoleic acid was one of the important factors to be considered in every case of parenteral nutrition (Wolfram et al. 1978).

The Essentiality of Linolenic Acid

The earliest studies of unsaturated fatty acids (in common and chemical names; see Table IV.C.1.1) showed that both linoleic and linolenic acids had beneficial effects upon the clinical signs of deficiency in rats. Linoleic and arachidonic acids cured the deficiency's symptoms of growth retardation, skin lesions, and excessive water consumption, whereas linolenic acid only cured growth retardation (Burr 1942). Attempts were subsequently made by a group of investigators at Berkeley to produce linolenic acid deficiency by maintaining rats for 3 generations on a diet lacking n-3 fatty acids. Levels of n-3 in tissues became very low, but small amounts remained and the rats showed no abnormality in growth, reproduction, or appearance (Tinoco et al. 1971). The Berkeley investigators then used radioactive carbon-labeled linolenic acid to trace the impact on dietary fat sources when linolenic acid was converted to docosahexaenoic acid (Poovaiah, Tinoco, and Lyman 1976). Measured in liver phospholipids, the radioactivity was recovered as 20:5n-3 and 22:6n-3. The dietary fat supplements containing n-6 fatty acids (linoleic and arachidonic acids) reduced the conversion of 20:4n-3 to 20:5n-3 (desaturation), whereas the n-3 supplements (18:3n-3 and 22:6n-3) reduced the conversion of 20:5n-3 to 22:5n-3 (elongation) (Figure IV.C.1.1). The researchers concluded that 22:6n-3 may control its own formation by regulating elongation.

Table IV.C.1.1. *Unsaturated fatty acids*

Chemical description	Chemical name	Common name
18:1n-9	9-octadecenoic	Oleic, 18:1ω9
18:2n-6	9,12-octadecadienoic	Linoleic, 18:2ω6
18:3n-6	6,9,12-octadecatrienoic	Gamma-linolenic, 18:3ω6
18:3n-3	9,12,15-octadecatrienoic	Alpha-linolenic, 18:3ω3
20:3n-6	8,11,14-eicosatrienoic	Dihomogamma-linolenic, 20:3ω6
20:4n-6	5,8,11,14-eicosatetraenoic	Arachidonic, 20:4ω6
20:5n-3	5,8,11,14,17-eicosapentaenoic	Timnodonic EPA, 20:5ω3
22:4n-6	7,10,13,16-docosatetraenoic	Adrenic, 22:4ω6
22:5n-6	4,7,10,13,16-docosapentaenoic	22:5ω6
22:5n-3	7,10,13,16,19-docosahexaenoic	Cervonic DHA, 22:5ω3

Evidence, though inconclusive, that linolenic acid is essential was gathered by examining tissues of rats depleted of the n-3 family. Brain and retinal tissue retained docosahexaenoic acid tenaciously through two generations of rat growth (Tinoco, Miljanich, and Medwadowski 1977; Tinoco et al. 1978), but prolonged deprivation of n-3 fatty acids resulted in reduced visual acuity in infant monkeys and defective electroretinographic responses in monkeys and rats (Neuringer, Anderson, and Connor 1988). As was the case with linoleic acid, patients requiring intravenous feeding have been important in proving that linolenic acid is essential in humans. Patients on TPN, observed by K. S. Bjerve (1989) from 1987 to 1989, experienced scaly and hemorrhagic dermatitis, hemorrhagic folliculitis of the scalp, growth retardation, and impaired wound healing. But the addition of different oils showed that 1.0 to 1.2 percent of energy as linolenate was necessary to obtain a normal concentration of n-3 fatty acids and relieve the symptoms.

The Discovery of Prostaglandins

Meanwhile, in Sweden, Sune Bergstrom and his colleagues (1962) had determined the structure of a new class of compounds that had been isolated from the vesicular glands of sheep and were named prostaglandins. The subsequent discovery that essential fatty acids were the natural precursors of the prostaglandins was made simultaneously by Bergstrom's team, by a group in Holland, and by another at the Upjohn Company in the United States (Bergstrom 1972). That essential fatty acid deficiency could affect prostaglandin functions was shown by Bergstrom and L.A. Carlson (1965).

The first international conference on prostaglandins was held in 1972, and Bergstrom, who opened the meeting, commented on the difficulty of evaluating analytical methods for prostaglandins. At that time, bioassay and gas chromatography–mass spectrometry (GC-MS) were being used. Radioimmunoassay was quite new and considered unreliable, as were bioassays. Bergstrom (1973) called for intensive discussion of the analytical questions. Daniel H. Hwang, at the time a doctoral student in nutrition, proposed that in order to study dietary effects on prostaglandin status, a reliable radioimmunoassay should be developed. GC-MS was not sensitive enough and was too time-consuming and expensive to be used for analysis of large numbers of biological samples.

Very little was known then about the metabolism of prostaglandins. The short half-life, explosive synthe-

OLEIC ACID

(dietary essential fatty acid)

Figure IV.C.1.1. Desaturation (Δ), elongation (E), and chain shortening (ß-ox, beta oxidation) of families of unsaturated fatty acids.

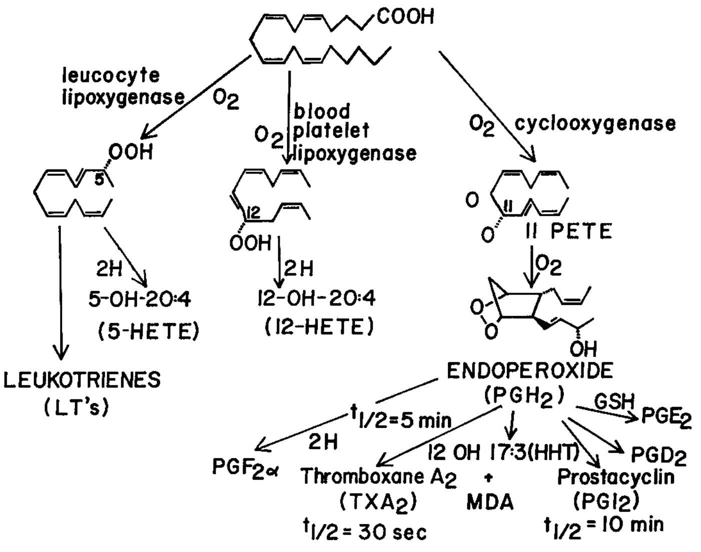

Figure IV.C.1.2. Conversion of arachidonic acid (eicosatetraenoic acid) into eicosanoids. Lipoxygenases convert 20:4n-6 to hydroxyperoxyeicosatrienoic acid (HETE) that is converted to leukotrienes. Cyclooxygenases convert 20:4n-6 to peroxyeicosatrienoic acid (PETE) that converts to endoperoxide (PGH_2) that is converted to prostaglandins (PG), thromboxane (TX), or prostacyclin (PGI_2). The half-life ($t_{1/2}$) of thromboxane in vivo is 30 seconds and that of prostacyclin is about 10 minutes.

sis in response to trauma, and tissue specificity were yet to be discovered. Serendipitously, Hwang and colleagues (1975) chose to analyze blood serum from rats that had been anesthetized, and these experiments were the first to apply the discovery of prostaglandins to the understanding of essential fatty acid functions and requirements. Rats were fed diets containing corn oil or beef tallow as the source of fat, which showed that there was a positive effect of corn oil (containing linoleic acid) on the synthesis of PGE_1 and $PGF_{2\alpha}$.

Subsequently, the laboratory of Melvin M. Mathias and Jacqueline Dupont (1985) demonstrated a biphasic response of prostaglandin synthesis to the dietary content of linoleic acid. The response to 0 to 2 percent of energy from linoleate was an increase in prostaglandin synthesis; with 2 to 5 percent of energy there was a decrease, and above 5 percent of energy there was a gradual increase up to the maximum content of linoleic acid fed (27 percent of energy). The 0 to 2 percent energy response to linoleate was associated with a disappearance of eicosatrienoic acid. Responses to a higher consumption of linoleate were not correlated with arachidonic acid concentration in serum (Fig. IV.C.1.2).

The importance of the relation of dietary linoleate to eicosanoid synthesis meant the addition of a functional measurement to the earlier indications of essential fatty acid deficiency, both clinical and biochemical. This functional indicator of essential fatty acid requirement suggested that 5 to 10 percent of linoleate is desirable (Dupont and Dowd 1990).

Modern History

Excessive extradermal water loss, one of the first symptoms described of essential fatty acid deficiency, has been explained. A major specific function of linoleate is in skin ceramides, where the linoleate is incorporated into acylglucosylceramides and acylceramides (Hansen and Jensen 1985). Linoleate is the only fatty acid substantially incorporated into these sphingolipids. On another front, the details of control of elongation and desaturation and interrelationships among the families of fatty acids are still being investigated (Cook et al. 1991; Cunnane et al. 1995; Sprecher et al. 1995).

Since the 1970s, an enormous literature about prostaglandin metabolism has accumulated. The term "eicosanoids" was introduced in 1980 to describe the class of substances having 20 carbon atoms derived from n-6 and n-3 fatty acids. Because eicosanoids are regulators of a large array of physiological functions, there are many possible manifestations of deficiency of their precursors. The attention given to the very long-chain fatty acids from marine animals (fish oils) has created another large body of literature about the interplay between metabolism of omega-3 (n-3) and omega-6 (n-6) families of fatty acids. The competition between the two families for enzymes of chain elongation, desaturation, and conversion to active metabolites first demonstrated by Holman (1964) has introduced additional complexity into the attempt to define the dietary requirements for the two families. We know that a source of 18 carbon n-3 and n-6 fatty acids is a dietary necessity, but whether there may be health benefits from consumption of the longer chain products - 20:4n-6, 22:5n-3, and 22:6n-3 - is a current topic of intensive research. Infant requirements for brain development are important considerations for assuring appropriate recommendations for infant formulas and supplements (Carlson et al. 1993).

A broad range of ongoing research is aimed at defining the functions of n-3 fatty acids, and a deficiency has been associated with the function of rhodopsin (Bush et al. 1994). Many aspects of brain and behavioral development are linked to the availability of linolenic acid and its products (Neuringer, Reisbick, and Janowsky 1994). The effects of the ratio of dietary linoleic to linolenic acids is the subject of current research (Jensen et al. 1996), and immune functions and cell signaling are also current topics of study of fatty acid functions and metabolism (Hayek et al. 1997; Hwang in press).

Summary

The evolution of an understanding of essential fatty acids has progressed through several scientific developmental phases. The earliest was the ability to prepare diets of sufficient purity to exclude lipids, which led to the conclusion that some fat was essential. The substantive proof of a human requirement – that is, that the fatty acids were essential to the diet – had to await the advent of total parenteral feeding. In about the same era, eicosanoids were discovered, which opened a new world for understanding the functions of essential fatty acids. With the tools of science today, the profound participation of fatty acids in all aspects of cellular life and function should provide great excitement as well as great challenges to all scientists interested in the expansion of the science of nutrition.

IV.C.2 Proteins

The word "protein" was coined by Jöns Jakob Berzelius in 1838. For the previous 150 years, however, there had been the concept of an "animal substance," slight variants of which were thought to make up muscles, skin, and blood. In each form the substance was initially believed to be gluey. But it turned into hard, hornlike material when heated and became foul-smelling when kept under moist, warm conditions, giving off an alkaline vapor. This contrasted with the properties of starch and sugar and most whole plants that went to acid during damp, warm storage.

For people interested in nutrition, the obvious question was: "How does the animal kingdom, which as a whole lives on the plant kingdom, convert what it eats into the apparently very different animal substance?" Humans were, of course, included in the animal kingdom and assumed to have essentially the same nutritional system as animals. Some eighteenth-century discoveries threw light on the problem.

In 1728, the Italian scholar Jacopo Beccari announced that he had discovered the presence of a material with all the characteristics of "animal substance" in white wheat flour. When he wetted the flour to make a ball of dough, then washed and kneaded it in water, the fine, white starchy particles washed out. What remained was a sticky pellet of gluten, which, if its origin were unknown, would be judged animal in nature. Beccari concluded that the presence of this portion of preformed "animal substance" made wheat particularly nutritive. Wheat flour, as a whole, did not show animal properties because the greater quantity of starch overwhelmed the reactions of the gluten.

Nitrogen in Nutrition

Later in the eighteenth century, with the development of the new chemistry, the main elements were identified, and ammonia, the "volatile alkali," was shown to be a compound of nitrogen and hydrogen. Gluten was also found to contain nitrogen, in common with animal tissues, whereas starches, fat, and sugars did not.

At first it was thought that the process of animal digestion and nutrition must consist of the combining of nutrients in plant foods with atmospheric nitrogen in order to "animalize" them. In particular, it seemed that this theory might explain the slow digestion process and large storage stomachs in ruminant animals. However, further work in France made this appear less likely.

First, François Magendie reported in 1816 that dogs failed to survive for more than a few weeks on foods like fats and sugars that contained no nitrogen. Then, in the 1830s, Jean Boussingault showed that the nitrogen present in the hay and potatoes eaten by a cow was enough to balance the quantities present in the milk it secreted together with its regular daily nitrogen losses. There was, therefore, no need to suppose that atmospheric nitrogen was involved in animal nutrition. But because of the importance of nitrogen in nutrition, Boussingault concluded that plant foods should be valued in terms of their relative nitrogen contents. Thus, he believed that dry beans, with roughly twice the nitrogen content of grains, had twice their nutritional value.

By this time, further work on the composition of plants had shown that although they all contained nitrogenous compounds, most of them, unlike wheat gluten, were soluble in water, yet could be precipitated by heat or acid. In 1838, Gerritt Mulder, a Dutch physician who had taught himself chemical analysis, published a claim that all the important "animal substances" he had analyzed had the same basic formula, corresponding to 40 atoms of carbon, 62 of hydrogen, 10 of nitrogen and 12 of oxygen, which can be expressed more simply as $C_{40}H_{62}N_{10}O_{12}$. They differed in their properties only because they had different numbers of atoms of sulfur and/or phosphorus adhering to them. He sent his paper to the Swedish chemical authority, Jacob Berzelius, who replied that this was a most important discovery of the "fundamental or primary substance of animal nutrition" and that this substance deserved to be called "protein" after the Greek god Proteus.

The leading German organic chemist, Justus Liebig, confirmed Mulder's finding and went on to argue that, from a chemical point of view, it was the plant kingdom alone that had the power of making protein. Animal digestion only loosened the association between their molecules to make them soluble and absorbable into the bloodstream and immediately ready for deposit into the animal system. The leading French scientists accepted this view but added that vegetable oils and carbohydrates were also required. Their combustion was needed within the animal body to maintain animal heat.

Protein as a Muscle Fuel

Liebig, although he had himself done no physiological work, developed a whole series of dogmatic statements as to the functions of nutrients in the body. He believed that the energy needed for the contraction of muscles came solely from the breakdown of some of their own protein, which was then immediately decomposed further, with the nitrogenous portion appearing as urea in the urine. A subject's requirement for protein was, therefore, proportional to his or her performance of physical work. The role of fats and sugars was merely to protect living tissues (which reacted with oxygen that penetrated them) from the danger of oxygen damage. Consequently, protein was the only true nutrient.

Liebig's views were accorded great weight, although there were many grounds on which they could be criticized. For example, in 1862, Edward Smith, a physician and physiologist who had been studying the health and diet of the inmates of London prisons, reported a study of factors influencing the daily output of urea. Prisoners who ate the same rations each day and engaged in hard labor three days per week were found to excrete almost the same quantity of urea on the day (and following night) of the labor as on the days when not laboring. However, the labor caused greatly elevated carbon dioxide output in the breath. The main factor influencing urea production appeared to be the amount of protein eaten in the previous 24 hours.

In 1865, Adolf Fick and Johannes Wislicenus, on the faculty of a Swiss university, followed up these findings. They put themselves on a protein-free diet for 24 hours and ascended almost 2,000 meters on a path to the summit of a convenient mountain. They calculated the amount of work done during the ascent and measured the amount of nitrogen in the urine they excreted. From this they calculated that they had each metabolized approximately 37 grams (g) of protein. Their friend in England, Edward Frankland, now calculated that the metabolism of protein yielded 4.37 kilocalories per gram.

By this time the principle of the "conservation of energy" had been accepted, and James Joules had estimated that 1 kilocalorie was equivalent to 423 kilogram-meters (kg-m) of mechanical work against the force of gravity. The energy released from the protein was, therefore, equivalent to some 68,000 kg-m. However, the net work required to lift each scientist up the mountain was approximately 140,000 kg-m, about twice as much. And further work has shown that muscles operate at something like 25 percent efficiency, so that four times the minimal theoretical amount of fuel is required. The conclusion was, therefore, that the energy required for muscular effort does not come primarily from protein but from dietary fats and carbohydrates.

Although Liebig's grand scheme had been discredited, German workers, in particular, continued to maintain that a high-protein intake was desirable to maintain both physical and nervous energy. They argued this on the grounds that people from countries where the diet was largely vegetarian and low in protein lacked "get-up-and-go," and that wherever people were unrestrained by poverty and could eat what they wished, they chose a high-meat, high-protein diet. The first U.S. government standards, issued at the end of the 1800s by Wilbur Atwater, the Department of Agriculture's nutrition specialist, followed the same line in recommending that physically active men should eat 125 g of protein per day.

Such a notion did not go unchallenged, however. From 1840 on, there had been a vegetarian "school" in the United States, which argued that eating meat was overstimulating and conducive first to debauchery and then to exhaustion of the irritated tissues. John Harvey Kellogg (cofounder of the family's breakfast-food enterprise) believed that meat and other sources of excessive protein in the diet could putrefy in the large intestine, resulting in autointoxication. These ideas were regarded by the scientific establishment as unscientific and not meriting attention. However, in 1902 a serious challenge to the "high-protein" school was mounted by Russell Chittenden, professor of physiological chemistry at Yale.

Chittenden had six of his colleagues, a dozen army corpsmen, and a group of Yale's athletes spend approximately six months on diets containing no more than one-half of the Atwater standard for protein. These men all remained healthy and vigorous in mind and body. Chittenden concluded, in his account published in 1904, that such diets were not only adequate but preferable because they put less strain on the kidney to cope with the excretion of both urea and the less soluble uric acid.

His findings stimulated an active debate among medical men. Most believed that Chittenden's findings were still too limited to recommend wholesale dietary changes. For example, the subjects in his study had not been subjected to sudden stresses or to periods of inadequate feeding in which they had to rely on reserves. Moreover, experiments with dogs kept on low-protein diets had revealed that although they remained healthy and in nitrogen balance for a time, they eventually weakened and died. Chittenden, however, followed up this line of work with dogs in his own laboratory and concluded that it was not lack of protein that was responsible for long-term problems with some diets but a lack of one or more unknown trace nutrients. This conclusion constituted one of the stimuli for the work that dominated nutritional studies for the next 40 years and revealed the existence of the vitamins.

Amino Acids in Nutrition

By 1905, another question gaining prominence was whether the proteins that had now been isolated from many foods could all be considered equivalent in nutritional value. It had long been known that gelatin, obtained by autoclaving bones, would not support growth in dogs, even though it had the same nitrogen content as ordinary tissue proteins. But because it displayed some physical differences, such as remaining soluble in boiling water, it had been set aside from the "protein" classification.

Advances in the study of proteins required a better knowledge of their composition. That they did not diffuse through fine-pored membranes showed them to be large molecules. But during digestion, their physical properties changed dramatically. With the isolation of the digestive agent "pepsin" from the stomach walls of slaughtered animals, and then of "trypsin" from pancreatic juice, the process could be studied in more detail.

As early as the 1860s, workers had been surprised to discover the presence of "leucine" and "tyrosine" in digests of protein with pancreatic juice. These two compounds were already well known. They were recoverable from the product of boiling proteins with sulfuric acid and had been shown to be "amino acids" – meaning that they contained both an acid group and a basic one and were relatively small molecules, each with less than 25 atoms. However, the procedure yielding them seemed so severe as to have no relation to the mild conditions of the digestive system, and it was thought that the compounds might well have been produced by the hot and strong acid conditions.

Gradually, by in vitro digestion, and milder acid or alkali refluxing of proteins, a whole range of amino acids were recovered, and crude methods were developed to analyze the quantities of each that were present. Also, evidence accumulated that the compounds actually absorbed through the gut wall after digestion were simple amino acids. Early investigators had felt it unlikely that nature would employ such a system because it seemed extremely wasteful to break proteins down, only to rebuild the same compounds within the animal. Or were they the same compounds?

Some of the first experiments comparing the nutritional values of different proteins were carried out by Lafayette Mendel (from Chittenden's group) and the plant chemist Thomas Osborne. They found that young rats would grow if given a diet of fat, carbohydrates, minerals, crude vitamin concentrates, and purified casein (a milk protein). However, with zein (a protein from corn) as the protein source, the rats did not grow unless the diet was fortified with *both* lysine and tryptophan. Chemical analysis had already indicated that zein lacked these two amino acids, and thus these two were characterized as "essential amino acids," meaning that they were essential or indispensable in the diet of growing rats. The results also indicated that animals used amino acids to build their own body proteins.

After 20 years of further experiments of this kind, W. C. Rose and his colleagues were able to obtain good growth in rats with diets containing *no* protein, but just a mixture of amino acids in its place. Table IV.C.2.1 summarizes their findings about the 20 amino acids present in animal proteins, some of which were indispensable ("essential") and some of which the rat could make for itself ("nonessential") if they were not supplied in its diet. Further work led to the development of values for the quantity of each indispensable amino acid that rats required for optimal growth.

Another group of studies compared the relative values of different protein sources (or of mixtures) for the support of growth in rats. The mixed proteins from individual vegetable foods (grains, beans, and so forth) all supported some growth, but not to quite the same extent as the mixed proteins in milk, meat, or eggs. The first limiting amino acid (meaning that this was the amino acid that increased growth when added as a single supplement) in most grains was lysine. This was to be expected in view of the growing rat's known requirement for lysine and the low analytical value of lysine in grains. The corresponding first limiting amino acid in most beans and peas was found to be methionine. Because the two classes of materials had different deficiencies, one would expect a mixture of grains and legumes to support better growth in rats, and this has been confirmed.

Table IV.C.2.1. *Reproduction of the final summary of the rat's requirements for amino acids, as determined by Rose and his colleagues in 1948*

Classification of amino acids with respect to their growth effects in the rat	
Essential	Nonessential
Lysine	Glycine
Tryptophan	Alanine
Histidine	Serine
Phenylalanine	Cystine*
Leucine	Tyrosine†
Isoleucine	Aspartic acid
Threonine	Glutamic acid‡
Methionine	Proline‡
Valine	Hydroxyproline
Arginine§	Citrulline

*Cystine can replace about one-sixth of the methionine requirement, but has no growth effect in the *absence* of methionine.

†Tyrosine can replace about one-half of the phenylalanine requirement, but has no growth effect in the *absence* of phenylalanine.

‡Glutamic acid and proline can serve individually as rather ineffective substitutes for arginine in the diet. This property is not shared by hydroxyproline.

§Arginine can be synthesized by the rat, but not at a sufficiently rapid rate to meet the demands of *maximum* growth. Its classification, therefore, as essential or nonessential is purely a matter of definition.

Human Requirements

Rats, however, although useful as models, differ from humans (even in this context) in important ways. Humans spend most of their lives as adults, not growing at all but needing protein just for "maintenance." And in childhood, human growth is extremely slow compared to the growth of rats. Thus, we take something like six months to double our birth weight, which a young rat does in a few days. And at six months, the rat is fully matured, yet the child is still only one-tenth of its mature size. Moreover, although the tissue proteins of rats and humans are similar, hair protein is very different, and the rat has to synthesize proportionally more.

It was necessary, therefore, to discover whether humans needed to be supplied with the same essential amino acids as those needed by rats. But because it was neither practical (nor ethical) to keep young children on what might be inadequate experimental diets for long periods in order to compare their growth rates, the normal method of experimentation was to feed adult volunteers for periods of two weeks or so on diets in which there were mixtures of amino acids in place of protein.

If an essential amino acid were missing, the subject would, within a very few days, show a negative nitrogen balance, meaning that the amount of combined nitrogen found in urine and feces, plus the smaller estimated quantity rubbed off in skin and hair losses, had exceeded the daily nitrogen intake. Fortunately, no harm seems to come to humans in negative balance for a short period, and bodily reserves refill rapidly on resumption of a complete diet.

The first major finding from this work was that essential and nonessential amino acid needs are the same for humans as for the young rat. However, researchers were surprised to discover how low the quantitative need for each essential amino acid appeared to be in order to maintain nitrogen balance. In fact, the combined total of essential amino acids came to only 16 percent of the total protein requirement, even though they make up about 45 percent of our body proteins. Thus, it seemed that almost any mixture of foods that provided at least the minimum amount of total protein needed would automatically meet adult needs for each essential amino acid. For young children, however, it was felt safer to set a higher standard for amino acids, corresponding more or less to the composition of the proteins in breast milk. For older children, a compromise was adopted in official recommendations, with a pattern midway between that found to be needed for nitrogen balance in adults and that in human milk. These standards are summarized in Table IV.C.2.2.

There have been recent criticisms of the practice of basing standards solely on short-term nitrogen balance experiments, with V. R. Young (1986) and colleagues (1988, 1989) at the Massachusetts Institute of Technology (M.I.T.) arguing that the method itself has sources of error. These researchers have carried out sophisticated studies using diets based on amino acids, with a single essential amino acid labeled with an isotope so that its metabolism can be followed. They concluded that the levels at which the essential amino acids are required, in relation to total protein needs, are quite similar to the levels in which they occur in the body. Even after subjects have had time to adjust to lower intakes, the rate of renewal of body tissues is reduced, which may have adverse effects in a time of stress.

Table IV.C.2.2. *The World Health Organization (1985) estimates of human requirements for protein and selected amino acids, by age*

	Protein (g/kg body weight)	Lysine (mg/g protein)	Methionine + cystine (mg/g protein)
Infant (3–4 months)	1.47	103	58
Child (2 years)	1.15	64	27
School child (10–12 years)	1.00	44–60	27
Adult	0.88	12	22

As Atwater suggested over a century ago, it is possible that intakes higher than those needed for nitrogen balance could confer some more subtle long-term benefits. However, there are as yet no studies of peoples living for long periods on diets borderline in protein but well served with all other nutrients that would clarify the situation. And in any event, it seems clear that even the higher amino acid levels proposed by the M.I.T. group are being fulfilled by the diets of most people, at least in the developed countries.

The Protein Contribution of Different Foods

The obvious way to express the level of protein in a food is as a percentage of the weight, like "g per 100g." But such a measurement can be deceptive. For example, it would show ordinary white bread to have nearly 3 times the protein content of cow's milk because milk is 90 percent water, whereas bread is only about 34 percent water. Alternatively, one could compare the amounts of protein in equal weights of dry matter, but the common nutritional value of the great majority of the dry matter is its contribution of usable energy, whether from carbohydrate, fat, or protein. Thus, nutritionists have found it useful to compare the protein concentration of different foods in relation to their total calorie values. This could be expressed as "g per 100 kcalories," but it is easier (as protein itself has an average energy value of 4kcal/g) to express the concentration as "protein calories as a percent of total calories" (PCals%).

Although most of the time people have an instinct to eat enough food to meet their energy needs, there is a question of whether this quantity will also include enough protein.

Returning to the comparison of bread and milk, we can make the following comparisons:

	Protein (g)	Energy (kcal)	PCals%
1 slice white bread (32 g)	3	96	12.5
1 cup whole milk (244 g)	8	150	21.3
1 cup skim milk (245 g)	8	86	37.2

In terms of PCals%, milk is richer in protein than bread, meaning that to get the same quantity of protein from bread as from a cup of milk, one would have to consume more total calories. Similarly, it can also be seen that although a cup of whole milk and one of skim milk (with the cream removed) have the same protein content, the PCals% values are very different, with the value for the skim milk being higher. There are equally large differences between different meat preparations, as can be seen in the comparison of a pork chop and a chicken breast:

Table IV.C.2.3. *The typical protein concentrations of a variety of foods (edible portions only) expressed as "protein calories as a percentage of total calories" (PCals%)*

Animal foods		**Grain products**	
Poached cod	86	Oatmeal	14.5
Roast chicken breast without skin	72	Whole wheat bread	13.5
Stewed rabbit	68	White bread	12.5
Broiled salmon	50	Sweet corn	12
Skim milk	37	Brown rice	11
Boiled egg	32	Cornmeal	10
Cheddar cheese	25	White rice	9
Fried pork chop	25	Sorghum flour	8.5
Salami (beef and pork)	22	Corn flakes, packaged	7.5
Whole milk	21		
Liver sausage	17	**Roots, fruits, etc.**	
		Baked potato	10
Legumes		French fries	5
		Banana	5
Tofu (from soy)	43	Sweet potato	4
Green peas	27	Plantain	3
Black beans	26	Cassava flour	1
Kidney beans	25	Fats and sugars	0
Chickpeas	21		

	Protein (g)	Energy (kcal)	PCals%
Pan-fried pork chop (89 g)	21	334	25
Roasted chicken breast without skin (86 g)	27	142	72

What this shows is that in a fried pork chop, for every 1 g protein (that is, 4 kcal) there are, in addition, 12 kcal from fat, whereas in the roasted chicken breast, 1 g protein is accompanied by only 1.6 kcal from fat. The PCals percentage values for a range of foods are set out in Table IV.C.2.3. These are "average" or "typical" values. Some animal carcasses are fatter than others, and the composition of plant foods can change significantly according to the environment in which the plants are grown, as well as the stage of harvesting. Wheats also differ significantly, with some strains being selected for high or low protein content according to the use for which the flour is marketed.

It is true that animal-product foods are generally higher in protein than plant products and also that people in the more affluent "Westernized" countries eat higher levels of animal products. However, the total protein intake in affluent cultures is not that much larger. The offsetting factor in these cultures is the higher consumption of sugars, fats, and alcoholic beverages, all of which contribute calories but no protein. Moreover, in many developing countries, some kind of beans forms a regular part of the day's food, and they are a rich source of protein. Thus, calculations commonly indicate that diets in both rich and poor countries have mostly between 10.5 and 12.5 percent of their total calories in the form of protein.

The Food and Agriculture Organization of the United Nations (FAO) publishes estimates of the daily food supplies per head that are available in different countries. Here are three examples:

	Total kcal	Protein (g) Veg.	Protein (g) Animal	% of protein from animals	PCals%	Fat (g)	Sugars (g)
U.S.A.	3640	37	72	66	12.0	164	579
Romania	3330	58	44	43	12.3	95	295
Ghana	2200	33	13	28	8.4	43	64

In this comparison, based on recent data, we see that in Romania, a relatively poor European country, the average individual took in only about 60 percent as much animal protein as a counterpart in the United States, but the total protein supply was almost identical. This was because the Romanians ate much less fat and sugar and received correspondingly more calories from grains, which generally have 10 to 13 PCals%. This offsetting, however, breaks down when the staple energy food is not a grain but a starchy root with only 1–3 PCals%, as in West Africa, where cassava is a common staple. The data for Ghana illustrate this. Despite the low fat and sugar intakes, there is still only an overall 8.4 PCals% in the food supply estimated to be available for the average person. Of course, the first "red light" that we see upon looking at the data is the low total calorie intake, which is only 60 percent of the corresponding U.S. value. Not all the U.S. foods are actually consumed of course: There is a great deal of waste, with fat trimmed off meat and stale food thrown out. Conversely, there may be some unrecorded food sources in Ghana. But it is a general finding that, even if there is a good supply of starchy roots, their sheer bulkiness makes it difficult to consume enough to meet energy requirements, particularly for young children, so that neither energy nor protein needs are fully met.

Not surprisingly, West Africa is also the part of the world where the disease kwashiorkor was first studied. It strikes children 1 to 3 years old who appear bloated, though their muscles actually are shrunken. They often have ulcerated and peeling skin and are utterly miserable. Unless treated, they are likely to die. The condition is now thought to be due to a combination of undernutrition (in both protein and energy) with the stress of infections. Recovery can be rapid if the victims are given concentrated food, by stomach tube at first, if necessary. The food mix does not need to be high in protein; mixes with as little as 5 PCals% have proven successful.

Except for children subsisting on bulky and very low protein staples, there seems to be no problem of protein deficiency for people in any culture who can afford to satisfy their calorie needs, unless they are consuming extremely atypical diets. The Recommended Dietary Allowances (RDAs) for protein in the United States are summarized here for three groups, together with the estimated energy needs of individuals in those groups if moderately active:

Population group	Assumed bodyweight (kg)	Protein RDA (g)	Energy needs (kcal)	PCals% required
Children, ages 1-3	13	16	1,300	4.9
Women, ages 25-50	63	50	2,200	9.1
Men, ages 25-50	79	63	2,900	8.7

It is interesting to note that when one calculates the proportions of protein required (PCals%) for each class, the results are unexpected. Traditionally, wives have thought that men, as the "breadwinners" of the family, needed most of the meat, and children at least some extra dairy protein, but as can be seen, it is actually women who are estimated to need the highest proportion of protein in their diet. And for people involved in greater levels of physical activity, all the evidence indicates that their calorie needs increase greatly but not their protein needs, so that the resulting PCals% of their needs is decreased. Put another way, the extra food they need to meet their needs can be of quite low protein content. Similarly, although the protein needs per kg body weight of a 1- to 3-year-old child are 50 percent greater than for an adult, its energy requirement per kg is nearly 200 percent higher so that, once again, the PCals% of its needs are lower.

Returning to the estimated average food supplies in Ghana, it can be seen that the mix is just about at the lower limit for protein. However, the RDA for protein, as for all other nutrients except energy, does include a margin of safety, and the level of physical activity is always higher in developing countries where there is less mechanical transport.

For countries like the United States or Romania, the protein supplies are clearly well above the standard requirement levels. Thus, it follows that a high intake of meat cannot be justified because of the protein that it contributes. In fact, a major concern of late has been that the protein intake of affluent individuals may be undesirably high. Some have problems because their kidneys are inefficient in excreting the urea resulting from protein metabolism. And, even in healthy people, high-protein diets cause increasing urinary losses of calcium. Certainly, this effect is undesirable in a society whose growing percentages of older people contain more and more individuals whose bones have been weakened because of the loss of a considerable proportion of their mineral substance (mostly calcium phosphate). It is now recommended that we not consume more than twice our RDA for protein. This would mean an upper level of 100 g protein for a woman weighing 63 kg (139 lb.).

IV.C.3 Energy and Protein Metabolism

In conventional scientific usage, when the word metabolism is joined with energy, it takes on a somewhat different meaning than when it is joined with protein. The latter - protein metabolism - usually includes consideration of the biochemical pathways of amino acids, the building blocks of protein, whereas energy metabolism is frequently assumed to include only the specific role of energy without consideration, in any detailed way, of the pathways involved in the breakdown and synthesis of the various carbohydrates and lipids that supply food energy.

In this chapter, the major thrust concerned with energy is an emphasis on historical considerations of understanding and meeting human food energy needs. In the case of protein, the role of amino acids in generating energy, protein quality (including digestibility), and human protein requirements will be given emphasis. Finally, there is some discussion of protein–energy relationships, the problems connected with an excess and a deficit of food energy in the diet, and protein–energy malnutrition.

Food Energy

The most pressing problem for humans throughout their history has been the basic one of securing food to satisfy hunger and food-energy needs. But the fact that the human population in different parts of the world (despite subsisting on different diets), seemed before about 1900 to experience approximately the same level of health had led some physiologists to believe that all foods were rather similar (McCollum 1957). In fact, this view was rooted in the ancient "many foods–single aliment" concept of Hippocrates and Galen. By the turn of the twentieth century, however, views were rapidly changing, and although knowledge of the specialized roles of amino acids, vitamins, and minerals was hazy and often contradictory, proteins, fats, and carbohydrates (starches and sugars) could be distinguished and analyzed in foods and diets. Thus, with the advances in food analysis and refinements of nutritional needs the "many foods–single aliment" concept was no longer tenable.

Heat and Life

Because the human body became cold after death, it was not surprising that some mechanism of heat production came to be considered synonymous with life at an early stage in human history. Hippocrates (born 460 B.C.) noted in one of his aphorisms:

> Growing bodies have the most innate heat; they therefore require the most food for otherwise their bodies are wasted. In old people the heat is feeble and they require little fuel, as it were, to the flame, for it would be extinguished by much. (Lusk 1933: 8)

The Greeks explained the mechanisms of health and illness in terms of the four "humors" in the body. When the body was in health, these humors were in balance, whereas excess or deficiency caused illness. Special foods or drugs could restore the proper balance and, hence, health. It was also observed from the earliest times that when an adult partook of a great deal of food, he or she did not necessarily gain in weight. Hippocrates believed this was due to a constant loss of insensible perspiration and the elimination of heat, which he conceived to be a fine form of matter.

Half a millennium later, Galen (130–200 A.D.) was more specific than Hippocrates in drawing a direct analogy between flame and innate heat, writing that "[t]he blood is like the oil [of a lamp], the heart is like the wick and the breathing lungs an instrument which conveys external motion" (Lusk 1933: 12).

The Middle Ages saw few developments in the area of nutrition, but during the Renaissance, Leonardo da Vinci (1452–1519) again took up the analogy of a flame to refer to life by stating that "where there is life there is heat" and "where flame cannot live no animal can sustain its existence" (Lusk 1933: 18). This remark was later echoed by Robert Boyle in 1660, who wrote that "neither a flame nor an animal can live in a vacuum" (Lusk 1933: 25). A contemporary of Boyle, John Mayow (born 1643), who died at the age of 36, appeared to have an understanding of respiration and the role of blood (that was only rediscovered a century later) when he wrote:

> Respiration consists furthermore in the separation of the air by the lungs, and the intermixture with the blood mass of certain particles absolutely necessary to animal life, and the loss by the inspired air of some of its elasticity. The particles of the air absorbed during respiration are designed to convert the black or venous blood into the red or arterial. (Lusk 1933: 35)

Development of Scientific Concepts

Fuel was long understood as burning to produce heat or power, but an understanding of the importance of air in supporting combustion and respiration had to await identification of the gases. Later, when burning was recognized as the combining of fuel with oxygen and the giving off of carbon dioxide and heat, the respiration of animals and humans was accepted as a special case of combustion. Although many still believed that a "vital" or God-given force controlled all life processes, quantitative relationships began to be developed between individual foods and their use in the body to produce predictable amounts of heat.

The concept of heat remained central to the explanatory framework of traditional physiology. Every part of the body had its own innate heat, and the heat in the extremities was continuously being dissipated into the surrounding environment. This heat had to be replenished from some source in the body, which was identified as the heart, and the heat, together with the beating of the heart, generated the "vital spirit" out of air and blood. The vital spirit was, in turn, carried by activated arterial blood.

This view was replaced following the discovery of circulation by William Harvey in 1628. In the process of searching for the origin of body heat, later investigators tried to decide whether the heartbeat was involved with producing it or whether the motion of the blood created friction, and therefore heat, as it passed through the vessels of the body. The lungs were considered by Harvey to represent an important heat-dissipating mechanism that prevented the cardiac generation of heat from exceeding the body's tolerance.

The Discovery of the Gases

Physiology prospered in the early years of the eighteenth century but during its latter part lost prominence to chemistry. By then, chemists had developed analytical methods to at least begin to determine the ultimate constituents of body fluids and tissues (Kinney 1988).

With the work of Joseph Priestley (1733–1804) oxygen was discovered (1774).

Antoine Laurent Lavoisier, in turn, recognized that carbon dioxide was a compound of carbon and oxygen and further demonstrated that the respiration of animals involved CO_2. A table from the 1790 English translation of his text *Traité élémentaire de chimie* indicates that the names oxygen, hydrogen and azote (nitrogen) were replacing several older terms for the gases. By use of an ice calorimeter (a device whereby heat produced from a living animal could be estimated from the amount of ice that was melted), Lavoisier was able to demonstrate that respiration was very slow combustion and that predicted heat agreed well with that which was measured.

Nutritional Experimentation

In the overlapping areas of protein and energy metabolism, French physiologist Jean-Baptiste Boussingault (1802–87), in 1844, performed a series of experiments using a cow fed only foods relatively low in protein (potatoes and beets) to prove that the manufacture of tissue protein did not require the incorporation of nitrogen from the air. A few years later, Carl von Voit and T. L. Bischoff (1860) in Germany confirmed that all the nitrogen in the body could come from the foods eaten and that the condition of nitrogen equilibrium or nitrogen balance could be established when the level of nitrogen intake was held constant. A major controversy developed during this period over the production of animal fat. Justus von Liebig maintained that the formation of fat from sugar was possible in the animal body, whereas other chemists, following the lead of Jean-Baptiste Dumas, maintained that fat in food was the only source of body fat. Boussingault, however, in 1845 proved conclusively that animals could produce fat from carbohydrates (McCollum 1957).

A series of studies that significantly linked protein and energy metabolism were those undertaken by Edward Smith in England in 1857. They demonstrated the effects of different conditions of life on the magnitude of energy requirements of human subjects. His major observation was that there was comparatively little change in the amount of urea (the major protein metabolite) voided during wide variations in the amount of labor performed, whereas the carbon dioxide produced increased in proportion to the amount of exercise. He devised a treadmill experiment with human subjects that provided strong evidence that the energy for muscular work could not have been derived from muscle degradation and almost conclusive evidence that the muscles were deriving energy from nonnitrogenous food. Unfortunately, the high authority of Liebig, who thought energy was derived from muscle degradation, prevented Smith's studies from securing the attention they deserved.

In 1866, however, Adolf Fick and Johannes Wislicenus reported their famous mountain-climbing experiment of the previous year, using themselves as subjects, to confirm Smith's tread-mill studies and also to put Liebig's theory of muscular work to a crucial test. They abstained from protein food for some 17 hours before beginning the ascent of the Faulhorn, a peak in Switzerland with an altitude of 1,656 meters (5,433 feet). The climb to the summit required 6 hours, and during this time and for another 7 hours afterward, they consumed only carbohydrates and fats. Throughout they collected their urine, which was later analyzed for nitrogen content. During the 13-hour period, Fick produced 5.74 grams of urinary nitrogen and Wislicenus 5.54 grams. They reported:

> We can assert from our own experience in the mountain ascent, that in spite of the amount of work and abstinence for 31 hours from albuminous food, neither of us felt the least exhausted. This could hardly have been the case if our muscular force had not been sustained by the non-nitrogenous food in which we partook. (McCollum 1957: 126)

In the same year, E. Frankland (1866) pointed out that these results could be interpreted only by taking into account the amount of energy evolved in the combustion of a unit of muscle substance and by considering the work equivalent of this energy. In addition, he showed that the energy that the body derived from protein was equal to the difference between the total heat of combustion less the heat of combustion of urea, the major substance whereby the nitrogen in protein foods was eliminated. Frankland thus confirmed the conclusions already reached by Smith and by Fick and Wislicenus that muscles work at the expense of energy derived from the oxidation of the nonnitrogenous fats and carbohydrates (McCollum 1957).

The development of the concepts of intermediary metabolism of foodstuffs – that is, the step-by-step conversion of materials to the ultimate products, water and carbon dioxide (CO_2), with the liberation of energy – was a slow intellectual process and had to await the accretion of knowledge of organic chemistry and, above all, the realization of the catalytic nature of the enzymes and their infinite variety (Levine 1978).

Respiration Chambers and Calorimetry

Voit and M. Pettenkofer were leaders in the new studies of respiration and energy balance, at first using small chambers for animals. A much larger apparatus was then constructed in which both the total carbon excretion (breath, urine, and feces) could be measured and the quantity of individual foods actually burned in the human body could be determined. This was a remarkable technological achievement and a significant scientific advance. On the death of Pettenkofer in 1901, Voit (quoted in Kinney 1988) wrote:

> Imagine our sensations as the picture of the remarkable process of the metabolism unrolled before our eyes and the mass of new facts became known to us. We found that in starvation protein and fat alone were burned, that during work more fat was burned and that less

Table IV.C.3.1. *Energy exchange in humans: An example from Atwater and Benedict*

	Total: 4 days	Daily average
a. Heat of combustion of food eaten	9848	2462
b. Heat of combustion of feces	304	76

> fat was consumed during rest, especially during sleep; that the carnivorous dog could maintain himself upon an exclusive protein diet, and if to such a protein diet fat were added, the fat was almost always entirely deposited in the body; that carbohydrates, on the contrary, were burned no matter how much was given and that they, like the fat of the food, protected the body from fat loss, although more carbohydrates than fat had to be given to effect this purpose; that the metabolism in the body was not proportional to the combustibility of the substances outside the body, but the protein which burns with difficulty outside, metabolizes with the greatest ease, then carbohydrates, while fat, which readily burns outside, is the most difficult to combust in the organism (Kinney 1988: 524).

Max Rubner (1854–1932), who was trained in the laboratories of Voit, determined standard food energy (caloric) values for the major foodstuffs. He continued to demonstrate, until well into the twentieth century, that the animal body followed the law of the conservation of energy.

W. O. Atwater (1844–1907), an American who had studied under Voit in Germany, returned to the United States to work with a physicist at Wesleyan University in developing a large calorimeter capable of measuring precisely the amount of heat given off by a person living in it.[1] This calorimeter confirmed the earlier experimentation of Voit, Pettenkofer, and Rubner and demonstrated that the energy expended by a person in doing any work, such as static bicycle riding, was equal to the heat released by the metabolism of food in the body. The physiologist F. G. Benedict extended Atwater's work by constructing special equipment at the Carnegie Institute in Boston for the simultaneous measurement of gaseous metabolism and heat production. An example from one of their studies is shown in Table IV.C.3.1. On a daily basis, the difference between heat determined and heat estimated was only –1.6 percent. The precision obtained in these experiments was remarkable and was obtained without computer assistance!

The finding from the calorimeter work that received the most attention in Atwater's lifetime concerned alcohol. In 1899 he reported that if a subject drank alcohol in small portions over the course of the day, it was almost fully oxidized and replaced the food energy equivalent of either fat or carbohydrate. At this level, therefore, it acted as a food (Atwater and Benedict 1899). This finding was advertised by the liquor trade, and Atwater was subsequently attacked by temperance advocates as a disgrace to his church and to his profession (Pauly 1990). He defended himself vigorously and, while agreeing that abstinence was certainly the safest way to avoid addiction, argued nevertheless that for most people, moderate consumption was possible and seemed to improve their well-being rather than damage it (Carpenter 1994b). (We have heard recent echoes of this debate following recommendations in the Dietary Guidelines for the United States concerning alcohol consumption.)

Further related studies undertaken by Atwater (1899) and his associates (Atwater and Bryant 1900), which overlapped those of Rubner, made determinations of the fuel value of foods by the use of a bomb calorimeter and by comparing those determinations with the heat produced in the body. A bomb calorimeter permits the complete combustion of the sample in the presence of oxygen under pressure, with the direct determination of the heat produced by measurement of the temperature rise in the surrounding water. A diagram of Atwater's bomb calorimeter is shown in Figure IV.C.3.1.

It was found that the total (gross) energy produced by combustion of food with oxygen in a bomb calorimeter was greater than the metabolizable energy of the same food when utilized in the body. However, when account was taken of digestibility (that is, not all the food consumed was absorbed into the body) and of the energy lost in the urine (that is, the urea produced from protein), then there was essential agreement. Fuel values of foods were compared with their analytical composition, and thus were born the 4:9:4 Atwater factors, where the metabolizable energy of foods, in kilocalories per gram, could be readily calculated from the contents of carbohydrate, fat, and protein. These concepts were reported, essentially in their present form, in the texts of R. Hutchison (1903) and H. C. Sherman (1914).

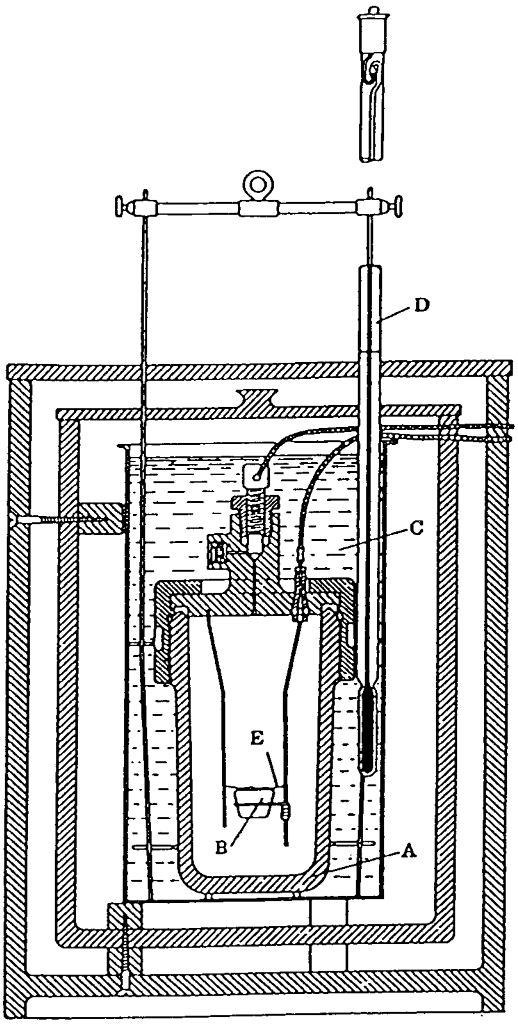

Figure IV.C.3.1. The Atwater bomb calorimeter: (A) heavy steel bomb filled with oxygen under pressure; (B) capsule inside bomb containing weighted sample; (C) weighed amount of water at known initial temperature; (D) thermometer of high accuracy; (E) electric ignition wire. (From Sherman 1952.)

The unit used today for food energy, deriving from these and other basic physical studies, is the kilocalorie (kcal). This is the amount of heat necessary to raise 1 kilogram of water from 15° to 16° Celsius. The international unit of energy is the more scientifically fundamental joule (J). Although not greatly used in the United States in a nutritional context, the joule is widely employed in Europe. To convert from kilocalories to kilojoules (kJ), the rounded value 4.2 may be used (1 kcal = 4.184 kJ). The classical Atwater metabolizable energy conversion factors of 4 kcal/gram (g) of food protein and carbohydrate and 9 kcal/g of food fat have been verified and are adequate for computation of the energy content of customary diets (Miles, Webb, and Bodwell 1986). Alcohol (ethanol) has a computed food energy value of 7 kcal/g or 5,600 kcal/liter (L). It should be noted that in the original Atwater calculations, carbohydrate was measured by difference (that is, only protein, fat, and minerals were determined in the food, and the residue after allowing for water content was considered to be mainly carbohydrate). This, therefore, included fiber.

The Development of Modern Nutritional Science

Although the complex details of intermediary metabolism remained to be discovered as the twentieth century began, the basic framework of the modern science of nutrition had been laid down. Free sugars and their polymers furnished glucose for bodily functions, including muscular work: Excess carbohydrate could be stored as glycogen and fats, thus providing a fuel reserve that could furnish energy during periods of fasting. The views of Liebig concerning heat and work were recognized as mistaken by Hutchison in his text of 1903:

> We now know that bodily heat is not a thing apart and requiring to be provided for by itself, but that it is an inevitable accompaniment of cell life. Life and heat are inseparable, and in fulfilling its other function in the body a cell cannot help producing heat also (Hutchison 1903: 3).

Hutchison went on to indicate that as far as the cells of the body were concerned, it was a matter of indifference whether carbohydrate, protein, or fat were the original sources of the food energy. In strict energy terms this remains true, although the specific role of the energy sources, especially fat, in relation to chronic disease risk is now central to dietary guidance.

Lusk, author of several monographs and texts on nutrition (Lusk 1914, 1928, and 1933), and yet another who trained with Voit in Germany, dedicated the first edition of his monograph *The Elements of the Science of Nutrition* to his mentor in 1906. That an essentially modern view of nutrition had developed by this time can be seen from Lusk's writing (1914: 4):

> The workshops of life require fuel to maintain them and a necessary function of nutrition is to furnish fuel to the organism so that the motions of life continue. Furthermore the workshops of life are in a constant state of partial breaking down and materials must be furnished to repair worn out parts. In the fuel factor and the repair factor lie the essence of the science of nutrition.

Lusk (1914) also held modern views on the social aspects of nutrition, as is indicated in his lecture to the New York Academy of Medicine, which advocated nutritious school meals, family nutrition education, and national nutritional labeling of foods.

Another major activity in the early years of the twentieth century became the determination of the basal metabolic rate (BMR) in many subjects together with the development of prediction procedures for estimating BMR from body weight or from body surface area (Harris and Benedict 1919). The BMR is the rate of heat production, measured directly or indirectly, when the subject is at rest and has not eaten for several hours. The normal range for large populations was thought to be relatively narrow. Variations in the BMR of supposedly normal individuals were often attributed to carelessness in experimental procedure, rather than to the existence of real differences. The field of calorimetry became devoted mainly to examining abnormalities in BMR associated with various diseases, in particular, thyroid disease, diabetes, and the more common fevers.

Equipment for determining BMR was standard in hospital laboratories until about 1950, at which time new chemical methods for measuring materials in the urine and blood related to thyroid metabolism caused hospitals to abandon the measurement and, consequently, to terminate the last remaining quantitative approach to energy metabolism in patients. In the hospital environment, research on energy expenditure in surgical patients returned under the leadership of Kinney (1988), who utilized a head canopy system that was acceptable to acutely ill patients and still permitted medical care as required.

There has been an enormous resurgence of interest in energy balance studies in recent years as a result of the growing concern over the hazards of obesity and the realization that we still have much to learn about energy metabolism and the control of energy balance.

World Supply of Food Energy

The energy, fat, and protein supply in rich and poor countries is shown in Table IV.C.3.2. Carbohydrate is the major source of food energy in both industrialized (52 percent) and developing (70 percent) countries. For the rich industrialized countries, the fat proportion (35 percent) is next in importance, but this proportion is much lower (20 percent) in developing countries. Whereas the proportion of the food energy as protein (PCal percent) is similar (12 percent to 10 percent) in both sets of countries, the proportion of that protein originating from animal sources differs greatly and is very much lower in developing countries, whose people receive considerably more of their protein from cereals.

The main dietary carbohydrates are shown in Table IV.C.3.3. Carbohydrates produce energy for metabolism through their initial conversion to acetyl coenzyme A (acetyl CoA), which is also the central point in the metabolism of protein and lipids for energy (Figure IV.C.3.2). Because storage fats can be synthesized from acetyl CoA, there is some degree of interconversion of the macronutrients, and we have the biochemical explanation of the fat synthesis controversy that taxed the early physiological chemists. The reverse conversion cannot occur to any significant degree, and fat is not a source of carbohydrate and protein.

Table IV.C.3.2. *Food availability data for industrialized and developing countries. Data for 1994*

	Industrialized countries	Developing countries
Food energy kcal/day	3356	2573
Total protein g/day	103.4	64.4
Animal protein g/day	62.2	17.1
Fat g/day	131.9	56.1
Derived data		
PCal%[1]	12.3	10.0
FCal%[2]	35.4	19.6
Animal protein % total protein	60.2	26.6
Cereal protein % total protein	24.3	53.3
Sugar as % total calories	9.5	5.9
Carbohydrates as % total calories	52.3	70.4

Table IV.C.3.3. *The principal dietary carbohydrates*

Source	Maize, rice, wheat, potato	Cane and beet sugar	Milk
Polysaccharide	Starch	-	-
Disaccharide	Maltose	Sucrose	Lactose
Monosaccharide	Glucose	Fructose + Glucose	Galactose + Glucose

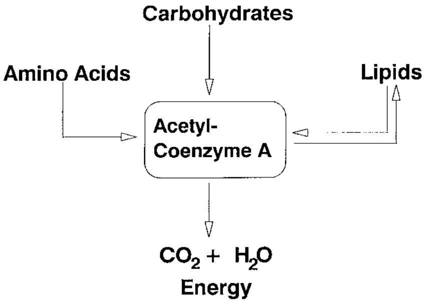

Figure IV.C.3.2. An overview of the combustion of fuels for energy. Acetyl coenzyme A is formed from carbohydrates, fats, and amino acids. Whatever the source, a large fraction of it is oxidized to CO_2 and H_2O, although any excess may be used to form lipids as an energy reserve.

Lipid is the overall chemical term used to describe the fats and oils; of these, the triglycerides (glycerol esterified with 3 fatty acid molecules) are the most abundant form in the diet. Although lipids differ widely in their compositions, the major pathways for their synthesis and breakdown begin and end with acetyl coenzyme A. Proteins are converted to acetyl CoA through a number of other intermediaries common mainly to the metabolism of carbohydrates. An outline of these latter pathways is shown in the section "Amino Acid Metabolism."

Thus, the energy of food is liberated by chemical changes, mostly oxidations, and is converted into mechanical work and heat. It is used to power the organic syntheses necessary for tissue maintenance and for growth in the young, and energy is also needed for the internal work of the body, the beating of the heart, the movements of the respiratory muscles, and the maintenance of the differences in the chemical contents of the cell fluids and the body fluids. Present descriptions of these processes include such terms as "biochemical energetics" and "free energy," but these modern explanations still conform to the broad descriptive strokes used in the early years of the century. The concept of burning fuels, not only for the energy with which to move but also for the energy necessary to build tissues and the like, is our rationalization of these processes (McGilvery 1979). Examples of the more important energy-producing and energy-consuming reactions in plants and animals include the following:

Energy-producing (exergonic)	Energy-consuming (endergonic)
Oxidation of fuels (carbohydrates, fats, and proteins)	Mechanical movement
Photosynthesis	Synthesis of cellular constituents
Fermentations	Creation of concentration gradients
	Storage of fuels

The sequence of reactions in the cell by which acetyl groups are oxidized is the "citric acid cycle" (or "Krebs cycle"), and for this discovery made in the 1930s, Hans Krebs (1900–81) shared the Nobel Prize in 1953. The reactions of the cycle function in sequence and as a unit to remove electrons from acetyl groups within the mitochondria and to feed the electrons into the oxidative phosphorylation pathway with the ultimate transfer to molecular oxygen. The overall result is the production of energy-rich adenosine triphosphate (ATP) from the oxidation of acetyl groups. A simple overview of energy production from the macronutrients is illustrated in Figure IV.C.3.2.

Human Energy Expenditure and Its Components

The main factors that influence daily energy need are basal metabolic rate (BMR) or resting energy expenditure (REE), physical activity, and thermogenesis. The last term may produce confusion for nonspecialists because the word means the generation of heat, and all energy expenditure generates heat. Thermogenesis is additional heat generation above that of REE and physical activity. All factors are affected directly or indirectly by individual variables, such as age, sex, body size, and, to a lesser degree, climate.

Resting Energy Expenditure

Unless the activity level is high, the most important single component of overall energy requirement is the energy expended at rest (REE). Customarily, basal metabolism, or basal metabolic rate (BMR), has been included as one of the factors affecting overall energy requirement. In practice, however, the chief interest is in resting energy expenditure (REE), namely, the energy expended by a person in a normal life situation while at rest and under conditions of thermal neutrality. The REE includes the thermic effect of meals and is an average minimal expenditure for the periods of the day and night when there is no exercise and no exposure to cold. REE is influenced by, among other things, age, height, weight, and sex. Although no equation for predicting REE can be completely accurate, several include age, sex, weight, and height and can predict REE with sufficient accuracy to serve as a first step in determining group or individual requirements.

An animal loses heat through the surface of the body, and the capacity for heat production is related to the volume of the body. It was therefore reasoned in the early 1800s that the larger the animal, the greater the heat production relative to the heat loss. Rubner later proposed that when metabolic rate was expressed in relation to the body surface area, the effect of body size disappeared. More elaborate studies were undertaken in the 1930s by Kleiber (see Kleiber 1961), who presented strong evidence against surface area being the determining factor of basal metabolism. Rather, he suggested that metabolism should be considered as a power function of body weight. Lacking a better definition of metabolic size, he proposed a three-fourths power of body weight as the best correlation between body size and resting metabolism. Later relationships were proposed with fat-free body mass, rather than with body weight alone. Lean body mass is a more recent term, and the concept has been further extended to the metabolizing body-cell mass by measuring total exchangeable potassium (Kinney 1988). Nevertheless, for humans, weight is the major variable and may, together with age and sex, be sufficient for predictive purposes.

The Food and Agriculture Organization of the United Nations (FAO) equations (FAO/WHO/UNU 1985) are shown in Table IV.C.3.4. The Harris-Benedict equations, which also include height, have been widely used in the United States for predicting the energy requirements of hospitalized patients; they are also shown in Table IV.C.3.4. In relation to the Harris-

Benedict equations, Sherman (1952) referred to their empirical nature and remarked that they "may be somewhat disconcerting at first glance. On working through the two formulas, however, it will be seen that there is . . . [no] great difference in the basal metabolisms of the sexes" (Sherman 1952: 161).

Thermogenesis

The thermic responses to food and to cold were formerly thought to be independent. N. J. Rothwell and M. J. Stock (1983) proposed that brown adipose tissue may perform a regulatory function in response to overfeeding. Rats could become obese on a palatable snack-food diet but maintained normal body weights when given less palatable rat chow. The brown adipose tissue of the rats with abnormal weight gain was markedly increased, suggesting that the overfeeding may have led to a substantial increase in dietary induced thermogenesis.

Diet-induced thermogenesis (DIT) is any change in energy expenditure induced by diet. This can be divided into obligatory and adaptive components. DIT reaches a maximum about 1 hour after the meal is consumed and virtually disappears 4 hours afterward. There have been reports of subjects who have apparently eaten excessively for long periods but who have gained much less weight than would have been predicted had they stored this excess as adipose tissue. The efficiency with which energy intake is utilized may vary greatly within the same individual and may explain the large variations noted in many experiments. Variations in thermogenesis have been an important research area in explaining some of the discrepancies between theory and actual observations of energy balance. Some researchers, however, now claim that the energy intake data in these observations may have been underestimated and that there may be no significant discrepancies (Heymsfield et al. 1995; Seale 1995).

Physical Activity

A dominant factor influencing overall energy needs is the proportion of time an individual devotes to moderate and heavy activities, in contrast to those that are light or sedentary. Little is known, however, about why apparently similar individuals differ in their selected

Table IV.C.3.4. *Equations for predicting basal metabolic rate from body weight (W) and age*

Equations from FAO

Age range (years)	kcal/day	Correlation coefficient	MJ/day	Correlation coefficient
Males				
0–3	60.9 W – 54	0.97	0.255 W – 0.226	0.97

level of physical activity (Hill et al. 1995). Average physical activity in Western society is now considered to be undesirably low. Estimates of energy needs were originally based on physical activity associated with different occupations, but occupational needs have declined significantly in recent years with the introduction of labor-saving machinery and devices. Simultaneously, there has been an increase in many discretionary activities, resulting in great variability among individuals. The widespread adoption of jogging and other forms of fitness activities are obvious examples. Thus, the traditional specification of energy needs based on occupation is no longer adequate.

Three categories of discretionary activity that affect energy needs have been recognized (FAO/WHO/UNU 1985): optional household activities, which include working in the garden or repairing and improving the home; socially desirable activities, which are especially important contributors to the energy needs of children, who require additional energy to explore their surroundings, to learn, and to adjust their behavior in order to relate to other children; and physical fitness activities, which contribute to the well-being of sedentary workers through leisure-time exercise. It is now considered more important in weight control to recommend increased physical activity, rather than reduced energy intake, because there is a range of benefits to health beyond the maintenance of energy balance (Conway 1995). This is in sharp contrast to the recommendations made by the American Medical Association in 1951 whereby it was stated that "it is seldom wise to attempt the alteration of calorie balance by changing the energy output; it is far easier and surer to adjust the intake" (AMA 1951: 274).

Other Factors Affecting Energy Requirements

Age. REE varies with the amount of metabolically active tissue in the body, with the relative proportion of each tissue in the body, and with the contribution of each tissue to total metabolism. These all vary with age. Changes in the body composition of children, adults, and elderly people are taken into account when energy requirements of a particular population group are calculated by use of the empirical equations that link REE with age. Activity patterns also change with age. Children become progressively more active once they are able to walk, and the physical activity patterns of adults are dependent not only upon their occupation but also upon their own leisure activity. When adults retire from work, their change in habits must be recognized when estimating energy requirements.

Sex. Although there are differences in the body weight and body composition of boys and girls beginning during the first few months of life, such differences are relatively small until children reach 9 to 10 years of age. Changes then accelerate throughout adolescence. After maturity, men have greater muscle mass, whereas women's bodies generally contain a greater proportion of fat. In practice, REE per unit of total body weight is not greatly different in men and in women. The energy requirement for physical activity has often been related to different occupational needs. In recent years, however, occupational and discretionary activity requirements of both sexes have become increasingly similar.

Body size. Persons with large (or small) bodies require proportionately more (or less) total energy per unit of time for activities such as walking, which involve moving mass over distance. Their hourly rates of REE will also be slightly higher or lower than the average. Energy allowances must be adjusted for the variations in requirements that result from such differences in body size. Weight may be used as a basis for adjusting allowances for different body sizes within a given age and sex category, provided the individuals are not appreciably over or under their desirable weights. Persons who are overweight often compensate for the increased energy cost of carrying their extra weight by decreasing daily activity.

Climate. In industrialized societies, most persons are protected against cold by warm clothes and heated environments. Many also live and work in air-conditioned buildings, so the effects of high temperatures are reduced. Yet, everyone is not insulated from environmental exposure, and when there is prolonged exposure to cold or heat, energy allowances may need adjustment.

Food Energy Requirements

The energy requirement of an individual has been defined as

> [t]hat level of energy intake from food which will balance energy expenditure when the individual has a body size and composition, and level of physical activity, consistent with long-term good health; and which will allow for the maintenance of economically necessary and socially desirable physical activity. In children and pregnant or lactating women the energy requirement includes the energy needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health (FAO/WHO/UNU 1985: 12).

As the definition suggests, energy expenditure can often be the basis for estimating energy requirements. The most frequently used procedure for determining energy expenditure consists of a combination of a timed activity record (that is, the total duration of each of the important activities throughout the whole 24 hours of the day) and an energy value in kcal or kJ per minute for each of these activities. These energy values may be derived from either published data or from actual measurement of oxygen consumption. Time spent at BMR or REE (sleep or rest) can often be a major component of the day's need.

A modified procedure for estimating average daily expenditure is to multiply the basal metabolic rate (BMR) or resting energy expenditure (REE) by an appropriate daily *average* activity factor, which is dependent on the degree and duration of physical activity. The latter is often termed the PAL (physical activity level). Thus: Daily Energy Expenditure = BMR × PAL. The PAL may vary from about 1.2 to 1.4 for relatively inactive people but up to 2.0 or more in the case of people who are physically very active. The value of the daily PAL may be obtained from questionnaires on habitual physical activity. Estimated values (FAO/WHO/UNU 1985; IDECG 1996) for PALs at various levels of habitual activity at different ages are shown in Table IV.C.3.5.

The doubly labeled water (DLW) method (Lifson, Gordon, and McLintock 1955) for the measurement of energy expenditure makes use of the stable isotopes ^{18}O and ^{2}H. The rates of disappearance from body water are determined following the oral administration of a known amount of doubly labeled water. Both energy expenditure and water output over several days can subsequently be calculated. Although the theoretical advantages of the DLW procedure, such as the ability to provide data on free-living individuals in almost any context, are considerable, there are counterbalancing drawbacks (Durnin 1996): The technicalities of the analysis of CO_2 output are such that expensive equipment and technical expertise are highly necessary. In addition, the isotope ^{18}O is expensive. Lastly, the calculations only provide information on CO_2 output for a period of several days. Nevertheless, the procedure is now widely used (Conway 1995), and many of the requirement data for various population groups – as well as estimates of PALs in the IDECG (1996) "Energy and Protein Requirements" report – are from DLW determinations. Comparisons between DLW and other procedures, demonstrating a close agreement in findings, have been reported by Seale (1995).

Table IV.C.3.5. *Physical activity levels suggested to estimate total daily energy expenditure from the mean basal metabolic rate of children, adolescents, and adults*

		Habitual physical activity		
Age (y)	Sex	Light	Moderate	Heavy
1–5	M, F	1.45	1.60	–
6–13	M	1.55	1.75	1.95
14–18	M	1.60	1.80	2.05
6–13	F	1.50	1.70	1.90
14–18	F	1.45	1.65	1.85
Adult	M	1.55	1.80	2.10
	F	1.55	1.65	1.80

Respiration chambers or whole-body calorimeters can have a role in assessing requirements but are highly expensive and technically complex. Few of these chambers exist, and their usefulness is restricted to specific basic problems that do not require a natural, free-living environment. But such devices can still play a research role in studying the relationship between energy metabolism and heart rate, diet-induced thermogenesis, DLW validation, and the influence of varying proportions of energy-supplying nutrients on energy metabolism. Extrapolation from heart rate to energy expenditure is useful for certain population groups, such as young children, the elderly, and those who are ill.

Energy expenditure has sometimes been indirectly estimated from energy intake, although the potential for error can be enormous, especially when intake is estimated from an interview based on a remembered food consumption for one day (24-hour recall). Self-recording of energy intake also frequently underestimates intakes when compared with measurements made by more direct procedures (Heymsfield et al. 1995; Seale 1995). However, when the procedure for measuring energy intake has been performed in an acceptable fashion by experienced observers, the results may be essentially the same as energy expenditure simultaneously measured (Durnin 1996).

Despite a much greater understanding of energy balance, many discrepancies still exist between self-reported food energy intakes and weight gain. Comparisons have been made by S. B. Heymsfield and colleagues (1995) between actual (DLW and indirect calorimetry) and estimated (self-reported) energy intakes. The studies revealed a considerable degree of underestimation of energy intake when using self-reporting procedures. In consequence, many of the cited discrepancies between food energy intake and weight gain may not really exist, and thermogenesis may not need to be invoked to explain the differences.

Table IV.C.3.6 presents energy intakes and requirements for various population groups in the early 1900s. The high requirement values it reveals were reasonable and acceptable when much manual labor was essential. However, the more recent international recommendations shown in Table IV.C.3.7 are much lower for all age groups. In Table IV.C.3.8, data on food energy and protein availability for a number of world regions are presented for the year 1994. These data are population averages, indicating that many people in the least developed countries are likely to be at risk of food energy inadequacy, whereas many of those in developed regions may be suffering from surfeit. The differences in protein availability, especially that from animal sources, are also noteworthy.

Table IV.C.3.6. *Early protein and energy intakes from Europe and America with requirement estimates*

Intake and requirement groups	Protein gm/day	Fat gm/day	kcal	PCal%	FCal%
Europe

Adult M	65.0	3200	2700	2700
Pregnancy	–	+ 450	+ 285	+ 225
Lactation	–	+ 1000	+ 500	+ 685

[1] 16–18 years.

Note: Adult requirements are for light-to-moderate activity levels:

Some international recommendations for requirements of food energy, together with discussions of the issues involved, have been provided by FAO (1950), FAO/WHO/UNU (1985), and IDECG (1996), whereas recommendations for the United States are discussed by Pellett (1990a). Food-energy requirements specifically for adults are dealt with by Shetty and colleagues (1996), and pregnancy and lactation are considered by Prentice and colleagues (1996).

Protein

Historical Background

Proteins are associated with all forms of life, an observation that dates back at least to the original identification of proteins as a class by G. J. Mulder (1802–80), who wrote in 1840:

> In both plants and animals a substance is contained, which is produced within the former, and imparted through their food to the latter. It is unquestionably the most important of all known substances in the organic kingdom. Without it no life appears possible on this

Table IV.C.3.8. *Distribution of food energy, fat, and protein in the various world regions*

Data for 1994	Food energy kcal/d	Total protein g/d	Animal protein g/d	Plant protein %	Animal protein %	Cereal protein %	FCal%

> planet. Through its means the chief phenomena of life are produced. (Block and Bolling 1951: v)

We now recognize that the major importance of protein in the diet is to act as a source of amino acids, some of which are essential (indispensable) dietary constituents. This is because their carbon skeletons are not synthesized in the bodies of animals. Others are nonessential (dispensable) because they can be made within the animal from readily available carbon and nitrogen precursors. All animal species need some preformed amino acids in their diets (Munro and Crim 1988). The essential amino acids (EAAs) for humans include histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine; moreover, cysteine and tyrosine are synthesized in the body from methionine and phenylalanine, respectively.

An additional 9 amino acids (alanine, arginine, aspartic acid, asparagine, glutamic acid, glutamine, glycine, proline, and serine) are also present in proteins but are not necessary in the diet because the body can usually manufacture them as needed, provided there is an adequate source of nitrogen and glucose. Sufficient synthesis may not take place in some circumstances, and some nonessential amino acids may become conditionally essential. This can occur, for example, in preterm infants (Tsang et al. 1993), following liver damage in the adult, and in the presence of certain potentially toxic materials.

The proteins of living matter act, among other things, as enzymes, as structural features of the cell, as messengers (peptide hormones), and as antibodies. The accumulation of proteins during growth and development, and the maintenance of tissue proteins in the adult, represent important objectives in ensuring nutritional well-being. A knowledge of the way in which dietary protein is optimally utilized by the body allows determination of protein needs for health and for the restoration of body tissue following disease (Munro and Crim 1988).

Amino Acids and the Quality of Protein

Before the first decade or so of the twentieth century, it was thought that proteins were all of generally similar nutritional value, despite recognition of very obvious differences in their chemical and physical properties.

Rubner, however, in the late 1890s, observed that proteins of varying origins were not of the same value in nutrition, and the earlier work of the Magendie Commission on Gelatin had demonstrated that gelatin could not support life (McCollum 1957). But these efforts and numerous nitrogen balance studies performed after the 1850s were essentially disregarded until the beginning of the next century (see Munro 1964a) when work reported from England confirmed that the different values resulted from lack of amino acids (Willcock and Hopkins 1906–7).

Sherman (1914), in the first edition of his textbook (the eighth edition appeared in 1952), defined protein in basically modern terms: "The word protein should designate that group of substances, which consist, as far as at present is known, essentially of combinations of alpha-amino acids and their derivatives" (1914: 26). By 1914, Lusk, in a lecture to the New York Academy of Sciences on the importance of proteins, could provide an almost complete list of those amino acids recognized today as constituents of proteins, with methionine and threonine the most notable absentees.

Within a decade of Lusk's lecture, Thomas B. Osborne and Lafayette B. Mendel at Yale University had convincingly demonstrated that there were major differences in the quality of proteins and had established the basis of our present evaluation techniques. Mendel suspected that the concentration of protein in a diet was not a completely satisfactory indicator of its ability to support growth, whereas Osborne had isolated a number of pure proteins. Thus began a most fruitful collaboration whereby Mendel studied the growth response of rats that were fed the proteins isolated by Osborne.

They found, quite early in their studies, that the various isolated proteins differed in their potential to support growth because the weight gain (of rats) per unit of protein consumed varied significantly. Hence was born the PER or protein efficiency ratio (Osborne, Mendel, and Ferry 1919), which remained the official method for the evaluation of protein in the United States (Pellett 1963) until the protein quality evaluation report by the FAO/WHO in 1991. From these collaborative studies came the early conclusions that rats grew better on animal proteins than on plant proteins, but that adding some of the then newly isolated and chemically identified amino acids to plant proteins could make them equal to animal proteins in their growth-promoting ability. The broad principles of protein nutrition that we accept today were well known by the second decade of the twentieth century (Mendel 1923).

Whether, however, there were fundamental differences between animal and vegetable proteins remained an important issue. It was a debate in which agreement was reached much earlier in scientific circles than in the public arena, where it remained an issue at least until the 1950s (Block and Bolling 1951). By that time it was agreed that an essential amino acid from a plant was the same as one from an animal but that the proportions present in plant and animal foods could differ and that mixing proteins in the diet (complementation) could confer nutritional benefits.

Nitrogen balance techniques had been in use at least since Boussingault in 1839, but the determination of the biological values of proteins from nitrogen balance data is generally attributed to K. Thomas (1909). The ability to scale the nutritional differences in proteins numerically arose in the first and second decades of the twentieth century with the introduction of the PER by Osborne, Mendel and E. L. Ferry (1919) and the refinement of Thomas's nitrogen balance techniques by H. H. Mitchell in 1924.

Protein and Amino Acid Analysis

Before nitrogen balance and other biological methods for the evaluation of protein quality could be used in any routine manner, improvements in procedures for the analysis of protein were required. Although the Dumas procedure (which converted the nitrogen of protein to gaseous nitrogen that could then be measured) had been available since 1835, it was not until 1883 that J. Kjeldahl described a convenient procedure for converting the nitrogen of most organic materials into ammonia. The procedure involved boiling the material in the presence of concentrated sulfuric acid and a catalyst. After release with a strong base, the ammonia could be determined by acid–base titration. Numerous modifications of the method have been proposed, but it remains remarkably similar in its essentials to the original procedure and is still widely used.

Nitrogen in foods comes not only from the amino acids in protein but also from additional forms that may, or may not, be used as part of the total nitrogen economy in humans and animals. The nitrogen content of proteins in foods can vary from between about 15 to 18 percent, depending on the amino acids in these proteins. In addition, purines, pyrimidines, free amino acids, vitamins, creatine, creatinine, and amino sugars all contribute to the total nitrogen present. Urea is also a major contributor in foods as important as human milk.

Because the average content of nitrogen (N) in protein is 16 percent, the nitrogen content multiplied by 6.25 is frequently used to convert N to protein. This should then be termed "crude protein." It is not always appreciated that the amino acids themselves show a very large range in their content of nitrogen. Whereas tyrosine has less than 8 percent N, lysine has 19 percent and arginine contains 32 percent. The presence of an amide group in an amino acid can double the N content; aspartic acid contains 10 percent N, but asparagine contains 21 percent. For other N-containing compounds, values can even be higher, with 47 percent N in urea and some 80 percent in ammonia. In practice, most protein evaluation techniques are actually evaluating the nitrogen present but are calling it protein (N × 6.25). Because a number of other factors from 5.3 to 6.38 (Jones 1941) may be used to convert food nitrogen to protein in different foods, considerable potential for confusion exists (Pellett and Young 1980).

Early in the twentieth century as the ability developed to detect and identify amino acids, it was realized that they were present in living materials, not only as components of their proteins but also as free amino acids. It also became clear that there were many more amino acids in living systems than the 20 or so known to be present in proteins. Because all amino acids behave in a rather similar chemical manner, additional techniques, often of a physicochemical nature, such as column chromatography, became necessary to solve the complex problems of separating and determining their presence in foods (Moore and Stein 1954; Moore, Spackman, and Stein 1958).

A major milestone was the description (Spackman, Stein, and Moore 1958) of an automatic analyzer allowing separation and quantitative analysis of amino acids based on ion-exchange column chromatography. As a result, modern dedicated amino acid analyzers quantitatively separate protein hydrolysates into their constituent amino acids in 1 hour or less and physiological fluids in about 2 hours.

In the introduction to the first edition of their major work on the amino acid composition of food proteins, R. J. Block and D. Bolling wrote:

> It has been our experience that a food protein may be a good source of those nutritionally valuable amino acids which are most commonly estimated (i.e., cystine, methionine, arginine, histidine, lysine, tyrosine and tryptophan) and yet be deficient in one or more of the other essentials for which analytical methods are more difficult and often less accurate (1951: xiv).

Threonine was not listed, but the other essential amino acids considered at the time to be difficult to analyze (leucine, isoleucine, valine, and phenylalanine) have rarely proved to be in deficit in normal foods or diets. Analytical techniques for amino acids at the time were chemical and followed in a direct manner from those developed by Fischer (1901). Large quantities of protein were required before amino acid composition could be undertaken, and accuracy was poor.

Even today, when techniques such as ion-exchange chromatography are in use, the accuracy and reproducibility of analyses for cystine, methionine, and tryptophan are problematic, not least because of destruction of amino acids during the hydrolysis stage of analysis (see FAO/WHO 1991). Current views are that although the supply of any of the essential amino acids and of total nitrogen may theoretically limit protein utilization, only lysine, threonine, tryptophan, and the sulfur-containing amino acids are likely to be limiting in normal foods or diets. Even further, we now believe that in diets based on predominantly cereal protein sources, lysine may be the only amino acid that conditions overall protein quality (Pellett and Young 1988, 1990; Pellett 1996; Young, Scrimshaw, and Pellett 1997).

Digestibility of Protein

Although one would have expected the concept of digestibility to have developed early in the history of nutrition, a view of digestion and digestibility that we would recognize today did not arise until the middle of the nineteenth century. Following Hippocrates, the common view was that although there were many kinds of foods, there was but a single aliment. The belief of a single aliment prevailed throughout many centuries because little knowledge of the chemical nature of the various foodstuffs existed. Even in the early days of scientific nutrition research, William Beaumont (famous for his studies on digestion using a subject with a fistulous opening in his stomach caused by a gunshot wound), still held to this belief despite the then-developing opinions on the role of proteins, fats, and carbohydrates as chemically present in foods (McCollum 1957). In his own words, "the ultimate principles of aliment are always the same, from whatever food they may be obtained" (Beaumont 1833: 275) and "no other fluid produces the same effect on food that gastric juice does; and it is the only solvent of aliment" (Beaumont 1833: 278).

Although the dictionary definition of digestibility – "capable of being digested" – embraces both the scientific and the popular conception of the term, scientifically the term should suggest a numerical proportion of the nutrient capable of being digested (absorbed). In contrast, popular usage of the word "digestibility" merely seems to imply that indigestion is being avoided. The concept of being absorbed applies to any nutrient, but in practice, the term digestibility is mainly employed for food energy and for protein, whereas "bioavailability" is used to describe the degree of absorption and/or utilization of other nutrients.

Digestibility considerations were recognized as important in studies published by Boussingault from the 1840s onward. He made a number of quantitative experiments to determine the rate at which different constituents of food disappeared from the digestive tract and at the same time tabulated the theoretical amounts of vegetable feeds that would produce equal effects on the growth of animal muscle. As an example, if a standard 10 pounds (lbs.) of hay were needed to produce a certain amount of muscle, only 2 lbs. of linseed oil cake and 5 lbs. of oats, respectively, were required to do the same. Or, again to produce the same growth, 52 lbs. of wheat straw and 61 lbs. of turnips were needed. These values were, in effect, comparative protein nutritional values of feeds and, as with the majority of our current biological techniques of protein evaluation, implicitly included digestibility as a component.

Boussingault (1850) was also the first to distinguish between nitrogen as ammonium salts and nitrogen as urea in urine and was instrumental in initiating nitrogen balance experiments in farm animals. His studies (see McCollum 1957) were followed at Rothamsted in England by the work of J. B. Lawes and J. H. Gilbert in 1859. They fed two pigs that were closely similar in weight, one with lentil meal containing 4 percent nitrogen and the other barley meal containing 2 percent nitrogen. The pig fed lentil meal excreted more than twice as much urea nitrogen as did the other fed barley meal. It was evident that the pigs on these two sources of protein retained very different percentages of their food protein for conversion into body protein.

Under the impetus of the naval blockades during World War I, Rubner, in Germany, took up investigations on the nutritive value of bread. His general conclusion, following a number of digestibility studies, was that flour milled at a rate above 70 percent was poorly used by humans. The nitrogen in bran was, however, an excellent food for cattle, and the high-fiber milling residue was therefore recommended for animal feed.

Although digestibility considerations were known to be important, and it was recognized that digestibility was inclusive in most biologically determined protein quality values, the concept suffered relative neglect for a long period, with amino acid composition data given far greater attention. Only recently has the relevance of digestibility as perhaps the more important component of protein quality (that is, compared to amino acid composition) again been emphasized (FAO/WHO 1991).

Amino Acid Metabolism

The development of the concepts of intermediary metabolism of protein and amino acids – that is, the stepwise conversion of these materials to the end products, urea, water, and CO_2, with the liberation of energy – has been a continuously evolving process since the early years of the twentieth century. Hopkins in 1913 emphasized that "in the study of the intermediate processes of metabolism we have to deal, not with complex substances which elude ordinary chemical methods, but with simple substances undergoing comprehensible reactions" (Hopkins 1913: 653). Probably the major event in this progression of knowledge was the discovery of the Krebs-Henseleit cycle (Krebs and Henseleit 1932; Cohen 1981). The concept of the "cycle" became fundamental, not only for understanding the excretion of urea but also to the whole future of biochemistry. As Krebs remarked (see Estabrook and Srere 1981) at his 80th birthday symposium:

> Perhaps the most novel and fundamental contribution was the discovery of the urea cycle. It preceded the tricarboxylic cycle for the Nobel Prize. It was very important to have the concept of "the cycle.". . . And we know, of course, by now that there are many dozens, if not hundreds, of cyclic processes (Estabrook and Srere 1981: xvii).

Dietary proteins are subjected in the body to a series of metabolic reactions, which are outlined in Figure IV.C.3.3. Following ingestion, protein foods undergo digestion, whereupon the amino acids are liberated by the digestive enzymes. Amino acids are then absorbed as free amino acids and as two and three amino acid compounds (di- and tripeptides). Nonabsorbed protein and/or nitrogen compounds appear in the fecal material but may have been subjected to further bacterial reactions in the large intestine. For most protein foods, nitrogen absorption is in excess of 90 percent. Following the distribution of the free amino acids between the extra- and intracellular amino acid pools, subsequent reactions can be considered in four categories:

1. Part of the free amino acid pool is incorporated into tissue proteins. Because of subsequent protein breakdown, these amino acids return to the free pool after a variable length of time and thus become available for reutilization for protein synthesis or for catabolism.
2. Part of the intracellular amino acid pool undergoes catabolic reactions, mainly in the liver. This process leads to loss of the carbon skeleton as CO_2 or its deposition as glycogen and fat, whereas the nitrogen is eliminated as urea via the Krebs-Henseleit cycle.
3. Nonessential amino acids are made in the body using amino groups derived from other amino acids (including the EAAs if they are in excess of requirement) and from carbon skeletons formed by reactions common to the intermediary metabolism of carbohydrate (Table IV.C.3.9).

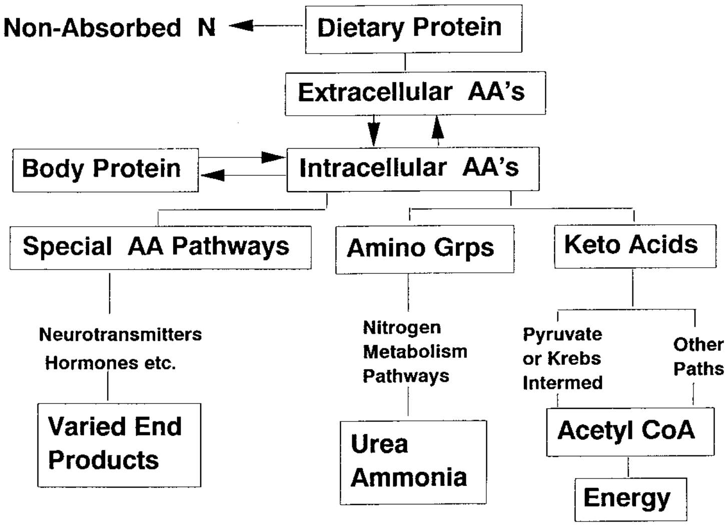

Figure IV.C.3.3. Metabolism of dietary protein. After the absorption of amino acids they are either incorporated into protein or are metabolized into α ketoacids and amino groups. Acetyl coenzyme A may either be used for energy or stored as fat. Pyruvate or Krebs cycle intermediaries may be used for the synthesis of glucose. Additional pathways involve the special role of amino acids for other uses as described in Table IV.C.3.10.

Table IV.C.3.9. *Summary of nonessential amino acid biosynthesis in mammals*

Amino acid	Precursor	Pathway
Alanine	Pyruvate	Transamination
Glutamate	αKG	Transamination
	αKG	GDH (+NH$_4$)
Glutamine (ATP/Mg)	Glutamate	+ NH$_4$
Aspartate	OAA	Transamination
Asparagine	Aspartate	+ NH$_4$
Serine	3-P glycerate	Phosphoserine HO-pyruvate
Glycine	Serine	THF needed
Methionine	Homocysteine	Betaine needed
Cyst(e)ine	Serine + homocysteine	Cystathionine
Tyrosine	Phenylalanine	Biopterin need
Proline	Glutamate	Semialdehyde
Arginine	Glutamate	Ornithine

Abbreviations: GDH glutamic dehydrogenase.
αKG alpha ketoglutaric acid
OAA oxaloacetic acid
THF tetrahydrofolate

Note: Methionine is an essential amino acid but can be synthesized from homocysteine, which, however, is not a normal dietary constituent.

4. Some free amino acids are used for synthesis of a number of new and important N-containing compounds. Examples are shown in Table IV.C.3.10 and include purine bases, creatine, gamma amino butyric acid, serotonin, and catecholamines. However, the portion of the total amino acid requirement devoted to this important function is small in absolute terms in comparison with the amount of amino acids needed for protein synthesis.

A summary listing of the end products formed from both the nitrogen and the carbons of the major amino acids as they are degraded is shown in Table IV.C.3.11, and a diagrammatic overview of the breakdown of the amino acids for energy and for other purposes is also illustrated in Figure IV.C.3.4.

Amino Acid Scoring Systems

Overlapping the development of animal assays for evaluating protein quality were significant advances in organic chemistry that allowed purification and isolation of both proteins and the amino acids. The next major advances in studies of protein metabolism were made by W. C. Rose and his associates at the University of Illinois. Their investigations, which began in the 1920s and extended until the 1950s, were able to distinguish, as unequivocally as is possible in the biological sciences, between the essential (indispensable) and the nonessential (dispensable) amino acids (Rose 1957).

Table IV.C.3.10. *Other functions of some amino acids*

Amino acid	Precursor of	Role
Alanine	Pyruvate	Amino transport Gluconeogenesis
Arginine	Creatine	Energy metabolism
	Ornithine	Urea formation
	Polyamines	Cell division?
	Oxaloacetic acid	Gluconeogenesis
Aspartic acid	Aparagine	Ammonia transport
	Purine, pyrimidines	Nucleic acids
Cysteine	Glutathione	Oxidation/reduction Amino acid transport
	Taurocholic acid	Fat absorption
Glutamic acid	α-ketoglutarate	Gluconeogenesis, transamination
	Glutamine	Ammonia transport
	Glutathione	Oxidation/reduction
	γ-amino butyric acid	Neurotransmitter
Glutamine	Purines, pyrimidines	Nucleic acids
	Amino sugars	Glycoproteins
	Citrulline	Ammonia transport
Histidine	Histamine	Biological amine
Lysine	Carnitine	Lipid transport
Methionine	S-adenosylmethionine	Methylation reactions
Phenylalanine	Tyrosine	Hormone synthesis
Serine	Ethanolamine, phosphoserine	Phospholipid synthesis
	4-sphingenine	Cerebroside synthesis
Tryptophan	Serotonin	Neurotransmitter
	Niacin	Vitamin
Tyrosine	Melanin	Pigment
	Catecholamines	Hormones
	Thyroxin	

Note: These functions are additional to the roles as constituents of proteins and as energy sources.

The early studies were on rats fed rations containing mixtures of the then-known amino acids in place of protein. The rats did not grow, despite the fact that the concentrations of amino acids were similar to those in milk protein (casein). They did grow, however, when a small amount of intact casein was added. This suggested the presence of an unknown substance in casein, which was later identified as threonine, the last of the essential amino acids in proteins to be recognized.

By the omission of amino acids one at a time, the 10 essential amino acids required by the rat were identified, and their daily needs could be estimated. Similar techniques were subsequently extended to humans, with the help of graduate students who not only isolated or synthesized the amino acids but also served as experimental subjects for nitrogen balance studies.

As human amino acid requirements became known, comparisons were made with the amino acid composition of foods and diets. Subsequently, the capacity of various proteins to meet human protein and amino acid requirements was compared and evaluated, and the results were called protein or amino

Table IV.C.3.11. *Fate of the nitrogen and the carbon atoms in the degradation of the amino acids for energy*

Amino acid	Nitrogen path	Carbon path
Aspartate	Used for argine or appears as NH_4 in purine nucleotide cycle	Fumarate formed from both pathways. Oxaloacetate can also be formed through transamination
Glutamate and precursors		
Glutamate	As ammonia (GDH) or as aspartate (AAT)	As alpha-ketoglutarate
Glutamine	Amide N as NH_4	As glutamate
Proline	As Glutamate	As glutamate
Arginine	Two appear in urea, one in glutamate	One appears in urea and five C in glutamate
Ornithine (if excess is produced)	Terminal N transferred to α-KG to give glutamate	Glutamate semi-aldehyde to glutamate
Pyruvate and precursors		
Alanine	In glutamate by transamination	As pyruvate
Serine	Direct to NH_4 by SDH	As pyruvate
Cysteine	In glutamate by transamination	As pyruvate (sulfur as sulfate)
Threonine	Direct to NH_4 by SDH	Succinyl CoA (a homologue of pyruvate) via propionyl CoA
Branched chain amino acids		
Leucine	In glutamate by transamination	As acetoacetate via 3-hydroxy-3-methylglutaryl CoA
Isoleucine	In glutamate by transamination	CoA (via propionyl CoA) and acetyl CoA
Valine	In glutamate by transamination	As succinyl CoA via propionyl CoA
Aromatic amino acids		
Phenylalanine	In glutamate by transamination	As acetoacetate and fumarate
Tyrosine (formed from phenylalanine by hydroxylase)	In glutamate by transamination	As acetoacetate and fumarate
Tryptophan	One N appears as alanine, one as NH_4	Three C appear as alanine, four as crotonyl CoA, and one as formate and three as CO_2
Other amino acids		
Lysine	Both Ns transferred to glutamate	Two appear as CO_2 and four as crotonyl CoA
Glycine	As NH_4	As CO_2 and pyruvate. Originate from two glycine via one-car-
bon		
		pathways
Histidine	One N and five C as glutamate, two N as NH_4	As glutamate and as methylidine-H_4 folate
Methionine	Released as NH_4 via homocysteine	Four carbons as succinyl CoA via cystathionine and propionyl CoA. Sulfur from homocysteine appears in cysteine

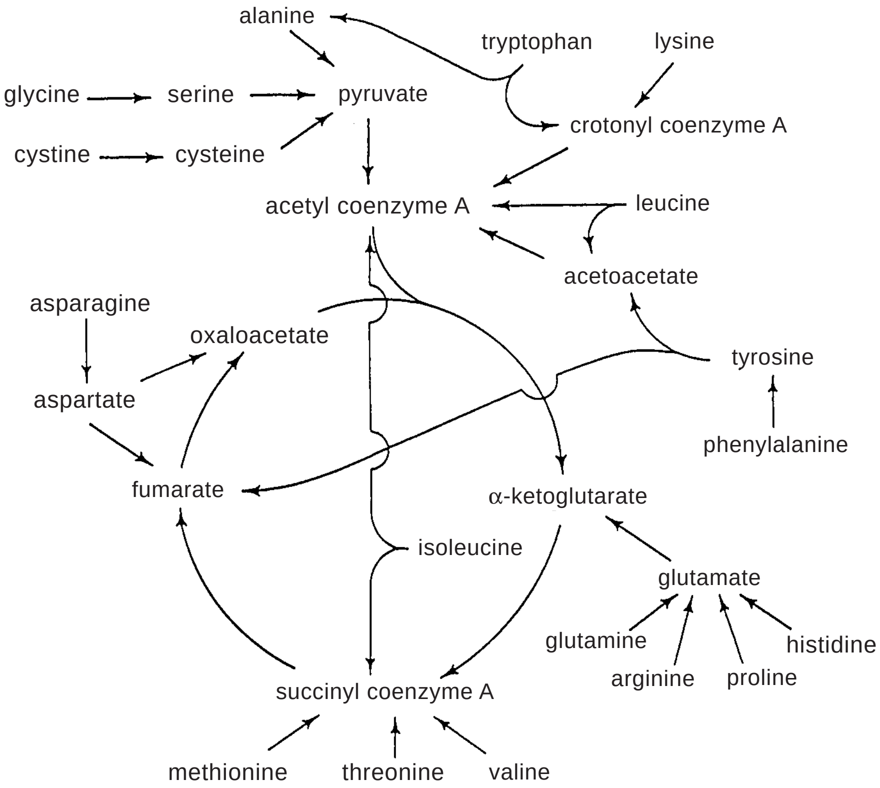
acid scores (Block and Mitchell 1946). The amino acid composition of egg protein was the first reference pattern proposed because it was known to be of high quality in animal-feeding studies. It did not, however, prove to be a suitable pattern, and many proteins scored poorly in relation to egg. This was because the levels of indispensable amino acids contained in egg were well above estimated human needs.

Direct comparison with human amino acid requirements soon followed as these data became available (FAO 1957; FAO/WHO 1973; FAO/WHO/UNU 1985; FAO/WHO 1991). The general expectation developed that not only should the score be able to predict the potential nutritional value of a food (or diet) for humans but that such a score should also correlate directly with the results of animal assays, such as net protein utilization (NPU). This did not always follow, and we now consider that the appropriate standard for dietary assessment for humans should be the human amino acid requirement pattern. Some amino acid scoring patterns recommended for protein evaluation purposes in recent years are shown in Table IV.C.3.12.

Protein Requirements

The earliest estimates of protein requirements, made by L. Playfair (1853), Voit (1881), and Atwater (1891), were derived from observations of protein consumption, whereas the later studies, including those of R. H. Chittenden (1904), Sherman (1920) and E. F. Terroine (1936) were based on a more physiological approach in that estimates were made of the minimum amount of protein required to support body nitrogen equilibrium.

Actual protein requirement data have been debated for many years; even as early as 1919, Osborne noted that the amount of protein that should be included in



alanine
tryptophan
lysine
glycine
serine
pyruvate
crotonyl coenzyme A
cystine
cysteine
acetyl coenzyme A
leucine
acetoacetate
asparagine
oxaloacetate
tyrosine
aspartate
phenylalanine
fumarate
α-ketoglutarate
isoleucine
glutamate
glutamine
histidine
arginine
proline
succinyl coenzyme A
methionine
threonine
valine

Figure IV.C.3.4. Metabolic pathways for the amino acids.

the human diet had long been a matter of debate among physiologists and nutrition experts, yet no agreement seemed to be in sight. Starting with a Health Committee of the League of Nations in 1936 and continuing to the present (IDECG 1996), estimates of human protein requirements and dietary protein allowances have been proposed by various national and international working groups. The major committees concerned with protein are shown in Table IV.C.3.13. These estimates, or "standards," have been the basis for food and agricultural policies and programs, and for the planning and evaluation of diets for groups of individuals. The strengths and weaknesses of such international committee efforts to establish protein requirements have been examined by N. S. Scrimshaw (1976), who recognized that the recommendations reached by a committee are often less rigorous than those that would be proposed by an individual.

Today, one might echo the sentiments Osborne penned in 1919, as each expert committee reports its findings. Nevertheless, agreement is now much closer, especially when we compare present recommendations (Table IV.C.3.14) with some of the high values for intakes and, hence, requirement recommendations proposed in the early 1900s (Table IV.C.3.6). These earlier data, especially those from the United States, are also remarkable for the very high levels of both fat and food energy recommended. In contrast, the recommendations from Chittenden (1907) are also shown in Table IV.C.3.6. Using himself as a subject, he consumed much lower levels of protein and maintained health. He did, however, eventually lose some weight. From his reported body weight his protein intake was 0.71 g/protein/kg/day, a little below the adult safe levels of 0.75 g/kg recommended by FAO/WHO/UNU (1985). In contrast, the Atwater (1891) recommendations for a man weighing 70 kg represented 1.6 g/kg/day.

Different committees have made different recommendations, sometimes based on the same original data (Irwin and Hegsted 1971). As an example, in a 1957 FAO report, the recommendations for adults were reduced significantly from the Sherman (1920) recommendations by applying different assumptions to the same data. These data extended back to the work of Atwater and others in the 1890s. At times, new recommendations have been generated based on data not available to earlier committees as, for example, with the young child data, originating from Guatemala, in a 1985 FAO/WHO/UNU report.

Revisions in the standards have had a profound effect on the interpretation of the possible protein nutritional status of a population. When, in the 1940s and 1950s, young child protein allowances were placed as high as 4.5 g/kg, a world protein problem was postulated. By revision of the protein requirement values downwards to about one-third of the previous allowances, total food energy rather than protein became the limiting factor, and the global "protein gap" disappeared at a stroke of a pen. These and other problems were discussed in scathing fashion by D. S. McLaren (1974) in an essay on "The Great Protein Fiasco." A more recent example that influenced international agricultural policy was the recommendation from the FAO/WHO/UNU (1985) group concerning adult needs for essential amino acids. The implications from the recommendations (subsequently replaced) were that EAA needs could be fully met in the adult by a cereal protein such as wheat, and that the consumption of complementary proteins was no longer necessary.

The requirement for dietary protein consists of two major components: (1) total nitrogen to serve the needs for synthesis of the nutritionally dispensable (nonessential) and conditionally indispensable amino acids, as well as for other physiologically important nitrogen-containing compounds, and (2) the nutritionally indispensable (essential) amino acids that cannot be made by human tissues and so must be supplied from the diet. The most recent recommendations by a UN committee (FAO/WHO/UNU 1985) for all age groups are shown in Table IV.C.3.15. Comparative recommendations by various groups for selected ages over a number of years have already been shown in Table IV.C.3.14.

Protein requirements can be estimated in several ways (Pellett 1990b). One is to measure all losses of nitrogenous compounds from the body when the diet is devoid of protein and then assume that sufficient nitrogen from high-quality dietary protein to replace these obligatory nitrogen losses will provide the adult human subjects with their requirements. For the child, the needs for growth must also be considered. This is called the factorial method because it is based on

Table IV.C.3.14. *Summary of some recent committee recommendations for practical protein allowances in various age groups*

		Committee					
Age group	League of Nations 1936	FAO 1957	U.K.[1] 1969	FAO/WHO 1973	NAS-NRC 1974	FAO/WHO/UNU 1985	IDECG 1996
	g protein per kg per day						
Infants (1–2 years)	3.50	1.65	1.20	1.20	1.35	1.20	0.97
Teenage (15 years, boys)	1.50	0.69	0.57	0.72	0.67	0.87	0.84
Adults (35 years, men)	1.00	0.53	0.46	0.57	0.60	0.75	0.53

League of Nations (1936) allowances are expressed in terms of mixed dietary protein. All other allowances are in terms of high-quality, highly digestible protein.

adding up a series of factors or fractions of total need, which represents maintenance requirements (obligatory nitrogen losses) as well as specific needs, such as those for growth in the child or milk production in the lactating female. The factorial approach as used by FAO/WHO (1973) is illustrated in Table IV.C.3.16. Enough protein to replace these losses and needs should meet requirements (Munro and Crim 1988).

A second procedure for estimating protein requirements is to determine directly the minimum amount of dietary protein needed to keep the subject in nitrogen equilibrium (balance). Ideally, the two methods should arrive at similar estimates of protein requirements. For infants and children, optimal growth, and not zero nitrogen balance, is the criterion used; similarly, the additional needs of pregnancy and lactation must be fulfilled. For the infant in the first months of life, however, human milk intake may be taken as equivalent to need. In an FAO/WHO/UNU (1985: 98) report, the basic assumption was that "protein needs of an infant will be met if the energy needs are met and the food contains protein in quantity and quality equivalent to breast milk."

The requirements for the nutritionally indispensable (essential) amino acids are currently a matter of considerable debate. This is largely because of the ^{13}C-tracer studies reported by Young, D. M. Bier, and Pellett at MIT in 1989. The term "pattern of requirements" means the amount of a specific amino acid required per unit of protein need. Some amino acid requirement patterns have been shown in Table IV.C.3.12. Such estimates have been criticized, in part because of the high food energy levels that were present in these diets (Young et al. 1989; FAO/WHO 1991) and have now been replaced by use of the FAO/WHO/UNU (1985) young child requirement pattern for all ages above infancy (FAO/WHO 1991).

Some average data on the amino acid composition of foods from the Massachusetts Nutrient Data Bank are shown in Table IV.C.3.17. Lysine is at a much lower concentration in cereals when compared with animal proteins. The sulfur-containing amino acids are distinctly lower in legumes and fruits, whereas threonine is lower in cereals and in fruits/vegetables. For the other indispensable amino acids, concentrations do not vary greatly, and these amino acids are also rarely in deficit in real diets. The nutritional significance of these data for humans is dependent on the choice of the reference amino acid requirement pattern used (Table IV.C.3.12). Clearly, if the FAO/WHO/UNU (1985) amino acid requirement pattern for the adult were to be used, it would indicate that no food protein, even from cereals, would show limitation and that complementation was no longer necessary to meet protein needs. Most cereal-based diets, however, would be lysine limited when compared to the FAO/WHO (1991) pattern. Because of these problems, use of the adult pattern from FAO/WHO/UNU (1985) has now been abandoned.

Table IV.C.3.16. *Factorial approach for human protein requirements: Adapted from FAO/WHO (1973)*

A. Estimate obligatory N losses (O_N): from the sum of urinary, fecal, skin, and miscellaneous losses. These data are obtained from measurements made when subjects are consuming nonprotein diets.

B. Estimate N requirements for growth (G_N), pregnancy (P_N), and lactation (L_N) from N content and amount of new tissue in growth, and in fetal and maternal tissues in pregnancy. For lactation, N content of milk is multiplied by average milk volume.

C. Thus minimum nitrogen requirement for growth = O_N + G_N. *Note:* G_N will be zero for an adult and will vary with age for a child.

D. Adjust for efficiency of N utilization: add 30% (not to be confused with protein quality; see G. below).
Requirement = $(O_N + G_N) \times 1.3$

E. Adjust for individual variability (an additional 30%)
Safe Practical Allowance (SPA) + $[(O_N + G_N) \times 1.3] \times 1.3$

F. Additional allowance for pregnancy (A_P) or lactation (A_L)
$A_P = (P_N \times 1.3) \times 1.3$ or $A_L = (L_N \times 1.3) \times 1.3$
Adjustments made both for efficiency of nitrogen utilization (+30%) and for individual variability (+30%).

G. Values for nitrogen as computed above are converted to protein (N × 6.25). These values are in terms of proteins of high quality, such as egg or milk proteins, and further adjustments are necessary to increase allowances when average protein quality value is less than 100%.
Thus:

$$\frac{\text{Recommended Protein Allowance}}{\text{(Adjusted for quality)}} = \frac{\text{SPA}}{\text{Protein Quality}}$$

Note: SDs are calculated from the observations recorded in the data bank but not all are truly independent variables.

Major differences exist between the lysine supply in developing and developed countries (Pellett 1996), as is illustrated in Table IV.C.3.18. Because of these differences, Young, Scrimshaw, and Pellett (1997) have speculated that in some regions of the world, lysine fortification of wheat flour may offer potential for overcoming limitations in protein quality in the available dietaries. Lysine fortification of cereal-based animal feeds is common practice.

Protein-Energy Ratios

Human nitrogen metabolism is highly sensitive to altered dietary intakes of both protein and energy caused by substrate availability, as well as by hormone mediation, which can influence the status of body nitrogen and energy metabolism. Other areas of concern relate to protein–energy malnutrition (PEM). Severe deficiencies of protein and/or food energy, especially in association with infections, can lead to PEM. However, imbalance between protein and energy levels, as for example with excess food energy together with low protein diets, can also produce metabolic abnormalities, such as the kwashiorkor form of PEM. The role of infection in the pathogenesis of PEM is mediated, at least in part, by hormonal changes, which can directly affect both protein and energy metabolism in previously well nourished individuals. The protein–energy ratio in formulas is of special importance in catch-up growth following infection (Dewey et al. 1996) and also for the needs of preterm infants (Tsang et al. 1993).

Body protein or nitrogen balance in the healthy mature human is maintained within relatively narrow limits, indicating a regulation that is achieved by varying the rate of N excretion in relation to changes in N intake and the individual's metabolic state. H. N. Munro (1951, 1964b), D. H. Calloway and H. Spector (1954) and Calloway (1975) have demonstrated that nitrogen balance is influenced by the intake of both protein and energy, even when that of energy is more than adequate; in consequence, estimates of protein requirements, based on nitrogen balance, can be affected by the level of energy available. Changes in

Calculated from food balance sheet data (FAOSTAT 1996).

food energy intake, below or above energy needs, affect nitrogen balance. The improvement in nitrogen balance caused by an increase in energy intake, however, can be attenuated if protein is inadequate; conversely, the beneficial effects of an increase in protein can be inhibited by an inadequate energy intake. Published nitrogen balance studies relating the influences of protein on energy and energy on protein requirements have been reevaluated by Pellett and Young (1992), who postulate that the effects on N balance are continuous when either protein or energy are increased and dispute the proposals of Munro and Calloway that the relationships exist as a series of plateaus. In summary, therefore, nitrogen balance must be seen as a result of both protein and energy intakes, and each must be defined before use can be made of the data for establishing protein requirements.

Metabolic Regulation of Food Intake

The initiation and termination of feeding are complex processes that involve a large number of signals to the central nervous system. In humans, cultural and social conventions are significant modifiers of the impact of metabolic and physiological signals. Historically, the focus of research on the regulation of energy intake has been motivated by observation on the physiological constancy of adult body weight and concern with deviations that occur in obesity and starvation. Maintenance of energy balance appears to be a primary goal of the mechanism controlling feeding behavior (Anderson 1988). Because metabolic energy is ultimately derived from the three macronutrients – carbohydrates, fat, and protein – each has been investigated for its role in control mechanisms (Mayer 1955). The presence of breakdown products in the gastrointestinal tract may directly or indirectly provide signals to the brain. Nutrients and hormones passing the liver result in changes in plasma concentrations, which, in turn, may signal the brain either directly or indirectly through a complex system of neurotransmitters. M. I. Friedman (1995) has proposed that eating behavior is triggered by a signal that is tied to ATP concentrations in the liver and is carried to the brain via afferents in the vagus nerve. The brain organizes the information arising from the metabolism of food and directs feeding so that the intake of energy and macronutrients is quantitatively regulated.

Problems of Excess and Deficit

Classification of body size by use of the Body Mass Index (BMI), a version of weight-for-height (W/H^2: weight in kg, height in meters), to assess for overweight and obesity has been in use since it was originally proposed by A. Quetelet in the latter part of the nineteenth century. More recently, it has been extended as a means of classifying undernutrition in adults (FAO 1994; James and Ralph 1994). Full agreement on the exact cut-off points to be used has not yet been reached, but a provisional classification that ranges from severe undernutrition to severe overnutrition is shown in Table IV.C.3.19.

Table IV.C.3.19. *A proposed classification using BMI (WT/HT^2)*

CED Grade III	<16.0
CED Grade II	16.0–16.9
CED Grade I	17.0–18.4
Normal	18.5–24.9
Overweight	25.0–29.9
Obese	30.0–40.0
Morbid obese	<40.0

Note: BMI (WT/HT^2) is defined using weight in kilograms and height in meters.

Source: Adapted from USDHHS (1988) and FAO (1994).

Obesity

That obesity could be a life-threatening condition was recognized by Hippocrates, who observed in one of his aphorisms that "[p]ersons who are naturally very fat are apt to die earlier than those who are slender" (Lusk 1933: 8). Because of the significant public health implications of obesity (see Pi-Sunyer 1988 and USDHHS 1988), much research activity has centered on its causation and prevention, but disagreements remain on most major issues. Nevertheless, it is generally agreed that obesity must represent the end result of a cumulative positive error in energy balance and, hence, a failure in whatever mechanism is supposed to maintain the situation. The nature of the mechanism is not agreed upon, although many hypotheses have been advanced. On one extreme is the view presented by L. S. P. Davidson and R. Passmore (1969), who wrote that "since the immediate causes of obesity are overeating and under-exercising the remedies are available to all, but many patients require much help in using them" (Garrow 1974: 4). Conversely, the opposite end of the spectrum is typified by E. B. Astwood, who suggested that "obesity is an inherited disorder and due to a genetically determined defect in an enzyme; in other words that people who are fat are born fat and nothing much can be done about it" (Garrow 1974: 4).

Malnutrition and Wasting

Associations between wasting, illness, and food were made early in the history of medicine but moved from being solely descriptive to the experimental with the studies of Lavoisier in the late 1700s. Release of heat from organic fuels metabolized in the living body was demonstrated to follow the same pattern of combustion as was observed in vitro. Loss of tissue mass during starvation was shown to involve oxidation of endogenous fuel stores in order to generate the energy required for life in sustaining metabolic activities. By the mid-nineteenth century there was a general consensus that the diet must contain a source of energy in order to maintain health, which was expanded later to the periodic, if not daily, need for some 40 essential nutrients. Health is characterized by a range of body compositions, tissue functions, and metabolic activities, and the fundamental aim of nutritional assessment is to gather information on these areas so as to compare with the healthy reference population (Heymsfield and Williams 1988). Such comparisons can allow for formal definitions of the undernourished.

Malnutrition and starvation are extreme conditions, and the terms were originally used in a rather synonymous sense. Lusk (1928) placed the study of starvation as fundamental to the study of nutrition and defined both terms:

> Nutrition may be defined as the sum of the processes concerned in the growth, maintenance, and repair of the living body as a whole or of its constituent organs. An intelligent basis for the understanding of these processes is best acquired by a study of the organism when it is living at the expense of materials stored within itself, as it does in starvation. Starvation or hunger is the deprivation of an organism of any or all the elements necessary to its nutrition. Thus when carbohydrates and fats only are eaten, protein hunger ensues. Complete starvation occurs when all the required elements are inadequate. (Lusk 1928: 75)

We no longer use "starvation" for the absence of a single nutrient, and the word now usually refers to a chronic, inadequate intake of dietary energy. Clinical starvation is, however, typically accompanied by multiple nutrient deficiencies. Quite divorced from the realities of the developing world, most scientific studies of starvation have used normal-weight or otherwise healthy subjects. Such investigations permit the clearest description of the metabolic response to starvation. One particular study (Keys, Brozek, Henschel et al. 1950), in which volunteer subjects, starting at normal weight, received about half of their normal intake over a 6-month period, is an acknowledged classic of physiological research. L. J. Hoffer (1988) noted that modern studies of starvation at the cellular level may not be directly applicable to the physiological situation. Whole-body studies thus remain essential but cannot always be ethically performed. Therefore, experimental data, including observations on "professional fasters" reported from the earlier years of the twentieth century (e.g. Lusk 1928), continue to be relevant.

How long a human can survive without food depends largely on the size of the individual's energy stores. Provided that water is supplied, there are many reliable records of healthy people who have survived 4 to 8 weeks with no food at all, and several of these were described by Lusk (1928). J. V. G. A. Durnin and Passmore (1967) have indicated that a healthy man or woman can fast completely for 2 weeks and suffer no permanent ill effects. Most well-nourished persons can afford to lose 25 percent of their body weight without danger to life. This is about the level achieved by the volunteers in the Keys study (1950). Very few have survived a loss of 50 percent of their body weight, although a dog recovered completely following weight reduction from 26.3 to 9.7 kg (Lusk 1928).

The essential features of the metabolic response to starvation are altered rates and patterns of fuel utilization and protein metabolism aimed at minimizing fuel needs and limiting lean tissue loss. The nature of the starvation diet determines the pattern of hormone levels and fuel consumption. In total fasting (and in other states of carbohydrate deprivation), fat oxidation dominates in a metabolic setting of low insulin levels and ketosis. Fuel utilization by the brain, kidney, and muscle is markedly altered in total fasting. The brain switches from exclusively glucose to predominantly ketone body oxidation. The fuel of resting muscle switches from predominantly fatty acids to ketone bodies, finally returning, after weeks of total fasting, to fatty acid oxidation again (Hoffer 1988). Other changes involve a rapid loss of labile body protein, followed by a prolonged period during which further protein losses are minimized in association with a slowed rate of synthesis and breakdown of body protein.

Unlike experimental starvation, the clinical diseases of protein–energy malnutrition are greatly influenced by associated environmental and health variables. Such conditions are commonly accompanied by many dietary deficiencies in addition to protein or energy, and the evolution of the syndrome is critically influenced by the effects of physiological stress. Severe undernutrition, now termed chronic energy deficiency (CED), is of major consequence worldwide and can be assessed by the use of Body Mass Index (see Table IV.C.3.19). Among the consequences to populations so affected are more sickness, lower work capacity and, hence, lower incomes, reduced social activity, and an increased risk of low-birth-weight (LBW) babies (FAO 1994; James and Ralph 1994).

Nutritional marasmus and kwashiorkor are considered to be the extreme forms of protein–energy malnutrition (PEM). The causes of PEM are complex and involve factors other than food insufficiency (Latham 1990). It is still unclear why some children develop nutritional marasmus, whereas others manifest features of kwashiorkor, including edema (Waterlow 1984). There is no doubt, however, that the major cause of nutritional marasmus is inadequate food intake, especially energy to meet the requirements for both metabolism and normal growth (Latham 1990).

Kwashiorkor was originally described and explained by Cicely Williams (1933) as a nutritional disease of childhood associated with a maize diet. Subsequently, protein deficiency in the presence of relatively adequate energy intake was identified as the main cause (Waterlow 1955). This hypothesis was supported by animal experiments in which kwashiorkor-like features were produced using a protein deficient diet with excess food energy. However, following publication of "The Great Protein Fiasco"

(McLaren 1974), it became widely accepted that energy deficiency was a much greater public health problem than was protein deficiency.

More recently, aflatoxin poisoning (Hendrickse 1984) was proposed as the cause of kwashiorkor; few, however, would agree that it is the sole cause, but it may be a contributing factor. The etiology of the disease remains under debate, but most scientists and physicians consider that although other factors play a role, kwashiorkor is usually due to a deficiency of protein relative to food energy (calories), with the disproportion exacerbated by infection. Even if the dietary intake itself is balanced, infection and infestation may cause anorexia, reduce food intake and nutrient absorption and utilization, or result in nutrient losses (Latham 1990). Kwashiorkor is not confined to children. Previously well-nourished adults have been found to develop the disease (termed famine edema) during food shortages (Latham 1990) or when food is withheld during a period of catabolic stress.

Peter L. Pellett

Notes

1. Atwater was such an important figure in the history of nutrition in the United States that it would be remiss not to expand on his role as the essential founder of the present-day, widespread, and important United States Department of Agriculture (USDA) nutrition activities. A Centennial Celebration Symposium was held in Washington in 1993 and is reported in a special issue of the *Journal of Nutrition* (Vol. 124, No. 9S). The abstract of the Centenary Lecture by Kenneth Carpenter (1994b) on the life and times of W. O. Atwater is quoted directly:

> Wilbur Atwater, the son of a Methodist minister, grew up in New England and was an undergraduate during the Civil War. He obtained his Ph.D. in agricultural chemistry at Yale in 1869, and spent the next two years in post-graduate study in Germany. In 1874 he was appointed to the Faculty of Wesleyan University, and was their first Professor of Chemistry. For two years (1875–77) he directed the first agricultural experiment station in the U.S. at Wesleyan. When it was transferred to Yale he gradually changed his interest to human nutrition, and how the poor could make more economical food choices, though he believed that they needed to maintain high-protein intakes if they were to remain productive. In 1887, with the passage of the Hatch Act, a second experiment station was established in Connecticut with Atwater as director. He also served for nearly 3 years as the first director of the Office of Experiment Stations in Washington, D.C. His next ambition was to have the first human calorimeter in the U.S. This was operating at Wesleyan by 1893, and his team was able to compare the net energy values of carbohydrates, fats and alcohol in sparing body tissues. He compiled data from many sources for the composition and digestibility of foods, and also organized the setting up of cooperative programs of nutritional studies, funded by the U.S. Department of Agriculture, in many States. His active life ended with a stroke in 1904 (Carpenter 1994b; 1707S)

IV.D
Deficiency Diseases

IV.D.1 ❧ Beriberi

The complex of clinical disturbances long known as beriberi has been recognized since early in the twentieth century as arising because of a deficiency of thiamine. Like others in the group of B vitamins, thiamine has essential coenzyme functions in intermediary metabolism. The principal role of this water-soluble molecule is that of precursor of thiamine pyrophosphate (thiamine diphosphate), a coenzyme (often referred to as cocarboxylase) in energy generation through oxidative decarboxylation of alpha-ketoacids, such as pyruvic acid and alpha-ketoglutaric acid. Thiamine pyrophosphate serves also as the coenzyme for transketolase, a catalyst in the pentose phosphate pathway of glucose metabolism. Measurement of transketolase activity in erythrocytes and stimulation of activity by added thiamine pyrophosphate is the most convenient and sensitive method for detecting human thiamine deficiency. As the pyrophosphate and/or the triphosphate, thiamine appears also to have a role in facilitating conduction in peripheral nerves.

Like most vitamins, thiamine cannot be synthesized in the body and must be acquired in the diet. It is found in many foods and is most abundant in grains, legumes, nuts, and yeast. All meats and most dairy products contain some thiamine, but the richest sources are pork and eggs. Milk, however, is not a rich source. As a water-soluble vitamin, thiamine is easily lost in cooking water. Fish can supply good amounts, but with fermentation of raw fish, the enzyme thiaminase may alter the thiamine molecule, blocking its biological activity. Dietary thiamine is actively absorbed, mainly in the small intestine. The recommended daily dietary allowance is 1.2 to 1.5 milligrams for adult males and 1.0 to 1.1 milligrams for adult females, depending upon age, with a 50 percent increase in requirements during pregnancy and lactation. Up to about 25 milligrams can be stored by a healthy person, especially in heart muscle, brain, liver, kidney, and skeletal muscle.

With a deficient diet, skeletal muscle soon begins to lose thiamine, followed by the liver, nervous system, and heart. Some intestinal bacteria are known to synthesize thiamine (Altschule 1978: 96), but this action probably contributes little, if at all, to human thiamine stores. Most thiamine excreted in urine is free, but some is also released as the pyrophosphate. Some thiamine may be lost in sweat, but the significance of this loss for workers in hot conditions remains to be clarified. Thiamine is low in toxicity, although very large doses may have some side effects. Large doses, however, are rapidly excreted, and so persistent toxic effects are rare.

The clinical consequences of advanced thiamine deficiency reflect, especially, the involvement of the cardiovascular system and the nervous system, both peripheral and central. The consequences of severe deficiency will certainly be disabling and may be fatal.

In the sections that follow, thiamine deficiency is first considered in the past, then in the present, with due attention to its distribution, to groups and populations at special risk, and to the range of clinical features. Cultural, socioeconomic, and behavioral factors, which influence risk, clinical responses, and outcomes, are noted. The final sections examine the history of research on etiology and of work leading to control and prevention.

Beriberi in the Past

Thiamine deficiency does not appear to leave behind any of the kinds of distinctive pathological evidence that permit paleopathologists to recognize diseases of the past. A comprehensive survey of pathological conditions in human skeletal remains (Ortner and Putschar 1985) includes no conditions assignable to deficiency of any of the B vitamins, and it seems unlikely that future studies of soft tissue remains will reveal any such evidence. Nevertheless, it is likely that thiamine deficiencies occurred in ancient populations, sporadically at least, even long before the beginnings of grain cultivation.

It has been shown that antithiamine factors occur in a variety of foods. Thermolabile thiaminases have been identified in the viscera of fresh fish, in shellfish, and in certain bacteria. Thermostable thiaminases exist in some animal tissues and in plants associated with caffeic and tannic acids (Paige 1988: 558). Some studies have shown an association of these factors with thiamine deficiency, and thus beriberi. S. L. Vimokesant and colleagues (1975), for example, have described thiamine deficiency in Thailand associated with the consumption of fermented raw fish, the chewing of fermented tea leaves, and the use of betel nuts. They suggest that the antithiamine activity of betel nuts and fermented tea may be induced by their high content of tannic acid. Ingestion of raw clams, which contain thiaminase, has also been shown to destroy thiamine in the human gastrointestinal tract. Some of these kinds of dietary preferences and practices have, no doubt, ancient origins in the human diet.

Early grain cultivation provided important new sources of dietary thiamine, and it is unlikely that simple milling procedures, even in rice-growing regions, led to severe thiamine deficiency, although diets based on rice stripped by steam milling and polishing of its thiamine-rich husks were later widely responsible for the disease. Ancient beriberi, as described in China, may more often have been due to thiaminase or other antithiamine activity than to the absence of the vitamin in the diet because of milling practices or dependence on thiamine-poor foods.

August Hirsch (1885: 572–3) records that beriberi, known as *kak-ke* ("disease of the legs"), can be traced back more than 2,000 years in China:

> Inquiries . . . have succeeded in proving that the word "kak-ke" occurs in a Chinese work dating from about 200 B.C., and that there is an unambiguous description of the disease in another work of some one hundred and thirty years later date. Other references to beriberi in China occur in writings of the third, seventh, and eighth centuries of the present era; and in a medicine book belonging to the end of the tenth century, there is already a distinction drawn between a "dry" or paralytic kak-ke and a "wet" or dropsical [one]. Of the disease in Japan the earliest record is in a medical treatise of the ninth century of our era. . . . For the East Indies the first notice of it occurs in the medico-topographical treatise of Bontius [De Medicina Indorum by Jacob Bontius (1592–1631), a Dutch physician], who was acquainted with the disease there in the seventeenth century under its colloquial name "beriberi."

B. C. P. Jansen (1956: 2) provides a slightly earlier Dutch record: "Already in the year 1611 the first Governor-General of the Dutch East India Company wrote that in the Dutch East Indies there was a disease named beriberi which caused paralysis in the hands and feet."

Beriberi is commonly recorded in dictionaries, encyclopedias, and other modern sources as a term derived from a word in Sinhala (Sinhalese), meaning weakness. Hugh M. Sinclair (1982), however, refers to Bontius's "excellent account of beriberi, the name meaning 'sheep,' since the partial paralysis of the disease caused patients to walk like sheep" – this, indeed, is the correct derivation of the word, as any comprehensive Malay–Indonesian dictionary will show. In Kamus Pelajar Federal (1973), for example, the Malay word *biri-biri* is assigned two meanings: (1) sheep, and (2) beri-beri (the disease). Hirsch (1885: 569), writing as early as the 1860s, casts doubt on alternative suggestions that the word beriberi derived from "Cingalese" or "Hindustani" words. Hirsch leaned toward a Malay origin, citing Bontius (who offered a mistaken transliteration of *biri-biri* – "bharyee" – a word said to mean "sheep"). Hirsch also noted another early Dutch author's suggestion that a Malay language word, "biribi" (obviously biri-biri, pronounced rapidly), meaning an "abrupt and tripping gait," was the origin of the term beriberi.

Thiamine deficiency remained an endemic problem until the second half of the nineteenth century. Although present in many parts of the world, beriberi usually appeared as a sporadic disease in individuals, groups, or populations at special risk because of "restricted," thiamine-poor diets. However, with the introduction of the steam-powered rice mill (about 1870), the disease became widespread and at times epidemic in some populations, especially in eastern and southeastern Asia. As a product of industrial and technological expansion, rice – commercially milled and relatively inexpensive – became generally available in a time of maritime competition and increasing establishment, in many societies, of prisons, asylums, military installations, and other institutions that offered only restricted diets.

In the closing decades of the nineteenth century in Japan, for example, beriberi (usually known as *kakke*) was present throughout the country, but was especially prevalent in military garrisons and on warships and naval training ships (Williams 1961). In Malaya, too, at the turn of the century, beriberi was widely distributed but especially conspicuous in closed institutions, such as jails and asylums for the mentally ill (Byron 1951).

It may be noted, however, that most populations in the Indian subcontinent, and Indian immigrant groups generally, remained almost free of beriberi during this period of technological, military, and institutional expansion – as they still do today. This is understandable because, throughout this region, rice has long been parboiled before milling. The unhusked rice, after preliminary soaking, is boiled in domestic vessels or steamed under pressure in the larger mills. The B vitamins are fixed in the grain so that they are not removed with the bran, and remain behind in the milled rice. The parboiling process has long been preferred because the woody outer husk is split, rendering its removal easier during milling (Davidson and Passmore 1966: 261). Beriberi has been endemic in only one Indian state, along the coast of Andhra Pradesh north from above Madras to Vishakhapatnam, and this, according to Sir Stanley Davidson and R. Passmore (1966: 412), is the only area in India where raw-milled rice is the principal cereal.

The vast literature on beriberi reflects its profound impact on morbidity and mortality during the late nineteenth and early twentieth centuries. But this literature also reveals the confusion that existed about the disease, its identity, its causation, and its clinical effects. Beriberi had acquired many other names – regional, local, and culturally specific – in previous centuries, but cosmopolitan medical practitioners and researchers added a considerable variety of their own terms (for example, endemic multiple neuritis, panneuritis epidemica, polyneuritis endemica, ship beriberi, infantile beriberi). These reflected the notion that beriberi might be several quite different diseases, an idea created by the diverse clinical effects of thiamine deficiency and by the common occurrence of several or multiple nutritional deficiencies in the same thiamine-deficient patient.

Beriberi Today

Thiamine deficiency disease persists in the modern world, but its epidemiology is very different from that of a century ago. Epidemic classical beriberi is rarely seen today. Although signs and symptoms of famine-related thiamine deficiency occur all too often, they are likely to be accompanied by clinical evidence of multiple deficiencies of vitamins and other nutrients. War, disaster, and drought-induced famines will continue into the future as contributors to deficiencies of thiamine, but beriberi as a distinct clinical entity will probably seldom occur in those circumstances.

As an endemic disease, however, beriberi has not disappeared. Some beriberi still occurs where rice is the staple cereal, polished rice is preferred, parboiling is not practiced, and few other sources of thiamine exist in the diet. In other areas, where rice is not the staple, beriberi may occur occasionally when refined carbohydrate foods are dominant in the diet. Davidson and Passmore (1966: 412), for example, mention the common occurrence of beriberi early in this century in the fishing communities of Newfoundland and Labrador. Often cut off during the long winter from outside provisions, people in these areas depended upon winter stores consisting mainly of flour made from highly milled wheat. Beriberi probably continues to appear today in similar circumstances of prolonged and extreme isolation.

In some countries, beriberi is so intimately associated with culturally maintained dietary preferences and practices that it is likely to persist well into the future. In northern Thailand, as noted, consumption of fermented raw fish has been reported to be an important cause of beriberi. Vimokesant and colleagues (1975) also concluded that antithiamine activity of fermented tea and betel nuts must contribute to persistent thiamine deficiency in that region. However, to what extent these effects may result from destruction of thiamine, or from loose binding and partial blocking of activity, remains unclear. Further evaluation of these findings is warranted because of the wide use of these substances not only in Thailand but elsewhere in Asia. If the extensive use of betel nut in some regions of India interferes with thiamine activity or retention, it appears, nevertheless, that the thiamine-preserving effect of rice parboiling can maintain a sufficient thiamine balance to minimize the appearance of signs and symptoms of deficiency. This too is, however, a topic in need of further study, particularly in relation to the occurrence and significance of subclinical or borderline thiamine deficiency.

In addition to the problem of endemic beriberi, thiamine deficiency occurs sporadically in many countries, especially as a result of chronic alcoholism, but also in association with some chronic illnesses and with long-term parenteral nutrition (Altschule 1978: 98). As Richard S. Rivlin (1988) reports, thiamine absorption is exquisitely sensitive to ingested ethanol, which can significantly interfere with absorption. Alcoholics may fail to absorb most of their dietary thiamine – thiamine which is likely to be limited, in any case, as the diet is increasingly impaired and restricted. Rivlin notes that about 25 percent of alcoholics admitted to general hospitals in the United States have evidence of thiamine deficiency by either clinical or biochemical criteria. He cites evidence as well that alcohol can adversely affect the intermediary metabolism of thiamine, and that chronic liver disease, resulting from alcoholism, may impair the conversion of thiamine to thiamine pyrophosphate.

Clinical Features

The clinical distinction between wet and dry forms of beriberi can be traced back at least to the ninth century in Japan (Henschen 1966: 170) and to the tenth century in China (Hirsch 1885). The wet–dry differentiation has continued to appear in clinical classifications of thiamine deficiency disorders to the present day, with infantile beriberi accorded separate status in most breakdowns. Some have chosen to describe the disease in terms of three clinical clusters characterized by edema, nervous system signs and symptoms, and symptoms of disorder in the cardiovascular system (Meade 1993). Sinclair (1982) offers the classification adopted here. He sees severe thiamine deficiency giving rise to the following forms of beriberi:

1. Acute beriberi – including acute cardiac beriberi and infantile beriberi, along with Wernicke's encephalopathy (as the acute or subacute component of the Wernicke-Korsakoff syndrome).
2. Chronic beriberi – including dry beriberi, wet beriberi, and chronic beriberi heart (and here

Korsakoff's psychosis may be added as the other, more chronic component of the Wernicke-Korsakoff syndrome).

Acute Cardiac Beriberi

The picture of acute cardiac beriberi is that of congestive failure and cardiac overactivity manifested by dyspnea, orthopnea, precordial pain, palpitations, tachycardia, and edema. In its most fulminant form it has been known in East Asia as *Shoshin* beriberi. These acute forms of cardiac beriberi, uncommon today, were well known to clinicians in Asia a century ago; many patients died of heart failure. With intravenous thiamine, acute cardiac beriberi can readily be treated, with dramatic results.

Infantile beriberi, a condition in infants who are breast-fed by thiamine-deficient mothers, is, as Sinclair (1982) notes, very similar to acute cardiac beriberi in adults. Once common in eastern Asia, the condition usually occurs very early in life, with sudden onset and rapid progression to death. The anorexic, restless infant shows signs of developing cardiac failure, including tachycardia, dyspnea, edema, and aphonia, responsible for a characteristic grunt (the beriberi cry). Although less often recognized today, infantile beriberi, like cardiac beriberi in the adult, will respond well to intravenous or intramuscular thiamine. Improvement of the nursing mother's thiamine nutrition is also essential.

Wernicke's Encephalopathy

First described by Carl Wernicke in 1881, Wernicke's encephalopathy is an acute or subacute cerebral form of beriberi, only recognized as a consequence of thiamine deficiency during and just after World War II, in prisoner-of-war camps. Today it is a disorder associated principally with chronic alcoholism. The pathological changes are characteristically localized, involving the optic nerve, the gray matter around the third and fourth ventricles, and the aqueduct of Sylvius. Clinical features include nystagmus, diplopia, ophthalmoplegia, anorexia, vomiting, insomnia, mental apathy and disorientation, hallucinations, and variable loss of memory. Ataxia appears occasionally. In many cases, signs of peripheral neuropathy are also evident. The condition responds well to treatment with thiamine injections.

Dry Beriberi

In this once common clinical variety of beriberi, it is primarily the peripheral nervous system that is disordered. Dry beriberi is an ascending symmetrical bilateral peripheral neuritis. Early in the course, the complaints may be vague, beginning with stiffness, leg cramps, and numbness in the feet and ankles. Knee and ankle reflexes are first increased, then diminished, and finally lost as the disease advances. Muscle weakness spreads upward in the lower extremities. Affected muscles become tender, painful, numb, and eventually atrophic, sometimes with hyperextension of the knee joints. Ataxia follows, with a characteristic gait (which led to the coining of the name "beriberi," meaning sheep). Hands and arms may also be affected, but not usually until signs and symptoms in the legs are pronounced. Thiamine therapy will arrest the progression and relieve the patient of most symptoms, but all of the damage in advanced disease may not be fully reversible.

Wet Beriberi

This chronic form of beriberi is primarily an edematous condition accompanied, in varying degree, by signs and symptoms of cardiac malfunction. Renal function generally remains intact. Early in the course, edema usually begins in the feet and legs, then extends upwards to the abdomen (producing ascites), thorax, pericardium, and face. Muscle wasting, if present, may be masked by edema. With pulmonary congestion, the chambers of the right heart dilate and the heart begins to fail. Anorexia is invariable, vomiting and diarrhea may occur, and thus the body begins to starve. The patient with wet beriberi is always at risk of a sudden increase in edema, circulatory failure, severe dyspnea, and death.

Chronic Beriberi Heart

Cardiac damage can occur as a result of thiamine deficiency without other signs and symptoms of beriberi. This chronic condition, now referred to as "beriberi heart," is most often associated with chronic alcoholism and/or a history of marked nutritional deficiency. When these causal factors are present, the diagnosis can be suspected when unexplained tachycardia, palpitations, venous congestion, characteristic electrocardiographic changes, and right heart enlargement are noted. Edema may also appear, but not with the same prominence as in cases of wet beriberi.

Causal Research

As beriberi extended its geographical range, incidence, and prevalence in the second half of the nineteenth century, it attracted increasing attention from medical investigators, who began the long process of causal research that extended into the first decades of the twentieth century. Hirsch, in his great *Handbook of Geographical and Historical Pathology,* first published between 1860 and 1864, gave many pages to a description of the disease and to a review and analysis of etiologic possibilities. He found it necessary to discard as principal causes climate, soil, lifestyle, and occupation, among other factors. He could only conclude that beriberi must arise as a result of some intoxication, that is, exposure to a poison. Later the idea emerged that beriberi might appear because of infection, and, until late in the century, theorizing was directed principally to these two causal possibilities.

The search for an infectious agent or a chemical poison, probably in food, continued throughout the remainder of the nineteenth century, but no one interested in beriberi and diet in this period considered the possibility of a deficiency of some specific substance (Williams 1961: 16). Two naval officers (the Dutch naval doctor, F. S. van Leent, and the chief of the Japanese naval medical service, K. Takaki) were successful in reducing the incidence of beriberi on shipboard by broadening diets previously limited largely to rice (Jansen 1956; Williams 1961). These achievements, pointing clearly to some dietary factor in beriberi, were not widely known or acknowledged at the time.

The first step toward the recognition of the role of thiamine deficiency in beriberi came in 1890 with the publication of a report by Christiaan Eijkman, a Dutch military surgeon in Java, of his studies of polyneuritis in domestic fowl. His experiments were initiated to uncover a presumed infectious cause of the disease by inoculating laboratory chickens with supposedly infectious material from beriberi patients. These birds, fed on crude rice, remained healthy, but when they were later switched to a diet of boiled and polished white rice, left over from the hospital, they began to show signs of polyneuritis not unlike that in human beriberi.

Still later, the chickens were returned to a crude rice diet, after the hospital chief forbade the use of the polished luxury rice for laboratory animals. The neuritis soon disappeared. Intrigued by this change, Eijkman fed two groups of fowl, one with crude rice, the other with polished rice. The latter group developed the same beriberi-like neuritis. The result of this simple experiment was decisive, not only in the history of beriberi but also as the beginning of the much wider field of research on vitamins and specific nutritional deficiencies. Eijkman expanded his investigations in Java until 1896, when he returned to Holland, eventually to a professorial appointment and to the award in 1929 (one year before his death) of a Nobel Prize in Physiology and Medicine, "for his discovery of the antineuritic vitamin."

Eijkman's experimental work with fowl in Java was continued by another Dutch scientist, Gerrit Grijns, who soon became the first to express the theory "that in food there occur in small quantities unknown organic substances essential for health" (Jansen 1956). Grijns called them protective substances. He was able to extract such a substance, soluble in water, from rice bran and to employ it in the treatment of human beriberi. Later Casimir Funk coined the name "vitamine" (later shortened to "vitamin") for a protective substance, an amine that he had isolated and assumed (wrongly as it turned out) to be the same as that studied by Eijkman and Grijns (Byron 1951; Jansen 1956).

The studies in Java were confirmed and extended in Malaya early in the new century (Byron 1951). W. L. Braddon, who published much evidence to show that the cause of beriberi was connected intimately with the consumption of polished white rice, could only explain his findings as due to a poison in the rice. His work provided a foundation for three scientists, H. Fraser, A. T. Stanton, and W. Fletcher, at the Institute for Medical Research in Kuala Lumpur. During the decade following 1905, in their studies of road workers (and in Fletcher's study of patients at an asylum), these investigators further demonstrated the significance of rice polishing in the causation of beriberi. Fraser and Stanton also failed in all attempts to isolate a poison from rice, and they concluded, as Grijns had earlier, that the answer to the problem of beriberi must lie in a nutritional defect, that is, in the absence of an essential protective substance. Fraser and Stanton were never able to isolate the substance, but their studies led them to call for, and advocate, practical measures to cure and prevent beriberi – measures that were to prove very successful. After 1911, the use of polished white rice was prohibited in all Malayan government institutions, the danger of polished rice consumption was widely publicized, and government rice mills began to produce undermilled rice for use in hospitals and public institutions, including prisons and asylums. These actions served to lower dramatically the incidence of beriberi in Malaya within just a few years.

After 1910, as the results of the Malayan studies and preventive actions became known, E. B. Vedder and others in the Philippines started similar programs for the prevention and treatment of the disease. Vedder also encouraged Robert Williams, a scientist at the Bureau of Science in Manila, to begin studies that were to lead, in 1933, to the isolation and final chemical characterization of the protective substance. Some years earlier, in Java, Jansen and W. F. Donath had succeeded in isolating crystals of the antiberiberi factor, but their chemical analysis, limited by the apparatus then at hand, was incomplete, missing the presence of sulfur in the molecule (Jansen 1956). After the final synthesis, in 1936, Williams named the chemical "thiamin." The spelling was later changed to thiamine, but Williams's original spelling is still often used.

Prevention

Southeast and East Asian countries pioneered in developing strategies for the prevention of beriberi. As we have seen, prevention of shipboard beriberi through dietary change was initiated by Japanese and Dutch naval medical officers late in the nineteenth century, long before the recognition of thiamine's role. The section "Causal Research" also took note of the development, early in the twentieth century, of countrywide preventive programs and policies, begun in Malaya and the Philippines many years before thiamine was isolated, characterized, and synthesized.

These programs stressed changes in rice milling to preserve bran, together with public education about the risks associated with dependence upon a diet based on polished white rice.

After 1936 the pace quickened as production of inexpensive synthetic thiamine made food enrichment possible. By 1941 the first standards for the enrichment of bread were established in the United States, and enrichment requirements soon followed, during World War II. Enrichment of whole-grain rice presented more problems than flour enrichment for bread, but even these difficulties were overcome so that today thiamine enrichment is available in rice-based diets, as well as in those for which bread is a staple.

For people throughout the world who consume many other kinds of processed foods, including corn and macaroni products, thiamine is also commonly available, as it is in many varieties of vitamin preparations. In the United States today, many individuals are consuming vitamins, often including thiamine, far in excess of the recommended dietary allowances, and it is estimated that one-third of individuals 65 years of age and older in this country are taking some kind of nutritional supplement (Rivlin 1988).

Williams concluded his 1961 book, *Toward the Conquest of Beriberi,* with a chapter on the prospects for eradication of the disease, as advocated by a joint United Nations committee (World Health Organization 1958). This committee, meeting under the sponsorship of the Food and Agriculture Organization and the World Health Organization, recommended six preventive measures that, taken together, could be expected largely to eliminate, if not actually eradicate, beriberi in countries where rice is a staple food:

1. General improvement of the diet to increase its thiamine content.
2. Encouragement of the use of undermilled rice.
3. Encouragement of the use of parboiled rice.
4. Promotion of methods of preparing and cooking rice to preserve its thiamine content to the greatest extent possible.
5. Enrichment of rice.
6. Increased use of synthetic thiamine in various ways other than rice enrichment.

Each of these measures continues today to have its role in beriberi prevention. It should be noted, however, that the committee was not aware, in the 1950s, of the possible extent of the problem of interference with thiamine activity and availability through the actions of thiaminase and other antithiamine agents. Even now this problem remains largely undefined, although in some countries, certainly in northern Thailand and, probably, in areas of Myanmar (Burma), dietary preferences, especially for fermented raw fish, are considered to be the most important causes of endemic beriberi.

Sporadic and subclinical or marginal thiamine deficiency persists today and will continue to do so. Eradication of this deficiency is not in prospect, but neither is recurrent epidemic beriberi.

IV.D.2 Iron Deficiency and Anemia of Chronic Disease

Until the nineteenth century, unspecified chronic anemia was known as chlorosis, or the "green sickness," referring to the extreme pallor that characterized severe cases. For centuries, "chlorosis, or green sickness, was attributed to unrequited passion. Medieval Dutch painters portrayed the pale olive complexion of chlorosis in portraits of young women" (Farley and Foland 1990: 89). Although such extreme cases are not common in Western societies today, less severe acquired anemia is quite common. In fact, acquired anemia is one of the most prevalent health conditions in modern populations.

Technically, anemia is defined as a subnormal number of red blood cells per cubic millimeter (cu mm), subnormal amount of hemoglobin in 100 milliliter (ml) of blood, or subnormal volume of packed red blood cells per 100 ml of blood, although other indices are usually also used. Rather than imputing anemia to unrequited love, modern medicine generally imputes it to poor diets that fail to replenish iron loss resulting from rapid growth during childhood, from menstruation, from pregnancy, from injury, or from hemolysis. One of today's solutions to the frequency of acquired anemia is to increase dietary intake of iron. This is accomplished by indiscriminate and massive iron fortification of many cereal products, as well as the use of prescription and nonprescription iron supplements, often incorporated in vitamin pills. However, a nutritional etiology of anemia as dietary has, in the past, been assumed more often than proven. Determining such an etiology is complicated by the fact that the hematological presentation of dietary-induced iron deficiency anemia resembles the anemia of chronic disease. Of the many types and causes of acquired anemia, only those associated with diet and chronic disease are discussed here (for an overview of others, see Kent and Stuart-Macadam this volume).

Anemia Due to Diet or Chronic Disease?

Although causes differ, patients with either iron-deficiency anemia or the anemia of chronic disease/inflammation have subnormal circulating iron levels called hypoferremia. Below-normal levels of circulating iron are manifested in low hemoglobin/hematocrit, serum iron, and transferrin saturation levels. Because serum ferritin is an indirect measure of iron stores, it provides a sensitive index to distinguish these two anemias (Cook and Skikne 1982; Zanella et al. 1989). When the body does not have enough iron as a result of diet, bleeding, or other causes, serum ferritin values are subnormal and reflect the subnormal amount of iron in the bone marrow. In the anemia of chronic disease/inflammation, however, serum ferritin levels are normal to elevated because circulating iron is transferred to storage, as reflected by the combination of subnormal circulating iron levels with normal or elevated serum ferritin values.

Removing iron from circulation reduces its availability to pathogens that require it for proliferation (Weinberg 1974, 1984, 1990, 1992). When compared with bone marrow aspirations, serum ferritin values correctly detected iron deficiency in 90 percent of patients; serum iron in 41 percent; total iron binding capacity in 84 percent; and transferrin saturation in 50 percent (Burns et al. 1990). Erythrocyte sedimentation rate (ESR) is a nonspecific measure of the presence of infection or inflammation. If used in combination with serum ferritin, ESR can be useful in distinguishing anemia of chronic disease from iron deficiency anemia (Beganovic 1987; Charache et al. 1987; Witte et al. 1988).

Although diet is most often attributed as the cause of iron-deficiency anemia, in the absence of blood loss or parasites, even the most frugal diets rarely result in iron-deficiency anemia. According to C. K. Arthur and J. P. Isbister (1987: 173), "iron deficiency is almost never due to dietary deficiency in an adult in our community [i.e., Western society]." The average person requires very little iron intake to replace that lost through perspiration, menstruation, and urination because as much as 90 percent of the iron needed for the formation of new blood cells is derived from recycling senescent red blood cells (Hoffbrand 1981). In addition, individuals suffering from iron deficiency absorb significantly more iron from the same diet and excrete significantly less iron than nondeficient individuals. In other words, "the intestine can adjust its avidity to match the body's requirement" (O'Neil-Cutting and Crosby 1987: 491). Nonetheless, it has been estimated that approximately 30 percent of a world population of nearly 4.5 billion are anemic, with at least half of this 30 percent (500 to 600 million people) thought to have iron-deficiency anemia (Cook and Lynch 1986). Even in affluent Western societies, 20 percent of menstruating females have been reported to be iron deficient (Arthur and Isbister 1987: 172). Recent surveys in the United States, however, indicate that these figures are much too high (Cook et al. 1986).

Elsewhere, researchers have discovered, to their surprise, that diet is not always responsible for the acknowledged high morbidity of a particular region. According to P. Aaby (1988: 290–1), "We started out by assuming that malnutrition was the major determinant of high child mortality and that changing this pattern would have a beneficial effect on mortality. Much to our distress, we found very little evidence that nutritional status [as measured by the presence of anemia] was strongly related to the variation in nutritional practices."

Failure to distinguish anemia etiology correctly can be seen in several studies. For example, Arthur and Isbister report that "of 29 patients 'diagnosed' as having iron deficiency anaemia, only 11 patients in fact had true iron deficiency when reviewed by the authors. Most patients had the anaemia of chronic disease that was misdiagnosed as iron deficiency. There is a strong clinical impression amongst hematologists that this problem of misdiagnosis is not unique to hospital based specialists but also applies more widely" (Arthur and Isbister 1987: 172). Almost 50 percent of infants diagnosed as iron deficient were found to have occult gastrointestinal blood loss without anatomic lesions, which was the source of their anemia (Fairbanks and Beutler 1988: 208). Although the following discussions are hampered somewhat by the fact that not all studies include serum ferritin tests needed to distinguish dietary iron-deficiency anemia from the anemia of chronic disease, an attempt is made to differentiate when possible and to indicate when this is not possible.

Diet and Iron-Deficiency Anemia

When iron-deficiency anemia is caused by severely deficient diets, it appears to be a straightforward problem: Not enough iron is ingested to replace losses. In reality, many cases of iron-deficiency anemia involve unidentified blood loss that causes, accentuates, and/or perpetuates dietary-induced iron-deficiency anemia. (Note that throughout this paper, we are specifically discussing iron and diet, not protein, vitamins, and other nutrients that are also integral parts of a diet).

Anemia is rarely caused by diet alone. This is partly because healthy humans lose only 1 to 3 milligrams (mg) iron per day and partly because almost all food and, in many areas, drinking water contain some iron. Women in a Swedish study lost between 0.6 and 0.7 mg of iron through menstruation and 95 percent lost on average *less* than 1.4 mg per day (Fairbanks and Beutler 1988: 205).

Most individuals are able to replenish these losses with a normal diet. For example, Westerners ingest meat almost daily and consume additional iron in fortified foods (such as that contained in many wheat products). Wine and cider can provide 2 to 16 mg or more iron per liter (Fairbanks and Beutler 1988). Moreover, depending on the quantity of the body's iron stores, between 15 and 35 percent of heme iron, which is found in red meat, poultry, and fish, and between 2 and 20 percent of nonheme iron in plants is absorbed (Monsen 1988: 787). Higher amounts of nonheme iron in vegetables are absorbed when consumed with heme iron in meat or in combination with iron absorption enhancers, such as ascorbic acid (Hallberg, Brune, and Rossander 1989). Several studies of the amount of iron ingested by North Americans indicate that normal individuals who are not suffering from unnatural blood loss consume sufficient iron to prevent deficiency. For example, a study of 51 women found that those who consumed only poultry or fish or who were vegetarians had a mean iron intake of 12 mg, whereas those who regularly ate red meat had a mean iron intake of 13 mg (Monsen 1988: 789). The mean iron intake of 162 women in another study was 11.1 mg (Subar and Bowering 1988). Female long-distance runners ingested between 11.5 mg and 14 mg per day (Manore et al. 1989).

Blood loss and true iron deficiency also result in increased iron absorption. Research shows that iron-replete men with sufficient iron stores absorb 2.5 percent of nonheme iron ingested, as compared to 26 percent of the heme iron consumed (Cook 1990). These percentages can be contrasted with iron-deficient males who absorb 22 percent more nonheme iron than normal males and 47 percent more heme iron (Cook 1990: 304). The same flexibility applies to iron loss. Normal males lose about 0.9 mg of iron per day. In contrast, hypoferremic males lose only about 0.5 mg per day, and hyperferremic males lose about 2.0 mg per day (Finch 1989).

Although 82 percent of women studied in New York State recorded an average consumption of only 75 percent of the United States Recommended Dietary Allowance (RDA) of iron, the amount ingested was a mean of 11.1 mg, which exceeds the amount of iron loss through normal physiological processes (Subar and Bowering 1988; also see Brennan et al. 1983 for similar conclusions based on a study of low-income pregnant women). Thus, if we arbitrarily assume an absorption rate of 18 percent of all iron consumed, the mean iron available is well above the 1.4 mg required by menstruating women. This suggests that previously recommended replacement needs of average menstruating women may have been set too high. More scientists today recommend that average menstruating women need to absorb only 1.4 mg iron daily to replace losses (Monsen 1988: 786). In fact, the RDA is higher than the average iron loss for all groups. As a result, many people take in less than the RDA levels of iron without suffering dietary iron deficiency.

Albeit rare, severely iron-deficient diets do exist, though not necessarily because of low iron intake. Adult East Indian vegetarians ingest large quantities of iron, as much as 30 mg per day (Bindra and Gibson 1986). At the same time, they consume such large amounts of inhibitory substances that some suffer from iron-deficiency anemia (Bindra and Gibson 1986). These items include tannin (especially from tea); dietary fiber; coffee; calcium phosphate; soy protein; and phytates in bran and nuts, such as walnuts, almonds, peanuts, hazelnuts, and Brazil nuts (Macfarlane et al. 1988; Monsen 1988; Muñoz et al. 1988). The larger the amount of phytate consumed, the less iron is absorbed (Hallberg, Brune, and Rossander 1989). What appears to occur is that although the diet contains sufficient iron for replacement of normal physiological losses, inhibitory factors limit the absorption of that iron.

In addition to malabsorption of iron, moderate-to-heavy consumption of fish has been associated with a significantly increased bleeding time test in both males and females (Herold and Kinsella 1986; Houwelingen et al. 1987; Sullivan 1989). The prolonged bleeding time presumably results in significantly more blood loss and lower iron stores. This may explain why young women who habitually eat fish as their major source of protein have levels of serum ferritin and anemia similar to those of strict vegetarians who consume iron inhibitory substances (Worthington-Roberts, Breskin, and Monsen 1988). Here again, we see that the amount of iron ingested is not directly related to levels of anemia. Occult blood loss and iron absorption are more important as relevant factors fostering iron-deficiency anemia than is the actual amount of dietary iron ingested.

Illness and the Anemia of Chronic Disease

The anemia of chronic disease/inflammation has the same hematological presentation as dietary iron deficiency anemia, with the exception of normal to elevated serum ferritin levels. As stated earlier, both normal-to-elevated serum ferritin (reflecting adequate or above-normal iron stores) and elevated ESR indicate the presence of infection and/or the inflammatory process. In fact, such conditions, created by the body's generalized nonspecific defense against invading pathogens or neoplasia (cancer), reduce the availability of circulating iron. This denies to many bacteria, parasites, and neoplastic cells the iron they need to proliferate. These hematological changes are caused by the production of interleukin-1, interleukin-6, and tumor necrosis factor alpha (Weinberg 1992).

There is abundant research to support the conclusion that anemia is one of the body's defenses against disease (fever and the manufacture of various cytokines are other defenses [Kent, Weinberg and Stuart-Macadam 1994]). A broad spectrum of illnesses is associated with the anemia of chronic disease (Cash and Sears 1989). The role of iron in enhancing infections and anemia as a defense have been detailed in a number of publications by Eugene Weinberg (1974, 1984, 1986, 1990, 1992). Most bacteria and parasites require iron but cannot store it. They survive and thrive by extracting needed iron from their host. As a consequence, increased available iron can be detrimental to health, as can be seen in modern populations receiving iron supplements or consuming large amounts of dietary iron. For example, the incidence of serious bacterial infections increased significantly when infants were given intramuscular iron-dextran (Barry and Reeve 1977: 376):[1] "When the iron administration was stopped the incidence of disease in Polynesians decreased from 17 per 1,000 to 2.7 per 1,000 total births." Other research substantiated the association between an increased incidence of bacterial infections, such as *Escherichia coli* sepsis, and the administration of intramuscular iron-dextran in neonates (Becroft, Dix, and Farmer 1977).

A number of health problems are connected with increased iron intake. In New Guinea, infants with respiratory infections given iron-dextran had longer hospital stays and higher morbidity than those not given iron supplements (Oppenheimer et al. 1986a). Malarial infection was greatly increased in infants with higher transferrin saturation levels, leading the investigators to conclude that hypoferremia has a protective role against malaria (Oppenheimer et al. 1986b). Furthermore, in a study of 110 patients in Africa, those with anemia had fewer malarial attacks than those with higher iron levels (Masawe, Muindi, and Swai 1974). Anemic patients who did not exhibit signs of malaria developed malaria *after* iron therapy was initiated. In contrast to nonanemic Turkana from Kenya, mildly anemic Turkana who consume little meat, poultry, or other heme iron have a lower incidence of infectious diseases, including such various infections as malaria, brucellosis, and amebiasis (Murray, Murray, and Murray 1980a). Among the Maasai, anemic individuals had a significantly lower incidence of amebic dysentery. Examination of the cow's milk consumed by Maasai "showed that it not only had a concentration of iron below the minimum necessary for the growth of *E. histolytica* [an amoeba] but also contained partly saturated lactoferrin and transferrin, which may actively compete with the parasite in the colon for ambient iron" (Murray, Murray, and Murray 1980b: 1351).

When associated with malaria and other infections, serum ferritin levels are generally increased in anemic children (Adelekan and Thurnham 1990). This indicates that iron stores are present in these children, despite the lowered serum iron, transferrin saturation, and hemoglobin levels, all of which suggests strongly that the anemia is not the result of dietary inadequacies. The body removes circulating iron to storage in an attempt to reduce its availability to invading malaria parasites or bacteria. Food taboos that restrict young children's intake of iron by prohibiting the consumption of meat are found in many areas where malaria is endemic, from Africa to India to Malaysia and New Guinea (Lepowsky 1985). These taboos may be partially explained as an attempt to aid the body's hypoferremic defense against malaria (Lepowsky 1985: 120).

Some diseases result in highly elevated transferrin saturation levels that make iron much more accessible to pathogens. In diseases such as leukemia, patients have been observed with sera that were 96 to 100 percent saturated (normal is 16 to 50 percent). As a consequence, leukemia patients are unusually susceptible to infection (Kluger and Bullen 1987). Thus in one study of 161 leukemia patients who died, 78 percent of the deaths were attributed to infection and not to leukemia directly (Kluger and Bullen 1987: 258).

Another investigation provides an excellent demonstration of the direct relationship between anemia of chronic disease and infection/inflammations. Over a period of 30 days, researchers analyzed the blood of healthy, well-nourished, and nonanemic infants before and after they were immunized with live measles virus (Olivares et al. 1989). After immunization, the hemoglobin, serum iron, and transferrin saturation levels fell significantly, whereas serum ferritin levels rose significantly as the body shifted circulating iron to storage. These levels persisted for 14 to 30 days, while the body produced hypoferremia, or low levels of circulating iron, in an attempt to make iron less available. Even "in those infants with prior evidence of normal iron status, the viral process induced changes indistinguishable from iron deficiency" (Olivares et al. 1989: 855). The authors noted that changes in the white blood cells mimicked a bacterial infection, as did changes in iron levels; in both cases, rapid proliferation of the virus imitated the rapid proliferation of bacteria (Olivares et al. 1989: 855). The body was unable to differentiate between the proliferation of bacteria and the proliferation of the virus and responded in the same manner by producing hypoferremia.

Anemia in Prehistory

In prehistoric populations, the distribution of anemia equaled or surpassed that found in today's world. There was a general increase in anemia through time, ranging from a few, extremely rare occurrences in the Paleolithic (Anderson 1968) to the Mesolithic (Janssens 1970), to more common occurrence in the Neolithic (Angel 1967), and the Bronze Age (Cule and Evans 1968). Anemia was even more frequent in recent groups, such as the prehistoric American southwestern Pueblos (El-Najjar 1977).

Prehistoric study is possible because anemia is identifiable in skeletal material by a cranial deformation called porotic hyperostosis (also known as cribia orbitalia when the orbits are affected). Physical effects include cranial lesions that are characterized by a sievelike porosity involving parts of the outer skull, often causing a thinning of the outer table, textual changes, and sometimes a "hair on end" appearance (Moseley 1965; Stuart-Macadam 1987). Porotic hyperostosis was originally thought to result from hereditary anemias, such as thalassemia or sickle cell anemia. More recently, chronic acquired anemia has been identified from roentgenograms (X rays) as a cause of porotic hyperostosis visible in living young anemic children (Shahidi and Diamond 1960; Powell, Weens, and Wenger 1965). More recent and conclusive studies confirm the link between porotic hyperostosis and acquired anemia (Stuart-Macadam 1987).

Whereas it is not difficult to identify anemia in skeletal populations, it is most difficult to differentiate dietary iron-deficiency anemia from the anemia of chronic disease. At first it was thought that the chemical makeup of bones was an indirect measure of the amount of meat consumed (Bumsted 1980, 1985). However, problems of chemical contamination through mineral loss and contact with minerals in soil have yet to be resolved. A study specifically designed to test the reliability of current bone chemical analyses concluded that their "results suggest that postmortem alteration of dietary tracers in the inorganic phases of bone may be a problem at all archaeological sites and must be evaluated in each case" (Nelson et al. 1986: 1941) Other problems associated with stable isotope and trace element analyses of bone are numerous, and interpretations utilizing current techniques are not conclusive (Klepinger 1984; Aufderheide 1989; Keegan 1989; Sillen, Sealy, and van der Merwe 1989). However, indirect measures of dietary iron and disease, which rely on a basic understanding of iron, anemia, diet, and disease, are possible. The presence of porotic hyperostosis in nonhuman primates, such as chimpanzees, gorillas, orangutans, and various species of Old World monkeys, including baboons (Hengen 1971), reinforce the unlikelihood that an impoverished diet is frequently the cause.

Anemia in the New World

Poor diet, sometimes in combination with infectious diseases, has served as the usual explanation for skeletal evidence of anemia among prehistoric Native Americans from the eastern United States to South America. However, faunal remains, mobility patterns, new medical information, and other nontraditional lines of evidence indicate that disease, rather than diet, may often be a better interpretation.

Eastern United States. Although some investigators still claim a maize-dependent diet as the sole or primary cause of porotic hyperostosis in prehistoric southeastern skeletal populations (Robbins 1986), more recent reevaluations suggest that diet may *not* have been a major cause. During the Mississippian period, an increase in porotic hyperostosis in children, particularly those under the age of six, occurred in the lower Illinois Valley. Nutritional anemia alone was probably rare in this age group, especially among breast-fed children. However, the condition coincides with a general increase in destructive bone lesions indicative of chronic inflammations in skeletal populations (Cook 1984: 257–9). During the period of these burials (between A.D. 1100 and 1300), Cahokia grew to be the largest pre-Columbian city in North America, with a population of 25,000 to 43,000 (Cook 1984). Non-Western sedentary, aggregated communities often have heavy pathogen loads, as discussed in the section "Anemia of Sedentism." The skeletal populations exhibit a concomitant increase in anemia and inflammation. This combination illustrates the link between increased population density and increased health problems. Diet cannot be implicated in anemia because during this time the:

> Mississippian diet based on archaeological data and ethnohistoric documentation . . . seems remarkably abundant in the essential elements: protein from both animal and vegetable sources, carbohydrates from cultivated and collected plant foods, and oils from seeds, nuts,

> and animal fat, all of these rich in minerals and vitamins from undepleted soils. . . . This ecological diversity, coupled with the sophisticated systems of multiple cropping, surplus food storage, and redistribution described by early European observers, offered protection against nutritional stress from local fluctuations in weather and resource populations. (Powell 1988: 58)

Also during the Mississippian period at Dickson Mounds, Illinois, the incidence of porotic hyperostosis rose from 13.6 percent to 51.5 percent, which coincided with dramatic increases in infectious bone lesions (Goodman et al. 1984: 289). According to investigators, samples from earlier periods had infection rates of 25 percent of the tibiae examined, but then rose to 77 to 84 percent during the later Mississippian period (Goodman et al. 1984). Although the authors attributed the rise in infectious lesions to nutritional stress brought on by an intensification of agriculture in the later period, a change in demography and, particularly, in aggregation may well be responsible. Studies indicate that the earlier Late Woodland sites in the area had population estimates of 50 to 75 individuals; later Mississippian sites had 440 to 1170 individuals (Goodman et al. 1984). Such an important and dramatic demographic change must have had serious health consequences. These Illinois examples are not isolated cases for the eastern United States. In fact, similar rates of increased infection and porotic hyperostosis through time are reported for the Ohio River Valley (Perzigian, Tench, and Braun 1984) and Georgia (Larsen 1984).

Southwestern United States. A maize-dependent diet has also been implicated in the increase through time of porotic hyperostosis in skeletal material from the southwestern part of the United States. Mahmoud Y. El-Najjar and colleagues were among the first and certainly the most prolific to detail the association between frequency of porotic hyperostosis over time and increasing horticultural activities (El-Najjar et al. 1976; El-Najjar 1977). However, as in the eastern United States, the archaeological data from the Southwest do not seem to support a view of diets sufficiently impoverished as to account for the spectacular increase in porotic hyperostosis through time in Anasazi skeletal populations. Instead, archaeological, ethnographic, and ethnohistorical sources all indicate a varied diet, including meat from both wild and domesticated animals, with the latter including turkeys and dogs (Kent and Lee 1992). In addition, wild plants were consumed in combination with maize, beans, and squash, all of which constituted an adequate diet in terms of iron (Kent 1986).

What, then, caused the increase in porotic hyperostosis? As the Anasazi began to adopt horticulture in general, and maize cultivation in particular, they became more sedentary and aggregated, living in communities called pueblos. Although this was not a linear progression that occurred everywhere, neither was the rise in porotic hyperostosis linear. Higher frequencies of porotic hyperostosis occur in skeletal populations from large, sedentary, aggregated pueblos in which disease was more common than in skeletal populations from smaller, more dispersed settlements where it would have been more difficult for disease vectors to infect populations (Kent 1986). Coprolite data (preserved fecal material) support this interpretation by documenting a lower parasite load for the upland populations in contrast to the valley groups. Coprolites containing parasites from various Anasazi sites are significantly correlated with porotic hyperostosis, whereas those containing different portions of either maize or animal residue are not (Reinhard 1992). In other words, dietary evidence of reliance on meat or maize was not correlated with skeletal evidence of anemia, but parasitism was correlated with porotic hyperostosis.

Elsewhere in the United States. Anemia, apparently caused by chronic diseases and inflammations, produced relatively high levels of porotic hyperostosis throughout the prehistoric United States. It can be seen in coastal California Native American skeletal populations who had a heavy dietary dependence on marine resources (Walker 1986). Eskimo skeletal populations also reveal relatively high percentages of porotic hyperostosis, some of which are even higher than those of southwestern and eastern prehistoric populations (Nathan 1966). Certainly the Eskimo example of porotic hyperostosis was not the result of an insufficient intake of meat. Instead, it was probably the result of seasonally sedentary aggregations and associated disease common to the winter villages. Prehistoric skeletons from all parts of Texas exhibit much lower incidences of porotic hyperostosis; less than 5 percent of 348 adult crania and 15.1 percent of 73 juvenile crania had any evidence of porotic hyperostosis (Goldstein 1957). Although precise locations of the various skeletal material were not cited, it is probable that the populations examined represent the nomadic groups that inhabited much of Texas; if so, this would explain the low incidence of infectious disease and porotic hyperostosis.

Central and South America. High frequencies of porotic hyperostosis were found on the crania of prehistoric Maya from Central America. For example, 21 skulls of Mayan children 6 to 12 years old were found in the Sacred Cenote of Chichén Itzá in the Yucatan; 67 percent had porotic hyperostosis. A number of the adult crania from the cenote also had healed examples of the pathology (Hooton 1940). Prehistoric Maya living in Guatemala suffered from both a high rate of infectious diseases, as evidenced by lesions thought to be related to yaws or syphilis, and to dietary inadequacies, such as vitamin C deficiency, as evidenced by bone lesions (Saul 1973). As a consequence, it is difficult to determine whether the porotic hyperostosis was caused by true dietary deficiency, by infectious diseases, or by a combination of the two.

In contrast, a study of Ecuadoran skeletal populations clearly demonstrates the influence of disease in promoting porotic hyperostosis. Although coastal populations ate iron-rich seafood, in addition to meat and cultivated products, skeletal populations reveal increasingly higher frequencies of porotic hyperostosis over time as they became more sedentary and aggregated (Ubelaker 1992). Coastal peoples suffered from conditions aggravated by large-village life, such as probable parasitic infestations, including hookworm, which causes gastrointestinal bleeding.[2] An examination of mummies from coastal Peru and Chile indicates that the most common cause of death was acute respiratory disease in adults and children (Allison 1984). Approximately half of the mummified individuals died from their first attack of pneumonia (Allison 1984). In contrast, porotic hyperostosis is not common in skeletons of maize farmers who occupied more dispersed habitations in the highlands of Ecuador, where parasites cannot survive because of the altitude and cold climate (Ubelaker 1992).

Although prehistoric cases of dietary-induced porotic hyperostosis may occur, they probably are not representative of entire populations. Iron-deficiency anemia caused by extremely inadequate diets is thought to result from factors not common until the twentieth century. Although not all paleopathologists (particularly those who are more diet-oriented and are less hematologically oriented), agree with the emphasis placed here on the anemia of chronic disease, many recent studies and reinterpretations agree that this is a better explanation than iron deficiency.

Anemia in the Old World

The Old World represents a vast area occupied by humans for a long time period, and thus only a few examples of prehistoric incidences of anemia are presented here.

Hereditary (for example, thalassemia) and acquired cases of anemia from the Mediterranean area cannot be differentiated, although porotic hyperostosis is found in skeletal populations from the area (Angel 1984). In the Levant, Mesolithic Natufians apparently had good health, as did the Paleolithic hunter-gatherers who preceded them, although sample size is very small (Smith et al. 1984). They remained a relatively healthy population during the early Neolithic. Deterioration began in later periods when population aggregations grew larger and more permanent and infectious diseases became endemic. According to P. Smith, O. Bar-Yosef, and A. Sillen, "This deterioration . . . seems to be related to chronic disease rather than to periodic bouts of food shortages, as indicated by the distribution of developmental lesions in the teeth and bones and the poor condition of all individuals examined" (Smith et al. 1984: 129).

In South Asia, there was a similar trend toward increasing porotic hyperostosis and infection, which has been attributed to nutritional deficiencies and disease (Kennedy 1984) but may also have been caused by demographic factors. Skeletons from the Harappan civilization city of Mohenjo-Daro on the Indus River, Pakistan, have a relatively high incidence of porotic hyperostosis; this led one anthropologist to suggest the possible presence of thalassemia and malaria in the area 4,000 years ago (Kennedy 1984: 183). However, the occurrence of malaria is difficult to evaluate, particularly in light of the high population density of Mohenjo-Daro, which could have promoted a number of infectious diseases common to such sedentary aggregations.

Porotic hyperostosis is found at varying frequencies throughout European prehistory (Hengen 1971), but as no systematic temporal study has been done to date, it is not possible to delineate and interpret trends. However, an interesting geographical pattern has been discerned that suggests that populations located closer to the equator have higher levels of porotic hyperostosis. This might be the result of generally higher pathogen loads in these areas (Stuart-Macadam 1992). However, porotic hyperostosis was well represented, particularly in children, in a large Roman-British cemetery (Stuart-Macadam 1982). This is interesting because it has been suggested that lead poisoning, which can cause severe anemia, was one of the factors that contributed to the ultimate collapse of the Roman Empire (Gilfillan 1965).

According to some research, prehistoric Nubian populations experienced nutritional deficiencies after they became agriculturalists (Armelagos et al. 1984). This interpretation is based on the occurrence of porotic hyperostosis, long-bone growth patterns compared to North Americans, dentition abnormalities, and premature osteoporosis. Moreover, bone growth patterns of skeletons from a medieval Nubian Christian cemetery, (A.D. 550 to 1450) have been used to interpret nutritional stress (Hummert 1983). Nonetheless, it is usually recognized that such stress can be caused by a number of nutritional deficiencies not necessarily related to iron. More recent coprolite data have been employed in support of the hypothesis that an impoverished diet caused the high frequency of porotic hyperostosis in Christian Nubian populations (Cummings 1989). However, it is possible to interpret the data quite differently. For example, it should be noted that meat does not usually preserve in coprolites, and humans do not usually ingest large bones that would be indicative of meat consumption. Therefore, the amount of meat consumed may be substantially underrepresented when interpreting coprolite data. Bearing this in mind, it is impressive that

33.3 percent of the 48 coprolites analyzed contained evidence of fish bones or scales, as well as one pig bone and an unidentifiable mammal bone (Cummings 1989: 86–92). Such evidence contradicts the contention that a diet poor in iron produced the high incidence of porotic hyperostosis in this population.

Anemia in Australia

Frequencies of both infection and anemia (porotic hyperostosis) are low in the desert region of Australia, particularly when compared to other parts of the continent, such as the Murray River area (Webb 1989). Murray River skeletons display a pronounced increase in porotic hyperostosis and infections coinciding with archaeological evidence of restricted mobility, aggregation, and possible overcrowding (Webb 1989: 145–8). Such evidence again suggests that the anemia in question is the result of chronic disease and not diet. Though lower than in the Murray River area, the relative high incidence of anemia and infection that occurred among prehistoric Aborigines occupying the tropical portions of Australia can be attributed to parasitism, such as hookworm (Webb 1989: 155–6).

Acquired Anemia in Today's World

The perspective of dietary deficiency and the anemia of chronic disease presented here permits new insights into a variety of issues facing contemporary populations. Because iron-deficiency anemia and the anemia of chronic disease have not always been distinguished, particularly in earlier studies, the two are discussed together and are differentiated whenever possible.

Anemia of Sedentism

As noted, heavy pathogen loads are characteristic of non-Western sedentary aggregations. In such settings, high morbidity rates are visible, not only hematologically but also in the frequency of parasitic infections. For example, studies indicate that nomadic Amazonians had a lower frequency of parasitic infection than seminomadic horticulturalists and sedentary villagers. In these latter populations, 100 percent of some age groups were infected with parasites (Lawrence et al. 1980). As a whole, the sedentary populations had many more multiple parasitic infections, ranging from 4.2 to 6.8 species per person (Lawrence et al. 1980). Sedentary and aggregated Brazilian Amazonian villages had roundworm *(Ascaris)* infections, ranging from 65 to 100 percent of the population, and heavy worm burdens, including hookworm and whipworm *(Necator americanus, Trichuris trichura)* (Chernela and Thatcher 1989). This situation contrasts with the inhabitants of more nomadic and dispersed villages that had half that rate of roundworm infection (34 percent) and light worm burdens that were asymptomatic (Chernela and Thatcher 1989).

From 60 to 100 percent of the residents of two Colombian villages were found to be infested with parasites (Schwaner and Dixon 1974). In one that lacked sanitation of any kind and in which shoes were rarely worn, 100 percent of the population had either double or triple infections (roundworm, whipworm, and hookworm). Of the 60 percent of those infected in the other village (that had outdoor latrines and where shoes were worn), 70 percent were infected by more than one species (Schwaner and Dixon 1974: 34). Sedentism, aggregation, and the lack of adequate sanitation are all implicated in creating breeding grounds for parasitic and other types of infections. Such conditions lead to high morbidity and chronic hypoferremia as the body attempts to defend itself against the heavy pathogen load. Furthermore, heavy infestations of hookworm and other parasites cause blood loss that even good diets cannot replenish.

The relationship between sedentism and anemia can be more easily seen by comparing nomadic and sedentary people who consume similar diets, thereby factoring out diet as a causal variable of anemia. Hematological research among recently sedentary and still nomadic Basarwa ("Bushmen" or San, as they have been referred to in the literature) illustrates hypoferremia operating in a modern population. The 1969 population of the !Kung Basarwa (who live in the northwestern part of the Kalahari Desert) contained a few ill individuals, as do most populations, but was judged as mostly healthy (Metz, Hart, and Harpending 1971). Their meat intake did not change dramatically between the dry seasons of 1969 and 1987 (Kent and Lee 1992). There were, however, significant changes in mobility patterns, from a relatively nomadic to a relatively sedentary pattern. Concomitant higher morbidity rates ensued. Also, the number of individuals with below-normal serum iron and transferrin saturation levels rose significantly between 1969 and 1987 (Kent and Lee 1992). It is significant that the 1987 Dobe !Kung population, with a roughly adequate meat intake, had more individuals with subnormal serum iron and transferrin saturation values than did the Chum!kwe !Kung population, with an acknowledged deficient diet (Fernandes-Costa et al. 1984; Kent and Lee 1992). It is furthermore significant that no individuals had low serum ferritin values among the Dobe !Kung, which would indicate a dietary deficiency.

To evaluate the role of sedentism in promoting the anemia of chronic disease, a hematological study was conducted in 1988 among a different group of recently sedentary Basarwa living near the Kutse Game Reserve in the eastern half of the Kalahari (Kent and Dunn 1993). Their diet was repetitive but adequate; meat was consumed several times a week (Kent and Dunn 1993). The Kutse Basarwa often complained of illness; respiratory problems were common. Both serum iron and transferrin saturation means were significantly lower for the 1988 Kutse Basarwa than those obtained in 1969 or 1987 among the Dobe Basarwa (Kent and Dunn 1993). At the same time, serum ferritin levels were higher in the adult Kutse population than in the 1987 adult !Kung. This is consistent with the view that the anemia of chronic disease is more prevalent in situations of high morbidity where the body attempts to protect itself from continuous cycles of insult. The children's mean ferritin remained approximately the same (Kent and Dunn 1993).

If hypoferremia operates in response to heavy and chronic pathogen loads, then it should be visible in more than just the hematological profile of a population. Ethnographic observations and informant interviews indicate that there is a high level of morbidity at Kutse but not a deficient diet (Kent and Dunn 1993). Both the 1987 !Kung and 1988 Kutse Basarwa hematological studies indicate that the anemia of chronic disease is common in these populations and is activated in situations of high morbidity. A 1989 follow-up hematological study of the Kutse community reinforces the interpretation of an adequate diet but high morbidity as a result of aggregation (Kent and Dunn n.d.). As pointed out, anemia is not a body defect or disease but is actually a defense against a heavy pathogen load, which operates by reducing circulating levels of iron required by organisms to proliferate.

Anemia of Development and Modernization

Development and modernization projects are often promoted both by local governments and by international businesses and foreign governments as a means to westernize a developing country. Generally, nontraditional subsistence activities are encouraged because the government or politically dominant group believes the change to be beneficial. Extremely deficient diets documented by Susan Stonich (1991), Benjamin Orlove (1987), and others are the consequence of governmental pressure to grow export crops for a world market, which is a relatively recent phenomenon. This type of severe dietary deprivation has usually been correlated with colonialism (Franke 1987; Ross 1987).

Nomadic peoples have been targets of development and modernization schemes. For example, sedentarization at Chum!kwe, located in Namibia on the western edge of the Kalahari Desert, began in 1960. At that time the South African administration of the Namibia Territory decided to move all the !Kung Basarwa of Nyae Nyae into a single settlement (Kent and Lee 1992). For the next 20 years the waterhole at Chum!kwe (augmented by boreholes) supported a standing population of 800 to 1,000 people. These conditions of high aggregation, with its attendant social, nutritional, and alcohol-related stresses, were prevailing when a 1981 study was made (Fernandes-Costa et al. 1984).

At Chum!kwe in 1981, hunting and gathering had fallen to very low levels due to the high level of aggregation and reduced mobility of the population (Fernandes-Costa et al. 1984). Store-bought foods and government rations, high in refined carbohydrates, formed the mainstay of the diet; some milk and grain from home-grown sources supplemented the diet. Meat was eaten infrequently. By the 1980s alcohol abuse had become a major social problem, with Saturday night brawls often resulting in injury and death (Volkman 1982). Young children as well as adults drank beer, which sometimes provided the only calories consumed all day (Marshall and Ritchie 1984: 58). The health of the Chum!kwe population was portrayed as poor.

The investigators attributed the incidence of anemia primarily to nutritional causes. However, 35.9 percent of all adults had a serum ferritin value above 100 nanograms per milliliter (ng/mL), indicating the presence of the anemia of chronic disease. No men and only 6 percent of women had subnormal serum ferritin levels (Fernandes-Costa et al. 1984). Diet was also thought to be responsible for the 33 percent of children who had subnormal serum ferritin levels (less than 12 ng/mL), although bleeding from parasitic infections could be another explanation. In fact, 3 of 40 stool samples contained *Giardia lamblia* and 8 of 40 samples had hookworm *(Necator americanus)* (Fernandes-Costa et al. 1984: 1302). Both parasites can cause lowered serum ferritin and other iron indices through blood loss and competition with the host for nutrients. Unfortunately, the age and sex of the afflicted are not mentioned; however, children tend to become infected from parasites more often than adults and tend to have a heavier parasite load than adults. Thus, parasites might explain the number of children with subnormal serum ferritin values.

A very similar situation occurred among the Australian Aborigines. They were encouraged to live at settlements where they subsisted on government subsidies of flour and sugar (Taylor 1977). The consequence of this planned social change implemented by the government was malnutrition and frequent infections:

> After weaning from breast milk, the children graduated to the staple and nutritionally deficient diet of the settlement and entered its unhygienic, usually overcrowded, and certainly highly pathogenic environment. Here they acquired repeated respiratory and gastrointestinal infections which, if they did not prove fatal, may have impaired the children's ability to absorb nutrients from the diet [through malabsorption caused by the anemia of chronic disease and by numerous types of infections]. Thus the problem was compounded and a vicious

> cycle seemed to be set up in which the survivors of the process proceeded to adulthood to rear more children under the same circumstances. (Taylor 1977: 147–8)

Anemia around the World

In the United States the frequency of anemia is fairly low, approximately 6 percent or less for children under 17 years of age; more girls than boys have subnormal levels (Dallman 1987). The number of children with subnormal hemoglobin values declined from 7.8 percent in 1975 to 2.9 percent in 1985 (Centers for Disease Control 1986). A similar decline occurred in adults as indicated in the Second National Health and Nutrition Examination Survey (NHANES II, 1976–80). In this study of 15,093 subjects, anemia was found in 5.7 percent of infants, 5.9 percent of teenage girls, 5.8 percent of young women, and 4.4 percent of elderly men (Dallman, Yip, and Johnson 1984). The later surveys included serum ferritin measurements and differentiated between iron-deficiency anemia and anemia of chronic disease (Expert Scientific Working Group 1985). Therefore, the decline may be more illusory than real in that the more recent surveys separated the two anemias, which made the overall frequency of each appear to be less. Although based on a small sample size, anemia of chronic disease accounted for 10 percent of anemic females between 10 to 44 years of age, 34 percent of anemic females between 45 and 74 years of age, and 50 percent of anemic males (Expert Scientific Working Group 1985: 1326).[3]

There are a few populations with a lower rate of anemia than that in the United States. One example is the Waorani Indian horticulturalist–hunters of eastern Ecuador. In 1976, none of the 114 individuals studied, including males and females of all ages, had subnormal hemoglobins or hematocrits, despite a few light helminth infestations and four children with presumed bacterial-induced diarrhea (Larrick et al. 1979: 155–7). Once again, the low frequency of anemia was probably the result of a seminomadic, dispersed settlement pattern.

Anemia frequency is much higher in other parts of the world. During the 1970s, studies conducted of nonwhite children in South Africa showed a higher prevalence of iron-deficiency anemia (38.8 percent) and anemia of chronic disease (18.8 percent) than figures reported for the same time period in the United States (Derman et al. 1978).

In regions such as southeast Asia, a high incidence of hookworm infections cause bleeding. Surveys in these areas show that the frequency of anemia is correspondingly high, ranging from 25 to 29 percent in males and from 7 to 45 percent in nonpregnant women and children (Charoenlarp et al. 1988). Approximately 20 percent of the subjects given oral iron for three months as part of a study in Thailand remained anemic, and some of the individuals ended up with serum ferritin levels above 100 μg/L (Charoenlarp 1988: 284–5). Both the lack of response to oral iron supplementation and the serum ferritin levels above 100 are common indications of the anemia of chronic disease; the other incidences of anemia can be attributed to various amounts of hookworm and other parasitic infections. Between 5 to 15 percent of women, 3 to 27 percent of children, and 1 to 5 percent of men in Burma were anemic, but no serum ferritin values were measured; hookworm infection rates varied from 0 to 70 percent, depending upon locality (Aung-Than-Batu et al. 1972).

Anemia was found in 22 percent of pregnant women, 12 percent of nonpregnant women, and 3 percent of men in seven Latin American countries (Cook et al. 1971). Unfortunately, serum ferritin was not measured, and so it is not possible to distinguish the percentage of individuals with iron deficiency or with anemia of chronic disease.

Anemia and parasites. Parasite load is an influential factor in the frequency of anemia around the world. Parasites both compete with the host for nutrients and can cause bleeding resulting in substantial iron losses. The body responds to parasitic infections with hypoferremia to deprive the parasites of needed iron. Most common in the tropical regions of the world, parasitic distribution is related to the ecological complexity and diversity that characterize such habitations (Dunn 1968; Stuart-Macadam 1992). Hookworms can cause as much as 0.21 ml of blood loss per worm per day in infected individuals (Ubelaker 1992).

In Bangladesh, where over 90 percent of children have helminth infections, between 74 percent and 82 percent of the children tested had subnormal hemoglobin levels (Florentino and Guirriec 1984). Serum ferritin studies were not included. However, because of the blood loss associated with helminth infections, individuals were probably suffering from iron-deficiency anemia, albeit not diet induced. Of 1,110 children tested in India, 33.8 to 69.4 percent were anemic; 26.7 to 65.3 percent suffered from roundworm *(Ascaris)* and *Giardia* infections, both of which cause anemia (Florentino and Guirriec 1984). Although the link with parasites is a little more tenuous among Nepal villagers, 67.6 percent of nonpregnant women had subnormal hemoglobin levels; the high consumption of dietary iron absorption inhibitors may also be a factor in causing anemia in this population (Malville 1987).

In Indonesia, 37.8 to 73 percent of children studied were anemic, and 22 to 93 percent were infested with hookworm, probably causing their anemia (Florentino and Guirriec 1984: 85). This study also reported that in Malaysia and Singapore, 83 percent of 30 children were anemic; in the Philippines, 21.1 to 47.2 percent of 2,509 children, depending on their age group, were anemic; and in China, 23 percent of 1,148 children were anemic.

Among various Pygmy hunter-gatherer groups, parasite levels are extremely high because of fecal contamination and the high level of parasites characteristic of tropical environments (Pampiglione and Ricciardi 1986). Various types of malaria *(Plasmodium falciparum, Plasmodium malariae,* and *Plasmodium ovale)* were found in 18.1 to 59.4 percent of 1,188 people from four different groups of Pygmies living in the Central African Republic, Cameroon, and Zaire (Pampiglione and Ricciardi 1986). Numerous other parasites were also present: hookworms (41.3 to 85.8 percent); roundworms (16.7 to 64.9 percent); amoebas (*Entamoeba,* 6.4 to 35.8 percent); *Giardia* (5.3 to 11.4 percent); whipworm (*Trichuris,* 77.9 to 91.9 percent); and others (Pampiglione and Ricciardi 1986). Many individuals suffered from several parasitic infections, in addition to yaws (10 percent with active symptoms), scabies, chiggers, and other afflictions (Pampiglione and Ricciardi 1986: 160–1). Neighboring Bantu-speaking farming peoples, despite more access to Western medical care and medicine, also have a high incidence of parasitism. Malaria *(P. falciparum)* was found in 91.2 percent of 321 persons; 26.8 percent suffered from amoebas; 53 percent from roundworms; 80.3 percent from hookworms; 69.8 percent from whipworm; and 16.5 percent from *Giardia* (Pampiglione and Ricciardi 1986: 163–4).

In Liberia, pregnant women in one study also had high rates of parasitism: 38 percent had hookworm; 74 percent had roundworm; and 80 percent had whipworm (Jackson and Jackson 1987). Multiple infections were also common; between 24 and 51 percent of the women had two infections and 12.5 percent had three infections (Jackson and Jackson 1987).

In Bolivia, 11.2 to 44 percent of children tested were anemic (Florentino and Guirriec 1984). Of these, 79 percent suffered from roundworm and 12 percent had hookworm infections (Florentino and Guirriec 1984).

The intention here is not to provide a detailed overview of anemia throughout the world, which would require an entire book. Rather, it is to show that anemia is a widespread condition in non-Western societies due to endemic chronic infections and parasitic diseases. In some of the cases mentioned in this section, poor health in general resulted from ill-planned development schemes or encouragement of cash or export crops at the expense of subsistence farming, creating contaminated water supplies and poor sanitation. This should present a challenge to Western societies to eradicate disease aggressively in developing countries. Development agencies need to become more aware of the underlying causes of anemia and high morbidity in many of these countries. Attempts to change agricultural patterns to produce more food per acre or the provision of iron supplements may not achieve the goal of eliminating anemia on a worldwide basis.

Anemia in infants and children. The decline in the number of children with acquired anemia in Western nations is as impressive as the decline in the number of adults with anemia. One study in the United States showed that in 1971, 23 percent of 258 children were anemic, whereas in 1984, only 1 percent of 324 children were anemic (Dallman and Yip 1989). More recent surveys show that of those few children who are anemic, the majority have the anemia of chronic disease rather than dietary iron deficiency, as evidenced by normal-to-elevated serum ferritin levels (Reeves et al. 1984; Jansson, Kling, and Dallman 1986).

There is a vast literature on anemia in infants and children (for example, Pochedly and May 1987). Most relate the anemia to the rapid growth of children and the low iron content of diets, although many do not distinguish between iron-deficiency anemia and anemia of chronic disease (Ritchey 1987). For example, a study of 148 British toddlers claims that lower hemoglobin levels are associated with diet: (1) prolonged lactation and (2) early introduction of whole cow's milk (Mills 1990). Consumption of cow's milk before 12 months of age has been shown to cause gastrointestinal bleeding in 39.5 percent of infants fed cow's milk versus 9.3 percent of infants fed formula (Fomon et al. 1981).

We cannot assume, however, that all of these cases of childhood anemia were the result of dietary factors because serum ferritin was not measured. In fact, there are more compelling reasons to suggest that at least some of the anemia was the anemia of chronic disease. Women who breast-feed their children the longest (a year or more) in Western societies tend to be the underprivileged, who are also subjected to higher rates of infection or inflammation due to crowding, inadequate housing, and the stress of minority status (see the section "Anemia and Sociopolitical Class and Race"). Such children may be at higher risk from pathogens and have greater incidence of the anemia of chronic disease. Clearly, serum ferritin must be measured in order to make reliable conclusions from any study of anemia. It is interesting to note that a study of 9 hospitalized children (6 fed formula and 3 fed cow's milk) indicated that those with lower hemoglobin levels, attributed to starting cow's milk at 6 months of age, were less likely to be hospitalized for infections than infants fed formula who had higher hemoglobin levels (Tunnessen and Oski 1987). This could be interpreted as the effect of lower hemoglobin levels, which provides protection against infections both in the contracting of diseases and in their virulence. Subnormal serum ferritin values revealed in the 17.4 percent of infants fed cow's milk versus only 1 percent of infants fed enriched formula could be the result of increased diarrhea and gastrointestinal bleeding associated with cow's milk feeding, as well as to allergies to cow's milk found in 0.3 to 7.5 percent of children (Foucard 1985;Tunnessen and Oski 1987).

Further difficulty in interpreting the etiology of anemia in children is caused by the fact that most minor illnesses that commonly afflict children, as well as immunization, can significantly depress hemoglobin levels (Dallman and Yip 1989). Iron-deficiency anemia is simulated in these cases because hemoglobin levels drop, but the anemia of chronic disease is the actual cause, as evidenced by normal serum ferritin levels. Moreover, serum iron levels drop significantly during the first year of life and are lower than adult levels as a normal physiological developmental change (Saarimen and Siimes 1977; Dallman and Reeves 1984).

In an attempt to combat anemia, most health-care workers routinely recommend iron-fortified infant formula without first ascertaining if an infant is anemic and if so, why. For example, the Women, Infant, and Children (WIC) program requires disadvantaged women to use iron-fortified formulas; nonfortified formulas are not provided (Kent, Weinberg, and Stuart-Macadam 1990). Fortified infant formulas were routinely prescribed by all but 16 percent of 251 physicians in Washington State (Taylor and Bergman 1989). It is hoped that the information presented here demonstrates the potential deleteriousness of this practice. Fortified formulas should be used only in cases where infants have anemia due to bleeding or other conditions known to create insufficient levels of iron to maintain health.

Anemia and Pregnancy

Pregnancy is often associated with a mild iron deficiency that has been linked to the nutritional needs associated with the rapid growth of a fetus. However, a few researchers have suggested that slight hypoferremia may help defend mother and fetus from invading pathogens (Weinberg 1987; Stuart-Macadam 1987). Such a defense may be particularly valuable during the latter phases of gestation when cell-mediated immunity lessens to prevent immunological rejection of the fetus (Weinberg 1987). That lower iron levels are a normal physiological part of pregnancy is supported by a number of studies that have failed to demonstrate any benefit derived from routinely prescribed prophylactic iron (Hemminki 1978; Bentley 1985). Nonetheless, many physicians continue to recommend that pregnant women take oral iron supplements.

There are anemic pregnant women with serum ferritin values below the normal 12 ng/mL. Premature labor was recorded in 48 percent of pregnant women with serum ferritin values below 10 ng/mL, in contrast to 11 percent who had normal serum ferritin levels (Goepel, Ulmer, and Neth 1988; Lieberman et al. 1988). However, a very large study of 35,423 pregnant women reported no reliable association between anemia and problem pregnancies:

> When the hematocrits of women in term labor were compared with those of women in preterm labor, a spurious dose-response effect for anemia was created. We conclude that anemia is not a strong factor in the pathogenesis of preterm birth and that comparison of hematocrits from women who are in preterm and term labor produces biased results (Klebanoff et al 1989: 511).

Furthermore, and importantly, "we do not believe that there is sufficient evidence to justify a randomized clinical trial of treatment of borderline anemia during pregnancy" (Klebanoff et al. 1989: 515).

Anemia and the Elderly

Elderly men and postmenopausal women have the highest incidence of the anemia of chronic disease among all North Americans surveyed (Cook et al. 1986). Although some physicians have regarded anemia as a "normal" part of aging, a number of studies have shown that it often is the anemia of chronic disease resulting from increased vulnerability to pathogens and neoplasia, perhaps because of lowered immune defense (Zauber and Zauber 1987; Daly and Sobal 1989; Thomas et al. 1989). Serum ferritin levels rise with age, probably because the elderly have increased susceptibility to systemic insults (Zauber and Zauber 1987; Baldwin 1989; Daly 1989; Stander 1989). Whereas only 13 percent of 259 elderly persons had anemia, 77 percent had the anemia of chronic infections (Guyatt et al. 1990: 206). The frequency of infectious diseases may not be primarily the result of age alone but, instead, of social factors involved with aging in Western society, such as depression, poor care, and crowding in nursing homes. That is, the anemia of chronic disease may be more common among the elderly than the population in general because of social variables unique to this group.

Anemia and Sociopolitical Class and Race

Whatever the cause of anemia, dietary or chronic diseases, it is still the poor person's disease. While the prevalence of anemia has dropped for African-Americans as it has for all Americans, the frequency of anemia is still higher than among other groups. Anemia among African-Americans dropped from 21 percent between 1975 and 1977 to 19.2 percent between 1983 and 1985 (Yip et al. 1987). Unfortunately, serum ferritin was not measured in earlier surveys, making conclusions based on improved iron and general dietary nutrition problematic. However, later studies that include ESR (sedimentation rate, an indication of infection) show that the anemia of chronic disease is more prevalent among lower socioeconomic classes, including African-Americans (Yip and Dallman 1988).

It was once proposed that a racial characteristic of blacks is a significantly lower hemoglobin level than that of whites, and as a result, some researchers suggested using separate hemoglobin standards based on race (Garn, Smith, and Clark 1975; Garn and Clark 1976; Garn, Shaw, and McCabe 1976). However, only hemoglobin and hematocrit were analyzed in these studies. Genetics, paleontology, physiology, anatomy, and other sciences all suggest that there are neither absolute races of humans nor corresponding genes that are restricted solely to one segment of the human population; that is, there are no "black" genes that all blacks share.[4] So-called racial groups are based on continuous traits that are arbitrarily divided into supposedly discrete groups. This is particularly true in Western society where so much gene flow (that is, interracial matings) has occurred.

What, then, accounts for the lower hemoglobin levels among African-Americans? There are a number of sociological reasons that cause one subgroup to be subjected to more bodily insults than another, particularly in a society where racism is, unfortunately, all too common (Kent 1992). There are hematological data to support this contention. Later studies that performed serum ferritin measurements show that whereas African-Americans have lower hemoglobin levels, they concomitantly have higher serum ferritin levels, ranging from 271.7 ng/mL in black men to 111 ng/ml in black women; this contrasts to 93.63 in white men and 37.9 ng/ml in white women (Blumenfeld et al. 1988). Even though sedimentation rates (or ESR) were not elevated among a sample of African-Americans in one study, there was a higher incidence of chronic diseases as indicated by the number of serum ferritin levels above 100 ng/ml, which, in combination with low hemoglobin levels, defines the anemia of chronic disease/inflammation. Other investigations corroborate these findings. Of 78 African-Americans studied, 17.6 percent had elevated serum ferritin levels, leading the investigators to conclude that in addition to the anemia of chronic disease, there also were a number of individuals with iron overload who also suffered from occult inflammatory conditions (Haddy et al. 1986: 1084). The reason that more blacks than whites have the anemia of chronic disease is probably related to poverty. Many suffer from overcrowding, inadequate shelter, poor medical care, and the stress of minority status.

Black and white economic levels were matched in the studies mentioned. However, blacks within the same level of income as whites may suffer more stresses and infectious diseases because of their minority position and associated problems, such as prejudice and alcoholism, which were not taken into account in these studies. Other research indicates that whereas blacks have a lower hematocrit, it is only 0.7 percent lower than that of whites; R. Yip, S. Schwartz, and A. Deinard report the the "lower value in blacks may be accounted for by mild thalassemias, which are associated with lower hematocrit values. The use of the same diagnostic criteria for anemia among all races will permit uniform detection of nutritional anemia" (Yip, Schwartz, and Deinard 1984: 824). The higher incidence of thalassemias associated with blacks in the United States is a geographical, not a racial, trait since whites indigenous to Mediterranean regions cursed in the past with endemic malaria also have a higher rate of thalassemias.

Various other minorities in North America are impoverished and suffer from prejudice, which is reflected in their hematology. The prevalence of anemia among Chinese-Canadians is similar to that of black Americans but dissimilar to that of white Americans (Chan-Yip and Gray-Donald 1987). Hispanic females between the ages of 20 and 44 had statistically higher levels of anemia than whites or blacks, although it is unfortunate that the etiology of the anemia was not determined (Looker et al. 1989). Thus, lower hemoglobin levels are not specifically a black-associated trait but do appear to be a minority-associated trait.

Native Americans are similarly affected with significantly higher incidences of anemia. Between 22 and 28 percent of Alaskan Native Americans were found to be anemic: Of these, 65 percent had iron deficiency and 35 percent had the anemia of chronic disease (Centers for Disease Control 1988). Parasites were not investigated in these studies, but earlier studies of this group indicate that they are common and a potential reason for the reported high frequency of iron deficiency (Rausch 1951; Schiller 1951). Pneumococcal disease also is endemic among Alaskan natives (Davidson et al. 1989). Poverty and poor nontraditional diets, combined with overcrowding in semisedentary and sedentary villages, contribute to this unfortunate situation. As discussed in the section "Elsewhere in the United States," skeletal material reveals that anemia was common in this population in the past as well, even though large quantities of heme iron in the form of meat were routinely consumed. Such anemia was the result of endemic health problems associated with winter village life and infection with parasites from contact with infected dogs, seals, polar bears, and other animals with which native Alaskans were in contact (Kent 1986).

By contrast, Native American children in Arizona were reported to have lower rates of anemia (Yip et al. 1987). This is difficult to assess because information was not provided as to which group of Native Americans was involved in the study. The frequency of anemia could be related to the dispersed settlement patterns of some groups, such as the Navajos, or to the season when the study was conducted, because many Native American children attend boarding schools during the winter but spend the summer at home. The frequency might also be attributed to the length of time children are breast-fed, which, at least in the past, was of longer duration than among Euroamerican children. In other studies, Native Americans had the same relatively low rate of anemia as Euroamerican children (Yip, Schwartz, and Deinard 1984). Whatever the cause, the lower incidence of anemia among Arizona Native Americans in contrast to Alaskan Native Americans again demonstrates that anemia is not related to genetic or racial factors but is related to environmental and sociopolitical factors, such as poverty and its associated diseases, like alcoholism.

Anemia and Alcoholism, AIDS, Drugs

Anemia, primarily of chronic diseases, is correlated with a number of health problems currently affecting all countries to various degrees. Although alcohol enhances iron absorption and can cause overload and consequent pathologies (Rodriguez et al. 1986), alcoholics may also suffer from anemia. Between 13 to 62 percent of chronic alcoholics are anemic, primarily as a result of acute blood loss and illness, including liver disease (Savage and Lindenbaum 1986).

AIDS, or acquired immunodeficiency syndrome, is associated with anemia, but its interpretation is difficult. Anemia may be the result of the body's defense against the virus or its defense against the many secondary infections associated with AIDS. Anemia in AIDS patients can also be partly related to malnourishment from malabsorption associated with the condition. The latter is the least likely explanation, however, because the anemia is associated with normal or increased serum ferritin levels (Beutler 1988).

Secondary infections are more likely to cause anemia in this group. Many AIDS patients suffer from neoplasia of various types (especially Kaposi sarcoma and non-Hodgkin's lymphoma) and from a wide range of bacterial infections that are particularly virulent because of the host's weakened resistance (Brasitus and Sitrin 1990). As a result of their compromised immunological systems, AIDS patients are often afflicted with atypical mycobacterial infections as well (Ries, White, and Murdock 1990). Whatever the ultimate cause of the anemia, it appears that the hypoferremia associated with AIDS is primarily the anemia of chronic disease and occurs as the body attempts to defend itself against very formidable infections.

Anemia and Performance

It has long been suggested that iron-deficiency anemia adversely affects performance, as measured by a battery of tests designed to evaluate activity, ability, and endurance (Dallman 1989). In fact, many studies claim to demonstrate a relationship between poor mental or physical performance and low hemoglobin level. However, a number of these studies indicate that changes noted were not statistically significant, did not include a control group, or were ambiguous in what prompted the improvements noted (Lozoff and Brittenham 1987; also see Lozoff, Jimenez, and Wolf 1991, who indicate the difficulties in determining cause and effect). The problem encountered here, as throughout this discussion of anemia, is the separation of cause and consequence: physiological problem or defense.[5]

Furthermore, serious questions exist in almost every study that interprets behavioral, mental, or other functional limitations associated with dietary iron-deficiency anemia. For instance, no one denies that someone severely iron deficient as a result of blood loss will perform poorly compared to a healthy person. However, when anemia is reversed, other health problems are also corrected. Intake of calories, protein, and vitamins is improved in most of the studies designed to investigate performance and anemia. In the case of anemia of chronic disease, disease and/or parasite loads were reduced as the result of medication. Is it the increase in iron that is causing the improvement in skills, or is it the improvement in overall health and nutrition? Ingestion of oral iron can stimulate appetite, and there is often a weight gain associated with higher hemoglobin levels (Kent et al. 1990). It is this overall improvement in nutrition that has been suggested as the cause of the improved mental faculties (Wadsworth 1992).

Iron is necessary to catalyze various facets of the humoral and cell-mediated immune systems (Weinberg 1984). However, severely deficient individuals are not usually part of the performance test groups reported in the literature. Although iron-deficient individuals have a lower maximum work capability and endurance (Gardner et al. 1977; Lozoff and Brittenham 1987), we again are left with questions. How much of poor performance is related to iron deficiency and how much is related to poor calorie, vitamin, and protein intake and to parasitic or other disease?

Other research cannot be assessed. For example, one study compared anemic and nonanemic Chilean infants by conducting various mental and psychomotor tests that included talking and walking. Anemic infants performed more poorly than nonanemic ones (Walter et al. 1989). The difficulty in interpreting this finding is that the mental and psychomotor skills were calculated for each group according to their iron status and not according to gender. Female infants, in general, maturate more rapidly than males; therefore, the gender composition of each group is vital for determining if the nonanemic group performed better than the anemic one simply because it was composed of more female infants, regardless of the presence or absence of anemia. After three months of iron supplementation, which reversed the anemia, "no significant improvement was detected between the scores at 12 and 15 months of age" (Walter et al. 1989: 12). This suggests either that the gender composition of the groups may have affected initial performance rates or that the anemia itself did not significantly affect the infants' ability on the tests.

Many studies, particularly earlier ones, also do not measure serum ferritin levels but simply define all anemia as iron deficiency from poor diets and ignore improvements in health during the study (Soemantri, Pollitt, and Kim 1985; Chwang, Soemantri, and Pollitt 1988). In one study, anemic and nonanemic Thai fifth-grade students received either an iron supplement or a placebo concurrently with an anthelminthic drug to kill parasites (Pollitt et al. 1989). In addition, all other infections were treated on the first day of the study. Consequently, the end results are not comparable to the initial test results; that is, the cause of changes could be attributed to improved general health as much as to improved iron status.

As noted by Moussa Youdim (1989), test results often implicate factors other than iron, such as social and economic status, as the causes of differences in anemic and iron-replete students' performance before treatment. Even without taking this into account, studies indicate no difference in performance between treated and untreated children, and research "provides no support for an assumption of causality [between test scores and iron supplementation]" (Pollitt et al. 1989: 695).

Iron-deficient infants in Costa Rica who were weaned early (average 4.9 months) or never breastfed (16 percent) were given cow's milk, known to cause gastrointestinal bleeding in a high percentage of infants (Lozoff et al. 1987). These children performed less well on a series of mental and motor tests than did nonanemic infants (Lozoff et al. 1987). Later, after their anemia was corrected with iron supplements, their performances improved (Lozoff et al. 1987). It is suggested that rectifying blood losses, rather than diet, made the difference.

Nondietary causes of anemia are prevalent in many of the populations studied, as in New Guinea, where both malaria (and anemia of chronic disease) and thalassemia are common. A series of tests to measure attention span were given to New Guinea infants: malaria-positive and negative and iron-dextran supplementation with malaria and without (Heywood et al. 1989). The only significant difference recorded was that malaria-positive infants, regardless of iron supplementation, had longer fixation times than did infants with no evidence of malaria, regardless of iron supplementation (Heywood et al. 1989). As Horowitz (1989) points out, the precise meaning of longer fixation times is not known; differences may not reflect mental development but the opposite, or may simply be a reflection of age, maternal education, or general health status.

The results of another study of iron-deficient children in Indonesia was also ambiguous. After receiving iron supplementation, neither anemic nor iron-replete children significantly improved performance on some tests, but both groups improved on other tasks (Soewondo, Husaini, and Pollitt 1989). Factors not investigated, such as increases in caloric intake, changes in psychological state, or normal physiological maturation, may improve scores, regardless of anemia. If such is the case, it creates problems with many of the studies that attempt to measure anemia and performance. An insightful commentary by Betsy Lozoff on this study concludes that "at this stage in the research on the behavioral effects of ID [iron-deficiency anemia], it seems reasonable to keep asking whether alterations in affect, motivation, or fatigue might underlie cognitive-test-score findings" (Lozoff 1989: 675).

Anemia and Sports

An interesting correlation exists between marathon runners and subnormal serum ferritin levels. Although a high cutoff of less than 20 ng/mL was used to determine iron deficiency among 30 female high school long-distance runners, 45 percent were classified as anemic; among 10 other female runners, 50 to 60 percent were classified as anemic (Rowland et al. 1988; Manore et al. 1989). Several studies indicate that regardless of dietary iron intake, individuals who ran the most miles per week had the lowest ferritin levels; if injury that prevented further running occurred, iron indexes rose (Manore et al. 1989).

Lowered serum ferritin levels in athletes have been attributed to many factors: increased iron loss through heavy sweating; trauma; slightly increased destruction of red blood cells in stressed tissues, such as muscles and the soles of the feet; common use of analgesics, such as aspirin and aspirinlike drugs, which cause blood loss; and gastrointestinal blood loss (Robertson, Maughan, and Davidson 1987). A significant, though clinically unimportant, increase in fecal blood loss occurred in male marathon runners who had not taken any drugs prior to running. The 28 percent who had taken an analgesic known to promote bleeding had blood losses that could eventually result in anemia (Robertson et al. 1987). Most physicians consider the blood loss and its cause inconsequential in healthy athletes and do not recommend routine hematological monitoring or iron supplementation (Wardrop 1987).

Conclusions and Direction of Future Studies

Despite many studies supporting the view that iron fortification and supplementation might be harmful for infants, pregnant women, and others (for example, Hibbard 1988), some physicians continue to advocate indiscriminate iron fortification (Arthur and Isbister 1987; Taylor and Bergman 1989). However, a growing number of studies concerning the anemia of chronic disease conclude that "[o]ur data . . . do not support the routine prescription of iron . . . in patients on CAPD [continuous, ambulatory peritoneal dialysis]" (Salahudeen et al. 1988). In fact, even though the use of iron chelators that bind iron to reduce chronic diseases is still experimental, initial studies look promising (Vreugdenhil et al. 1989). That is, less iron rather than more may reduce morbidity.

Treating all anemia as dietary iron-deficiency anemia can have potentially deleterious effects on populations most needing health-care assistance. Iron-deficiency anemia occurs in areas where war, export or cash cropping, and other extreme situations deny people their basic requirements of calories, vitamins, and nutrients to sustain life. Dietary improvements are sorely needed in those situations. Anemia from blood loss primarily from parasites, and also from the premature introduction of cow's milk to infants, is an acute health-maintenance problem. Rectification through medication and improved sanitation and education is needed. Anemia of chronic disease is a positive defense against infections and inflammation and, as such, should not be interfered with; however, the underlying diseases that cause the anemia need to be eradicated.

Iron supplementation is a relatively easy, inexpensive counter to dietary anemia. Perhaps that partially explains why so many people cling to the idea that iron taken orally or through injections will reduce morbidity. However, the complexity of iron and its relationship to anemia are emphasized here to show that simple solutions cannot solve complex problems.

Susan Kent

This chapter is dedicated to Dr. Eugene Weinberg and his work. I greatly value the comments and suggestions made by Drs. Steven Kent and Weinberg. I thank Dr. Kenneth Kiple for giving me the opportunity to write this paper and for editorial advice. Marian Blue also provided editorial suggestions.

Notes

1. One study (Baltimore, Shedd, and Pearson 1982) contends that studies in vivo do not support the conclusions from studies in vitro of excess iron predisposing individuals to infections. One explanation for their finding that increased iron does not increase *E. coli* growth is that a few bacteria, including *E. coli* possessing K_1 antigen, are virulent even without iron supplementation (Payne and Finkelstein 1978). This group of pathogens "appeared to produce greater quantities of compounds (siderophores) which stimulated microbial growth in low-iron media than did the nondisseminating pathogens" (Payne and Finkelstein 1978: 1428). Unfortunately, the Baltimore, Shedd, and Pearson (1982) study does not specify whether the *E. coli* they investigated contained the K_1 antigen, but it is possible that other mutants of a bacterium may be able to proliferate in low-iron media. The vast majority of other studies contradict these authors.
2. Although at one time it was thought that hookworm was not indigenous to the Americas, hookworm was found in a 1,100-year-old Peruvian mummy and in a 3,500-year-old Brazilian mummy (Allison 1974; Ferreira, de Araujo, and Confalonieri 1980, 1983).
3. The same hematological surveys detected iron overload in 1.3 percent of 157 healthy urban adults, a figure similar to the percentage of anemic individuals for males (Haddy et al., 1986). However, in a larger study that involved 11,065 subjects, iron overload as measured by elevated transferring saturation levels was detected in only 0.8 percent of men and 0.3 percent of women (Edwards et al. 1988). The problem with interpreting this study is that the subject population was drawn from blood donors, a practice that tends to lower transferrin saturation levels. The actual prevalence of iron overload appears to be roughly similar to anemia in males under the age of 45.
4. There are a few specific genes associated with particular populations within black or other racial categories but not genes that only blacks share to the exclusion of all other groups.
5. A similar problem of distinguishing cause and effect can be seen with the immunological system and anemia. Some investigators claim their studies illustrate that anemia causes an impairment in the immunological system, which affects the body's ability to ward off disease (e.g., Vyas and Chandra 1984). Others claim their studies illustrate that anemia improves immunity from disease (Murray and Murray 1977). For instance, despite in vitro studies that show experimentally that there is a decrease in bactericidal capabilities in neutrophils, in vivo studies of human infections show that "no noticeable increase was observed in respiratory, gastrointestinal, or in morbidity, either in the few days before the initiation of iron therapy, or in the subsequent 15 days of close clinical and laboratory follow-up, confirming previous observations that iron-deficiency anemia, even when severe, does not appear to compromise immune mechanisms to the extent of allowing ominous clinical manifestations" (Walter et al. 1986).

IV.D.3 ~ Keshan Disease

Discovery and Characteristics of the Disease

Keshan disease (KD) is a unique endemic cardiomyopathy in China with high incidence and mortality. Its etiology and pathogenesis are not as yet completely clear.

In the winter of 1935, an outbreak of an unknown disease with sudden onset of precardial oppression, pain, nausea, vomiting (yellowish fluid), and fatal termination in severe cases occurred in Keshan County, in Heilongjiang Province of northern China. Because its cause was not known, it was named after the place of outbreak by a Japanese military surgeon (Apei 1937).

Later, Keshan disease was also reported from other parts of China and, in fact, research now indicates that the condition has been prevalent in that country for close to 200 years. The earliest-known account of the disease was found in an inscription on a stone pillar at Jinling Temple, Xiaosi village, Huanglong County, Shaanxi Province, in 1812 (Shan and Xue 1987).

Epidemiological Characteristics

There are three major epidemiological characteristics of Keshan disease. The first is its regional distribution. Keshan disease areas are focally distributed in a belt extending from northeast to southwest China and usually located in hilly land. There are isolated spots known as "safety islands" surrounded by affected areas. The second is population susceptibility. Children below 15 years of age and women of childbearing age in northern China, and children below 10 years of age in southern China, constitute the most susceptible populations. They all live in rural areas and in farm families. The third characteristic is seasonal prevalence. The peak season of Keshan disease in northern China is in winter, but in the south it is in summer. There is also a natural fluctuation of prevalence from year to year.

The annual incidence, mortality, and case fatality of Keshan disease in China are shown in Figure IV.D.3.1. The peak years of 1959, 1964, and 1970 had incidences of 6.02, 4.17, and 4.04 per 10,000, respectively, and the mortality was 1.996, 0.978, and 0.676 per 10,000 (Sun et al. 1982; Sun 1987; The Ministry of Public Health of China 1987–95).

Clinical Manifestations

There are no specific symptoms and signs that clearly identify Keshan disease. But according to the degree of heart function insufficiency and of compensative status, Keshan disease is classified into four clinical types: acute, subacute, chronic, and latent (Ge et al. 1983).

Acute cases usually occur suddenly, with acute heart function insufficiency such as cardiogenic shock, severe arrhythmia, and pulmonary edema. The prominent characteristic of the chronic type is chronic congestive heart failure, which is the consequence of acute or subacute types or a result of a long-standing cardiac disorder of an insidious onset. Moderate or severe heart enlargement is always seen in chronic cases.

Subacute cases occur primarily in children. The onset is less sudden and the insidious period is about one or two weeks. The clinical manifestations of the subacute type are mainly cardiogenic shock and/or chronic congestive heart failure, and most patients have facial edema and galloping rhythm of the heart. Latent cases may be discovered as only an incidental finding upon routine physical examination. They usually show a mildly enlarged heart with normal heart function, abnormal electrocardiogram changes of the right bundle branch block, and infrequent premature ventricular contractions.

Pathological Observations

A large number of autopsies have been carried out since the recognition of Keshan disease in 1935. More than 3,600 autopsy cases were collected in the 1950s,

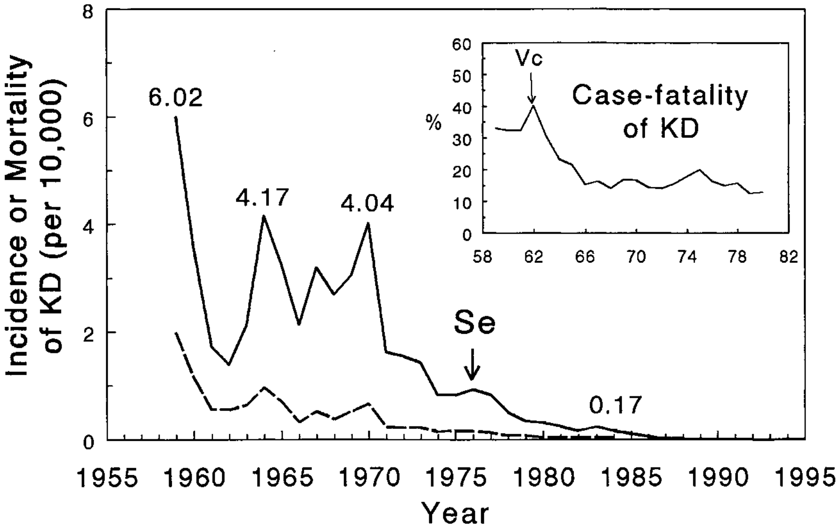

Figure IV.D.3.1. The incidence, mortality, and case-fatality of Keshan disease in China. Solid line (—) is the incidence of Keshan disease (1/10,000). Dashed line (- - -) is the mortality of Keshan disease (1/10,000).

when there was a heavy prevalence of the disease in northern China. Later, an endemic cardiomyopathy that was prevalent in children in southern China was studied and in 1965 identified as Keshan disease. Since then, large amounts of epidemiological, clinical, and pathological data have been accumulated in the south.

Multifocal necrosis and fibrous replacement of the myocardium are the principal pathological features of Keshan disease (Ge et al. 1983). Two patterns of myocardial necrosis are distinguishable by light microscopy. One is myocytolysis; the other is contraction band necrosis. Myocytolysis exists in the majority of cases and is regarded as a representative lesion of Keshan disease. It seems to be initiated by mitochondrial disorganization and results in the final disappearance of the myofibers. Contraction band necrosis is characterized by myofibril segmentation and has been considered to be the consequence of the severe circulatory disorders predominantly observed in acute cases.

Treatment

There is no specific therapy for Keshan disease. However, the method of administering a megadose of ascorbic acid (vitamin C) in cases of acute and subacute Keshan disease was discovered by Xian Medical College in 1961 (Research Laboratory of Keshan Disease of Xian Medical College 1961). It was a breakthrough in the treatment of Keshan disease and particularly effective in patients with cardiogenic shock. Since then, the case fatality of the acute type of Keshan disease has decreased significantly from 80 percent to less than 20 percent (Figure IV.D.3.1). Patients with congestive heart failure require prompt and optimal digitalization, although the response in some cases is poor. Other treatments (antibiotics, oral diuretics, and moderate restriction of salt) are used for the control of congestive heart failure (Yang et al. 1984).

The Relation between Selenium and Keshan Disease

In the 1960s, it was found that white muscle disease (WMD) in young ruminants caused by selenium (Se) deficiency often occurred in areas affected by Keshan disease, and some similarities in clinical symptoms and pathological features between Keshan disease and white muscle disease were found. The scientists in the Institute of Shaanxi Veterinary Medicine suggested that both Keshan disease and white muscle disease could be responsive to selenium. Small-scale human intervention studies were carried out by several research groups, and some encouraging results were obtained; however, the effectiveness of Se supplementation was demonstrated only by a large-scale selenium intervention study in Mianning County, Sichuan Province, in southwestern China. This study was carried out from 1974 to 1976 by the Keshan Disease Research Group, Chinese Academy of Medical Sciences (Keshan Disease Research Group, Chinese Academy of Medical Sciences 1979).

Sodium Selenite Intervention

In 1974, 119 production teams observed children of susceptible age (1 to 9 years) in three villages of Mianning County. In 1975, the study was extended to include 169 teams in four villages. One-half of the children were given sodium selenite tablets and the other half a placebo. The assignment to one of these groups was made randomly and remained unchanged during the two years of the investigation. The subjects took sodium selenite once a week, with a dosage of 0.5 milligrams (mg) for those aged 1 to 5 years and a dose of 1.0 mg for those 6 to 9 years old. Because of the convincing results obtained in 1974 and 1975 (to be discussed shortly), the control groups were abandoned and all subjects were given sodium selenite in 1976 and 1977.

A Keshan disease hospital was established in the area under investigation; there, diagnosis and subtyping of the disease were carried out according to the criteria set up in 1974 by the National Seminar of the Etiology of Keshan Disease. Electrocardiograms, heart roentgenograms, and physical examinations were performed on patients admitted to the hospital for observation. In some cases, blood Se content, glutathione peroxidase (GPX), serum glutamic oxalacetic transaminase (GOT), and glutamic pyruvic transaminase (GPT) activity were determined. Patients receiving treatment at other medical units were transferred to the hospital after the improvement of their general condition. Follow-up examinations were carried out each year to study the progress of individual patients.

The incidence and prognosis of the subjects investigated are shown in Table IV.D.3.1. In 1974, among the 3,985 children in the control group, there were 54 cases of Keshan disease (13.55 per 1,000), whereas only 10 of the 4,510 Se-supplemented subjects fell ill (2.22 per 1,000). The difference between the incidence of the two groups was highly significant ($P < 0.01$). A similar difference was found in 1975. In 1976, when all subjects were given selenite, only 4 cases out of 12,579 subjects occurred, which further lowered the incidence to 0.32 per 1,000. There was 1 case of the typical subacute type among 212 children who failed to take selenite. In 1977, there were no new cases among the 12,747 supplemented subjects. These results indicated that sodium selenite intervention had a significant effect in reducing incidence of Keshan disease. The Se-supplemented subjects had not only a lower incidence but also lower mortality and better prognosis.

In 1976 and 1977, liver function tests and general physical examinations were given to 100 subjects who had taken Se tablets weekly for three to four years. The results were not significantly different from

Table IV.D.3.1. *Keshan disease incidence and prognosis of selenium-supplemented and control children (1–9 years old) in Mianning County, Sichuan Province, China, during 1974–7*[a]

					Prognosis			
Groups	Year	Subjects	New cases	Incidence (‰)	Turned chronic	Turned latent	Improved	Death
Se-supplemented	1974	4,510	10	2.22	1	9	0	0
	1975	6,767	7	1.03	0	6	0	1
	1976	12,579	4	0.32	0	2	0	2
	1977	12,747	0	0	0	0	0	0
(Total)		36,603	21	0.57	1	17	0	3
Control	1974	3,985	54	13.55	2	16	9	27
	1975	5,445	52	9.55	3	13	10	26
	1976	212	1	4.72	1	0	0	0
(Total)		9,642	107	11.10	6	29	19	53

[a] There are significant differences of incidence between the two groups in each year and in total ($P < 0.01$).

those for the unsupplemented children and indicated that selenium-supplementation produced no untoward side effects.

In 1976, observations on the effects of sodium selenite were extended beyond Mianning County to include Dechang, Xichang, Yuexi, and Puge Counties. All children (1 to 12 years old) in some of the most severely affected areas were supplemented with selenite as just described, whereas the children in the nearby areas served as unsupplemented controls. The results, summarized in Table IV.D.3.2, show that in each year the incidence of Keshan disease among the Se-supplemented children of the five counties was significantly lower than that among the unsupplemented children. Similar results were obtained by Xian Medical College in a study in Huanglong County, Shaanxi Province, from 1975 to 1977 (Research Laboratory of Keshan Disease of Xian Medical College 1979).

Because of the convincing evidence of the efficacy of sodium selenite in preventing Keshan disease, it has been widely used since 1976 in tablet form, as an addition to table salt, and as a fertilizer. Concomitantly, the incidence and mortality of Keshan disease decreased to 0.17 and 0.04 per 10,000, respectively (Figure IV.D.3.1).

Occurrence in Selenium-Deficient Areas

Since regional distribution is the first epidemiological characteristic of Keshan disease, the discovery of environmental differences between areas that are affected by Keshan disease and those that are not has been an important goal in the study of its etiology.

A fluorometric method for determining Se content and another method for determining glutathione peroxidase (GPX) activity were adapted and set up by the Keshan Disease Research Group of the Chinese Academy of Medical Sciences in 1972 and 1975. Sampling techniques indicated that blood and hair Se content and blood GPX activity of residents in Keshan disease–affected areas were lower than those of people in nonaffected areas (see Table IV.D.3.3). However, after the oral administration of sodium selenite for 1 year, the blood GPX activity of children in Keshan disease–affected areas had increased to levels comparable to those of children in nonaffected areas (see Table IV.D.3.4).

It was assumed that the low-selenium status of people living in Keshan disease–affected areas was caused by a low dietary selenium intake. Therefore, large samples of cereals, soil, water, and human blood, hair, and urine from Keshan disease–affected areas (11 provinces, 42 counties, 77 spots) and nonaffected

Table IV.D.3.2. *Keshan disease incidence in selenium-supplemented and control children (1–12 years old) in five counties of Sichuan Province, China, during 1976–80*[a]

	Se-supplemented			Control		
Year	Subjects	New cases	Incidence (‰)	Subjects	New cases	Incidence (‰)
1976	45,515	8	0.17	243,649	488	2.00
1977	67,754	15	0.22	222,944	350	1.57
1978	65,953	10	0.15	220,599	373	1.69
1979	69,910	33	0.47	223,280	300	1.34
1980	74,740	22	0.29	197,096	202	1.02
Total	323,872	88	0.27	1,107,568	1,713	1.55

[a] There are significant differences of incidence between the two groups in each year and in total ($P < 0.01$).

Table IV.D.3.3. *Selenium levels in human blood and hair from residents in Keshan disease-affected and nonaffected areas in 1972–3*

Subjects[a]	Blood Se (ng/g)[b]	Hair Se (ng/g)[b]
KD-affected areas		
KD patients	18 ± 9 (42)^{a}	107 ± 53 (21)^{f}
Farmers	21 ± 7 (24)^{a}	
Nonaffected areas (near KD areas)		
Farmers	32 ± 4 (20)^{b}	187 ± 51 (20)^{g}
Staff members in town	41 ± 21 (10)^{c}	
Nonaffected areas (far from KD areas)		
Staff members (A) in city	173 ± 44 (16)^{d}	712 ± 97 (13)^{h}
Staff members (B) in city	255 ± 38 (17)^{e}	834 ± 156 (11)^{k}

[a] Staff members (A) were the members of a KD research group of the Chinese Academy of Medical Sciences and had been in KD areas for less than one year; staff members (B) had never been in KD areas.

[b] Values are means ± SD; number of samples is in parentheses; values not sharing a common superscript in a vertical column are significantly different ($P < 0.05$) by the t-test.

areas (20 provinces, 86 counties, 110 spots) were collected. The data indicated that the samples containing less than 20 nanograms/gram (ng/g) of Se in blood or 120 ng/g in hair or 10 ng/g in cereals were almost exclusively from Keshan disease–affected areas, whereas samples with Se content of more than 50 ng/g in blood or 200 ng/g in hair or 20 ng/g in cereals were all from nonaffected areas (Yang et al. 1982). These data could be considered the threshold of Se content in assessing the risk of Keshan disease, especially for those who live on a rather simple diet composed mainly of locally grown cereals (Table IV.D.3.5).

Similar results from more than 10,000 samples were reported by the Institute of Geography, Chinese Academy of Sciences (Group of Environmental and Endemic Disease 1982; Xu et al. 1982). Based on a large amount of data, a map of selenium distribution in China was published in *The Atlas of Endemic Diseases and Their Environments in the People's Republic of China* (1989). It shows that low-selenium areas are distributed in a belt extending from northeast to southwest China, which is consistent with the geographical distribution of Keshan disease.

Table IV.D.3.4. *Blood gluthathione peroxidase (GPX) activities of children from Keshan disease–affected and nonaffected areas in 1975*

Subjects	Blood GPX (units)
KD-affected areas	
KD child patients	57.1 ± 6.1 (22)^{a}
Healthy children	60.5 ± 5.6 (63)^{a}
Se-supplemented children	76.1 ± 8.4 (58)^{b}
Nonaffected areas (near KD areas)	
Children in farmer's family	73.6 ± 13.8 (20)^{b}
Nonaffected areas (far from KD areas)	
Children in farmer's family	77.5 ± 9.8 (22)^{b}

Note: Values are means ± SD; number of samples is in parentheses; values not sharing a common superscript are significantly different ($P < 0.01$) by the t-test.

Table IV.D.3.5. *Selenium contents of blood, hair, and grains in Keshan disease–affected and nonaffected areas*

Samples	KD areas (ng/g)	Overlapping areas (ng/g)	Non-KD areas (ng/g)
Human blood	< 20	20–50	> 50
Human hair	<120	120–200	>200
Staple grain	< 10	10–20	> 20

The results obtained by medical, veterinary, and geographical scientists all indicated that Keshan disease occurs only in selenium-deficient areas, which explains the epidemiological characteristic of its regional distribution. The fact that the blood and hair Se levels and GPX activity of farming residents are lower than those of nonfarming residents in the same Keshan disease–affected areas at least partially explains the characteristic of population susceptibility. In view of the results just described, it was concluded that selenium deficiency is the basic cause of Keshan disease occurrence.

Biochemical Changes

There were no significant differences in Se status and GPX activity between Keshan disease patients and other residents of the same areas (Zhu, Xia, and Yang 1982). There were also no changes in hair Se content to accompany the seasonal or yearly fluctuation of Keshan disease prevalence (Sun et al. 1980). These facts suggest that the etiology of Keshan disease cannot be explained by selenium deficiency alone and that there is a need to understand the ways in which selenium prevents Keshan disease.

A Study on Keshan Disease Patients

A comprehensive scientific survey of Keshan disease in Chuxiong prefecture, Yunnan Province, southwestern China, was conducted from 1984 to 1986 by 293 workers from 16 laboratories in seven provinces. The objective was to examine 3,648 children from 56 villages in Keshan disease–affected and nonaffected areas and compare the two groups. One hundred and sixty-seven children who were Keshan disease patients were treated, and 27 autopsies were carried out on patients who had died of subacute Keshan disease. Autopsy controls consisted of those who died from other diseases in both affected and nonaffected areas. The results of this survey were published in the *Collected Work of Comprehensive Scientific Survey on Keshan Disease in Chuxiong Prefecture (1984–1986)* (Yu 1988).

Table IV.D.3.6 *Selenium contents and glutathione peroxidase (GPX) activities in tissues from patients with subacute Keshan disease (Sub-KD) and controls in affected (Control-A) or nonaffected areas (Control-NA)*

		Sub-KD	Control-A	Control-NA
Selenium (ng/g fresh)	Heart	25 ± 10 (6)[a]	55 ± 32 (4)[a]	134 ± 32 (3)[b]
	Liver	52 ± 30 (6)[a]	89 ± 50 (4)[a]	256 (1)
GPX (U/mg protein)	Heart (H_2O_2)	10 ± 5 (11)[a]	26 ± 21 (7)[b]	73 ± 12 (20)[c]
	(t-BOOH)	10 ± 5 (11)[a]	29 ± 25 (7)[b]	80 ± 12 (2)[c]
	Liver (H_2O_2)	7 ± 4 (4)[a]	38 ± 11 (3)[b]	
	(t-BOOH)	23 ± 5 (4)[a]	47 ± 25 (3)[b]	
	Kidney (H_2O_2)	20 ± 7 (4)[a]	78 ± 39 (3)[b]	
	(t-BOOH)	32 ± 2 (4)[a]	85 ± 36 (3)[b]	

Note: Values are means ± SD: number of samples is in parentheses; values not sharing a common superscript in a horizontal row are significantly different ($P < 0.01$) by the t-test.

The comparison of Se content and GPX activity in the tissues of patients with subacute Keshan disease (Sub-KD) and those of the controls in affected (Control-A) and nonaffected areas (Control-NA) is shown in Table IV.D.3.6. There was a tendency for Keshan disease patients to have lower heart and liver Se levels than the controls, and their GPX activity was significantly lower than that of the controls. Other results supported the hypothesis that the heart is the organ most susceptible to selenium deficiency.

Other oxidant defense indices in the myocardium of child patients with Sub-KD were measured. The results showed that the activity of superoxide dismutase (SOD) in the myocardia of Sub-KD patients was significantly lower than that of Control-NA subjects, but malondialdehyde (MDA) and free radicals were higher than those of Control-NA. These results indicated that there was an accumulation of lipid peroxides and free radicals in Keshan disease patients. However, there were no differences between Sub-KD patients and controls in glutathione reductase (GR) and glutathione-S-transferase (GST) activity.

Ultrastructural observations showed that mitochondria in the myocardia of Sub-KD patients appeared to be most commonly and conspicuously affected and were involved early. In general, the changes in biochemical functions occurred before the structural damage. The results indicated that the activity of succinate dehydrogenase (SDH), cytochrome C oxidase (CCO), and H^+-ATPase, and content of Co Q in the myocardial mitochondria of Sub-KD patients were lower than those of Control-NA. These findings implied that the lesions of the mitochondria affect mostly the respiratory chain of the inner membrane. Changes in membrane potential and decreased fluidity of membrane lipid were observed in the myocardial mitochondria of Sub-KD patients. The content of Se in the mitochondria was one-eighth that of Control-NA (Yu 1988). It is likely that the structural and functional abnormalities of the myocardial mitochondria of patients with Keshan disease may result from selenium deficiency. In addition, the mitochondria constitute one of the calcium pools and play an important role in regulating the calcium concentration in cells. The increased calcium content in the myocardial mitochondria of Sub-KD patients may have an intrinsic relationship with the functional abnormalities.

From this comprehensive survey, it was concluded that relatively weak oxidant defenses, mainly low GPX activity, and insufficient vitamin E (less than 8 μg/ml plasma in people living in Keshan disease–affected areas) created a selenium-deficient population susceptible to oxidant stresses that resulted in damage to myocardial structures and functions and finally in the occurrence of Keshan disease.

Effects of Se Deficiency

It was not clear whether differences in dietary patterns (aside from selenium intake) between people in Keshan disease–affected and nonaffected areas were involved in the etiology of Keshan disease. Three studies were carried out in 1987, 1989, and 1991 in Mianning and Dechang Counties, Sichuan Province, where there was a very high incidence of Keshan disease there was during the 1970s. These two counties are only 150 kilometers (km) apart and have the same dietary patterns. According to the results from a nutrition survey in 1985, conducted by the Anti-Epidemic Station of Liangshan Autonomous Prefecture, the dietary selenium intake was 11 μg per day for both counties. The only difference was a supplementation of selenized salt (15 μg selenium per g salt, as sodium selenite) in Mianning County from 1983 onward, so the people of Mianning had 69 μg of extra selenium per day, giving them a total selenium intake of 80 μg per day. Table IV.D.3.7 shows the results of a study conducted in 1987 (Xia, Hill, and Burk 1989; Hill et al. 1996) following selenized salt supplementation for 4 years. Not only were the blood Se levels of children in Mianning County higher than those in Dechang County, but the GPX activity of their plasma was three times as high, and plasma selenoprotein P concentrations were also much higher. Linear regression analysis of plasma showed that selenium concentration, GPX activity, and selenoprotein P concentration correlated well with each other. There were no differences in other indices for oxidant defense capability between the residents of the two counties.

Table IV.D.3.7. *Indexes for oxidant defense capability in the blood of children from Dechang and Mianning Counties in 1987*

		Dechang (–Se)		Mianning (Se-salt)	
Selenium	Blood (ng/g)	18 ± 10	(22)^{a}	47 ± 9	(18)^{b}
	Plasma (ng/g)	13 ± 55	(22)^{a}	40 ± 11	(18)^{b}
	RBC (ng/g)	26 ± 9	(22)^{a}	47 ± 9	(19)^{b}
GPX	Plasma (U/L)	29 ± 15	(21)^{a}	87 ± 15	(15)^{b}
	RBC (U/gHb)	2.8 ± 1.7	(21)^{a}	8.4 ± 3.3	(19)^{b}
Selenoprotein P	Plasma (U/L)	0.10 ± 0.04	(22)^{a}	0.39 ± 0.17	(17)^{b}
SOD	RBC (U/mgHb)	17 ± 7	(22)	17 ± 3	(19)
Catalase	RBC (U/gHb)	238 ± 48	(22)	231 ± 29	(19)
Glutathione reductase	RBC (U/gHb)	3.3 ± 1.0	(22)	4.2 ± 1.3	(19)
GSH	Plasma (µM)	4.7 ± 0.6	(21)	4.4 ± 1.0	(16)
	RBC (mM)	2.5 ± 0.4	(19)	2.1 ± 0.7	(19)
Vitamin E	Plasma (µg/ml)	4.0 ± 1.2	(22)	3.8 ± 1.2	(19)
MDA	Plasma (nmol/ml)	6.7 ± 2.2	(22)	6.0 ± 2.6	(19)

Note: Values are means ± SD: number of samples is in parentheses; values not sharing a common superscript in a horizontal row are significantly different ($P < 0.001$) by the t-test.

Effects of age and sex. In the 1989 study, blood samples were taken from 401 healthy subjects (half male and half female) in Dechang County. The lowest levels of selenium and GPX activity were found in the youngest (2 to 5 years old) and oldest (more than 60 years old), and no significant sex difference was found. These data were consistent with the occurrence of Keshan disease in children, the susceptible population group (Xia et al. 1994).

Changes in selenium intake. It was found that the selenium status and GPX activity of residents of Dechang County increased gradually year after year to reach the levels of persons in nonaffected areas in 1991. Coincidentally, there was no occurrence of Keshan disease in this year. Therefore, it was necessary to check the selenium intake of the local residents. In the 1991 study, the selenium contents of rice, table salt, and the mixed diet were measured. The data showed that selenium in rice was 16.6 ± 4.3 µg/kg ($n = 10$), which was in the same range as that of KD-affected areas (<20 ng/g in grain, see Table IV.D.3.5), but selenium intake from the diet was estimated to be 38 ± 28 µg/day ($n = 30$), which reached the minimum requirement of 20 µg/day (Yang et al. 1985; Yang and Xia 1995). This change probably resulted from the inadvertent distribution of selenized salt in Dechang County and, with the improvement of the local economy, the increased consumption of food from selenium-adequate areas. It was confirmed that the decrease of Keshan disease incidence in Dechang County correlated with an improved selenium status because of an increase in dietary selenium intake.

Marginal vitamin E status. Vitamin E (VE), an important constituent of the oxidant defense system, protects biological membrane tissue as a free-radical scavenger and has a synergistic effect with selenium. Animal studies have indicated that cardiac injury can be developed in animals fed a diet deficient in both selenium and vitamin E but that neither deficiency by itself causes cardiac injury (Van Vleet, Ferrans, and Ruth 1977; Konz et al. 1991). Other animal studies have indicated that myocardial injury can occur in animals fed a diet of foods from Keshan disease–affected areas and that this condition can be alleviated by the supplementation of selenium or vitamin E or both (Wang et al. 1991). Plasma vitamin E of residents of Keshan disease–affected areas ranged from 2 to 8 µg/ml, which is a low marginal status (Keshan Disease Research Group, Chinese Academy of Medical Sciences 1977a; Li et al. 1988; Xia et al. 1989; Zhu et al. 1991). This low marginal vitamin-E status could act as a promoting cofactor in the occurrence of Keshan disease. If so, vitamin E supplementation might be helpful in improving the low selenium status of residents of Keshan disease areas.

The Etiology of Keshan Disease

Although the overall incidence of Keshan disease has steadily declined since the 1980s, there was a question of whether there was a corresponding change in the selenium status of local populations at risk. Geographic scientists collected 4,600 samples (rock, soil, water, cereals, animal fur, and human hair) from 217 sampling spots and monitored the incidence of Keshan disease for three years in the 1980s (Tang et al. 1991). The results (see Table IV.D.3.8) indicated that the environmental selenium status was still as low as that in the 1970s, but the selenium level in hair had increased to a normal level (see Table IV.D.3.5). It is believed that in addition to deliberate selenium supplementation, there has been inadvertent supplementation as a previously self-sufficient lifestyle gave way to a commodity economy, in which foods with higher selenium content were imported into the affected

Table IV.D.3.8. *Comparison of selenium contents in cereals and human hair between the 1970s and 1980s*

	1970s	1980s
Corn (µg/kg)	13 ± 6 (157)^{a}	10 ± 9 (90)^{b}
Rice (µg/kg)	14 ± 8 (47)	15 ± 11 (31)
Wheat (µg/kg)	14 ± 7 (115)	13 ± 9 (96)
Hair (µg/kg)	85 ± 32 (815)^{a}	192 ± 96 (44)^{b}

Note: Values are means ± SD; number of samples is in parentheses; values not sharing a common superscript in a horizontal row are significantly different ($P < 0.001$) by the t-test.

areas. In addition there has been an increase in the consumption of animal products in recent years. All of this would seem to confirm that an adequate selenium status is necessary for the prevention of Keshan disease.

Although selenium deficiency can explain the epidemiological characteristic of the regional distribution of Keshan disease, it only partially explains the susceptibility of populations. Because the selenium status of residents in Keshan disease–affected areas does not change with seasonal fluctuation of the incidence of the disease, another potential cofactor (or cofactors) must be involved in its occurrence. Such cofactors would act as promoters or stimulators during selenium deficiency.

The potential cofactors in the etiology of Keshan disease can be classified into four categories:

1. An insufficiency of nutrients that have relative biological function with selenium, such as VE, methionine, and iodine.
2. An excess of elements that have antagonistic interaction with selenium, leading to poor availability of selenium.
3. The prevalence of mycotoxins that contaminate foods and damage the myocardium.
4. A virus infection in which the target organ is the heart (Su 1979; Bai et al. 1984).

Present information does not permit ruling out any one of these as a cofactor in selenium deficiency and in the etiology of Keshan disease.

Clearly, much work remains to be done, even though studying the etiology of Keshan disease presents some difficulties. One problem is that there are no ideal animal models for Keshan disease; another is that almost no new Keshan disease patients can be found (only 57 new patients were reported in the whole country in 1995). However, it is believed that the pathogenic factors in Keshan disease areas are still active because, according to the Annual Report from the Ministry of Public Health of China there are about 50,000 latent Keshan disease patients in the country. Therefore, work will continue.

IV.D.4 Osteoporosis

Calcium and Life

Calcium is the fifth most abundant element in the biosphere, after oxygen, silicon, aluminum, and iron. It is present in high concentration in seawater and in all fresh waters that support an abundant biota. Fortuitously, the calcium ion has just the right radius to fit neatly within the folds of various peptide chains. Calcium thereby stabilizes and activates a large number of structural and catalytic proteins essential for life. In this capacity calcium serves as a ubiquitous second messenger within cells, mediating such diverse processes as mitosis, muscle contraction, glandular secretion, blood coagulation, and interneuronal signal transmission. Controlling these activities requires careful regulation of the concentration of calcium in critical fluid compartments. This regulation is accomplished in two basic ways.

At a cellular level, calcium is ordinarily sequestered within intracellular storage compartments. It is released into the cell sap when needed to trigger various cellular activities, and then quickly pumped back into its storage reservoirs when the activity needs to be terminated. This control mode is exemplified by the accumulation and release of calcium by the sarcoplasmic reticulum of striated muscle. The second type of control, utilized by many tissues in higher organisms, is the tight regulation of the calcium level in the blood and extracellular fluids that bathe all the tissues. Individual cells, needing a pulse of calcium, simply open membrane channels and let calcium pour in from the bathing fluid; they then pump it back out when the particular activity needs to cease.

Bone and the Regulation of Calcium Levels

Each mode of control requires both a reserve supply of calcium and a place to put an excess of calcium: In the first mode, the source and sink are within the cell; and in the second, they are outside the cell but still within the organism. The extracellular calcium reserve (and sink) in the higher vertebrates has, over the course of evolution, become the organ system we call bone. Along the way, building on the hardness of calcium deposits, bone acquired the mechanical and structural functions that have become its most prominent features.

The fossil record shows that bone evolved independently many times over the course of vertebrate evolution, usually in a marine environment where bone probably functioned primarily as a sink for calcium (since the fluid in contact with the gill surfaces represented an essentially inexhaustible source). The hardness of bone served many useful, but secondary purposes, ranging from dermal armor, to teeth, to internal stiffening. As mechanisms of controlling concentration of minerals in the internal environment evolved to higher levels of refinement and an internal sink became less necessary, the internal skeleton dropped out of many fish genera, which retained only the structural portions that were vital – teeth and dermal armor.

But in amphibians and terrestrial vertebrates, living outside of a buoyant medium, the internal stiffening could not be dropped. It provided structural support and mechanical strength, and it permitted movement against gravity. Also, deprived of constant contact with a bathing medium high in calcium, the organism now became more dependent upon internal reserves of calcium to ensure maintenance of constant calcium concentrations in the extracellular fluids.

While this need for a calcium reserve in terrestrial vertebrates is virtually self-evident, it is useful to note that the sink function, sequestering of excess calcium, remains important on dry land as well. (If calcium were constantly in short supply, of course, then a reserve sufficient to serve a structural function could never be accumulated in the first place.) Typically, in the life of a terrestrial vertebrate, the reserve function of the skeleton is called upon only intermittently. At other times the skeleton stores excesses of calcium made available from the environment. This process, as already noted, is constantly needed in a marine habitat but occurs mainly on feeding for most terrestrial vertebrates.

Once vertebrates came out onto dry land, two sometimes competing objectives had to be managed: maintaining the extracellular fluid calcium level and maintaining the size of the skeletal reserve. Whereas the former could be managed in a marine environment by adjusting fluxes of ions across the gill membranes, on dry land it had to be done by adjusting the net flow of calcium into and out of bone. In this process bone mass itself actually changes as the skeleton functions to support the body fluid calcium levels, and skeletal structural strength necessarily changes in parallel. The size of the reserve, which is the basis for bone strength, is ultimately limited by forces acting outside the skeleton, that is, by adjusting inflow from ingested foods and outflow through the kidney, as well as by a mechanical feedback system within the skeleton (see following discussion). It must be noted, however, that the extraskeletal portion of that regulatory system works adequately only when ingested food contains sufficient calcium.

Calcium Abundance in the Diets of Terrestrial Vertebrates

Calcium is so abundant in even the terrestrial environment that most wild foods contain relatively large quantities of it. In fact, much of the calcium content of several leafy plants, notably the halophytes (for example, spinach), represents a plant tissue analogue of the bony sink of marine vertebrates. In other words, the plant creates calcium deposits as a means of keeping calcium levels from rising too high in plant tissue fluids. However, that sequestered calcium remains a part of the plant and hence becomes available to the animal eating it.

By the time they eat sufficient food to meet total energy needs, most mammals have inevitably ingested a great deal of calcium. This calcium load is generally so great that higher vertebrates have evolved mechanisms to prevent being swamped by an excess of calcium. One of these has been the development of a relative absorptive barrier at the intestine, and the second has been the ability to damp out any elevations in extracellular fluid calcium by promptly transferring an excess of absorbed calcium into bone.

But there are some delicate trade-offs involved here, particularly in terrestrial vertebrates, where the structural significance of the skeleton is crucial (even if a secondary function, from an evolutionary standpoint). The absorptive barrier can only be partial, or it would not be possible to accumulate adequate skeletal mass to serve a structural function, nor to repay temporary withdrawals from the reserve. Urinary excretion might take care of an absorbed surplus, and in fact certainly does so in most vertebrates, but calcium is relatively insoluble, and renal capacity for handling large excesses of calcium is limited by the propensity of the kidney tissue to calcify. Thus, organisms evolved mechanisms for temporarily putting excess calcium into the skeleton during the absorptive phase after feeding and then withdrawing it from the skeleton, as needed, during periods of fasting or starvation.

The need for a reserve during fasting is not because calcium is consumed in the various metabolic processes that it activates (as would be the case, for example, with ascorbic acid or the B vitamins) but because calcium is lost every day through skin and excreta. Further, during childbearing, calcium is transferred from the mother to the progeny, both in utero and through lactation. Hence, there is an obligatory calcium need throughout life, first to accumulate skeletal mass during growth and then to offset daily losses at all ages.

Bone Remodeling and Bone Mass

Bone has no capacity simply to soak up or release calcium ions on need. Rather, these functions are served by forming and destroying actual packets of bony tissue. Collectively these processes of formation and resorption are termed "bone remodeling." Remodeling occurs throughout life and serves several essential functions.

In the adult skeleton, the first step in remodeling is almost always bone resorption; the old material has to be cleared away before new bone can be deposited. In reabsorbing bone, osteoclasts attach to a bony surface and secrete acid to dissolve the mineral and proteolytic enzymes to digest the matrix. They thereby physically remove a volume of bone. The calcium content of that volume is released into the bloodstream and becomes available both to support the level of calcium in the extracellular fluids of the body against the various drains to which it may be subject and to meet the calcium demands of bony sites elsewhere in the body that happen currently to be in their mineralization phase.

Bone is formed by osteoblasts, which first deposit a protein matrix on an excavated surface and then act on it to create crystal nuclei of calcium phosphate. Thereafter, these nuclei grow by accretion, without further cell work, spontaneously adding calcium and phosphate ions drawn out of the blood that flows past the mineralizing site. Once deposited at any given site, calcium is permanently trapped and can be removed only by the process of bone resorption at that site.

Remodeling fluxes into and out of bone, in the mature adult, are typically in the range of 300 to 500 milligrams of calcium (mg Ca) per day, or about two to four times as large as the aggregate of the external calcium fluxes (absorption and excretion).

Calcium Homeostasis

The balance between bone formation and resorption is adjusted so as to keep the calcium concentration of the extracellular fluid constant. The process is mediated mainly through the action of what are termed "calciotrophic hormones" – principally parathyroid hormone, calcitonin, and calcitriol – with parathyroid hormone being the most important in mature adults, and calcitonin and calcitriol notably more important in infancy.

Parathyroid hormone secretion is evoked by a fall in extracellular fluid calcium level, and calcitonin secretion by a rise. Parathyroid hormone acts to raise falling calcium levels by activating bone remodeling, by reducing renal calcium losses, and by increasing renal synthesis of calcitriol, the active hormonal form of vitamin D (which enhances intestinal absorption efficiency). Activation of remodeling helps raise a falling calcium level because resorption precedes formation, and thus in its early phases, remodeling provides a temporary surplus of calcium. Calcitonin, in contrast, lowers elevated calcium levels by temporarily suppressing bone resorption, thus stopping the release of calcium from bone.

The activity of maintaining the constancy of extracellular fluid calcium concentration is termed "calcium homeostasis." The body's ability to adjust bone remodeling balance is an important physiological defense of the calcium levels in the extracellular fluids of the body, providing needed calcium when the level would otherwise drop and soaking up surplus calcium when it would otherwise rise.

Given the calcium abundance in the diets of virtually all mammals, the reserve function in subhuman species operates mainly during periods of excessive skeletal demand or transient environmental scarcity. Such episodic withdrawal from the reserves is illustrated most clearly in what happens during antler formation in several species of deer each spring. Antlers consist of bone; their growth is usually so rapid that absorbed food calcium cannot keep up with demand, particularly given the relatively poor nutritional quality of early spring food sources. Accordingly, parathyroid hormone secretion increases sharply when antler formation begins, and a burst of bone remodeling is initiated throughout the skeleton. Because the initial phase of remodeling is resorptive, a temporary surplus of calcium is made available for antler mineralization. Later, antler growth slows or stops, and the remodeling loci throughout the skeleton enter their own phase of bone formation (which proceeds at a somewhat slower pace than for the antlers). Those sites then get the calcium they need from a diet that now contains calcium-rich summer grasses and foliage.

Averaged over the year, environmental calcium is usually quite sufficient to permit deer to build and to discard all that accumulated antler calcium annually, and then to start the process all over again. Remodeling is adjusted in this case to help with a temporary calcium "cash-flow" problem.

So long as the microscopic scaffolding of bone from which calcium is borrowed remains intact, as in the deer, there is always the potential for restoration of most or all of the bone lost through remodeling imbalances. But this is only true if adequate exogenous calcium becomes available in time. This borrowing mechanism creates a structural problem for the skeleton when absorbed dietary calcium remains chronically below the demand created by daily losses. Since, under those circumstances, the calcium borrowed from bone cannot be repaid, the remodeling imbalance continues and bone mass continues to be eroded. If this process reaches the point where structural elements are lost (for example, trabecular plates are perforated or trabecular spicules disconnected), much of the loss becomes effectively irreversible, and the deficiency can no longer be corrected, at least by restoring the missing nutrient.

Intrinsic Control of Skeletal Mass

While the ability of the skeleton to release calcium for homeostatic purposes (by tearing down its own bony substance) is effectively limitless, the ability to store excess calcium is much more limited. This is because, as has already been noted, calcium can be stored only by forming new bone in excess of the amount resorbed. But there has to be some ceiling here. Otherwise, in a typically calcium-rich environment, higher vertebrates, storing continuing surpluses of calcium, would become all bone.

How much bone an organism possesses when calcium intake is not the limiting factor depends mainly upon the degree of mechanical strain each bone experiences. Throughout the terrestrial vertebrates each bone adjusts its density (through balancing resorption and formation) so that it experiences in the range of 1,000 to 1,500 microstrain in ordinary use. (Strain is the bending any structure undergoes when it is loaded; 1,000 microstrain is a dimensional deformation of 0.1 percent.) So far as is now known, no surplus of nutrients will lead to more bone accumulation than what is required to produce and maintain that degree of stiffness. Thus, homeostatically, bone mass is adjusted to support body fluid calcium levels; and structurally, bone mass is regulated to produce an optimal stiffness (not too massive, not too flimsy).

The control system regulating this structural aspect of bone mass is not fully understood, but it is known to be site-specific and to be intrinsic to bone (rather than extrinsic as with calcium homeostasis). What this system amounts to is that local bone formation exceeds local bone resorption when bone deforms excessively, making it stiffer, and the opposite occurs when local bone deformation is minimal. Thus, like muscle, bone hypertrophies with use and atrophies with disuse.

Both the intraosseous stiffness-optimizing system and the extraosseous calcium homeostatic system alter bone mass by regulating the balance between bone formation and bone resorption, that is, they both use the remodeling apparatus to alter bone density. In certain circumstances they reciprocally influence one another. For example, when the homeostatic system acts to reduce density, it thereby leads to increased strain on routine loading of the skeletal region involved. This, in turn, creates a signal to restore lost bone as soon as environmental calcium becomes available once again.

This departure from optimal mass levels is always downward – borrowing and then paying back. There is only limited capacity to store calcium above current structural needs for bone. Although the homeostatic surplus is literally vast, relative to metabolic functions of calcium, there is virtually no bodily ability to build a structural surplus, at least relative to current levels of mechanical usage. Instead, the structural reserve of the skeleton lies in the fact that normal bone can withstand greater deformation than the 1,000 to 1,500 microstrain of everyday use. The limit is closer to 7,000 microstrain, but its actual value depends upon how rapidly and how often a load is experienced. This margin of safety is what protects us from fracture when we experience low-level falls and bumps.

Osteoporosis

Definition and Expression

Osteoporosis is a disorder of bone characterized by excessive fragility due either to a decrease in bone mass or to microarchitectural deterioration of bone tissue (or both). It is a structural weakness in an organ system that, as has already been noted, serves as a source and a sink for calcium in its primary evolutionary function.

The bony fragility that constitutes osteoporosis is expressed in a propensity to develop fractures on minor injury. This fragility may involve virtually any bone in the skeleton. Stereotypical fracture syndromes involve such regions as the spine, the upper end of the femur (hip fracture), and various extremity sites, for example, wrist and shoulder. But ribs, pelvis, hands, and feet are also common fracture sites in patients with osteoporosis.

Bases for Bony Fragility

Osteoporosis is not a unitary disorder and does not have a single pathogenesis. Basic engineering considerations make it clear that the strength and stiffness of bone, as is true for any structure, derive from four main sources: the intrinsic physical properties of its component material; the mass density of that material; the spatial arrangement of the material; and the loading history of a given member (which expresses itself in an accumulation of ultramicroscopic defects called "fatigue damage"). When any structure fails under load, it is because of relative weakness due to insufficiency of one or more of these strength determinants.

In most of the osteoporotic fracture syndromes there is, currently, no recognized abnormality of the bony material itself. The bony substance in the skeleton of patients with osteoporosis is qualitatively much like the bony substance in normal individuals. Instead, the principal bases for weakness in osteoporotic bone are to be found in (1) a decreased amount of bony material, or mass density (to which the term "osteoporosis" literally refers); (2) accumulated fatigue damage in that bone which is present; or (3) architectural defects in the latticework of trabecular (or cancellous) bone. These latticework defects, in turn, are of two types, microfractures of trabecular elements, which have previously occurred under loading but have not yet fully healed (and which thereby render the latticework weak), and preferential severance (and loss) of the horizontal bracing trabecular elements that give the lattice much of its stiffness.

Interactions of several of the more important contributing factors are illustrated in Figure IV.D.4.1. Where nutrition, and specifically calcium, come into this complex interplay of fragility factors is predominantly through their effect on bone mass density, that is, through the size of the calcium reserve. Thus, although important, calcium intake is only one of several interacting factors that can lead to osteoporosis. Some individuals will develop fragility fractures because bone mass is reduced, but others will develop them because of failure to repair fatigue damage or because of defective trabecular architecture. Even in regard to decreased bone mass, calcium shares the stage with other important factors such as gonadal hormone deficiency, physical inactivity, and a variety of lifestyle factors such as alcohol abuse and smoking. These factors also reduce bone mass, but their action on bone is largely independent of nutrition. (High blood alcohol levels poison bone cells, just as they do cells of other tissues. Hence, it is not surprising that bone tissue fails variously in habitual alcohol abusers. The mechanism of the effects of tobacco is unknown. Smoking women have earlier menopause and lower postmenopausal estrogen levels than nonsmokers, but this is probably only part of the explanation.)

Until the multifactorial character of osteoporosis causation was fully understood, there had been confusion about the importance of calcium, mainly because published studies did not always show a protective effect of an adequate calcium intake. Figure IV.D.4.1 forcefully emphasizes why a universal protective effect is an unrealistic expectation. All that an adequate calcium intake can do is to help the organism build the largest possible skeleton during growth and to protect the skeleton against one-sided calcium withdrawals during maturity. But a high calcium intake will not counteract, for example, effects of alcohol abuse or physical inactivity.

Nevertheless, available evidence suggests that if a fully adequate calcium intake could be assured for every member of the population, as much as 50 percent of the osteoporosis burden of the developed nations would be alleviated. Even so, there would still be 50 percent that persists. These cases would have bases other than nutritional inadequacy.

Osteoporosis: A Disorder of a Nutrient Reserve

Although osteoporosis, when caused by inadequate calcium intake (either during growth or during the adult years), can be said to represent a nutritional disorder, it is important to recognize that the primary metabolic function of calcium is never even remotely compromised. Thus, those forms of osteoporosis that result from inadequate calcium intake can be said to be disorders of a nutritional reserve, and not nutritional deficiency in the usual sense (as might occur with vitamin C and scurvy, or with vitamin D and rickets). Fat may be the only analogue of this unique nutritional situation, serving not only as an energy reserve but as insulation for warm-blooded organisms living in a cold environment.

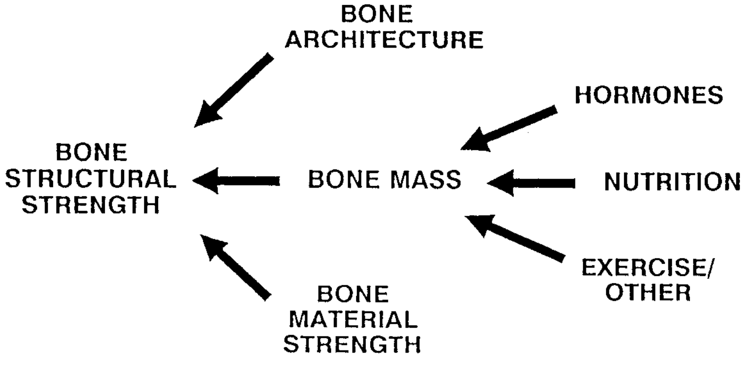

Figure IV.D.4.1. Causal connections of some of the major factors influencing bone strength. Nutrition is only one of the factors that influence bone mass, and bone mass, in turn, is only one of the factors influencing bone strength. Bone material strength, in this diagram, includes the effect of fatigue damage discussed in the text. (© Robert P. Heaney 1991; reproduced with permission.)

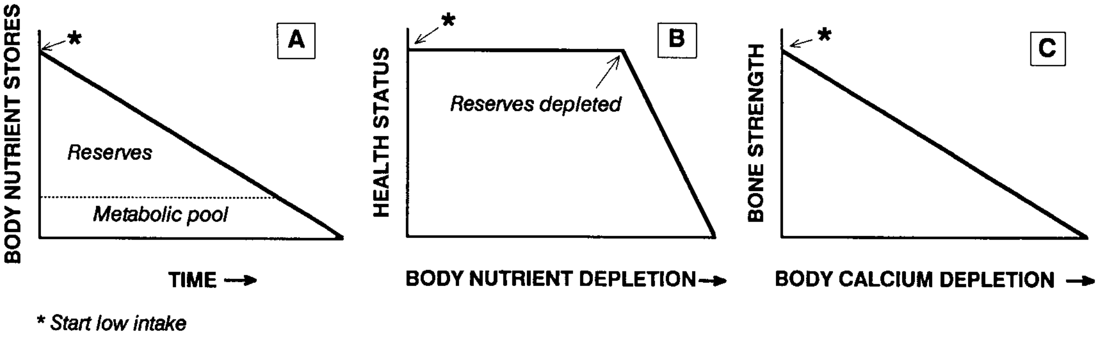

Figure IV.D.4.2. Schematic illustration of the relationship between body depletion of a nutrient and health status: (A) the depletion of body stores of a nutrient after placing the organism on a deficient intake; (B) the pattern common to most vitamins, in which health is maintained unchanged until the reserve is exhausted; (C) the pattern exhibited by calcium, in which health, as reflected in skeletal strength, declines steadily as the reserve itself is depleted. (© Robert P. Heany 1992; reproduced with permission.)

The difference between these two types of nutritional deficiency is illustrated schematically in Figure IV.D.4.2, which contrasts the effects produced by depletion of the body content of a nutrient such as vitamin C with the effects of calcium depletion. In the former case, where the reserves are only that, and serve no other function, health is maintained until the entire reserve is depleted. Then, as the active metabolic pool declines, dysfunction develops. With calcium, by contrast, any depletion of the reserve produces a corresponding decrease in skeletal strength. The skeleton would be rendered totally useless as a structure long before the metabolic pool of calcium would be compromised.

One of the problems this arrangement creates for the nutritional scientist is that a deficiency of calcium sufficient to compromise the structural dimension of the reserves will have no impact upon the basic metabolic function of calcium. Thus, a calcium deficiency sufficient to produce osteoporosis will not be reflected in appreciable decreases in calcium concentration in the circulating fluids, nor in the critical cell compartments where calcium functions as a second messenger, nor even in the ready availability of calcium ions for that crucial function. For this reason there are no blood or urine tests that, alone or in combination, are diagnostic either for this phase of calcium deficiency or for osteoporosis.

Calcium Requirement

Definition

A requirement for a specific nutrient has traditionally been defined as the intake necessary to prevent the expression of the disease or disability associated with deficiency of that nutrient. In recent years there has been a tendency to broaden that definition to read: the intake required to promote optimal health. In the case of calcium, neither approach is particularly apt, as the foregoing discussion has emphasized, inasmuch as health in this instance is not a matter of the basic metabolic function of calcium but of the size of the calcium reserve. Hence a calcium requirement relative to bone health needs to be defined as the intake necessary (1) for building the largest bone mass possible within the genetic program of the individual, and (2) for maintaining that reserve against unbalanced withdrawals after growth has ceased. Any unrepaired decrease in the size of the reserve, other things being equal, reduces bone strength.

The Bases for a Calcium Requirement

Because providing during times of need is precisely what a reserve is for, this process cannot properly be considered harmful in itself. A problem develops only when the process is one-sided, with reserves drawn down but not replenished. In this connection, it will be useful to review here both certain quantitative aspects of how the body maintains constant calcium levels in its blood and extracellular fluids, and how and why an unbalanced situation develops.

As mentioned previously, foods available to high primates and hunter-gatherer humans in their natural states are rich in calcium. In fact, nutrient densities of such foods average in the range of 70 to 100 mg Ca/100 kilocalories (kcal). When calculated for an energy intake sufficient to sustain a hunter-gatherer of typical body size, this density range translates to a daily calcium intake of 2,000 to 3,000 mg, substantially in excess of what most modern humans get, and four to six times what an adult female in the United States typically ingests.

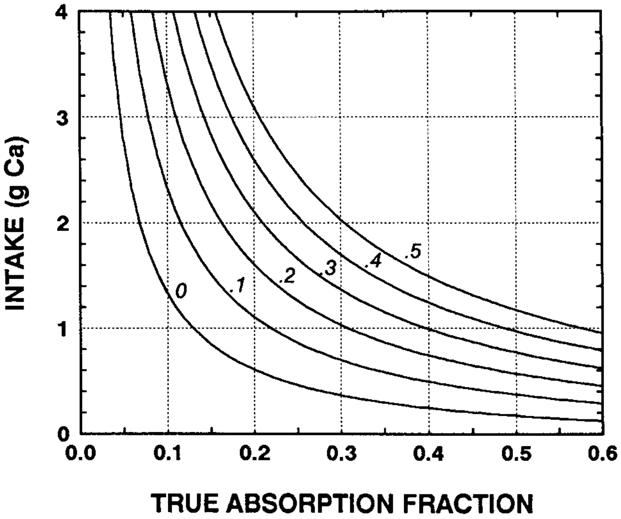

Figure IV.D.4.3. Relationship of calcium intake, absorption efficiency, and net absorption. All the points along a single curve represent the same net absorption value and thus define, for that value, what the intake would have to be to achieve that level of net absorption for any given absorption fraction. (© Robert P. Heaney 1991; reproduced with permission.)

Only after the advent of cultivated cereal grains at the agricultural revolution did humans shift from a diet with a high calcium density to one with a low calcium density.

Intestinal absorption. As already noted, calcium absorption is inefficient, averaging in the range of 30 percent of ingested intake in healthy adults at intakes in the range of the current Recommended Dietary Allowance (RDA) (800 mg for adults). Absorption efficiency varies inversely as roughly the square root of ingested intake, which means that although efficiency rises as intake falls, the evoked rise in absorption fraction will not be sufficient to offset the actual drop in intake.

Furthermore, digestive secretions themselves contain calcium (typically in the range of 150 mg/day in a healthy adult). Because this calcium is secreted along the length of the gut, it is reabsorbed at only about 85 percent the efficiency of ingested calcium (which is itself absorbed inefficiently). This secreted calcium constitutes a cost of digestion, and most of it will be lost in the feces.

This two-directional traffic means that net absorption will always be less than gross absorption. For example, at an intake of 600 mg/day and an absorption efficiency of 30 percent, net absorption will be only about 63 mg, or barely 10 percent of intake. In fact, at low intakes, net absorption will commonly be negative, that is, there will be more calcium going out in the feces than is coming in by way of the mouth. This does not represent intestinal pathology but is an inevitable consequence of the combination of low absorption efficiency and calcium secretion with the digestive juices.

The quantitative character of this relationship is depicted schematically in Figure IV.D.4.3, which shows various iso-absorption contours relating intake and absorption efficiency to various values for net absorption (from 0 to 500 mg Ca/day). For example, to achieve a net absorption of 200 mg/day (close to the figure required to offset extraintestinal losses in healthy adults), intake must be 1,030 mg at an absorption efficiency of 30 percent, and 1,605 mg at an absorptive efficiency of 20 percent.

The fact of low, and even negative, net absorption might be construed to indicate that the organism does not need much calcium after all, but that would be a misreading of the evidence. With the naturally high calcium intake of the hunter–gatherer diet, the customary exposure of the gut is to a calcium-rich ingestate, and even with low absorption efficiency, net absorption would always be positive. But in fact, the low absorptive performance of the gut in mammals is an evolutionary adaptation to this environmental surfeit. Unfortunately, a low absorption fraction is maladaptive for modern diets. Our bodies have adapted to a high-calcium diet, and the time span from the agricultural revolution to the present has been much too short to have allowed evolution toward greater absorptive efficiency.

Some nutrient factors interfere with calcium absorption and thereby raise the calcium requirement. Certain kinds of fiber bind calcium and thereby reduce its absorption. Wheat bran does this, for example. However, this is not true for all fiber: The fiber of green leafy vegetables does not interfere at all with absorption. Overall, the effect of fiber in our diets is relatively small, and even widely ranging fiber intakes would not be expected to exert very large effects on calcium absorption. A second factor reducing calcium absorption is caffeine, a substance widely considered among the lay and the scientific communities to be a risk factor for osteoporosis. It turns out, however, that the caffeine effect is also small and, except for very high daily coffee intakes, would not pose much of a problem. For example, the negative effect on calcium absorption of a single brewed cup of coffee is such that calcium balance deteriorates by about 3 mg. This quantity is so small that its impact can be easily offset by as little as an ounce of milk.

Renal and dermal losses. Urinary and dermal calcium losses are also important determinants of nutrient requirement. Dermal losses occur through sweat and also through shed epithelial structures (dry skin, nails, and hair – all of which contain calcium). For the most part dermal losses are unregulated and thus constitute an irreducible daily drain that must be offset from the diet or, failing that, from the bony reserves.

Urine calcium in humans is determined predominantly by body size and by intake of protein and sodium and only to a lesser degree by calcium intake itself. Protein intake increases urinary calcium loss largely through the catabolism of sulfur-containing amino acids and the excretion of the consequent sulfate load (an endogenous equivalent, as it were, of the acid rain problem produced by burning sulfur-containing fossil fuels). High sodium intake also tends to wash calcium out through the kidneys. High sodium intake is another major dietary change that has occurred for the most part only very recently. Hunter-gatherers and high primates typically have sodium intakes nearly two orders of magnitude (something on the order of 100 times) lower than modern-day humans. In Switzerland, where careful records of salt imports have been kept, per capita salt consumption has increased by a factor of 10 since 1850 alone.

Urine calcium rises with body weight from infancy to adolescence. Infants can reduce urinary calcium losses to near zero when calcium intake drops. Children have an intermediate ability to conserve calcium at the kidney, and adolescents, strikingly, maintain high urinary calcium values irrespective of their calcium intake. This makes them, at a time when calcium requirements for bone growth are at their absolute maximum, particularly vulnerable to environmental scarcity. A partial explanation for the change with age may lie in the fact that infants and small children have relatively low salt intakes, and instead of burning ingested protein as fuel, they build at least some of it into new tissue. Thus neither of the factors driving the higher urine calcium values of older persons are prominent early in life.

The combination of unrecovered digestive juice calcium, minimal urinary calcium loss, and dermal loss, which occur under conditions of calcium restriction, constitutes what is called "obligatory loss." In normal adults consuming typical Western diets, this loss amounts to something in the range of 150 to 250 mg/day, probably more often on the higher side of the range than on the lower. Whenever the absorbed intake is insufficient to compensate for this obligatory loss, bone remodeling will be adjusted so that resorption exceeds formation and thus bone mass will decrease. In other words, the organism calls upon its calcium reserves.

Recommended Dietary Allowances

A Recommended Dietary Allowance (RDA) is a population-level estimate of the daily intake that would be sufficient to meet the actual requirement for a given nutrient for virtually every member of the population. RDAs are deliberately set above the average requirement so as to assure meeting the needs of those with above-average needs.

The RDAs for calcium in the United States are 800 mg/day for children up to age 11, 1,200 mg/day from ages 12 to 24, and 800 mg/day thereafter. (During pregnancy and lactation, the RDA rises to 1,200 mg/day.) There is growing evidence that these requirements are low, and what follows will summarize the best current information about what the true requirement may be. In this connection it is worth recalling once again that wild plant foods are rich in calcium. As a result, the human calcium intake for foragers was almost certainly substantially above not only current intakes but even the RDAs. While there has been a bias in the scientific community in favor of current dietary practices, there should be no surprise when evidence indicates that intakes closer to (though still on the low side of) what our foraging forebears apparently got, may in fact better meet our needs.

Requirements during Growth

Threshold intake. One aspect of the relationship of calcium to bone health, relevant to a consideration of requirement, is the fact that calcium is a threshold nutrient. This means that calcium intake will limit the amount of bone a growing organism can acquire, at least up to some threshold value, and that above that intake further increases will no longer have any effect on bone mass accumulation. This concept is illustrated in Figure IV.D.4.4, which shows, first in Panel A, what the idealized relationship between intake and bone mass accumulation during growth would look like, and then, in Panel B, what experiments studying the effect of calcium intake on bone accumulation during growth have actually found in laboratory animals.

As far as bone is concerned, the optimal intake during growth would be an intake at or above the threshold, and the RDA would be a value sufficiently above the *average* threshold value to allow for the fact that different individuals will have differing values at which the threshold occurs. This interindividual variation reflects differences in absorption efficiency and in ability to restrict urinary loss.

It is important to recognize, in this regard, that calcium intakes below the threshold value will not necessarily limit growth in stature. It takes very serious depletion for that effect to occur, and even then it is hard to be certain that a low intake of calcium is the responsible factor, since intake of other essential nutrients is commonly reduced under such circumstances, as well.

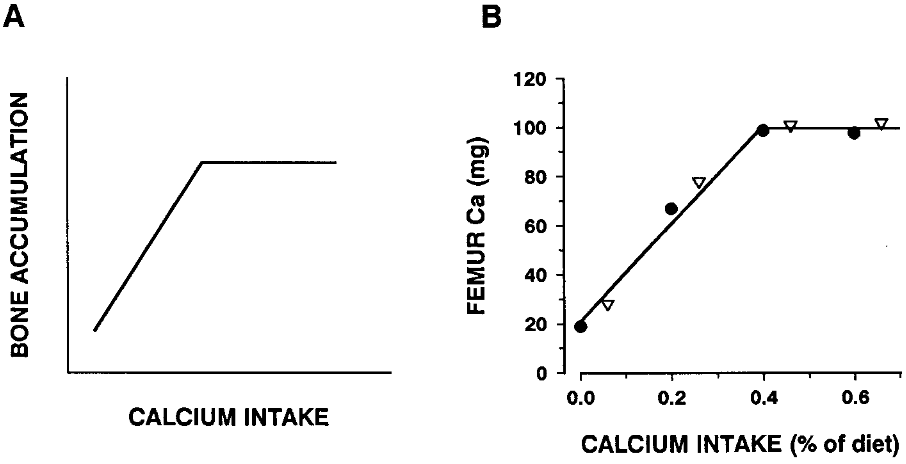

Figure IV.D.4.4. Threshold behavior of calcium intake: (A) Theoretical relationship of bone accumulation to intake. Below a certain value – the "threshold" – bone accumulation is a linear function of intake; in other words, the amount of bone that can be accumulated is limited by the amount of calcium ingested. Above the threshold, bone accumulation is limited by other factors and is no longer related to changes in calcium intake. (B) Actual data from two experiments in growing rats, showing how bone accumulation does, in fact, exhibit a threshold pattern. (Redrawn from data in Forbes, Weingartner, Parker, et al. 1979, in *Journal of Nutrition* 109: 1652–60; © Robert P. Heany 1992; reproduced with permission.)

What happens during growth under conditions of suboptimal calcium intake is, instead, simply that the skeleton achieves its genetically programmed external size and shape but is internally flimsier, meaning the bone cortices are thinner and more porous, and the trabeculae thinner and more widely spaced. Less mass is spread over a growing volume and the structure is thus intrinsically weaker.

While it is relatively easy to do threshold experiments in laboratory animals (as in Figure IV.D.4.4), it is much harder to do (or to justify) such experiments in growing children. Instead of the threshold approach, much of the judgment in regard to calcium requirement and RDAs during growth has been based upon actual food practices in populations that seem to be developing "normally." There is an obvious circularity in that reasoning, because if current bone mass values are normative, then current intakes are manifestly sufficient to support "normal" bone development. Thus current intakes conform with the requirement, the average child is getting what he or she needs, and all is right in this best of all possible worlds.

However, osteoporosis has now reached epidemic proportions in the developed nations, and failure to develop the peak bone mass genetically programmed has to be considered a partial explanation. Thus current intakes, although "normal" in the sense of being usual, are not necessarily optimal.

Estimating the threshold intake. A traditional approach to the determination of nutrient requirements has been to perform what is technically referred to as a metabolic balance study – a study in which human subjects live in a laboratory environment and in which intake and output of the nutrient under study are carefully measured. The balance between intake and output is computed, and for nutrients that are not altered by their metabolism, such as minerals like calcium, that balance is a surrogate for body retention or loss, that is, skeleton building or destruction.

One of the problems with the metabolic balance technique is that although theoretically ideal, the result that it produces is inherently imprecise. That problem can be minimized by doing a large number of such studies, because the uncertainty range about the average estimate of balance declines as the square root of the number of studies. But balance studies are so difficult and expensive to perform that few investigators can accumulate a large enough experience to give the required precision at the several levels of intake that must be studied in order to determine the requirement.

Velimir Matkovic of Ohio State University has attempted to solve this problem by assembling all of the published balance studies performed on growing humans, spanning a 70-year period from 1922 to 1991. After excluding those that did not meet certain a priori criteria, he was able to assemble over 500 published studies, a number large enough to give some reasonable certainty to the estimates and also to ascertain whether the threshold behavior observed in animals (Figure IV.D.4.4) is also found in growing humans.

He and I, working together on this project, found that the threshold behavior did, in fact, apply to growing humans, one example of which is shown in Figure IV.D.4.5. This work also allowed us to estimate the average threshold intake at various stages during growth. These threshold values are presented in Table IV.D.4.1, by age group from infancy through age 30. Equivalently, these values are average requirements for the population of growing humans. As already noted, the corresponding values for RDAs would be higher still. It can be seen that all of the threshold values in Table IV.D.4.1 are above the current RDAs in the United States. Nevertheless, intakes at or above these threshold values would have been common in human hunter-gatherers living in equilibrium with their environment, and hence, although such intakes would be atypical by modern standards, they can hardly be considered unnaturally high.

Corroborating evidence. This means of estimating requirements during growth is probably the best available approach to the problem, and although it produces values above the current RDAs, it is important to recognize that its estimates are not, in fact, at variance with other recent data, which tend to show that, other things being equal, more calcium intake during growth leads to more bone mass accumulation. Thus, very recently C. C. Johnston, Jr., and his colleagues from Indiana University reported results of a double-blind, placebo-controlled study in identical twin children. Calcium supplementation given to one member of a twin pair produced more bone mass accumulation than in the unsupplemented twin. A striking feature of that study was the fact that the unsupplemented members of each twin pair averaged an intake that was already above the official RDA for calcium for the age concerned. This behavior suggests that the official RDA value is below the threshold (see Figure IV.D.4.4).

Similarly, R. R. Recker and his colleagues from Creighton University have recently reported results from a longitudinal study of bone mass accumulation in women aged 20 to 30. They showed both that bone mass continues to accumulate at a rate of about 1 percent per year to age 30, and that calcium intake (specifically the calcium-to-protein ratio of the diet) was the single most important determinant of how much bone was added during that decade.

Requirement during Maturity

From age 30 until menopause in women, and from age 30 until the beginning of senescence in men, the requirement for calcium can be defined as the intake necessary to offset obligatory losses, or, put another way, the intake needed simply to keep the body in equilibrium, neither gaining nor losing calcium. Current estimates indicate that the mean requirement is in the range of 800 to 1,200 mg/day for typical Western diets for both men and women. It would probably be substantially less in individuals who have low protein or low sodium intakes (or both). This is because, as already noted, both high protein and high sodium intakes increase urinary calcium loss and hence decrease the ability of the body to conserve calcium when calcium intake is reduced.

Incidentally, this observation is not to suggest that calcium is somehow a "good" nutrient and that protein and sodium are somehow "bad." Rather, it simply emphasizes that requirements are not abstract absolute values but are reflections both of metabolic activity of the organism and of other constituents in the diet.

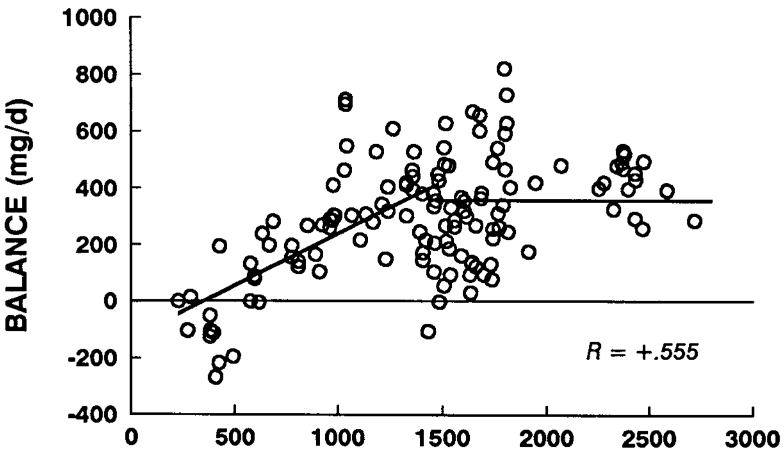

Figure IV.D.4.5. Relationship of calcium intake to calcium balance in adolescents. Above the threshold intake value (1,480 mg/day), balance no longer changes with intake, whereas below the threshold, balance and intake are directly correlated. (© Robert P. Heaney 1991; reproduced with permission.)

Table IV.D.4.1. *Threshold calcium intakes during growth*

Age (in years)	Threshold intake (mg/day)
0–1	1,090
2–9	1,390
9–17	1,480
18–30	957

If one can judge from the food habits of contemporary hunter-gatherers, they would not have had much experience with sodium; however, high-protein diets would have been common. Meat is a very efficient food source, rich in many essential nutrients, and some studies have suggested that for human foragers, protein intake might have accounted for as much as 35 percent of total calories – a higher intake than even that achieved by typical citizens of developed nations. But the diet of hunter-gatherers, as has already been noted, was also very high in calcium, and so a high protein intake would not have created an effective calcium deficiency as it does when calcium intake is as low as is commonly found in U.S. diets.

Requirements during Postmenopause and Senescence

During the declining years, the calcium requirement can no longer be defined as the intake required to offset obligatory losses. This is because bone loss occurs now for intrinsic reasons as well as for homeostatic ones. Even the richest of diets cannot totally prevent this kind of bone loss.

Menopausal bone loss. The first example is the bone loss that occurs in women during the early postmenopause (from cessation of menses to 5–10 years later). To the extent that there has been any controversy or apparent disagreement about the importance of an adequate calcium intake in adults, that controversy has centered around what occurs during this brief period in a woman's life. This is a time when typical women lose something approaching 15 percent of the bone mass they possessed immediately before cessation of ovarian function. Virtually without exception, studies of calcium intake or calcium supplementation during this time have shown that calcium has little or no effect on this bone loss.

There is now general agreement that bone loss at this time is due almost exclusively to loss of gonadal hormones. (The same type of loss follows castration in males.) While many of the details of the mechanism remain uncertain, it can be said that this loss reflects a downward adjustment of bone mass to a new steady state, just as occurs with immobilization. During that approach to a new postmenopausal equilibrium value, nonhormonal forces, such as calcium or exercise, are without effect – simply because the change in bone mass is due specifically to the diminution of gonadal hormones and not to low calcium intake or inadequate exercise. In fact, during the few years after menopause, so much calcium may be made available from bone that there may be no external calcium requirement at all. However, when the new steady state is approached and bone loss slows, all the old interactions reappear.

This conceptual framework was not available to investigators until recently, which may explain why so many previously published studies of the effect of calcium chose to address the early postmenopausal period. Those years are, of course, the time when bone loss is the most rapid and the value of successful intervention is most evident, so it is not surprising that it has been extensively studied. But loss at that life stage is caused by estrogen lack and is best prevented by estrogen replacement.

Senescence. Bone loss during senescence in both men and women is a complex process and has many determinants. This is to some extent true earlier in life as well, but nonnutritional factors loom larger during the declining years of life. As a general rule, mechanical loading on the skeleton decreases with age, in part because older people do less strenuous work and in part, also, because with maturity they become more graceful and efficient in what they do. Thus, some downward adjustment in bone mass simply reflects a decline in mechanical need. Inevitably that decreases the effective strength reserve, which is useful to resist the impact of falls. As already noted, the mechanical adjustment system responds to current usage, not to potential injury. This type of decline in skeletal mass is not nutritionally related and, in the practical order, cannot be appreciably altered by assuring a high calcium intake.

However, a number of changes also occur in the calcium economy of the aging person. There is a decline in absorption efficiency at the intestine, a partial resistance to vitamin D action on the intestine, and a decrease in the ability to synthesize calcitriol, the active hormonal form of vitamin D. Additionally, in women who are deprived of estrogen after menopause, there is deterioration in the ability to conserve calcium at the kidney. For all of these reasons, older persons absorb calcium less well from the diet and retain less of what they do absorb.

This means that calcium intake requirement rises in the elderly. Unfortunately, actual intake tends to go in the wrong direction. With a decline in physical activity, there is a tendency for food intake itself to go down, and that almost always reduces the intake of all nutrients, calcium among them. This combination of increased need and decreased intake in the elderly sets the stage for intake-related bone loss.

The majority of investigations of the relationship of calcium intake to bone status in the elderly – particularly the double-blind, placebo-controlled trials of B. Dawson-Hughes and her colleagues at Tufts University and of Petra Elders and her colleagues at the Free University of Amsterdam – show that additional calcium intake will reduce, to a substantial extent, the degree of bone loss that is otherwise occurring in ostensibly normal, healthy individuals. Total intakes shown to be adequate for this purpose have generally been in the range of 1,000 to 2,000 mg of Ca/day. As already noted, although such intakes are higher than current practice, they cannot be considered high when compared with the typical intakes of our foraging ancestors.

The fact that published studies show such a dramatic reduction in what had otherwise been considered an inevitable, age-related loss of bone indicates that a substantial fraction of that loss was not inevitable after all but was diet-related. This conclusion is even more forcefully emphasized by the findings of three important European studies. One, performed in France, randomized more than 3,200 elderly women (average age 84) to receive either a placebo or 1,200 mg calcium plus 800 IU vitamin D. Not only did the supplemented women stop losing bone, but fractures also declined dramatically within 18 months of starting treatment. The other studies, one undertaken in Finland and the other in Switzerland, although differing somewhat in design from the French study, nevertheless also clearly showed fracture reduction in elderly individuals given calcium or vitamin D supplements.

Miscellaneous Considerations

Calcium Intake and Bone Remodeling

We have already noted that one of the causes of bone fragility is the accumulation of unrepaired microscopic fatigue damage, something that occurs inevitably in all structural materials when they are loaded, but which, given the living character of bone in most vertebrates, is susceptible of repair. That repair is accomplished by bone remodeling, which has been visited, so far in this chapter, mainly as a means of altering bone mass. In fact, bone remodeling has the dual function of both adjusting mass and replacing damaged bone. Failure to effect that replacement in a timely fashion permits fatigue damage to accumulate to the point where serious structural failure can occur on application of relatively small forces.

Effecting this repair depends first upon the body's ability to sense the presence of microscopic damage. Available evidence suggests that the threshold of bone sensitivity to such damage is determined to a substantial extent by the circulating level of parathyroid hormone (PTH). But PTH secretion, in turn, is influenced predominantly by calcium need, and ultimately, therefore, by calcium intake. Thus, a constant high-calcium diet, particularly with the intake spread out over the course of the day, leads to low PTH levels, and therefore to a low sensitivity of the apparatus that detects fatigue damage. The practical import of these considerations is not known for certain, but several investigators have expressed concern about the possible dangers of a constant suppression of the remodeling process.

How could this be a problem if, as already noted, human hunter-gatherers had calcium intakes substantially higher than we now experience? Presumably, their PTH levels would have been substantially below ours. However, there is no fossil evidence that hunter-gatherers suffered an undue fracture burden. Thus either the PTH levels in human foragers were not, in fact, constantly low, or the threshold for detection of fatigue damage is below even the low PTH levels produced by a chronic high calcium intake. The former seems to be the more likely explanation.

Although *average* calcium intakes would have been high for the hunter-gatherers, it becomes clear on reflection that under field conditions, food intake, and thus calcium intake, could not have been a constant affair. There would have been inevitable periods of fasting and of environmental scarcity. In fact, the PTH mechanism evolved precisely to handle such times of calcium need, and its very presence in mammals may be taken as presumptive evidence of at least periodic calcium deprivation.

In addition to seasonal variation in food availability, females were subject to the regular predictable calcium drain of pregnancy and lactation. Another example of periodic need, already cited, is antler formation in deer. At the beginning of antler formation, there is a burst of PTH-mediated remodeling throughout the skeleton. This causes, as it were, a flurry of "spring housecleaning," which, if it had not occurred earlier, serves to remodel areas of fatigue damage that had accumulated in the skeleton over the preceding year. In this way, antler formation in male deer produces a drain analogous to that produced by pregnancy and lactation in female mammals generally.

Thus, even superficial reflection serves to make clear that the "natural" situation would have been one in which PTH is periodically evoked, and therefore one in which conditions would periodically be right for resorption and replacement of damaged bone.

That, however, is not the situation that obtains in civilized, adult, affluent humans who have few children, who lactate even less often, and who rarely experience prolonged periods of fasting or deprivation – in other words, typical adults in developed nations. Is a constant high intake of calcium optimal for these individuals? One cannot say with any assurance one way or the other. Possibly a periodic calcium "vacation" might be salutary. Possibly the once common Christian practice of fasting during Lent and four times a year at the Ember Days, and the still prevalent practice among observant Muslims of fasting during Ramadan, may evoke effects that are as salutary for the body as for the soul.

Recovery after Illness, Injury, and Disability

One common, if not quite universal, feature of even an affluent, protected, developed-world life is the fact of injury, illness, and disability, events that, however temporary and repairable, nevertheless enter the lives of most humans. Generally, these events are periods of reduced nutrient intake, sometimes of enhanced excretory loss of critical nutrients, and often periods of reduced mobility and physical activity as well. Reduced physical activity always leads to a reduction in bone mass, even in well individuals; such disuse loss is aggravated in the presence of illness.

What happens during recovery from such episodes? Usually, as far as a sense of well-being, health, and vigor are concerned, we return to our former status. But if our regular calcium intake is just sufficient to maintain equilibrium, that is, to offset daily losses, then, ipso facto, that intake will not be sufficient to permit replacement of the bone lost during the preceding illness or disability. We have no consciousness of our bone mass, so we are unaware that this part of our bodies has not fully recovered.

Periodic episodes of this sort over a person's adult life, and particularly during the declining years, can contribute significantly to age-related bone loss. Such loss, however, is not necessarily irreversible until, as already noted, it proceeds to the point where some of the bony scaffolding is lost. (Then there is no chance of rebuilding what was once there.) It would seem important, therefore, to ensure, during recovery from periodic episodes of illness or disability, that our calcium intake is augmented, for the simple and obvious reason that the intake must be sufficient, at that time, not only to offset obligatory losses but also to replace bone mass lost during the preceding weeks.

Calcium in the Treatment of Osteoporosis

Although calcium is a necessary component of most treatment regimens for established osteoporosis, it is rarely sufficient by itself. Calcium is *necessary* because it is not possible to restore lost bone without providing adequate quantities of the building blocks of bone. That means a high calcium intake. But calcium alone is rarely sufficient because a high calcium intake suppresses bone remodeling. Although this suppression helps to stabilize bone mass and slow bone loss, at the same time it impedes substantial gain in bone mass. Bone gain requires additional stimulation by osteogenic factors or medications (such as growth hormone or sodium fluoride). Then, with that kind of bone-building stimulus, an adequate calcium intake helps to assure that the weakened bone can be rebuilt without having to shift calcium from other skeletal regions – robbing Peter to pay Paul, as it were.

One might wonder why a high calcium intake is compatible with bone gain during growth yet does not act the same way in older persons with established osteoporosis. The answer is simply that during growth, the body produces large quantities of tissue-building factors such as growth hormone. These factors are nearly absent in older persons with osteoporosis. Furthermore, the violent mechanical loading of the skeleton typical of childhood and adolescence creates a powerful local stimulus to strengthen the skeleton. By contrast, a partially disabled, hurting, elderly person with one or more osteoporotic fractures generally decreases his or her physical activity – a situation that leads to bone loss irrespective of calcium intake.

Because of lowered calcium absorptive efficiency both with age and with decreased physical activity, generally large quantities of calcium are required as part of an osteoporosis treatment regimen. The exact quantities are uncertain, but they probably fall in the range of 1,500 to 2,500 mg/day. This is more than most persons with restricted activity can get from readily available foods, and some resort will usually have to be made to calcium-fortified foods or to calcium supplement tablets.

Ethnicity

Although bony fragility is not confined to Caucasians, it is much more common among whites than among blacks or Asians, and among Caucasians it is more common among those of northern European ancestry. Partly for these reasons, most of the research relating calcium to osteoporosis has been done in Caucasians. Despite a generally lower calcium intake than their white counterparts, blacks in the United States have heavier bone mass at all ages, from infancy onward. Moreover blacks, both in Africa and in the United States, have lower fracture rates than whites, even after correcting for differences in bone mass. Asians have bone mass values at least as low as Caucasians and seem to lose bone with age much as do whites, but available data suggest that fragility fractures, particularly hip fractures, are less common among them. These ethnic differences in fracture rate probably reflect the fact, noted earlier, that fragility has many bases, and that it takes more than just bone loss to result in a fracture. For example, the angled upper segment of the femur is shorter in Asians than in Caucasians. Engineering analysis has shown that long upper segments are structurally weaker than short ones. This difference, based ultimately in genetics, has a mechanical, structural basis, rather than a nutritional one.

American blacks have been studied somewhat more intensively than other non-Caucasian groups, and thus more is known about their calcium economy. Norman Bell and his colleagues at the Medical University of South Carolina have shown that at least a part of the explanation for their greater bone mass is a generally higher resistance of their bones to serve as a calcium reservoir. Thus, in maintaining extracellular fluid calcium levels, blacks require a higher level of PTH to release calcium from bone than do whites.

As noted earlier, PTH also enhances both intestinal absorption and renal conservation of calcium. Thus the higher PTH levels of blacks result in better utilization of dietary calcium, with a consequent skeletal-sparing effect.

Conclusion

Calcium is a nutrient, not a drug. The only disorder it can be expected to prevent or alleviate is calcium deficiency. The skeleton serves both as structural support for our bodies and as a reserve of calcium needed to maintain the constancy of body fluid calcium levels. Calcium deficiency, as it affects us, is a reduction in the size of the reserve and thus in its structural strength. An adequate intake will ensure that calcium deficiency will neither cause skeletal weakness in its own right nor aggravate the weakness produced by other causal factors. But calcium will not prevent or reverse the bone loss and fragility due to other factors. The evidence indicates that calcium deficiency is prevalent in the adult populations of Europe and North America and that it contributes in an important way to their osteoporotic fracture burdens.

IV.D.5 Pellagra

Pellagra is a chronic disease that can affect men, women, and – very rarely – children. The onset is insidious. At first, the afflicted experience malaise but have no definite symptoms. This is followed by the occurrence of a dermatitis on parts of the body exposed to sunlight. A diagnosis of pellagra is strongly indicated when the dermatitis appears around the neck and progresses from redness at the onset to a later thickening and hyperpigmentation of the skin in affected areas. The dermatitis appears during periods of the year when sun exposure is greatest. Other symptoms, including soreness of the mouth, nausea, and diarrhea, begin either concurrently with the skin changes or shortly thereafter. Diarrhea is associated with impaired nutrient absorption, and as a result of both dietary inadequacies and malabsorption, pellagrins frequently show clinical signs of multiple nutritional deficiencies.

Late signs of pellagra include mental confusion, delusions of sin, depression, and a suicidal tendency. Occasionally, these psychiatric signs are accompanied by a partial paralysis of the lower limbs. In the final stages of the disease, wasting becomes extreme as a result of both a refusal to eat (because of nausea) and pain on swallowing (because of fat malabsorption). Death is from extreme protein–energy malnutrition, or from a secondary infection such as tuberculosis, or from suicide (Roe 1991).

Pellagra as a Deficiency Disease

Since 1937, it has been known that pellagra is the result of a deficiency of the B vitamin niacin (Sydenstricker et al. 1938), and that the deficiency usually arises as a consequence of long-term subsistence on a diet lacking in animal protein or other foods that would meet the body's requirement for niacin (Carpenter and Lewin 1985). However, a sufficient quantity in the diet of the amino acid tryptophan – identified as a "precursor" of niacin (meaning that the body can convert tryptophan into niacin) – has also been found to cure or prevent the disease (Goldsmith et al. 1952). This explains why milk, for example, helps combat pellagra: Milk contains relatively little niacin but is a good source of tryptophan. Pellagra is most strongly associated with diets based on staple cereals, especially maize. This grain has historically been the daily fare of those who develop the disease: Maize is high in niacin content, but much of this niacin is in a chemically bound form that prevents absorption of the vitamin by the body (Goldsmith 1956).

History

Early Observations in Europe

Pellagra was initially described during the first third of the eighteenth century, when Gaspar Casal, a Spanish physician, wrote of an illness that had arisen among the peasants of the town of Oviedo, who subsisted largely on maize. The disease was termed *mal de la rosa* because of a peculiar sunburn-like dermatitis – its telltale mark. Casal's book, published posthumously (1762), includes a frontispiece showing a classical figure with a "rose" on the top of each hand and foot and a chain of "roses" around the neck. The "roses" appear as if branded on the skin, suggesting that their appearance betokened a stigmatized condition (Roe 1973).

Casal studied the multisymptom disease that appeared to affect only the poorest laborers in this sharecropping region. He described how the afflicted lived on a diet of maize flour made into flat, baked cakes. The only other items of their diet were a few turnips, chestnuts, cabbages, beans, and apples. Casal found that the disease could be treated by providing milk, cheese, and other foods of animal origin to those afflicted.

Shortly after pellagra made its appearance in northern Spain, it was seen in Italy, where there was extreme poverty among the peasants of Tuscany, as well as those living in the area of Venice. A diet of polenta, or corn mush – and very little else – was the usual fare of those who earned their living under the Italian system of *mezzadria,* or sharecropping. Their poverty meant little access to animal foods, and by the turn of the nineteenth century, pellagra had reached epidemic proportions in parts of Italy, especially in Lombardy, where it was estimated that from 5 to 20 percent of the population were its victims.

It was in northern Italy, where the peasants called the disease "the Rose," that another new but lasting name, "pellagra" (*pelle* plus *agra,* or "rough skin"), was given to the illness by Italian physicians and other educated observers, who also developed new theories to explain its etiology and epidemiology. Some suggested that pellagra was caused by "insolation" or excessive exposure to the sun. Most, however, suspected that pellagra was caused by eating moldy maize meal, and indeed, this belief persisted until the time of World War I.

Maize was a grain of the New World, unknown in Europe before the voyages of Christopher Columbus. At first, its food value was of little interest to Europeans, although one seventeenth-century herbalist, Caspar Bauhinus, cautioned against consuming too great a quantity of the new grain, as it produced an "itch." But maize proved superior to other food crops, not only because of its higher yield of grain per acre but also because – as a new crop – it was not immediately subject to taxes, tithes, and feudal dues. By the end of the eighteenth century, it was grown in much of southern and eastern Europe, especially in Italy, Romania, and Spain.

It seems likely that by the time of Casal, pellagra was already endemic in parts of Europe. Political and economic trends had made peasants in both Italy and Spain even poorer, which forced an extremely limited diet on them. Interestingly, however, French peasants at that time, although equally poor, neither raised nor consumed as much maize as their southern neighbors. Consequently, it was only later, during the first third of the nineteenth century, that pellagra struck in France – at just about the time that that country's expanding maize crop was becoming a more significant part of the diet.

Casal recognized that pellagra had some relation to diet: He was aware of its close association with maize consumption and knew that it could be cured by improving and varying what people ate. François Thièry, a French physician who studied Casal's still unpublished manuscript, announced these conclusions when he wrote the first published account of the disease, which appeared in 1755. Following the 1762 publication of Casal's work, little was heard of pellagra in Spain until the 1840s. In that decade, however, a second French physician, Théophile Roussel, conducted an investigation and concluded that a number of differently named illnesses then plaguing Spain were all, in fact, pellagra. Soon afterward, Roussel began to work for the adoption of effective pellagra-preventing policies in his own country.

Africa

Throughout the rest of the nineteenth century, it became clear that pellagra was rampant in other parts of the world as well. During the 1890s, British epidemiologist Fleming Sandwith, working in Cairo, realized that endemic pellagra was all around him and began a systematic study of the disease. Like his predecessors, he found that pellagra was associated with a maize-based diet and extreme poverty (he added that residence in rural areas and exposure to the sun also seemed to be factors) and voiced agreement with the view that consumption of spoiled maize was the primary cause.

With his findings on endemic pellagra in Egypt, and a similar study he conducted of pellagra among the Bantu people of South Africa during the Boer War, Sandwith had shown that the illness was by no means confined to Europe; in fact, at the end of the nineteenth century, it seemed obvious that pellagra had established far greater footholds elsewhere. His discovery was a significant accomplishment, but perhaps an even greater one was that through his reports and publications on pellagra (the first important ones to be written in English), he helped create awareness of the condition among physicians in the United States, who were unwittingly facing a pellagra epidemic of their own and would soon take the lead in fighting the disease.

The Americas

American Indians. It is generally accepted that at the time of Columbus's first voyage to the New World, maize cultivation was already widespread among the various American Indian groups (especially those of Central America and Mexico) and exerted a profound influence on their cultures. So important was this crop that a number of traditions described the origins of maize in miracle stories and creation myths (Roe 1973). Many such legends suggested "that man was formed from maize"; all saw maize as the "basic sustenance for the body and the soul" (Roe 1973: 10–11).

But despite the importance of maize in pre-Columbian culture and diet, the peoples of Mesoamerica seem not to have been troubled by pellagra. Indeed, their reliance on maize, while they apparently remained immune to the disease, posed a problem for early investigators advocating a link between maize-based diets and pellagra incidence (Roe 1973). But unlike European pellagrins, who consumed cornmeal mostly as mush, the Indians made their corn into tortillas – a process that involved soaking the maize grains in a lime solution, or perhaps liming them through treatment with campfire ashes. According to sixteenth- and seventeenth-century Spanish reports, such techniques were already in use at the time of European contact, and, in fact, archaeological evidence suggests that the process, virtually unchanged today, was first developed many centuries earlier (Roe 1973).

Many modern specialists in nutrition have suggested that the lime treatment of maize grain released its chemically bound niacin and made the vitamin available to the Indians, and some evidence indicates "that the amount of niacin so freed can be just sufficient to prevent pellagra" (Roe 1973: 15). But this explanation has not seemed sufficient to others, who have pointed to additional factors that operated (and still operate) to prevent the disease. Chief among these are the other niacin-containing vegetable foods that were eaten as well as maize, including squashes, chillies, and especially beans (both grown with maize and eaten with maize products). In addition, some sources of animal protein (usually rich in niacin), such as corn grubs and locusts, were consumed more or less regularly (Roe 1973).

Slaves, sharecroppers, and millworkers. Although the American Indians had historically not suffered from pellagra, other groups were not so fortunate. Even though physicians in the United States lacked knowledge of the disease, medical records permit the identification of a number of cases as far back as the early nineteenth century; in fact, it now seems clear that by the end of that century, pellagra was virtually epidemic, especially in the American South, and had been for some time. Southern agriculture, too long geared toward the production of cotton, had failed to diversify, with the result that the diet of the poorest classes of society lacked much in the way of variety (Etheridge 1972, 1993; Roe 1973; Beardsley 1987). Pellagra seems to have been a periodic visitor to slave cabins during antebellum decades and, later, plagued the southern poor generally; however, it was frequently ignored or – because of its protean symptoms – confused with other diseases (Kiple and Kiple 1977).

In the early years of the twentieth century, however, a pellagra epidemic occurred among mental patients at the Alabama Institution for Negroes, and unlike previous incidents, this outbreak received a measure of publicity. Moreover, it appears that this was not the first time physicians at the institution had seen the disease, and two of them, George H. Searcy and Emit L. McCafferty, produced a report on 88 pellagra patients, 57 of whom had died. Published in the *Journal of the American Medical Association* in 1907, this study provided the kind of information that helped other physicians to recognize the disease (Roe 1973). In the months that followed, thousands of cases were diagnosed, most of them in southern states.

Miracle "cures" for pellagra began to appear, and physicians, despite the debatable effectiveness of such "medicines" and the danger posed to their patients, made liberal use of "Fowler's solution," "Atoxyl," "Salvarsan," and other arsenical preparations. They also employed purges, antiseptic injections, various tonics, blood transfusions from recovered pellagrins, and, in one case, "treatment" with static electricity. A U.S. congressman referred to the latter "cure" as "simply marvelous" (Roe 1973: 95).

Also much in evidence were patent medicines such as "Ez-X-Ba River, The Stream of Life," which was sold for 5 dollars a bottle by the Dedmond Remedy Company, founded in 1911 by Ezxba Dedmond. This product was reputed to cure pellagra within weeks, and early in its history the company claimed hundreds of cures. Another such was "Pellagracide," made by the National Pellagra Remedy Company. Both of these firms, based in South Carolina, were challenged in 1912 by that state's Board of Health, and their products were attacked as fraudulent by the American Medical Association. Analysis of the concoctions revealed no active elements at all, but the companies remained in business. In 1913, "Doctor" Baughn's

American Compounding Company followed much the same course with its "Baughn's Pellagra Remedy" in Alabama. The quack medicines enjoyed much more popularity and confidence among the general public than did the treatments offered by legitimate physicians; indeed, the first encounter many poor pellagra victims had with a medical doctor was when they were near death and committed to a mental hospital (Roe 1973).

Except for institutionalized people (frequently victims of nutritional deficiency diseases because of a restricted diet), southerners suffering from pellagra were generally to be found among the rural poor, many of whom eked out a living by sharecropping, or among the workers in textile mills and their families. It could be said that the millworkers themselves "were in a way institutionalized" in areas where much of the housing, employment, food sources, and medical care were controlled by the firms operating the mills. Indeed, the millworkers' situation was perhaps fractionally worse than that of their rural counterparts, who sometimes had greater access to what little fresh food was produced (Beardsley 1987: 56–7).

Following the epidemic at the mental home in Alabama, the U.S. Public Health Service entered the battle against pellagra, and beginning in 1914, epidemiologist Joseph Goldberger succeeded in curing institutionalized pellagrins by altering their diets. His next trial, also successful, was to induce the disease in prison inmates who volunteered to subsist on a restricted diet. In addition, he proved through experiments on himself and his colleagues that pellagra was neither transmittable nor infective.

Moreover, Goldberger initiated a multiyear study of the disease which revealed that poverty and lack of dietary variety were consistently associated with pellagra in the American South. This study, which later attained renown as a classic model of epidemiology, showed conclusively that pellagrous millworkers and agricultural laborers were on the lowest rung of the economic ladder, and that the traditional diet of the southern poor – cornmeal bread, "fatback" pork, and molasses – was all the food that most such people had access to, or could afford. Thus, poverty, manifesting itself through bad nutrition, had resulted in pellagra attaining epidemic proportions among the lowest-paid classes in the society.

Goldberger had proved that the cause of pellagra was a dietary deficiency and, furthermore, had demonstrated that the deficiency – and therefore the disease – resulted from the prevailing social and economic conditions. Further dietary tests indicated that the diet of pellagrins lacked some crucial element, which was referred to as the pellagra-preventing factor (the "P-P factor" for short), and that this substance, though yet unidentified, was present in meat and dairy foods and some vegetables.

A Disease of an Inferior Social Group

Class inequalities have been used from early times to account for variances in the prevalence of endemic diseases among social groups. Yet the reasons advanced to explain why the poor are more susceptible to certain diseases have changed over the years. In the past, their disease vulnerability was blamed on "bad blood," unclean habits, angry gods, and – somewhat more correctly – the fact that they lived in close proximity to their animals. Today, the blame is placed on an unwillingness to seek preventive health care or to eat the type of diet known to reduce disease risks.

In the case of pellagra, almost all major contributors to the literature of the past subscribed to the view that it was found only among indigent people. Indeed, "the Rose" was considered to be a "brand" of extreme poverty. However, as with other diseases, explanations of why the poor contracted pellagra – and more affluent people did not – have varied.

Hereditary Weakness and Susceptibility

From the time that pellagra was first described until the end of World War I, the occurrence of multiple cases of pellagra in a single family was explained as a hereditary weakness within that family. That pellagra was a manifestation of "bad blood" was a common extrapolation of the beliefs of the Eugenists. At the height of the Eugenics movement, it was believed that children with "bad" traits were born of marital unions between parents who carried these predispositions. Such a theory might be considered a forerunner of human genetics. However, Eugenists believed that "bad blood" was a function of moral traits as well as of traits relating to physiognomy and disease susceptibility. Clearly underpinning the Eugenists' apparently scientific explanation of the pellagra trait was the traditional association of moral weakness and disease. The origin of the concept of "bad blood" lies in the idea that evil is inherited (Ricoeur 1967).

G. K. Chesterton wrote in his book *Eugenics and Other Evils* (1922) that H. G. Wells should be given a medal as the Eugenist who destroyed Eugenics. Wells's argument (1903) was that we cannot be certain of the inheritance of health because health is not a quality but rather a comparative term. Yet despite Chesterton's assertion that Wells put the Eugenists' theories to rest, the idea of "bad blood" persisted and has been frequently used to refer to the taint of syphilis as well as that of pellagra. Moreover, disease vulnerability was somehow supposed to be related to inferior social position. Curiously, physicians who viewed pellagra as the result of inferior parentage could also think in terms of traits that were risk factors for the disease – these same traits also being risk factors for criminal behavior and alcohol abuse.

Diathesis and Biotype

Jean-Marie Gustave Hameau (1853) wrote that "*[l]a pellagre est une diathèse particulière,*" a statement that reflects the viewpoint of many observers of the disease from the late eighteenth through the nineteenth century. The people considered susceptible to pellagra were indigent peasants whose vulnerability was somehow linked to their lifestyle.

A corollary idea was that specific "biotypes" were susceptible to pellagra. Dr. Charles Davenport, for example, believed that pellagra was a communicable disease, but only among people of particular biotypes. In a paper published in 1916, he wrote of the risk of acquiring pellagra: "It appears that certain races or blood lines react in the pellagra families in a special and differential fashion." He also believed that the type of constitution a person possessed determined the progress of the disease (Davenport 1916).

Criminality and Hereditary Pellagra

Pellagra was also thought to occur more frequently among the criminal classes, or at least among those with the potential for wrongdoing. Thus, particularly in the nineteenth century, the social environment of pellagrins was believed to play a definitive role in explaining their disease.

Cesare Lombroso, who became professor of psychiatry at Pavia in 1862, centered his research on relationships between mental and physical disorders. He thought that criminals could be identified by certain physical characteristics. He was also convinced that there were intrinsic physical and moral characteristics that explained an individual's susceptibility to toxins in moldy maize grain, which (he believed) caused pellagra (Lombroso 1869, 1893).

Lombroso thought in terms of a hereditary pellagra that existed in both a mild and a severe form. Hereditary pellagra, he wrote, could be recognized in the second year of life when it was manifested by pain, indigestion, a voracious appetite, diarrhea, and cachexia. Moreover, those afflicted with hereditary pellagra also suffered physical anomalies such as faulty development of the skull with brachycephaly or dolichocephaly, a receding forehead, badly set ears, asymmetry of the face, and abnormalities of the external genitalia (Lombroso 1893).

Pellagra and Alcohol Abuse

Once pellagra had been noted as endemic in the United States, it was observed to be common among those who drank to excess, and the term "pseudopellagra" was sometimes used to describe the disease when it occurred in alcoholics. Such a term implied only that these patients had a pellagra-like disease, but eventually it was recognized that genuine pellagra was particularly common among alcoholics, although the reasons for their vulnerability were not understood.

In 1928, J.V. Klauder and N.W. Winkleman reported their studies of pellagra among alcoholics and stressed that the disease was most likely to occur in chronically heavy drinkers who had been on binges lasting several weeks. The researchers also made the observation that during these "debauches," the alcoholics ate very little food, and usually only food of one type – soup. The soup in question was, no doubt, frequently a handout of soup kitchens and not likely to be laden with nutrients. Thus, in the case of some alcoholics, pellagra vulnerability was to some extent linked to a dependence of the have-not group on donated food provided as charity.

N. Jolliffe (1940) was the first nutritionist to observe that there were different reasons why alcoholics so often developed pellagra. He suggested that there were four causal relationships between the disease and alcohol abuse. First, the gastritis associated with heavy alcohol consumption could lead to poor food intake. Second, alcohol-related changes in the gastrointestinal tract could interfere with vitamin absorption. Third, alcohol might be substituted for foods containing vitamins. And last, there was probably an increased vitamin requirement in alcoholics, which resulted from alcohol ingestion.

But despite the possibility of a scientific explanation for the prevalence of pellagra among alcohol abusers, both physicians and the lay public were – and often still are – of the opinion that pellagra strikes alcoholics because of their bad health habits in general (and, perhaps, because of their "immoral ways" in particular). In a 1911 review of cases of pellagra, Dr. Beverley Tucker of Richmond, Virginia, discussed the "pernicious habits" of 15 of her 55 patients with the disease. The habits she considered "pernicious" included the abuse of alcohol, tobacco, and opium.

Revelation of the Social Causes of Pellagra

In the United States, support for the concept that endemic pellagra was a result of extreme poverty came from the studies carried out by Goldberger and his colleagues, G. A. Wheeler and the economist Edgar Sydenstricker. These individuals comprised the first American team to employ epidemiological methods and economic analysis to explain the prevalence and distribution of pellagra in the South. In their 1916 study of cotton-mill villages in South Carolina, the investigators found that the proportion of families with pellagra declined as income increased. Those families with more than one case were always within the lowest income group.

Poor hygiene and sanitation, as well as differences in age and gender distribution – all of which had been considered significant factors – were only gradually eliminated as causes. It became clear that, in general, households with higher incomes and access to food sources outside the factory commissaries, including the produce of home-owned cows, pigs, and poultry, enjoyed a much lower incidence of pellagra. Thus, buying power and access to pellagra-protective foods conferred disease "immunity" (Goldberger, Wheeler, and Sydenstricker 1918, 1974). Sydenstricker also showed in a later study that family income had to be very low before the standard of living forced consumption of a pellagra-producing diet (Sydenstricker 1933; Roe 1973).

Eradication Policies in France and the United States

Soon after its discovery (by the mid–eighteenth century), pellagra was also explained as either an outcome of exposure to extreme climates or a product of contagion. In the mid–nineteenth century, Daniel Drake (1850) grouped causes of disease into three classifications. These included telluric or geological, climatic or meteorological, and social or physiological influences. Later in the century, diseases were also found to be caused by agents such as light, food toxins, and pathogens. As each of these agents of disease was recognized, it became a suggested cause of pellagra. Infection, for example, was popular as a causative agent because it seemed plausible that poor sharecroppers, living in fly-infested dwellings, might acquire the supposed "germ" from their surroundings.

Yet the applicability of the germ theory to pellagra could not be demonstrated, and – especially as nutrient deficiencies had been implicated in other diseases, like scurvy – the interest of researchers returned to the diet of the afflicted. But partly because of deliberate attempts to downplay the poverty of workers, and partly because of the reluctance of medical practitioners to agree on a nutritional explanation, it took a long time for the etiology of pellagra to be understood.

In an interesting observation, S. J. Kunitz (1988), in a paper dealing with hookworm infestation and pellagra, remarked that past explanations of these diseases were influenced by investigators' ideologies and values rather than being derived from analyses of the intrinsic nature of the illnesses. Kunitz further suggested that such biases also conditioned approaches to disease prevention and cure.

Perhaps such influences can be seen in the totally different public-health approaches to pellagra eradication adopted in France in the 1840s and in the United States in the 1940s. In France, Roussel, without any knowledge of the biological cause of pellagra but with a keen observer's eye for the social environment, urged the French government to drain the salt marshes in southwestern France, where the disease was most prevalent, so that a diversity of food crops could be grown and animals raised. More generally, he was also remarkably successful in getting the French government to change the country's agricultural system in ways that contributed to the health of the inhabitants of the rural regions (Roussel 1845, 1866).

In the United States, Conrad A. Elvehjem of the University of Wisconsin discovered the pellagra-preventing factor, first called nicotinic acid and later named niacin. This "breakthrough" occurred in 1937 as a result of his study of blacktongue, the canine equivalent of pellagra (Elvehjem et al. 1938), and Elvehjem was subsequently influential in promoting the enrichment of bread and cereal grains with niacin in an effort to bring the career of pellagra to a close. The mandatory enrichment program was instituted in 1943, following the recommendation of the Food and Nutrition Board, of which Elvehjem was a member (Wilder and Williams 1944).

Yet, as T. H. Jukes (1989) has pointed out, however successful the bread- and cereal-enrichment program was in preventing endemic pellagra, it was already generally accepted by the 1940s that pellagra could be prevented – and also cured – by what he termed a "good" diet; in this context, a "good" diet was one that included milk and meat. The government, however, chose not to concentrate on changing the living conditions of the disadvantaged, such as sharecroppers and millworkers, but rather adopted a policy of providing them with cheap, niacin-containing staple foods.

Thus, neither the sharecropping system nor pellagra were ended by enlightened public policy. Although the beginning of the end of pellagra in the United States lay in the expedient of food fortification, its ultimate demise can only be found in the economic events of the 1930s and 1940s, which, by bringing greater affluence to the South, both eliminated pellagra as a major health concern and spurred the end of sharecropping (Roe 1974).

Endemic Pellagra in Refugee Camps

Pellagra, however, is far from dead in the developing world and is often seen in the midst of chaotic situations. For example, the disease surfaced a few years ago in Malawi, when thousands of Mozambicans fled the civil conflict in their own country to seek refuge there. Once in Malawi, they lived in refugee camps or nearby villages, where – between July and October 1989 – 1,169 cases of pellagra were diagnosed among refugees living in 11 sites. From February 1 through October 30, 1990, another 17,878 cases were reported among a population of 285,942 refugees; in other words, over 6 percent were afflicted. But the rate of affliction varied from one location to another, ranging from 0.5 percent to 13.2 percent. Moreover, females were more than seven times as likely to be afflicted as males; young children, however, were substantially less affected than adults, as has generally been the case during outbreaks of pellagra. The disease was also less common among those who lived in integrated villages rather than in camps (Editorial 1991).

French epidemiologists working for *Médecins*

Sans Frontiéres, who investigated the epidemic, found that those refugees who escaped pellagra were more likely to have gardens, have a daily supply of peanuts (an important niacin-containing staple of the region), or have the ability to mill maize. At the time of the epidemic, peanut distribution had been disrupted, and the maize sent in by donor nations was neither vitamin-enriched nor even ground into meal. Thus, those who developed pellagra were totally dependent on the maize ration, and the greater vulnerability of women was explained by the tendency of males to appropriate nuts, meats, and fish (foods high in niacin as well as tryptophan, its precursor) for themselves.

Clearly, the appearance of a major epidemic of pellagra toward the end of the twentieth century – when the means of preventing the disease have been known for more than 50 years – suggests a substantial error in judgment by supposedly compassionate nations.

Lessons to Be Learned

At the risk of belaboring points that have already been made, by way of conclusion it seems worthwhile briefly to revisit some past notions about pellagra. The first of these is that pellagra was the fault of the afflicted, rather than of those who maintained the existing inequalities of the social system. The second (not all that different from the first) was that the eating habits of pellagrins were the consequence of an unwillingness to change their lifestyles.

Some social critics of the past did better than the scientists in understanding pellagra. French novelist Edmond About (1858), for example, clearly indicated his grasp of the social causes of the disease when he had one of his characters remark that pellagra would continue to exist in the marshy southwestern area of his country (the Landes region) until the nature of the environment changed. His succinct prediction,

> *Tant que Lande sera lande,*
> *La pellagre te demande*
>
> (As long as the Landes remains a moor,
> There pellagra will claim the poor),

suggests that pellagra was the fault of the society in which it raged rather than that of the peasant who suffered the deprivations of such a society.

In rural areas of the southern United States, the sharecroppers' "bad habit" of eating an unvaried diet of cornmeal with occasional fatback and molasses – the "three Ms": maize, molasses, and meat (but only the fatback type of meat) – was understood to increase their nutritional risk of pellagra. In urban environments, the "bad" food habits of alcoholics were thought to explain their pellagra susceptibility. Lost in this tendency to blame the victim was the fact that sharecroppers ate a deficient diet because they had little or no access to food other than the "three Ms." Similarly, pellagra susceptibility in "down-and-out" alcoholics can be explained by society's inability to accept alcoholism as a disease and the consequent belief that alcoholics should not receive adequate nutritional assistance because this would only encourage them to continue in their lifestyle.

In the case of refugee camps, not only were the refugees viewed as an inferior social group, but (as with the alcoholics who were the urban pellagrins of the 1920s and 1930s) they were fed with indifference by donor nations without any effort to improve their health and quality of life. Even today, nations that send food to those living in such camps assume little responsibility for providing an adequate diet for the recipients. Rather, they continue to ship food – like maize – that is unfamiliar to the consumers and is grossly deficient in nutrients.

Certainly, past – often elitist – views of pellagra as the fault of the pellagrin are no longer acceptable today. Moreover, instead of claiming the conquest of endemic pellagra as a scientific triumph, we might ask why pellagra came about in the first place and why it persisted for so long. Finally, we should ask why, even after the means of pellagra prevention are fully understood, there are still serious outbreaks of the disease in various parts of the world.

IV.D.6 Pica

Broadly stated, pica is the term given to the compulsive consumption of substances not generally considered food. However, a precise definition of pica is somewhat elusive because understandings of what constitutes "food," what symptoms signify pica, and explanations of what causes the condition vary with historical and cultural context. A more specific definition of pica is "the chronic, compulsive eating of nonfoods such as earth, ashes, chalk, and lead-paint chips . . ." (Hunter 1973: 171), but it may also include a "false or craving appetite" or "deliberate ingestion of a bizarre selection of food," as well as the compulsive ingestion of nonnutritive or nonfood items such as ice and ice water (Parry-Jones and Parry-Jones 1994: 290).

Pica, in various forms, has been widely noted historically and geographically, primarily in medical texts and anthropological writings (see, for example, Laufer 1930; Cooper 1957; Anell and Lagercrantz 1958). Its practice, although not considered a disease, is of medical concern because ingestion of some substances may result in disease. Additionally, there are types of pica that have been linked by medical researchers to the correction of mineral deficiencies (see, for example, Coltman 1969; Crosby 1971; Hunter 1973). Pica is classified by the DSM-III-R (American Psychiatric Association 1987) and the ICD-10 of the World Health Organization (1992) as an eating disorder, along with anorexia nervosa, bulimia, and infant rumination. Various forms of pica have also been associated with mental retardation.

The incidence of pica in any particular population is difficult to determine because of a tendency to conceal eating behavior that may be considered abnormal or deviant within the cultural context. In addition, the varying definitions of pica we have taken note of also contribute to difficulty in documenting the scope of the behavior. Thus, although pica has been widely observed (both historically and geographically) and has been the subject of much research in many disciplines, it remains poorly understood.

Classifications

Pica is generally classified according to the type of substance consumed. Names for subclassifications of pica are comprised of the Greek word for the ingested substance and the suffix from the Greek word "phagein," meaning "to eat" (Moore and Sears 1994). Cross-culturally, the most commonly noted and explored type of pica is geophagy or geophagia, the consumption of earth and especially clay. Other types include ingestion of ice or ice water (pagophagia); laundry starch (amylophagia); hair (trichophagia); gravel, stones, or pebbles (lithophagia); leaves, grass, or other plants (foliophagia); feces (coprophagia); and unusual amounts of lettuce (lectophagia), peanuts (gooberphagia), and raw potatoes (geomelophagia). Paint, plaster, coal, chalk, cloth, pepper, coffee grounds, paper, cigarette butts, and other household items are also commonly consumed by those engaged in pica (Feldman 1986: 521).

There is some agreement historically and cross-culturally that the populations most prone to pica are young children, pregnant women, persons with mental illness, and the mentally retarded. There is also similarity cross-culturally in the types of items most frequently consumed. These include coal, ice, chalk, plaster, and various types of earth, in particular clay.

As a rule, children who engage in pica are under the age of 6 (Castiglia 1993). The things they consume are restricted by proximity to their grasp and normally tend to be relatively harmless items such as cloth, dirt, leaves, sand, and small rocks or pebbles (Parry-Jones and Parry-Jones 1992). Children who chew furniture or eat paint or plaster can be harmed, and plumbophagia, the ingestion of lead paint, is an important cause of lead poisoning. In fact, the practice of plumbophagia has led to the banning of lead-based paints for interior use in homes.

Trichophagia refers to the ingestion of hair and is one of the types of pica found most often among children. It is especially associated with the habit of girls chewing on long hair and is believed to be related to other, somewhat common, behaviors such as chewing one's fingernails and chewing pencils (Higgins 1993). Trichophagia is of medical concern when substantial amounts of hair result in the formation of "hair balls" within the intestinal tract.

History

The term "pica" was first coined by the French physician Ambroise Paré in the sixteenth century, although references to the syndrome predated him by centuries. Aristotle and Socrates both wrote about "earth eating," and during the classical periods of Greece and Rome, red clay lozenges from Lemnos were believed by physicians such as Galen to be antidotes for poison and cures for illnesses. They were also believed to facilitate childbirth. The lozenges were called *terra sigillata* (sealed earth) and stamped with the seals of the goddesses Artemis and Diana. As Christianity spread, these seals were replaced with Christian symbols and the lozenges, blessed by monks, were traded throughout western Europe and the Mediterranean region with the approval of the Roman Catholic Church (Hunter and De Kleine 1984).

The word "pica," and its older variant, *cissa,* come from the Latin word for "magpie," a bird thought to have a not very discriminatory appetite where edible and nonedible substances were concerned. Nineteenth-century medical texts describe both the eating behavior of magpies and that of humans with pica as consisting of an appetite for unusual edible and nonedible items (see, for example, Hooper 1811). The misconception that the magpie consumed earth and clay was likely based on observations of magpies collecting clay to build nests.

Pica was classified in Greek and Roman medical texts as a form of morbid or depraved appetite. In 1638, M. H. Boezo distinguished pica, the consumption of nonfoods, from "malacia," a voracious appetite for "normal" foods. He attributed malacia in pregnant women to mental changes thought to occur in pregnancy. (As early as the sixth century A.D., pica was thought to result from the cessation of menstruation during pregnancy [Cooper 1957]). Today, malacia, or the craving and binge eating of specific foods, is considered a form of pica (Castiglia 1993). (For the early literature on pica, see Cooper 1957 and Halsted 1968.)

In mid-sixteenth-century England, pica was associated with coal eating among pregnant women and children. But within western Europe and the United States from the sixteenth century through the late nineteenth century, pica was commonly understood as the consumption by young women of substances such as lime, coal, vinegar, and chalk so as to achieve a pale complexion and otherwise improve on appearance (Parry-Jones and Parry-Jones 1994: 290). Historically, this condition was said to be accompanied by "chlorosis" or "green sickness" in prepubescent girls and young women. Chlorosis, a disease recognized from the sixteenth century through the late nineteenth century, was characterized by a loss of menses or irregular menstruation and was accompanied by symptoms such as listlessness, pallid skin, loss of appetite, and weight loss.

It is interesting to note that the debate in early medical literature about the causes of chlorosis prefigures the current debate about pica and iron deficiency in terms of cause and effect. For example, the consumption of nonfoods by young women in order to achieve a pale complexion could easily have resulted in iron-deficiency anemia or chlorosis. However, iron-deficiency anemia can cause cravings for nonfoods, and chlorotic females ingested large amounts of unusual foods such as pepper, nutmeg, and raw corn, as well as nonfoods such as plaster. In addition, psychological reasons such as sexual frustration and nervous conditions were considered possible causes of both chlorosis and pica (Loudon 1980). In the twentieth century, pica among young women has been manifested by excessive consumption of real foods such as fruit and vegetables and nonfood substances like ice (Parry-Jones and Parry-Jones 1992). (For an extensive historical account of pica within Western industrialized cultural contexts, see Parry-Jones and Parry-Jones 1994).

In various regions of the world, especially in tropical zones, pica most often takes the form of geophagy. Harry D. Eastwell has noted that geophagy is associated with the "world's poor or more tribally oriented people" (1979: 264). Other investigators have characterized such groups as constituting "subsistence" societies (Hunter 1973), although in this chapter, the term "nonindustrialized" societies is used. In these societies, geophagy has been observed for many centuries and variously attributed to religious, cultural, and physiological causes (Hunter 1973; Hunter and De Kleine 1984; Parry-Jones and Parry-Jones 1992). Geophagy, or "dirt eating," was also thought to be a peculiar affliction of enslaved Africans and, later, lower-income African-Americans and whites in the southern United States, who were characterized as "dirt eaters" (Forsyth and Benoit 1989).

Etiology

Explanations of pica are numerous, reflecting the diversity of items consumed and the geographical regions within which the compulsive consumption occurs. In addition to the historical and cultural practices just mentioned, explanations also include psychiatric disorders and psychological and physiological needs, satisfaction of oral needs, behavioral disorders, responses to physiological or psychological stress, and the use of nonfoods for medicinal or pharmacological purposes (see, for example, Talkington et al. 1970; Hunter 1973; Crosby 1976; Eastwell 1979; Hunter and De Kleine 1984; Prince 1989; Horst 1990; Reid 1992). In fact, the practice of pica is so widespread both geographically and historically that one might be tempted to question its characterization as an abnormal practice.

Nonetheless, at least in the West, pica is considered an aberrant behavior warranting medical or psychological treatment. Within the medical literature, pica is discussed in terms of possible biological causes and their negative consequences. The psychological literature characterizes pica as a pathological behavior linked to other eating disorders or found among populations of children and the mentally retarded.

However, this tendency to view pica as a pathological eating practice, an idiosyncracy of "primitive" peoples, or an affliction primarily of the rural and impoverished has resulted in a failure to recognize the nutritional, medicinal, and cultural importance of geophagy in nonindustrialized cultural contexts.

Geophagy (Geophagia)

Geophagy, or the consumption of earth substances, is the most widely observed and researched type of pica. The term "geophagy" was first coined by Aristotle and means "dirt eating." Geophagia has also been termed *allotriophagia* by Sophocles, *erdessen* in medieval Germany, *mal d'estomac* in French, *citta* in Latin, and *cachexia africana* – literally meaning a "wasting away of Africans" – a phrase employed by slave owners and physicians in the West Indies and southern United States.

Despite the historical evidence for various forms of pica throughout the world, geophagy is the only type to be discussed extensively from a cross-cultural perspective, especially in ethnographic anthropological and geographical literature. In transcultural perspective, both anthropologists and geographers have described it as a socially acceptable custom, with specific cultural meanings and functions. Such literature reports geophagy to be most frequently practiced in tropical areas of Africa, Latin America, and the Caribbean, as well as in the southern United States. It is also practiced widely in parts of Iran, India, and China, and in tropical areas of Indonesia and Oceania (Anell and Lagercrantz 1958; Hunter 1973).

In the Andes Mountains of Peru and Bolivia, two dozen comestible or edible earth substances have been found listed in pre-Columbian Incan sources, and about six different comestible earths have been discovered archaeologically in pre-Incan contexts. In fact, evidence that the practice of eating earth is at least some 2,500 years old in the Andean region was discovered when a specimen of comestible earth was recovered from a Bolivian site dating from 400 B.C. (Browman and Gundersen 1993). Although cultural explanations have been popular, physiological explanations of geophagy as an adaptive human behavior are also important (Hunter 1973; Hunter and De Kleine 1984; Johns and Duquette 1991; Browman and Gundersen 1993).

Some of the first domesticated plants contained substances toxic to humans and were treated in processes involving earth substances to make them less toxic. The absorptive properties of clay were well known to ancient physicians who included *terra sig-*

illata and *terra silesiaca* in their pharmacopoeias for the treatment of poison (Dannenfeldt 1984). Several authors note the example of a condemned man, during the sixteenth century, who elected to swallow a lethal dose of mercury if he were first allowed to ingest clay. He reportedly survived an amount of mercury three times the normal lethal dose and was granted a pardon for having contributed to the medical knowledge of the time (Halsted 1968; Dannenfeldt 1984). In our times, kaolinite is the common type of clay used in medicines and the primary ingredient in commercially marketed Kaopectate.

Clay is also used medicinally in nonindustrialized societies where hookworm is a common ailment. This intestinal parasite causes gastric distress that is frequently alleviated with clay. Clay is also employed as a treatment for diarrhea, heartburn, and intestinal gas and has been used to relieve nausea and vomiting in pregnant women (Anell and Lagercrantz 1958; Hunter 1973). But authorities caution that the practice of geophagy can also introduce intestinal parasites into the body (Castiglia 1993) as well as cause intestinal blockage and excessive wear of dental enamel.

John M. Hunter (1973) hypothesized that a connection exists between mineral deficiencies (particularly those resulting from increased nutritional requirements during pregnancy) and the cultural practice of geophagy in Africa. Moreover, along with Renate De Kleine, he suggested that clay eating in Central America may be a "behavioral response to a physiological need" created by various mineral deficiencies, particularly during pregnancy (Hunter and De Kleine 1984: 157). Similarly, Donald E. Vermeer investigated geophagy among the Tiv of Nigeria and the Ewe of Ghana and discovered that clays were consumed during pregnancy as a treatment for diarrhea as well as for the minerals that they contain (Vermeer 1966; Vermeer and Frate 1975).

Hunter, who described geophagy in Africa as "common among children and adults" (1973: 171), acknowledged that the practice also has a cultural basis. For example, earth, taken from a shrine or holy burial site, is eaten for religious purposes or to swear oaths. However, earth eating is most commonly viewed as a remedy. Syphilis, diarrhea, and gastrointestinal discomfort caused by parasitic diseases (such as hookworm) are all conditions treated with geophagy by the general population, but in Africa, the practice of consuming clay is most frequently found among pregnant women. In a field study conducted in the Kailahun District of Sierra Leone, Hunter (1984) found that 50 percent of pregnant women ate clay from termite mounds and 7 percent ate vespid mud or clay from mud-daubing wasps' nests. In both cases, the mud was cooked over a fire until dried and blackened. An analysis of the clay to determine mineral content and availability for humans led Hunter to conclude that the practice of geophagy was "sensible and appropriate behavior" – as the clays made a significant contribution to the calcium, manganese, iron, and other mineral requirements of pregnant women (1984: 11).

In other parts of Africa, well-known and highly regarded clays are "extracted, processed, and passed from producers through middlemen to retailers and reach a wide consumer public through a network of periodic markets" (Hunter 1973: 173). Analysis of the nutritional content of a sample of such clays from Ghana revealed that clays of distinctive shapes (indicating a sort of brand) provided mineral supplementation in distinctive, varying proportions. For example, Hunter wrote:

> a distinctive end-to-end, truncated cone-shaped clay (sample six), is richest in two macronutrients, potassium and magnesium, but is poor in calcium. Another distinctive clay, sample 12, the slim, fingerlike bar, is richest in two micronutrients, zinc and manganese, but is weak in iron and copper. (1973: 177)

Hunter concluded that in view of the deficiencies inherent in the diets of many Africans, clays supplement those diets with a wide range of minerals important for pregnant women.

Moving to the other side of the world, Hunter and De Kleine (1984) also evaluated the nutritional properties of clay used to make tablets sold at religious shrines in Belize. Samples were tested for 13 minerals, and the conditions of digestion were simulated to determine the bioavailability of those minerals. Although the tests showed great variation in the amount of minerals available, in all cases the mineral content (and mineral availability) was sufficiently strong to suggest that the clay did indeed provide nutritional supplementation. A daily dose of from 1 to 6 tablets delivered 11 minerals in varying degrees, depending on the clay sampled. For example, 1 tablet yielded 73 milligrams of calcium and 68 micrograms of copper, among other minerals. A sample dose of 6 tablets provided 10 milligrams of iron, more than 200 micrograms each of nickel and manganese, and 12 micrograms of cobalt. When compared with U.S. Recommended Dietary Allowances and recommended supplements during pregnancy, a single tablet provided about 9 percent of the recommended iron and calcium.

Yet some types of clay are suspected of having properties that inhibit the absorption of minerals from the gastrointestinal tract, and there is no consistent agreement that iron from clay is useful in correcting anemia. Still, Hunter (1973), De Kleine (Hunter and De Kleine 1984), and David L. Browman and James N. Gundersen (1993) have asserted that clays can serve as a culturally acceptable and nutritionally functional source of mineral supplementation within some nonindustrialized societies.

In addition, there is an economic factor. Vermeer (1966, 1971) and Hunter (1973) have both documented how clay is incorporated into trade practices and how its processing has been the basis for local cottage industries.

Cultural Diffusion: Case Studies

Perhaps the best approach to understanding the phenomenon of geophagy involves the merging of nutritional, cultural, and economic explanations. In other words, from an African standpoint it might be viewed as a physiologically based adaptive behavior supported by religious and other cultural beliefs and institutionalized within the local economy.

Moreover, many have noted the diffusion of geophagy via the slave trade with the result that the practice was frequently observed among enslaved Africans in the West Indies, South America, and the southern United States. In addition, forms of geophagy continue to be documented among African-Americans in the southern United States and among those who migrated to northern cities and took the practice with them. It was common to have dirt or clay from a particular site in the South sent north by relatives. However, more recently, amylophagia (consumption of laundry starch) seems to have replaced clay eating, and geophagy generally seems to have declined significantly in recent decades.

During the last century, *cachexia africana* was of concern to physicians and plantation owners, who viewed it as an important cause of death among enslaved Africans. The condition they described seems similar to the syndrome of chlorosis we have already described. Both chlorosis and *cachexia africana* were characterized by a seemingly uncontrollable desire for the substances that are eaten. Although the reasons advanced for the aberrant appetites of young white women and African slaves are different, in both cases questions of cause and effect arise. David Mason (1833) was one of the first to suggest that obsessive dirt eating or *atrophia a ventriculo* (stomach atrophy), as he termed it, was actually a consequence of disease, and not its cause. He wrote:

> The train of symptoms that progressively arise from atrophy of the stomach and dirt-eating are indigestion and emaciation; a bloated countenance; a dirty-yellow tinge in the cellular tissue of the eyelids; paleness of the lips and ends of the fingers; whiteness of the tongue; great indolence, with an utter aversion to the most ordinary exertion; palpitation of the heart; difficult, or rather frequent and oppressed, respiration, even during moderate exercise, which never fails to induce a rapid pulse; habitual coldness of the skin; and occasional giddiness of the head, attended with a disposition to faint, sometimes causing a state of stupor. (1833: 292)

In addition, he noted a change in the color and density of blood, the appearance of skin ulcers, polypi in the heart, and pathologies of the liver and gallbladder. Mason also reported that the obsession with nonfood items extended to eating "cloth, both linen and woolen . . ." (1833: 291).

Mason and later authors (Laufer 1930; Anell and Lagercrantz 1958) discussed a variety of conflicting explanations for the disease. Plantation owners often considered it either a kind of addiction or a means of escaping work, or both, and punished geophagy with confinement, beatings, and the use of metal mouthlocks. But others believed that homesickness and depression or abusive conditions led to the consumption of dirt; Berthold Laufer (1930) and Bengt Anell and Sture Lagercrantz (1958) mention the conviction, held by some, that geophagy was a deliberate, slow form of suicide among the enslaved Africans. Mason, by contrast, foreshadowed the current general debate about iron deficiency and pica in his belief that dirt eating was "rather a consequence than a cause of the disease" and suggested that the earth eaten contained "useful ingredients mixed up with much hurtful matter" and that "iron and alkalis are of great efficacy in this disease" (1833: 289, 292). He recommended exercise, proper diet, cleanliness, and proper clothing, as well as purely medical treatment with emetics, purgatives, and tonics. Unlike geophagy more generally, *cachexia africana* appeared to afflict both men and women in large numbers.

Hunter (1973) has noted similarities between geophagy in Africa and that practiced more recently by African-Americans in the United States, leading him along with others (see, for example, Vermeer and Frate 1975) to the view that geophagy arrived in the United States with enslaved Africans in a process of cultural diffusion. In both geographical locations the practice is found most often among women (especially pregnant women), and clays are gathered from special sites such as anthills, termitariums, or river banks and often referred to by the location (Forsyth and Benoit 1989). In Africa and in the southern United States, clays are shaped, baked, or sun-dried before eating and are claimed to have health-giving properties, as well as providing satisfaction. Reasons cited by southern women (black and white) reflect folk beliefs about the medicinal qualities of earth eating, while also indicating its character as an addiction:

> I craves it. I eat dirt just the same way you would smoke a cigarette. I crave something sour like the taste of clay. It seems to settle my stomach. I know I shouldn't eat it. When I go up in Jasper County I get it, but can't find any good dirt here. This Biloxi dirt ain't no good, so I gets my sister in Birmingham to send it to me. I never heard of a man eating dirt. They not got the same taste a woman has. My mother eats it because she be's in the change and they say it will help her. When I was a child I was coming home from Sunday School and it had rained. I

> could smell the dirt on the bank and started to eat it then. Have kept it up. I would eat more dirt than I do, but I have a hard time getting it. (quoted in Ferguson and Keaton 1950: 463)

In moving to non-Western case studies of pica, we can encounter one of the few of a psychological nature. This one concerns an "epidemic" of pica (geophagy) that took place in Aboriginal coastal towns of northern Australia during 1958 and 1959 (Eastwell 1979). As diarrhea was presumed to be the cause of the earth eating, white nurses in the area treated patients with placebo tablets and with Kaopectate. The "epidemic" was ended, but the cessation of geophagy produced a community-wide disorder of hypochondriasis, and another outbreak of geophagy occurred among Aboriginal women who were past the years of childbearing.

Eastwell (1979), who discussed the epidemic, believed that the hypochondriasis and the earth eating of postmenopausal women had deep sociocultural causes. He argued that within the aboriginal hunting-and-gathering mode of subsistence, geophagy was originally practiced for medicinal purposes, but this function disappeared after these small-scale societies were colonized by the British. As the traditional hunting and gathering came to an end, the practice of geophagy was transformed into an indigenous cultural statement of Aboriginal status. Thus, bereft of its traditional medicinal function, the practice of pica among Aboriginal women became not only a type of protest, reflecting gender status, but also constituted a psychological adjustment strategy for women, whose economic importance diminished during the shift from a nomadic to a sedentary existence.

In a separate example, involving cultural diffusion and social change, Hunter and De Kleine (1984) provided a case study demonstrating the interaction of cultural and nutritional aspects of geophagia in Belize, where the indigenous population was resettled by the Spaniards in Santiago de Esquipulas, a pre-Columbian town of economic and religious importance to the Maya. "Esquipulas was noted for its shrine, health-giving earth, and sulfurous springs; thus it served as a place of spiritual significance and healing activity" (Hunter and De Kleine 1984: 157). The Spaniards built a chapel at the site to house a crucifix carved of balsam and orangewood. The crucifix darkened over time with the burning of incense and candles and became known as *Nuestro Senor de Esquipulas, el Cristo Negro,* or "the Black Christ." The Black Christ was worshiped by the Indians and symbolized a cultural fusion of Christian and Mayan beliefs by bringing an "Indian saint" into what was a new religion for the Mayas. The Black Christ also became known for its miraculous cures, which focused attention on the healing properties of the spring and mud at the site.

In the 1700s, the site was formally recognized by the Catholic Church, and a sanctuary for the Black Christ was constructed. The shrine continues to be of religious importance; pilgrims visit it, particularly on January 15, the Day of Esquipulas, and during Lent. Prior to the institution of border regulations requiring passports and visas, an estimated 100,000 pilgrims annually visited the shrine to be cured of ailments including "leprosy, blindness, muteness, insanity, paralysis, rabies, yellow fever, malaria, tetanus, and hemorrhages" (Hunter and De Kleine 1984: 158).

Many of the alleged cures were credited to the *tierra santa* (holy clay) at the site, which is believed to have health-giving properties and is blessed by the Roman Catholic Church. *Tierra santa* was (and is) sold at the shrine in the form of clay pressed into small cakes, stamped with images of the Virgin Mary, the Black Christ, and other saints. The clay tablets or *benditos* (blessed ones) (either eaten or dissolved in water and drunk) are believed to alleviate diseases of the stomach, heart, and eyes, to ease menstrual difficulties, and to facilitate pregnancy and childbirth.

As the cult of the Black Christ and the reputation for cures spread throughout Central America, new shrines were built that also became associated with curative, blessed earth. Indeed, by the end of the eighteenth century there were shrines in at least 40 towns where supposedly curative earths were available for consumption.

Pagophagia and Amylophagia

Within Western industrialized societies, recent medical literature on pica is dominated not so much by geophagy as by pagophagia and amylophagia. The term "pagophagia," first used in 1969 by Charles Coltman, a U.S. Air Force physician, refers to the compulsive consumption of ice and other frozen substances. Some, however, do not view pagophagia as a form of pica because ice (and ice water) consumption can be a positive measure in controlling body weight and addictions such as the use of tobacco. In addition, of course, chewing ice is more socially acceptable within industrialized countries than eating dirt. Like geophagy, pagophagia is strongly associated by many researchers with iron and other mineral deficiencies.

Amylophagia, by contrast, is the eating of laundry starch, which is associated almost exclusively with women. It was first observed in rural areas of the southeastern United States, where it was thought by some to have replaced dirt eating. As we have already noted, Hunter described a process of cultural diffusion and change occurring as geophagy from Africa was brought first to the southern United States:

> Next came the northward migration of blacks to the urban ghettos of Cleveland, Chicago, New York, and Detroit. Such migrants ask their southern relatives to mail them boxes of clay for consumption during pregnancy. At this

> state, however, the forces of culture conflict come to the fore: lack of local clay in the concrete jungles of the North, pressures of poverty, and stress on kinship ties with the South lead to the consumption of laundry starch replacing traditional geophagy. But micronutrient minerals are totally lacking in the starch. Calories apart, nutritional inputs are zero; gastric irritation is caused. A cultural practice is now divorced from nutritional empiricism; cultural adjustment to socioenvironmental change has broken down, and atrophy and decay are the result. (1973: 193)

Perhaps significantly, a similarity between dirt and laundry starch in texture (although not in taste) has been noted by investigators. The reasons cited by women for consuming laundry starch include the alleviation of nausea and vomiting associated with pregnancy and various folk beliefs, found largely among African-Americans, that consuming starch during pregnancy helps the baby "slide out" during delivery, promotes a healthy baby, or a whiter (or darker) baby (O'Rourke et al. 1967).

Like pagophagia and geophagia, as well as other forms of pica, amylophagia has also been associated with iron deficiency. Deleterious consequences include impacted bowels and intestinal obstructions.

Pica during Pregnancy

Pica has been associated since classical times with pregnant women. Until the twentieth century, pregnancy was commonly believed to cause mental instability – manifested, for example, in unusual food cravings. More recent studies of food preferences during pregnancy, however, report that changes in these, as well as the onset of specific cravings, are not universal phenomena.

Much of the research on pica among pregnant women in the United States has focused on those living in rural areas. The prevalence of pica among women considered at risk seems to have declined by about half between 1950 and 1970, but it has remained fairly constant from 1970 to the present. Nonetheless, it was estimated that pica is practiced by about one-fifth of pregnant women in the United States who are considered at "high risk" for this behavior. "High-risk" factors include being African-American, living in a rural area, having a family history of pica, and having practiced pica during childhood (Horner et al. 1991). Pregnant black women are over four times more likely than their white counterparts to engage in pica behavior. Additionally, pregnant women living in rural areas are more than twice as prone to pica as those living in urban areas.

Although some investigators have found no significant association between age and pica among pregnant women (Dunston 1961; Butler 1982), others have observed that pregnant women who practice pica tend to be relatively older than those who do not. It is interesting to note that women who report consuming clay tend to be older than those who report consuming starch (Vermeer and Frate 1979). One study, reanalyzing data from previous research, indicated that pregnant women who did practice pica were six times as likely to have a history of childhood pica than pregnant women who did not. Women who practice pica during pregnancy are also more likely to report pica behavior among family members, particularly their mothers and grandmothers (Lackey 1978). Little evidence of pica among white and upper-income women may reflect a lack of research among these populations (Keith, Brown, and Rosenberg 1970; Horner et al. 1991).

Among pregnant women in the United States, the three forms of pica that occur most frequently are geophagia, amylophagia, and pagophagia (Horner et al. 1991). Although, as we have noted, some researchers believe that as African-American women migrated to northern urban areas, laundry starch became a substitute for the more traditional clay eaten in the South (Keith et al. 1970), other research indicates that consumption preferences themselves might be changing, with younger women preferring starch over clay. In one study of rural women in North Carolina, participants indicated a preference for starch, even though their mothers had consumed both clay and starch (Mansfield 1977). Explanations of pica during pregnancy, like those of pica in general, range from the psychological through the cultural, to the nutritional (Horner et al. 1991; Edwards et al. 1994).

A recent study of eating habits and disorders during pregnancy mentions the case of a woman who, at 32 weeks of pregnancy, developed a craving for coal, reporting she found it "irresistibly inviting" (Fairburn, Stein, and Jones 1992: 668). Two other participants in the study developed a taste for eating vegetables while still frozen, which indicates something of the difficulty involved in determining pica incidence. The consumption of frozen vegetables, although not defined as pica by these researchers, would surely be considered a type of pagophagia by others.

In terms of medical consequences, pica has been related to anemia and toxemia among pregnant women and newborn infants (Horner et al. 1991). In some cases, pica reportedly contributed to dysfunctional labor (through impacted bowels) and maternal death (Horner et al. 1991). Pica during pregnancy has also been associated with a "poor" functional status of fetuses and infants, perinatal mortality, and low birth weight.

The authors of a report on pica in the form of baking-powder consumption that caused toxemia during pregnancy have pointed out that previous investigators discovered a significant correlation between toxemia and geophagia, but not between toxemia and amylophagia (Barton, Riely, and Sibai 1992). The case involved a 23-year-old black woman with anemia and hypokalemia who admitted to a one-and-a-half-year history of consuming up to 7 ounces of Calumet baking powder daily. The baking powder was considered a family remedy for gas discomfort. Ingestion of baking powder, comprised of 30 percent sodium bicarbonate with cornstarch, sodium aluminum sulfate, calcium acid phosphate, and calcium sulfate, is known to increase blood pressure. In this case, liver dysfunction and hypokalemia also resulted.

The psychological aspects of pica among pregnant women are similar to those of other pica practitioners. In addition to reporting a craving for the ingested substance, pregnant women exhibiting pica commonly say that they feel anxious when the substance is unavailable yet experience a sense of considerable satisfaction during and after eating the substance (Horner et al. 1991).

Pica and Iron Deficiency

Although no definitive connection has been established between pica and nutritional deficiencies, many have consistently linked pica with iron deficiency and its consequent anemia. Indeed, some have estimated that upward of 50 percent of patients with iron-deficiency anemia practice pica (Coltman 1969; Crosby 1976). It is interesting to note that the correlation of pica with anemia dates back to medieval times, and that iron therapy was prescribed as a cure even then (Keith et al. 1970).

As pointed out previously, pica behavior during pregnancy has also been strongly associated with iron-deficiency and iron deficient anemia. What remains unresolved is a problem of cause and effect. As Dennis F. Moore and David A. Sears wrote: "Some authors have suggested that the habit may induce iron deficiency by replacing dietary iron sources or inhibiting the absorption of iron. However, considerable evidence suggests that iron deficiency is usually the primary event and pica a consequence" (1994: 390). Although some insist that ingested starch inhibits iron absorption, Kenneth Talkington and colleagues (1970) have reported that this is not the case. These authors concluded that iron deficiency and anemia result from amylophagia only when laundry starch replaces nutritional substances in the diet.

Turning to clay ingestion, studies have found that its effect on iron absorption varies and depends upon the type of clay ingested. Some clays impair iron absorption, whereas others contain large amounts of iron. However, as already mentioned, there is no consistent agreement that iron from clay is useful in correcting anemia (Coltman 1969; Keith et al. 1970; Crosby 1976).

Coltman (1969), who first used the term pagophagia, was also one of the first to link the practice with iron deficiency. Indeed, he reported that the compulsive consumption of ice could be stopped within one or two weeks with iron treatment, even in instances where iron supplementation was not sufficient to correct iron-deficiency anemia. This dovetails with the work of William H. Crosby (1976), who has noted that although ice neither displaces other dietary calories nor impairs iron absorption, it is still the case that pagophagia is diminished when treated with iron supplements. Moreover, other cases of pica involving unusual ingested substances (e.g., toothpicks, dust from venetian blinds, and cigarette ashes) also respond positively to iron supplements (Moore and Sears 1994).

Perhaps even more powerful support for iron deficiency as a cause of pica comes from findings that intramuscular injections of iron diminish the habit of pica in children. But there is also evidence that intramuscular injections of a saline solution have the same effect, suggesting that the additional attention paid to children with pica behavior may help to reverse the condition (Keith et al. 1970).

Countering this theory, however, are two cases of childhood pica in which parental attention was apparently not a factor. One involved a 6-year-old boy with a 2-year history of ingesting large amounts of foam rubber, whereas the second case was that of a 2-year-old boy with a 6-month history of eating plastic and rubber items. Both of these cases of pica behavior were resolved through the administration of iron supplements, even though there was no increase in parental attentiveness (Arbiter and Black 1991).

In 1970, Louis Keith, E. R. Brown, and L. Rosenberg summarized the medical questions surrounding pica that required further investigation and clarification. These were:

> 1. Is iron-deficiency anemia a direct adverse consequence of pica?
> 2. Is iron-deficiency anemia an indirect result of nutritional replacement by unnatural substances, allaying the appetite for nutritional foods by filling?
> 3. Are so-called cures of the habit of pica among children the result of increased attention or of injections of iron or saline solution?
> 4. If those "cures" among children are the result of therapy, should the therapy consist of iron injections, saline injections, or an adequate diet high in iron content?
> 5. Is the mechanism of pica among children different from that among adults, especially pregnant women? Would injections of iron reverse the habit in pregnant women?
> 6. Does the coexistence of amylophagia and anemia adversely affect the pregnant woman, or are these two separate and distinct unrelated concomitant adverse conditions? (1970: 630)

As we have seen, although almost three decades have elapsed, there is still no consensus within the medical community regarding the answers to these questions. Instead, they are still being asked.

The physiological mechanism linking iron deficiency and pica behavior is not known. As Crosby noted, "Somewhere in our emotional circuits iron deficiency can sometimes cross the wires" (1976: 342). Somewhat more scientifically, it has been suggested that pica cravings are generated by a functional disorder of the hypothalamus, which is sensitive to changes in iron levels (Castiglia 1993).

As for pagophagia, Mary Elks (1994) has made two observations. She noted that even in industrialized nations, both geography and culture play a role in determining how pagophagia is viewed. For example, in England and other European countries compulsive ice eating is considered pathological behavior, perhaps indicative of disease. However, in the warmer climate of the southern United States, ice eating may be regarded as normal. In addition, she reported a case involving an entire family practicing pagophagia, including a 14-month-old girl for whom, Elks believed, ice consumption should not be assumed to be a learned behavior. She suggested that in some cases, familial or heritable factors cause pagophagia that is independent of other types of pica and probably not correlated with iron deficiency.

Psychological Explanations of Pica

Pica, as we have observed, is included as an eating disorder (along with anorexia nervosa, bulimia, and rumination in infancy) in the classification systems of the DSM-III-R of the American Psychiatric Association (APA) (1987) and the ICD-10 of the World Health Organization (1992). Pica is defined by the APA as the repeated consumption of nonnutritive substances for a period of at least one month, when the behavior is not attributable to another mental disorder.

It is interesting to note that psychological literature on eating disorders discusses pica in early childhood as a risk factor for bulimia in adolescence (Marchi and Cohen 1990). Moreover, some aspects of pica, such as excessive consumption of ice, ice water, lemon juice, and vinegar, are linked with anorexia nervosa (Parry-Jones 1992; Parry-Jones and Parry-Jones 1994). Pica has also been associated with rumination in children and persons with mental retardation; in such cases, the behavior may be interpreted as a regressive behavior reflecting oral needs that have not been met (Feldman 1986). Poor feeding and weaning practices are more frequently observed in children with pica than in those without (Singhi, Singhi, and Adwani 1981). In addition, comparisons of children who have iron-deficiency anemia and who practice pica and children with anemia who do not practice pica show that the former score higher on measures of stress, including that caused by maternal deprivation, child abuse, and parental separation (Singhi et al. 1981).

It is important to understand that psychological explanations themselves tend to reflect cultural beliefs in the Western industrialized world, in contrast to religious and spiritual beliefs of cultures in other areas. To view all types of pica behavior as pathology risks a failure to recognize other important issues, such as cultural variation in food preference, indigenous medicinal and nutritional knowledge, and the very real question of the effects of nutritional deficiencies.

Discussion

Although explanations of pica vary with the type of substance consumed and with the cultural context, there are several consistent themes in the literature. One is that whereas men do practice pica, the behavior is most frequently associated with women and children. Second, regardless of cultural context and whether pica is considered acceptable among adults, there seems to be a uniform concern about the practice of pica by children.

A third has to do with similarities shared by the substances most frequently consumed. They tend to be brittle, dry, and crunchy. Moreover, the smell of the clay and soil is cited as important in a variety of cultural contexts, as is the location from which the clay or earth is obtained. These sites are frequently the homes of living things such as termites or crayfish. There is also a pattern, historically and geographically, of consumption of earth or clay from sites of special significance. Such sites may be religious, as in Latin America and Africa, locally distinctive, as in the southern United States, or they may be places of burial, as in Asia, Africa, and Europe. Finally, there is a cross-cultural consistency in the debate concerning the relationship of pica to iron and other mineral deficiencies, and in the debate over whether the practice is psychologically or physiologically based.

One question that remains unexplored (in fact, it is barely mentioned in the literature) is why the definitions and syndromes associated with pica are not extended to the many practices in which men rather than women more typically engage, such as chewing tobacco and cigars or pipe stems, using snuff, and chewing toothpicks, betel nut, and chewing gum. While these habits may not generally involve consumption, they are not so dissimilar from the practices of pagophagia. Certainly, it appears that the relationship between the forms of pica we have discussed and other cravings and sources of oral satisfaction is an area in need of further investigation.

IV.D.7 Protein–Energy Malnutrition

Protein–energy malnutrition (PEM) is the current term for a group of nutritional diseases related to dietary protein and energy (calorie) intake. These diseases are most frequently seen in infants and young children in developing countries but may be a feature of famine or the result of illness for people of all ages throughout the world. Research during the twentieth century has considerably clarified the causes and manifestations of what are now known as dietary-related effects on the growing or mature individual. PEM includes conditions known in the medical world as kwashiorkor, marasmus, and growth retardation in children. Related to PEM are pellagra, starvation, and protein malnutrition. Infection, debilitating disease, and surgical procedures are frequently complicated by PEM. It is, therefore, a factor of importance in determining morbidity and mortality and has to be taken into account by health-care personnel at all levels.

Historical Concepts of Protein and Energy

Early reports of what may have been PEM lack the clinical, pathological, and biochemical details that make identification certain. The history of PEM is thus confined to the nineteenth and twentieth centuries, and it is only in the last 50 years that clarification of the various forms that PEM can manifest has emerged.

In his book *Protein and Energy,* Kenneth J. Carpenter has provided a detailed survey of nutritional science as it was known in the period from 1614 to 1893 (Carpenter 1994: 1–99). Of particular interest in relation to later discoveries is that the first "balance studies" were carried out by Italian scientist S. Santorio in 1614. He weighed his food and drink as well as his excreta (urine and feces) and measured changes in his own weight. There was an unexplained daily disappearance of 5 pounds of material that he attributed to a breakdown of body tissue that was then secreted through the skin as insensible perspiration; the losses were made good by the nourishment ingested. This was only a more quantitative restatement of Galen's view in the second century that "[o]ur bodies are dissipated by the transpiration that takes place through the pores in our skins that are invisible to us; therefore we need food in a quantity proportionate to the quantity transpired" (Carpenter 1994: 1).

Anton Lavoisier's work in the late eighteenth century (1770 to 1790) made him the "Father of Nutritional Science." His first contribution was the recognition of the distinction between compounds that could change their character and simple substances or elements (e.g., carbon, hydrogen, nitrogen, oxygen, and others). His second contribution was an understanding that combustion and respiration involved similar processes of oxidation that could explain the phenomenon of "animal heat."

Among those who followed Lavoisier was Jean-Baptiste Boussingault, who published the first table of the nitrogen content of foods in 1836. The protein radical was discovered just two years later by Gerrit Mulder and was considered to be the essential ingredient for both body building and physical activity. By the end of the nineteenth century, however, it was realized that protein was not the main or obligatory source of energy and that it is the oxidation of carbohydrates and fatty acids on which we rely for continued physical work.

Definition and Nomenclature

Description of the various syndromes that we now include in PEM began around 1850, and in the subsequent hundred years, much confusion in terminology arose. However, E. Kerpel-Fronius, a well-known Hungarian pediatric investigator who bridged both the pre- and post-1950 eras, clarified the old and new nomenclature, which has made it possible to identify references in early case reports (Kerpel-Fronius 1983: 30–4). He showed that the contradictions in terminology were rooted in regional differences, age of weaning, local foods, and prevalence of infections, and he classified the various types of malnutrition we now call PEM in the following way:

1. Hypoalbuminemic forms (low serum proteins)
    i. Edematous
        a. Kwashiorkor
        b. Mehlnährschaden
    ii. Hypoalbuminemic forms without edema
2. Dry forms without hypoalbuminemia
    i. Underweight (dystrophic infants)
        a. Stationary stage
        b. Repairing stage with retardation in height (stunted infants)
    ii. Marasmus (atrophy)
        a. Moderately severe
        b. Severe forms
    iii. Severest form in young infants (athrepsia or decomposition in the classic texts of pediatrics)

Reference to this classification assists considerably in identifying in older literature the various forms of what is now known as PEM. A current definition of PEM is the Wellcome classification shown in Table IV.D.7.1, which refers to children (Wellcome Trust Working Party 1970), whereas a broad current understanding of the nutritional basis of PEM is as follows:

> 1. Protein quantity and/or quality (amino acid pattern of the protein) intake that is below the minimal requirements for growth and health, with or without an energy intake that is less than energy expenditure on muscle activity, heat production, growth, and other energy requirements.
> 2. Excessive loss of protein and energy in diarrhea and acute and chronic diseases. (Waterlow 1992: 152–8)

PEM can, of course, be complicated by mineral deficiencies (e.g., of sodium, potassium, calcium, phosphorus, or iron), by deficiencies of trace elements (e.g., zinc or chromium), and by vitamin deficiencies (e.g., of vitamins A, D, C, or K). Much of this understanding has come about through intensive worldwide research during the last 50 years, which is discussed in the remainder of this chapter. We begin with marasmus.

Table IV.D.7.1. *The Wellcome classification of PEM*

Weight (percentage of standard)	Edema Present	 Absent
60–80	Kwashiorkor	Underweight
60 or less	Marasmic Kwashiorkor	Marasmus

Source: Wellcome Trust Working Party: 1970.

Marasmus 1850 to 1950

"Marasmus" means "wasting away of the body" (from the Greek *marasmos*) and is a term applied mainly to infants and children (the term "wasting" is employed for similarly afflicted adults) (Figure IV.D.7.1). It occurs when the diet is grossly deficient in energy. Such a diet also necessarily fails to meet protein requirements. Marasmus may become manifest in wholly breast-fed infants when the milk is quantitatively insufficient, but more frequently it occurs after

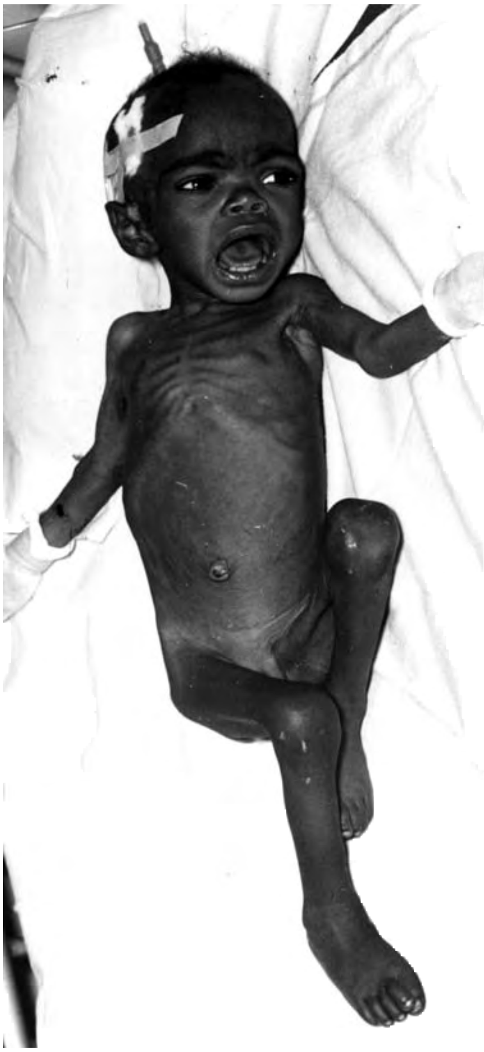

Figure IV.D.7.1. Marasmus. Age about 7 months grossly underweight. No skin lesions and no edema. (Photograph courtesy of Groote Schuur Hospital, Cape Town, South Africa.)

early weaning to diluted or low-energy bottle feeds or cereal paps. In the age group from 1 to 5 years, marasmus occurs when food of any kind is in short supply, as in conditions of war, civil unrest, famine, extreme poverty, or just lack of care for the child. Often, it is produced by starvation that occurs during treatment of diarrhea or other infections, but it can also stem from severe weight loss brought on by chronic pyogenic disease, tuberculosis, syphilis, AIDS, and tropical infestations.

The presenting symptoms are failure to thrive, irritable crying, or apathy. Diarrhea is frequent, and the child has a shrunken or wizened appearance, even though it is ravenously hungry. The degree of underweight for age is extreme, and the muscles are weak and atrophic. Currently, marasmus is diagnosed when the weight is 60 percent or less of the 50th percentile of the National Center for Health Statistics (NCHS) standards (Table IV.D.7.1). However, based on prewar literature, Kerpel-Fronius wrote that if the degree of wasting reaches 35 to 40 percent of the average body weight, recovery is impossible (Kerpel-Fronius 1947).

An interesting description of the clinical signs of marasmus was given in a speech by Charles Dickens at a fund-raising dinner for the Hospital for Sick Children on February 9, 1858. After discussing the tens of thousands of children who were dying because of poverty and sickness, he described a tour of the old town of Edinburgh, where lived some of the city's worst-lodged inhabitants. In one of the most wretched dwellings, "there lay, in an old egg box, which the mother had begged from a shop, a little feeble, wasted, wan, sick child. With his little wasted face and his little hot, worn hands folded over on his breast, and his little bright, attentive eyes looking steadily at us" (Dickens 1956: 607).

Prevalence

Exact figures of the prevalence of marasmus are difficult to obtain because of the confusion of nomenclature and diagnosis. But marasmus must have been a leading cause of morbidity and mortality among infants and preschool children during the latter half of the nineteenth century and the early part of the twentieth century – and in Europe and North America as well as the rest of the world. A large percentage of the victims were illegitimate foundlings, who represented from 15 to 45 percent of all newborn infants in most European capitals. In the poor hygienic conditions of the "foundlings' homes," death claimed between 30 and 90 percent during the first year of life.

Similar rates of mortality occurred in North American institutions. H. D. Chapin (1915), examining 11 foundling institutions in New York, discovered a death rate of 422 per 1,000 for children under 2 years of age – compared with a community-wide figure of only 87 per 1,000. In 1921, Oscar M. Schloss, the author of the annual report of the Infants' Hospital in Boston, called attention to "the frequent relationships of both malnutrition and acute infections to infant deaths" and stressed their importance as fields of research (Smith 1983: 138). Marasmus and atrophy do not appear as diagnoses in lists of patient admissions from the period 1883 to 1913, but figures for debility, dysentery, and diarrhea are high. In 1882, more than one-third of admissions were for "debility."

With the two world wars, marasmus was especially prevalent in besieged cities of Europe, such as Warsaw, Leningrad, and Budapest. But by 1950, and since then, marasmus resulting from poverty and sickness has become very rare in the so-called developed world. It remains, however, a nutritional problem in the developing countries of Africa, the Middle East, South and Central America, and Southeast Asia (Bellamy 1996: 98).

Research

From 1850 to 1950, numerous medical research reports on marasmus appeared, and many of these have been outlined, at least in part, in recent publications (Kerpel-Fronius 1983; Hansen 1991). Early in the twentieth century, German and French pediatricians stressed that the fate of undernourished infants depended on whether they escaped infection: It was thought that a rapid decline in the weight curve, ending in severe marasmus, could seldom be caused just by semistarvation (Kerpel-Fronius 1983: 64–8).

In a 1905 analysis of the bodies of marasmus victims and normal infants, a striking difference was discovered in fat content. Fat content in marasmic infants was only 1.7 percent of body weight, compared with 13.1 percent in normal babies. In 1920, body water in marasmic infants was found to be increased from 70 to 80 percent, and it was noted that the brain, kidneys, and skeleton were relatively preserved in marasmus.

Ten years earlier dextrose saline had been used for collapsed and dehydrated cases – including those of infantile atrophy, as recorded in an article about the activities of the Boston Floating Hospital (Beaven 1957). Losses of potassium, sodium, and chloride in diarrhea had been demonstrated by K. Schmidt in 1850, L. F. Meyer in 1910, L. Tobler in 1911, and I. Jundell in 1913 (Darrow 1946). In 1915, it was confirmed that increased water, fat, chloride, sodium, and potassium losses occurred in loose stools of infants, including those with marasmus (Holt, Courtney, and Fales 1915). The authors of this study pointed out that in therapy, potassium and magnesium were needed in addition to water and sodium, but it was not until 1946 (when it was proved that potassium could safely be added to intravenous fluids) that this advice was followed. This addition cut mortality from 32 to 6 percent (Darrow 1946; Govan and Darrow 1946).

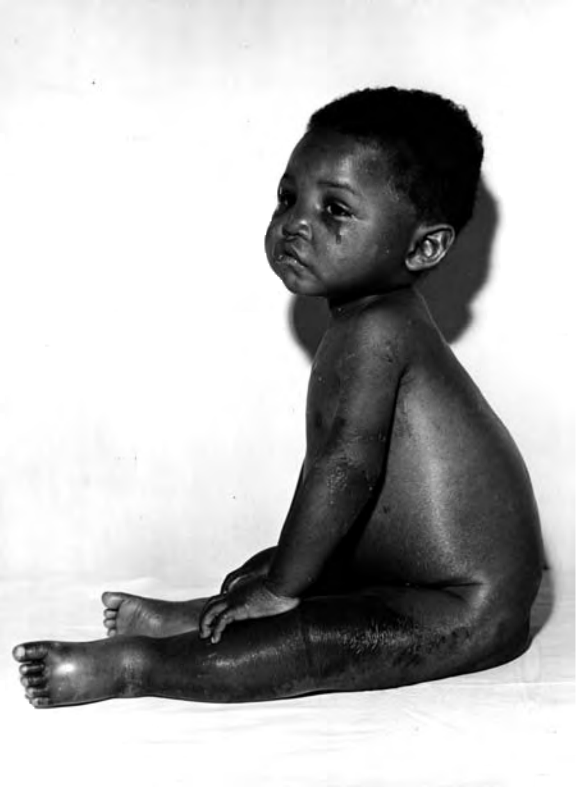

Figure IV.D.7.2. Kwashiorkor. Age 10 months. Skin lesions and edema. (Photograph courtesy of Groote Schuur Hospital, Capetown, South Africa.)

Kwashiorkor to 1954

Marasmus was the first syndrome of what we now know as PEM to become the focus of wide interest, concern, and research, especially between 1850 and 1950. But from 1935 onward, kwashiorkor became another intensively studied and important nutritional disease. The term "kwashiorkor" was introduced by Cicely Williams, who wrote: "The name kwashiorkor indicates the disease the deposed baby gets when the next one is born, and is the local name in the Gold Coast for a nutritional disease of children, associated with a maize diet" (1935: 1151–2) (Figure IV.D.7.2). Williams explained (1973) that the word comes from the Ga language of Accra, Ghana, and J. C. Waterlow (1991) has identified at least 31 distinct vernacular names in tropical Africa. Other regions also have words that doubtless frequently mean kwashiorkor. Among the common names in English, for example, are nutritional dystrophy, infantile pellagra, nutritional edema, and wet marasmus. In Spanish-speaking countries, kwashiorkor was referred to as a multiple deficiency state – *distrofia pluricarencial.*

Before naming the disease, Williams had published a paper giving its clinical description (Williams 1933). Afflicted infants were of preschool age (1 to 4), and their diet generally involved breast feeding with supplementary feeds of maize paps low in protein content. On examination, there was edema, wasting diarrhea, sores of mucous membranes, desquamation of the skin on the legs and forearms, and a fatty liver. The disease was uniformly fatal unless treated. This description provided by Williams fits perfectly with our current clinical definition of kwashiorkor, except that since 1933, retardation of growth has been more emphasized and there is now detailed knowledge of the changes in function of various systems and organs (Hansen and Pettifor 1991).

In a 1952 World Health Organization (WHO) report, the name kwashiorkor was applied to the syndrome in Africa, and the relationship of the disease to a low-protein diet was firmly established (Brock and Autret 1952). This study and report had been initiated by the Joint FAO (Food and Agriculture Organization)/WHO Expert Committee on Nutrition at its first session in Geneva in October 1949. The committee had found that one of the most widespread nutritional disorders in tropical and subtropical areas was an ill-defined syndrome known by various names such as kwashiorkor, malignant malnutrition, polydeficiency disease, and so forth. It was resolved that WHO conduct an inquiry into the various features of kwashiorkor, and, subsequently, the FAO was asked to cooperate. J. F. Brock (WHO) and M. Autret (FAO) traveled extensively throughout Africa over a period of two months in 1950, after which they concluded "that kwashiorkor is the most serious and widespread nutritional disorder known to medical and nutritional science" (Brock and Autret 1952: 72).

In subsequent years, FAO and WHO sponsored other studies in Central America, Brazil, and southern India, and research units in various parts of the world began to concentrate their efforts on determining the etiology, pathogenesis, treatment, and prevention of kwashiorkor.

The similarities and differences between marasmus and kwashiorkor soon became evident and gave rise to intensive debate. D. B. Jelliffe proposed the term "protein calorie (energy) malnutrition" (PEM) to cover the spectrum of syndromes that range from marasmus to kwashiorkor (Jelliffe 1959). This concept was a major contribution in understanding the variations of this group of nutritional diseases.

A history of kwashiorkor appeared in 1954 (Trowell, Davies, and Dean 1954). It discussed an early description of the disease, written by J. P. Correa in 1908 in the Yucatan. Waterlow, in his recent article on the history of kwashiorkor, found an even earlier description from Mexico by F. Hinojosa in 1865 (Waterlow 1991: 236). H. C. Trowell and his colleagues (1954) made it apparent that up to 1954, kwashiorkor had a worldwide distribution. They supported their contention by listing approximately 250 publications from Africa, Asia, Europe, North and Central America, and South America that contained details on established or probable cases of the disease (Trowell 1954). Most of these dated from between 1920 and 1950, and some early reports from German workers on *Mehlnährschaden* are of especial interest (Czerny and Keller 1925–8). This term, which is best translated as "damaged by cereal flours," was used to indicate infant malnutrition resulting from imbalanced (excess starch) feeding habits, and the researchers described a clinical picture similar to that of kwashiorkor. In Germany at the time, it had become popular to use cereal gruels instead of milk when a child had gastrointestinal difficulties. The gruels were usually made without milk, and the return of loose stools when milk was once again added to the diet was too often regarded as an indication of sensitivity to milk. The many similarities between *Mehlnährschaden* and kwashiorkor in terms of etiology, pathology, and treatment suggest that these German researchers – in a developed country – may well have been describing kwashiorkor in the early part of the century.

In their book on kwashiorkor, Trowell and colleagues (1954) present a fascinating historical description of the puzzling features of the disease that had confounded investigators and triggered controversies. Among these were the similarities of kwashiorkor to pellagra, the fact that many cases did not have skin rashes, that fatty livers were found in nearly all cases, the role intestinal parasites might play in the disease, and the various forms of treatment. However, what emerged clearly was that lack of protein in the diet was an important cause – a lack caused by dependency on foods that supply adequate carbohydrate but little protein, such as cassava and cereal foods like rice, corn, millet, and sorghum. A distinction between kwashiorkor and infantile pellagra was based on a difference in the distribution of dermatosis (in kwashiorkor the diaper area; in pellagra on exposed areas such as the face, hands, and feet) and a failure of kwashiorkor victims to respond to nicotinic acid unless a high-protein diet was simultaneously given (Trowell et al. 1954: 118–19).

The treatment recommended for kwashiorkor in 1954 was cow's milk, given in a concentrated form with little lactose and less fat. However, the exact nature of the factor(s) responsible for bringing about improvement in the children's condition had not been determined. Serum biochemistry showed that treatment increased serum albumin, cholesterol, nonspecific esterase, and cholinesterase. But the completeness of recovery and the ultimate prognosis could not at that time be assessed. Moreover, the authors felt that many children suffered from a mild form of kwashiorkor that could not be accurately defined and needed much further investigation (Trowell et al. 1954).

Earlier, the distinction between marasmus and kwashiorkor in tropical countries had been made in an important monograph, in which children with fatty liver disease (kwashiorkor) were distinguished from those who were undernourished but had no evidence of liver damage (Waterlow 1948). The clinical manifestations of the second group were retarded growth and loss of body fat and resembled the condition known in Europe as infantile atrophy or marasmus. Cases of marasmus were mostly below 60 percent of expected weight for age – the current criterion for a marasmus diagnosis.

Kwashiorkor Since 1954

Following the authoritative reports of Brock and Autret (1952) and Trowell and colleagues (1954), there was intense research into PEM on a worldwide basis. This research was funded by international and national agencies now aware of the high infant and child morbidity and mortality occurring in developing or underdeveloped areas. In addition, academic institutions and individual researchers alike were stimulated to look into such questions. The results have been summarized in recent authoritative publications that have brought our knowledge of PEM up to date (Waterlow 1992; Carpenter 1994).

Dietary Treatment of Kwashiorkor

By 1954, it was clear that milk – as a source of protein – induced recovery, although mortality was still high in seriously ill cases. Brock (personal communication) posed the questions: What was it in milk that brought about recovery? Was it the protein in milk, and if so, what factors or amino acids of that protein initiated it? Were the other constituents of milk, such as the fat, carbohydrate, minerals, trace elements, vitamins, or as yet unknown factors, important for recovery?

A series of clinical trials and balance studies, conducted at Cape Town, South Africa (a nontropical area), from 1953 to 1956, concentrated on what exactly brought about the cure for kwashiorkor and established that a vitamin-free synthetic diet of 11 mostly essential amino acids, glucose, and a mineral mixture could cure the skin rashes, regenerate serum albumin concentration, improve appetite, and eliminate the edema suffered by kwashiorkor victims (Hansen, Howe, and Brock 1956). It was further shown that potassium deficiency as a result of diarrhea and poor intake of potassium-containing foods was an important cause of edema. In fact, edema could resolve without change in serum albumin concentration if potassium depletion was corrected (Hansen 1956).

These studies ended the mystery of what milk contained that initiated recovery from the disease by establishing that protein (amino acid) deficiency was an essential feature of kwashiorkor and that there was no unknown factor involved. Nonetheless, energy deficit was subsequently emphasized by many authors, but often children with kwashiorkor had enjoyed adequate energy intake and, as with all nutritional deficiency disorders, concurrent vitamin, mineral, and trace-element deficiencies can cause added complications. Milk contains all of these elements except for iron and was thus shown to be an ideal food with which to treat children suffering from kwashiorkor.

Because milk is not universally available, however, there was much interest during the 1950s in the question of whether plant proteins could provide a satisfactory substitute. Nitrogen balance studies during recovery from kwashiorkor (Hansen et al. 1960) revealed that nitrogen (protein) retention was very strong with a milk diet. On a maize (corn) diet, nitrogen retention was much less, but it was greatly improved by the addition of the amino acids missing in maize (lysine and tryptophan), or a legume (pea flour), fish flour, or milk (Hansen 1961). The Institute for Nutrition in Central America and Panama (INCAP) successfully developed a mixture of corn, sorghum, cottonseed flour, and yeast that had good results. It was commercially produced as "Incaparina" in Guatemala and other Central American countries, but it became too expensive for the people who needed it most (Carpenter 1994: 173–5). The extensive study and work with "Incaparina" did, however, prove that commercial vegetable mixtures could be used as a weaning food to promote growth and prevent kwashiorkor.

Between 1955 and 1975 there were numerous other efforts to find substitutes for milk (Carpenter 1994: 161–79). A Protein Advisory Group (PAG) was established by WHO in 1955 and subsequently supported by FAO and the United Nations International Children's Emergency Fund (UNICEF) to stimulate worldwide research into high-protein foods that might close the so-called protein gap between developed and underdeveloped countries. However, in 1974, a challenging article by D. S. McLaren called into question the importance of protein in the prevention of PEM and stressed that energy depletion was at least as important as lack of protein, if not more so. He argued that marasmus was a more widespread disease than kwashiorkor and that too much emphasis had been placed on – and too much money invested in – the production of protein-rich food mixtures, ". . . whilst children were lost in the unchecked scourge of malnutrition" (McLaren 1974: 95). Although much controversy followed this article (Carpenter 1994: 180–203), the emphasis on the production of high-protein foods waned, and interest became focused on improving food quantity rather than quality (Waterlow and Payne 1975).

Unfortunately, the debate that continues to the present day on the relative importance of protein and energy has often lost sight of the earlier concepts of kwashiorkor and marasmus. Marasmus implied wasting from overall energy lack or starvation, whereas kwashiorkor was characterized by a low-protein diet that frequently had an adequate energy component. In between the two extremes is marasmic kwashiorkor, which has features of both. Milder cases that manifest only growth retardation (Table IV.D.7.1) can result from a lack of either protein or energy or a combination of the two. A current explanation of the dietary background of PEM is that variations in energy intake, total protein intake, and "quality" of protein (the amino acid pattern) are responsible for the individual clinical forms of PEM.

A protein intake of less than the minimal requirements will result in low serum proteins (hypoalbuminemia) and failure of growth, even in the presence of adequate energy intake (Hansen 1990). Unfortunately, in many parts of the world, most of the dietary protein comes from a single source, often a cereal. Cereals have the disadvantage of being low in total protein content and lacking in essential amino acids, such as lysine (in the case of wheat) or both lysine and tryptophan (in the case of maize). Populations subsisting solely on these foods are thus at risk of energy and protein depletion, and children in particular are at risk of PEM in one form or another. Inevitably, vitamin, mineral, and trace-element deficiencies can complicate PEM in varying degrees, as does infection.

In a review of much new work on protein and energy requirements, Waterlow (1992: 229–59) has concluded that contrary to much that has been published in recent years, some weaning diets in developing countries contain marginal amounts of protein, even when consumed in quantities that satisfy children's energy needs. Such a marginal diet may satisfy the protein needs of many – perhaps most – children, but not all. Any group of children, as of adults, appears to have a range of protein (and energy) requirements. On marginal intakes, children at the upper end of the range will be at risk. This does not conflict with a controversial finding (Gopalan 1968) that there was no difference, quantitative or qualitative, between the diets of children who developed kwashiorkor or marasmus.

The Liver and Kwashiorkor

A well-described characteristic of kwashiorkor is a fatty infiltration of the liver (Williams 1933). As already mentioned, Waterlow even described kwashiorkor as "fatty liver disease" and distinguished it from cases of undernourishment (marasmus) that showed no evidence of fatty infiltration (Waterlow 1948). In 1945, the Gillman brothers in South Africa published a paper on the successful treatment of fatty liver with a powdered stomach extract, "Ventriculan" (Gillman and Gillman 1945). They referred to their patients as cases of infantile pellagra and, using the liver biopsy technique, observed that such infants had greater or lesser amounts of fat in the liver (without infection) and that the fat accumulation resolved with successful treatment. The Gillmans felt that

"Ventriculan" supplied an essential substance, but other investigators could not confirm their findings and speculated that it was the protein in the diet that was producing the cure.

At that time, there was a high prevalence of cirrhosis of the liver in Africa, and it was thought that suffering PEM early in life might be an underlying cause. This suggestion was refuted, however, by a five-year follow-up study of kwashiorkor cases in a non-tropical environment, which demonstrated that there was complete recovery of the liver with no residual cirrhosis (Suckling and Campbell 1957). In 1969, it was found that there was a connection between fatty liver and serum lipoprotein concentrations (Truswell et al. 1969), and it was hypothesized that fat accumulates in the liver because of the failure of fat transport out of the liver – a failure resulting from the impaired synthesis of apolipoprotein B, which, in turn, is a consequence of protein deficiency. This remains the current view (Waterlow 1992: 61–5).

PEM and Infection

A classic work on the synergistic association of malnutrition and infection was published in 1968 (Scrimshaw, Taylor, and Gordon 1968). In the case of PEM, the condition predisposes to other diseases, but diseases can also bring on the condition. For example, children with PEM are particularly susceptible to respiratory and gastrointestinal infections, whereas measles frequently precipitates severe PEM. An intriguing question is whether PEM interferes specifically with the protective immune responses or whether the generally poor environmental conditions associated with PEM (which implies frequent exposure to infection) means the child with PEM has less metabolic reserve to resist infection. For example, although exposure to measles will infect a well-nourished child and a child with PEM equally, the well-nourished child will survive with some weight loss, whereas the child with PEM, already underweight, becomes severely ill and frequently dies.

The various and complex ways in which immunity to infection can be impaired by PEM has been recently reviewed (Waterlow 1992: 290–324). Although in some communities the relationship between PEM and infection is linear, in others there is a much weaker association. But what is clear is that a child with severe PEM is seriously at risk of infection in any community. An early observer of reduction of cell-mediated immunity in PEM (Smythe et al. 1971) also noted reduction in the weight of the thymus gland as well as a reduced size of the spleen, lymph nodes, tonsils, appendix, and Peyer's patches.

Much interest has also been shown recently in the role of vitamin A deficiency in the susceptibility of PEM victims to infection, especially respiratory disease and diarrhea (Sommer, Katz, and Tarwotjo 1984). Earlier, it was demonstrated that some patients with kwashiorkor had dangerously low levels of plasma vitamin A (Konno et al. 1968), and treatment of measles with large doses of vitamin A has given good results (Hussey and Klein 1990), which, in conjunction with widespread immunization, means that measles is no longer the threat to the life of PEM victims that it was in 1969 (Morley 1969).

Diarrhea has always been a clinical characteristic of kwashiorkor and marasmus, both as a precipitating factor in a marginally malnourished child and as a continuing recovery-retarding drain of electrolytes, energy, and protein. The organisms and viruses responsible have been well defined (Waterlow 1992: 297), but in the case of PEM victims, frequently no pathogens are isolated. Balance studies on patients recovering from kwashiorkor have revealed a remarkably high daily fecal loss (500 to 1,000 grams [g] per day compared with a normal figure of 100–150 g/day), part of which was found to have been caused by lactose intolerance as a result of secondary lactase deficiency in the duodenum (Bowie, Brinkman, and Hansen 1965; Bowie, Barbezat, and Hansen 1967).

At the time, this discovery was thought to be a breakthrough in the cause of the diarrhea in PEM; further experience, however, revealed that lactose intolerance is not universal in PEM, although it can explain the severe diarrhea that frequently occurs when PEM cases are treated with milk. Diarrhea also occurs in PEM because the gastrointestinal tract atrophies and becomes paper-thin and almost transparent. The mucosa of the intestine has a reduced absorptive surface, and electron microscopy reveals considerable disorganization of the intracellular architecture (Shiner, Redmond, and Hansen 1973). Marked improvement occurs within a few days of treatment.

Looking back on the last 50 years of research on diarrhea in PEM, it is apparent that infection, intestinal atrophy, lactose intolerance, and immunological deficiencies all play their part. Recently, the advent of AIDS has particularly affected the immunological defenses in infected children, resulting in diarrhea, severe wasting, and marasmus or kwashiorkor. In a summing up of all the recent evidence, it can be said that there is a causal relationship between a state of malnutrition (PEM) and diarrhea morbidity and mortality (Waterlow 1992: 313, 339). The same may be said for respiratory disease (pneumonia) and measles, but not for malaria, which has little or no relation to the state of nutrition (Waterlow 1992: 333). Confounding factors in morbidity and mortality are vitamin A deficiency, breast feeding, sanitary facilities, and the mother's education, caring capacity, and availability.

PEM and Body Composition

The profound physical changes in marasmus (wasting) and kwashiorkor (edema) stimulated research into body composition when new techniques became available after 1950. In Waterlow's (1992) extensive review of the subject, he shows the inconsistencies between different studies and points out that there is still no agreed-upon understanding of the mechanisms of fluid-retention edema. There is a considerable loss of muscle mass and of fat, particularly in marasmus, and as a result, there is an increase of total body water as a percentage of body weight both in kwashiorkor with edema and in marasmus without edema.

Based on evidence available so far, the difference between the two could be that children with edema have more extracellular fluid, which is probably related to the extent of potassium depletion (Mann, Bowie, and Hansen 1972). Kwashiorkor children with edema have lower total body potassium than marasmus cases without edema. It is of interest that the increase of total body water – and of extracellular water as a percentage of body weight – represents a reversion to an earlier stage of development. This means that the weanling child with PEM has the composition and size of a younger child (Hansen, Brinkman, and Bowie 1965). Total body protein is severely depleted in PEM victims, and compared with normal children of the same height, there is a greater deficit of total protein than of body weight. Cellular protein is greatly depleted, but collagen (structural protein) is little affected (Picou, Halliday, and Garrow 1966). The brain is relatively well preserved when compared with other organs in PEM. However, computed tomography has recently shown there is some reversible shrinkage of brain mass (Househam and De Villiers 1987).

PEM in General

Growth Retardation and PEM

A constant feature of kwashiorkor has been growth retardation, occurring in children even before the disease is recognized. Weight, height, and bone development are all affected. In the second half of the twentieth century, anthropometric indices – weight, height, weight-for-height, arm circumference, and skinfold thickness – have been greatly refined and used extensively in the assessment of health and disease. In the Wellcome classification of PEM (Table IV.D.7.1), weight is used as a basis of defining differences between the various syndromes, which has proved most valuable in comparing PEM in different communities and countries.

F. Gomez, R. Ramos-Galvan, S. Frenk, and their colleagues in Mexico were the first to divide deficits in weight-for-age into three categories of severity, based on Harvard growth standards (Gomez et al. 1956). This classification had the drawback that it combined in one number the figures for height-for-age and weight-for-height (Waterlow 1992: 189) and was not widely adopted. The Harvard growth charts for height and weight of children in the United States proved valuable as a standard against which to compare the growth of children with PEM. They were used in the initial Wellcome classification of PEM (Table IV.D.7.1), although later they were superseded by charts from the U.S. National Center for Health Statistics (NCHS), which – though similar – were more thoroughly worked out in terms of statistics. These charts were accepted and published by WHO as international standards (WHO 1983).

There have, however, been controversies concerning the use of these standards, ranging from questions about possible ethnic and environmental influences on growth to debates over the desirability of using national growth charts. Yet environmental and income differences have enormous effects in local surveys (Wittmann et al. 1967), which makes the use of local standards impractical, especially as there is often a secular trend toward improvement in disadvantaged groups. Currently, for the community and individual assessment of children with PEM, cutoff points on the international charts are employed; for example, children who are below the third percentile, or 2 standard deviations below the mean figures for height, weight, or weight-for-height indices, are suspect for PEM (Waterlow 1992: 212–28).

In clinic and field assessments, the "Road to Health" weight charts have revolutionized preschool health assessment even among the most unsophisticated populations. These charts are issued to mothers at the birth of their children and updated at each visit to a primary care center, physician, or hospital. D. Morley (1973) had demonstrated the value of continuously monitoring weight gain and of making the mother responsible for keeping the record. This is an interesting example of the practical procedures that grew out of the early observations of the growth of African children with kwashiorkor (Trowell et al. 1954: 70–3).

The retardation of growth caused by kwashiorkor immediately raised questions about its reversibility. Provided there were improvements in nutrition and environment, could a preschool child regain his or her genetic potential for growth? An early prospective study, started in 1959, monitored children admitted to hospitals with kwashiorkor for a subsequent period of 15 years (Bowie et al. 1980). This study showed that growth retardation resulting from severe PEM is reversible if environment and food intake are reasonably adequate during the prepubertal years. In similar studies, the increment in height was very much the same as that achieved by children in the United States, regardless of the degree of stunting at 5 years (Waterlow 1992: 195–211). As Waterlow has discussed, however, where catch-up has not occurred, stunting caused by long-continued protein and energy lack can lead to functional consequences, for example, a reduction in absolute capacity for physical work. For a given workload, people who are small, even though fit, are at a disadvantage. Thus, research on body growth in PEM has gone on to stimulate investigation into many interesting aspects of human development and function.

PEM and Intellectual Development

In 1963, a pioneering follow-up study of marasmic infants in South Africa focused on the possible effects of PEM on brain size and intellectual development (Stoch and Smythe 1963). This sparked ongoing worldwide research and intense political interest. Decreased brain weight in a state of malnutrition was reported from East Africa in 1965 (Brown 1965), and, as mentioned earlier, computed tomography has demonstrated that there is a reversible shrinkage of brain mass in kwashiorkor (Househam and De Villiers 1987). The more difficult assessment of the effect of PEM on intellectual development is confused by the interaction of nutrition per se and other environmental factors such as poor social conditions, nurturing, education, and environmental stimulation. In addition to protein and energy, other nutrients – iron, potassium, trace elements, or vitamins, to name a few – may be deficient, and this, too, may affect mental development (Grantham-McGregor 1992).

There is, however, some evidence that PEM does not necessarily cause permanent damage to the intellect. Follow-up studies have failed to demonstrate differences in intellectual development between ex-kwashiorkor patients, their nonaffected siblings, and other children from the same environment (Evans, Moodie, and Hansen 1971). Planned stimulation in hospital has produced recovery of cognitive development (to a normal level) in kwashiorkor children (Cravioto and Arrieta 1979: 899), and a recent study in Jamaica showed that a nutritional supplement provided significant benefits to stunted children between 9 and 24 months of age, as did stimulation alone – but the two together had the best result (Grantham-McGregor 1992).

A WHO symposium in 1974 concluded that in spite of the widely held opinion that PEM in early life permanently jeopardizes mental development, the evidence to support this contention was scanty. Twenty-three years later, this still appears to be the case, but it does seem probable that there is an interaction between malnutrition and other environmental factors, especially social stimulation, and that a child's intellectual status is the result of this interaction. However, good nutrition in the first two years of life enables an underprivileged child to make better use of what stimulus there is in the environment. This kind of beginning has a long-lasting effect on intelligence even if nutrition after this period is less than optimal (Evans et al. 1980).

The Social Background of PEM

Trowell and colleagues (1954: 49–51) pointed out that PEM has always been associated with poor communities and occurs among the most depressed social classes. These researchers also mentioned social customs at the time of weaning, and of course Williams interpreted the word kwashiorkor to mean the "disease of the displaced child" – displaced by the next baby (Williams 1935). In addition to these basic factors, overpopulation and the movement of rural people to urban areas were considered important. A. Moodie (1982), a social worker who devoted her working life to the study of the background of PEM, as seen in a nontropical area of Africa, has reviewed the literature, including some of her own studies. She noted the following as constituting the essential background of PEM:

1. Economic inadequacy or poverty – rural or urban.
2. Lack of sophistication and knowledge loosely termed ignorance and the cultural factors underlying this state.
3. Problems of overpopulation and too large families. (Here the mother suffers and it is through the mother that child nutrition is mediated. In all programs for prevention the well-being of the mother should be a priority.)
4. Social disorganization, especially illegitimacy and alcohol abuse.
5. High incidence of infection and diarrhea.
6. Early weaning and decline of breast feeding.

In an urban study funded by WHO, low income was found to be critical (Wittmann et al. 1967). In another investigation, sociological and cultural factors such as the working mother appeared to be more important (Shuenyane et al. 1977). There have been many studies throughout the world showing what Waterlow has termed the multiplicity of causes. He grouped them under three headings: lack of food, infection, and psychosocial deprivation (Waterlow 1992: 9–11). It has been pointed out that economists and other planners are now recognizing that nutritional indicators (for example, growth retardation or the clinical features of PEM) provide a more sensitive, objective, and easily collected measure of socioeconomic development than conventional indicators such as per capita income (Church, Burgess, and Burgess 1991: 569–70).

Prevention of PEM

With the high prevalence of PEM in some areas of developing countries (marasmus afflicts 5 to 10 percent and stunting 30 to 60 percent of the under-5 population), prevention has received much attention from international and government agencies. These organizations have been aided by economists and social scientists as well as by nutritionists and health scientists, and the literature has grown enormously (Waterlow 1992: 361–92).

The basic strategy for achieving "health for all" by the year 2000 is Primary Health Care (PHC). This plan includes growth monitoring, health education, maternal and child health care, family planning, immunization against major infantile diseases, and appropriate treatment of common diseases, like oral rehydration treatment for diarrhea. There is no doubt that these measures, implemented by PHC teams, have had an overall effect on preventing PEM, which has shown a decline in prevalence in many countries (Bellamy 1996: 54). The details of nutrition inputs in primary care are well described in a recent publication (Church et al. 1991). The problem of PEM needs a *holistic* approach. Health teams and public-health authorities can reduce mortality and morbidity with active programs of clinical care, rehabilitation, and food supplementation, but they cannot affect the prevalence of PEM resulting from underlying socioeconomic and cultural realities. Physicians must have the active, integrated, and effective cooperation and assistance of economists, agriculturalists, and governments to eradicate PEM.

Treatment of PEM

In a remarkable but little-quoted paper, published in an obscure journal, skimmed lactic acid milk was shown to reduce the 40 to 60 percent mortality of severe kwashiorkor to 20 percent (Altmann 1948). The author stressed the importance of small feeds initially until appetite returned. He also stressed the danger of severe dehydration that causes 5 out of 6 of the deaths. A colleague at the same hospital later found that the use of intravenous fluids in dehydrated cases cut mortality by half (Kahn 1959: 161–5). The same principles of feeding and rehydration are followed today (Waterlow 1992: 164–86), with perhaps more emphasis on oral rehydration. Refinements include supplements of potassium, magnesium, zinc, vitamin A, folic acid, and iron. Blood transfusion is used only for very severely anemic children. Because of the frequency of infections, antibiotics are routinely given and, in tropical areas, malaria and other infestations have to be dealt with, using appropriate therapy and prophylaxis. Mortality of severe PEM cases should now be less than 10 percent. Less severe cases of PEM respond well – with negligible mortality – to diets providing adequate energy and protein.

History of the Cause of PEM

Waterlow (1992) has concluded that there is no reason to abandon the concepts put forward many years ago, namely, that kwashiorkor develops when the diet has a low protein–energy (P/E) ratio and that when energy is limiting, the end result is marasmus. To this it should be added that individual children vary in their requirements of nutrients. If the P/E ratio is marginal, protein or energy may be a limiting factor for some children but not for others. Research has shown that total protein intake and the quality of the protein (the amino acid pattern) are also important. In areas where PEM occurs, vitamin, mineral, and trace-element deficiencies can complicate the basic syndrome to varying degrees, as does infection.

Recently, it has been hypothesized that all the serious features of kwashiorkor – edema, fatty liver, infection, and mortality – can be explained by an excess of free radicals (Golden and Ramdath 1987). This theory has not yet been firmly established, and in any case, children still have to be short of protein or energy before they become susceptible to free-radical excess. Another theory is that kwashiorkor results from aflatoxin poisoning (Hendrickse 1984). Aflatoxins come from fungi growing on improperly dried nuts. However, aflatoxins cannot be blamed for kwashiorkor and marasmus that occur where there is no aflatoxin contamination of the diet.

PEM in Perspective

In the nineteenth and twentieth centuries, PEM, as a particularly important nutritional deficiency in infants and children, has become recognized and better understood. This has come about through extensive worldwide observation and research, and recent emphasis has been on the effect of PEM on health, growth, and intellectual development.

As we enter the twenty-first century, we have the knowledge, if not always the means, to limit the prevalence of PEM in individuals and communities at risk. A looming danger is the "demographic trap," the situation that arises when population growth exceeds growth in food production or availability (King and Elliot 1994: 528). Signs of the trap are already present in several countries, particularly in Africa (Bonneux 1994). If this situation is not addressed by fertility control, PEM is likely to remain with us for the foreseeable future.

IV.D.8 ~ Scurvy

The human body requires an adequate supply of ascorbic acid (L-xyloascorbic acid or vitamin C) to enable it to function normally, and a lack of the vitamin results in the emergence of the condition known as scurvy (scorbutus or avitaminosis C). Unlike plants, and the majority of animals thus far studied, humans are unable to produce ascorbic acid endogenously and, thus, are dependent upon dietary sources – mainly fruit and vegetables – for a supply of the vitamin. In the absence of vitamin C, formation of collagen, an essential glycoprotein component of connective tissue, is impaired, which is believed to be the main underlying biochemical lesion in scurvy (Counsell and Hornig 1981; Englard and Seifter 1986).

The earliest signs of scurvy (fatigue and lassitude) may emerge in humans some 12 weeks after removal of dietary vitamin C, and the more overt traditional signs (hemorrhagic spots under the skin *[petechiae],* softening of the gums, and defective wound healing) after some 17 to 26 weeks of deprivation.

In 1753, James Lind concluded his pioneer study of scurvy with a chronological *Bibliotheca Scorbutica,* which imparted a mild historical flavor to his text (Stewart and Guthrie 1953). But more than a century was to pass before the first sustained efforts to produce a history of the disease emerged. One of these was J. Maré's 200-page article in the *Dictionnaire Encyclopédique des Sciences Médicales* in 1880, and the second was August Hirsch's 60-page article in his *Handbook of Geographical and Historical Pathology* (1883–6). Both of these pioneer works are now completely eclipsed by K. J. Carpenter's comprehensive *History of Scurvy and Vitamin C* (1986), to which the reader is referred for a more extended treatment.

Simple logic dictates that scurvy became a clinical possibility when evolving hominoids (unlike most other animals) lost the ability to biosynthesize vitamin C from carbohydrate precursors. This loss would, presumably, only have occurred in an environment that provided early humans with an adequate intake of dietary vitamin C. By the same token, scurvy itself would not have emerged until a change in food consumption patterns or in the seasonal availability of the vitamin resulted in a deprivation of vitamin C.

The main dietary sources of vitamin C are fruit and vegetables, particularly when eaten raw, and to a much lesser extent, fresh meat (salting or drying meat results in a loss of its vitamin C content). Grains, nuts, eggs, and dairy products (with the exception of fresh milk, which contains small amounts) provide little or no vitamin C.

There can be little doubt that the unstable and fluctuating environmental conditions of primitive humans must have, from time to time, produced highly scorbutigenic situations, but the precise frequency of the disease in prehistoric and early historic times is obscure. Some commentators have claimed to discern descriptions of scurvy in the writings of early classical writers such as Pliny and Paulus Aeginita, but this must remain a matter of considerable conjecture.

There is some evidence that scurvy afflicted the armies of the Crusaders in the thirteenth century, and the writings of Jacques de Vitry (c. 1220) and Jean Sire de Joinville (1224–1319) have been quoted in this respect (Major 1978: 585–6). Indeed, de Joinville's description of the "army sickness" reveals a situation at least as fearful as the depredations of the attacking Turks:

> . . . our legs shrivelled up and became covered with black spots, and spots of the colour of earth, like an old boot: and in such of us as fell sick the gums became putrid with sores, and nor man recovered of that sickness, but all had to die. . . . The proud flesh in our men's mouth grew to such excess that the barbour-surgeons were obliged to cut it off, to give them a chance of chewing their food or swallowing anything. It was piteous to hear through the camp the shrieks of the people who were being operated for proud flesh, for they shrieked like women in childbirth. (Major 1978: 586)

Scurvy as an Occupational Disease

Curiously enough, the change that most clearly and finally precipitated the emergence of scurvy as a recognizable disease was not so much dietary as technological. Scurvy first established itself as a discrete and clearly definable feature of early medicine because of those technological advances that enabled the building of ships capable of prolonged sea voyages.

By the end of the fifteenth century the ship had acquired the structure that was to characterize it for the next three centuries, and the newer naval technology meant that humans could now remain at sea for months at a time – long enough to deprive themselves of an adequate supply of the fresh fruit and vegetables that are the main dietary source of vitamin C. Consequently, it was during the early voyages of exploration in the fifteenth century that the first clear pictures of scurvy emerged. In this sense scurvy (or scorbutus as it was described in the Latin texts of the day) may truly be regarded as one of the earliest occupational diseases.

Perhaps the most widely quoted example of explorer's scurvy is that described by Jacques Cartier, the Breton explorer, who during his discovery of the Saint Lawrence River in 1536 lost 25 of his crew to a "strange and cruell disease." Certainly his description of their condition – the loss of strength and "their skins spotted with spots of blood of a purple colour . . . [and] their gummes so rotten, that all the flesh did fall off, even to the rootes of the teeth, which did also almost all fall out" is consistent with the petechiae and connective tissue defects now accepted as cardinal features of scurvy (Major 1978: 586).

But a similar condition prevailed among the crew of Vasco da Gama during his return voyage from Africa in 1498; and almost a hundred years later Richard Hawkins could assert that during his 20 years at sea he had witnessed some 10,000 cases of scurvy (Carpenter 1986: 1–26).

A century and a half after that, George Anson lost three-fourths of his men and officers, mostly to scurvy, in his 1740–4 voyage around the world. In fact, it has been estimated that during the critical period between 1600 (when long sea voyages had become more common) and 1800 (when the prophylactic effect of lemon juice rations had proved effective), scurvy was responsible for over 1 million deaths among seamen – almost certainly more than the sum total lost during the same period in naval battles, shipwrecks, and to diseases other than scurvy (Roddis 1951: 48, 72).

In the seventeenth century scurvy was considered primarily a scourge of sailors and soldiers. "In Navies and Camps, Scorbutick Feavers are very frequent, and arrive to a great height of malignity, sweeping them away like the Plague sometimes" wrote Everard Maynwaringe in 1664, adding "And I remember, in a hard and long voyage at sea, most of our people were very Scorbutick . . . who at our first setting out were sound and healthy" (Maynwaringe 1679: 57).

Much was written about the possible causes of scurvy among sailors. Bad (i.e., cold and wet) air, poor diet, idleness, and a melancholy outlook were viewed as major predisposing causes. Overindulgence in salted meat was held to be a main dietary cause – particularly as this could explain the peculiar prevalence of the condition among sailors. And some commentators introduced their own specific dietary causes. Thomas Willis, for example, blamed sugar, whereas Maynwaringe accused tobacco, although neither explanation gained general acceptance.

"Land Scurvy"

George Budd, one of the more competent writers on scurvy in the early nineteenth century, wrote, "Scurvy has, unquestionably, existed in the north of Europe from the most remote antiquity. That we have no mention of it in the early history of the northern nations must be imputed to the extreme ignorance of the people, especially as regards medicine" (Budd 1840: 58).

It is the case that medieval medical texts and herbals contain no clearly identifiable references to scurvy, although the numerous remedies for loose or "wagging" teeth have sometimes been thought to indicate unrecognized scurvy (e.g., Henslow 1899: 112). Nor does scurvy appear to have been included among the main diseases responsible for hospitalization in medieval England (Clay 1909). Thus, as already suggested, the general consensus would appear to relate the recognition and acceptance of scurvy as a specific clinical lesion to its occurrence among sailors during the fifteenth and sixteenth centuries.

Certainly it was in the sixteenth century that sporadic references to scurvy began to appear in the medical texts and herbals. Thus, although there are no recognizable references to scurvy in the herbals of Leonhard Fuchs (1542), Hieronymus Bock (1552), and Pietro Andrea Mattioli (1565), William Turner's *Herbal* (1568) comments on its appearance on the Continent. And Henry Lyte's translation of R. Dodoens' *Cruÿdeboeck* (1578) refers to:

> Spooneworte [*Cochlearia* sp., scurvy grass] . . . a singular remedie against the disease of the mouth . . . called by the Hollanders and Friselanders Scuerbuyck, against whiche evill it hath bene lately proved to be very good and is in great estimation and much used of the Hollanders and Friseans. (Dodoens 1578: 117–18)

Similarly, J. C. von Kraftheim's *Consiliorum et Epistolarum Medicinalium* (1591: 285) gave dietary precepts to be followed in scurvy. But surprisingly, Philip Barrough's comprehensive *The Method of Physick* (third edition, 1596) contained no reference to scurvy, nor did Felix Plater's *Observationum in Homines Affectibus Plerisque, Corpori & Animo* . . . (1651). However, William Clowes, in his *A Profitable and Necessary Booke of Observations* . . . (1596) described treating two sailors who were "sicke at the sea of the Scorby."

One of the earliest descriptions of scurvy in English can be found in Thomas Johnson's version of J. Gerarde's *Herbal* (1633) as part of the entry for scurvy grass *(Cochlearia officinalis),* the most favored of the antiscorbutic herbs (see following). It related scurvy to its supposed classical "precursors" and is worth quoting in some detail:

> The juice of Spoonewort given to drinke in Ale or Beere . . . perfectly cureth the disease called of *Hippocrates, Voluulus Hematites:* of *Pliny, Stomacace;* of *Marcellus, Oscedo* and of the later writers, *Scorbutum* of the Hollanders and Frisians, *Scuerbuyck:* in English, the Scurvie . . . this filthy, lothsome, heavy, and dull disease, which is very troublesome and of long continuance. The gums are loosed, swolne, and exulcerate, the mouth greevously stinking; the thighes and legs are withall very often full of blew spots, not much unlike those that come of bruises; the face and the rest of the body is oftentimes of a pale colour: and the feet are swolne, as in a dropsie . . . a disease haunting the campes, which vexe them that are besieged and pinned up and it seemeth to come by eating of salt meates, which is increased and cherished with the cold vapors of the stone walls . . . Hippocrates has written: their gums (saith he) are infected, and their mouthes stinke that have great spleenes or milts and . . . can hardly be cured of this malladie, especially of the ulcers in the legs and blacke spots. The same is affirmed by Paulus Aegineta in this third booke, 49 chapter, where you may easily see the difference between this disease and the black jaunders, which many times are so confounded together that the difference or distinction is hard to be known but by the expert chirurgions who offentimes serving in the ships, as wel her Majesties as merchants, are greatly pestered with the curing thereof. . . . (Gerarde 1633: 402)

By the early seventeenth century references to cases of scurvy among land dwellers were beginning to appear; initially, it was believed that there were two forms of the disease, and references were made to "sea scurvy" and to "land scurvy." This dichotomy continued until it was finally dispelled by Lind in 1753. Such an apparent sudden increase in the incidence of scurvy among land dwellers in Britain during the seventeenth century was commented on by a number of writers. Marchmont Nedham in his *Medela Medicinae* (1665) supported his claim that scurvy was on the increase in England by referring to the Bills of Mortality, which recorded an increase in the deaths from scurvy from 5 in 1630 to over 100 in 1656. Similarly, Gideon Harvey commented in 1675:

> Many years it [scurvy] remained on that Coast [i.e., Holland] before we were sensible of it here in England: for there are many Physicians yet living who in the former part of their Practice had so much as heard of the Name of this Disease, whereas within the last 20 or 30 years past it's grown very familiar among us. (Harvey 1675: 211)

There is confirmatory evidence that in Wales, too, scurvy was regarded as a new disease at the beginning of the seventeenth century. Sir Thomas Wiliems of Trefriw, a priest and practicing physician, compiled the manuscript for his projected *Thesaurus Linguae Latinae et Cambrobritannicae* during the period 1604–7; under the entry for the plant "Britanica" he refers to scurvy as "a new disease in our land, Wales" ("clevyt newydh yn ein gwlad ni Cymru") (Hughes 1990).

William Vaughan (1575–1641), also writing from Wales, reflected the growing importance of scurvy in seventeenth-century medicine in his *The Newlanders Cure* (1630). He recommended the tops and leaves of turnips as antiscorbutics; more significant, perhaps, he used contemporary thought on scurvy to illustrate his anti-papist sentiments in his verses "Description of the Catholicke Scurvy ingendered by the Mystery of Iniquity . . .":

> . . As doth the former scurvy beate
> For want of Sunne and Motions heate
> Upon the Spleene, the Breathe and Skinne
> So doth that Old and Scurvy sinne
> Withe Purple Spots go on to Stayne
> Both Soule and Body, all for Gaine . . .
> (Vaughan 1630: 112)

Whether these writings reflected a true increase in the incidence of scurvy among land dwellers, or merely indicated a greater awareness of its presence, is not known. According to John Floyer (better known for his introduction of a minute watch to measure pulse rate), "Scurvy was a new Name for an old Disease" – and there were others who regarded scurvy merely as an older disease that had changed its nature (Floyer 1722: 3; King 1970: 149).

Diet and Scurvy

A true increase in the incidence of scurvy would have required a fairly substantial change in the dietary pattern (or in the dietary availability of vitamin C), and there is little evidence that any such substantial and sudden change occurred in Britain at the time. Rather, such knowledge as is available would appear to suggest that the consumption of turnips, cabbage, and other vegetables by the "husbandman" sector of the population of Britain in the seventeenth century would have provided them with adequate amounts of the vitamin (Powicke 1926).

Yet with diets of the poorer classes of the day, one is less certain. And of earlier centuries little is known, although if one accepts the general view that the pre-sixteenth-century working-class diet was predominantly grain-based with supplements of salted and/or dried meat or fish but with very little fresh fruit and vegetables, then scurvy must have been of frequent occurrence (Prentice 1939: 118–36).

Of the fifteenth-century peasant diet, it has been written:

> . . . it seems likely that the winter diet of salt bacon, bread and peas gave little protection against scurvy, so that by the end of the winter most of the poor country people must have been in at least a pre-scorbutic condition. (Drummond and Wilbraham 1964: 77)

However, the comparative absence of any clearly recognizable references to scorbutic afflictions among a population that during the winter period presumably subsisted on a scorbutigenic diet is somewhat puzzling.

It was not until the enthusiasm of the Dutch market gardeners spilled over into seventeenth-century Britain that a general, albeit small, reduction in the scorbutigenic potential of the British diet occurred. Yet this, for some unaccountable reason, would seem to be the period that witnessed an apparent increase in the incidence of scurvy. However, a much more significant change in the British diet was yet to occur. The end of the seventeenth century witnessed the introduction of the potato on a large scale – a crop that was subsequently to become, for a very substantial proportion of the population, the main dietary source of vitamin C and, hence, the prime protector against widespread scurvy.

Potatoes and Scurvy

In 1662 a Committee of the Royal Society considered a proposition "to plant Potatoes through all ye parts of England," and in 1664 Forster pressed the case for widespread cultivation of the potato in his *England's Happiness Increased.* It is not known to what extent Forster's advice was acted upon, although Thomas Moffet claimed in 1665 that "pottato-roots are now so common and known amongst us, that even the Husbandman buys them to please his Wife" (Moffet 1746: 324). In 1691 Richard Baxter, the religious writer, in his last literary composition *(The Poor Husbandman's Advocate)* suggested that all smallholders should plant a quarter of an acre of potatoes to provide themselves with "a half year's wholesome food" (Powicke 1926).

Nevertheless, it is unlikely that these statements reflected any widespread use of the potato, and it is probable that until the end of the seventeenth century it remained primarily a horticultural curiosity cultivated by that sector of the populace least likely to suffer from dietary inadequacies, a situation reflected by the somewhat esoteric recipes for its use in the cookery books of the period (e.g., Salmon 1696: 263).

In the eighteenth century, however, potatoes were much more widely grown. According to *The Complete Farmer* (1777):

> the culture of this plant has, within these last thirty years, been extended to almost every part of England. . . . It is esteemed, and now very generally used at the tables of persons of all ranks; and inestimable for the poor being a cheap and very wholesome food . . . in Ireland, particularly in the province of Munster, they are the principal, and almost the only food of the poor there for almost eight months in the year. (Society of Gentlemen 1777)

The importance of the potato in the social etiology of scurvy has not always been fully appreciated, although Carpenter has clearly underlined the significant role that it played in the history of scurvy, particularly in Britain and in Ireland. Its significance stems from two facts. First, although comparatively low in vitamin C (10 to 20 milligrams [mg] per 100 grams [g]), potatoes were eaten in such large amounts that they frequently accounted for a very high proportion of the vitamin, and for many they represented its sole source. In Ireland, during the nineteenth century, daily consumptions of up to 4.5 to 6.5 kilograms (kg) per person were recorded (Letheby 1870: 26; Salaman 1970: 331), which would have provided an estimated daily intake of about 400 to 600 milligrams of vitamin C – some 40 to 60 times the quantity required to prevent scurvy. In the 1840s, scurvy was, therefore, a natural consequence of the failure of the potato crop. As suggested earlier, unlike potatoes, cereal grains contain no vitamin C, and thus the maize imported to alleviate the famine had no effect at all against scurvy.

It is also important to note that potatoes can be stored for many months with very little loss of fluid (and consequently with a retention of ascorbic acid), thereby providing a source of the vitamin well into the winter when fresh sources are absent. Even today a substantial sector of the population of Britain obtains the bulk of its vitamin C from potatoes, particularly in the winter months.

By the same token, many of the outbreaks of scurvy in the nineteenth century (as in the Irish Famine of 1845–8 and in the Exeter hospital epidemic in 1846) were directly traceable to a reduced supply of potatoes (Carpenter 1986: 101; Shapter 1847: 945–8). In charting the history of scurvy, a role of paramount significance must be accorded to the potato; its establishment in Italy and Spain some centuries before it attained popularity in Britain was possibly a factor in determining the higher frequency of scurvy in northern Europe in the sixteenth and seventeenth centuries (Salaman 1970: 142–6). During the last three centuries the potato has doubtless protected millions of people from the ravages of the disease.

Early Writers and Theories

Many of the reports of scurvy in Europe in the sixteenth century emphasized its essential prevalence in the colder northeastern areas. "The Scurvy is properly said to be endemical in most of our Northern Countrys, that border upon the Baltick Sea, or adjacent to the German Ocean: As Denmark, Swedland, Norway, Ffrisland, Holland, England etc. But in High Germany, France, Spain and Italy, the Scurvy is accounted sporadical . . . but here and there one" (Maynwaringe 1679: 16). Such was the comparative rarity of scurvy in southern France that Lazarus Riverius, writing "from my study in Montpelier on the 8th of July 1653," dismissed the condition, commenting, "The scurvy is usual in the North [of France?] but almost unknown in the South . . . (Riverius 1655: 357–61). The non sequitur that a cold and damp atmosphere conduced to scurvy prevailed in Europe until well into the eighteenth century.

A. S. Hess, however, in commenting on the apparent absence of references to scurvy in the classical medical writings, offered a truer explanation: "Greek, Roman and Arabic writers do not seem to have been acquainted with scurvy. This is as we should expect, for fruits and vegetables grew in such plenty in these southern countries that scurvy must have been a disorder of rare occurrence" (Hess 1920: 1). This (together with the comparatively early adoption of the potato in southwestern Europe) is presumably also the explanation of the differential distribution pattern of scurvy reported for Europe in the sixteenth and seventeenth centuries.

A parallel development to this apparent increase in scurvy (or the recognition of it) among land dwellers in parts of northern Europe in the seventeenth century was the appearance of the first medical texts devoted entirely to the condition. Unfortunately, however, it is impossible to determine whether the appearance of the texts resulted in an increased awareness of the condition, and hence an apparent increase in its incidence, or whether the texts were produced in response to a genuine increase in the frequency of the disease.

In any event, these medical texts first appeared on the Continent, and J. Ecthius's *De Scorbuto* (1541) is usually regarded as the pioneer study; the ensuing two centuries saw a substantial proliferation of "scorbutic" texts – Lind in 1753 referred to some 40 of them in his *Treatise;* but few of these early compilations showed any great originality of thought or interpretation. Probably the two most influential were John Wier's *De Scorbuto* published in Basel as a part of his *Medicarum Observationum* . . . in 1567 and Severinus Eugalenus's *De Morbo Scorbuto Liber* . . . first published in 1604 and then again in much changed forms under the hands of subsequent editors up to 1658.

John Wier [Wierus] – better known perhaps for his *De Praestigiis Daemonum* (1563) (a treatise opposing the persecution of witches) – was probably the more scientific of the two. His treatise on scurvy was reprinted in its entirety by Daniel Sennert in 1624 as one of the six component works in his *De Scorbuto* (1624). In the prefatory remarks to an English translation that appeared in 1622, the translator indicated that he had translated Wierus rather than Ronsseus or Langius or Ecthius because of a tendency on their part to "wade into deep difficulties" and because they "paynteth out the signes, and poynteth to the cure, but affordeth not the pith and marrow of speciall medicines . . ." (Wier 1622: ii).

Wier's *De Scorbuto* was also the basis of the *Traetice of the Scorbut* written in 1676 by Gwilym Pue [Puw], a Welsh Catholic recusant priest and physician. Pue's treatise, incidentally, contained a case history of a supposedly scorbutic patient – probably Pue himself (Hughes In press). S. Eugalenus exerted a similar influence during a slightly later period, and he was freely quoted until well into the eighteenth century, but his work, even in the later "improved" editions, was less well presented and much more anecdotal than that of Wier. Lind was highly critical of Eugalenus and of Willis, the English physician who uncritically represented Eugalenus in his *Tractatus de Scorbuto* (1667).

Despite the considerable attention that it attracted, very little, in reality, was known about scurvy in the seventeenth and eighteenth centuries. There was fairly general agreement about its main clinical features but little was known of its cure and still less of its cause. The traditional belief that it was essentially a disease of the spleen persisted until well into the eighteenth century. The situation was further complicated by a tendency to assume that there were different types of scurvy. As indicated earlier, it was believed that "sea scurvy" was a different condition from "land scurvy"; there were references too to "hot scurvy" and to "cold scurvy," to "acid scurvy" and to "alkaline scurvy," and the situation was further confused by the belief that these categories were not mutually exclusive.

Furthermore, there were probably different "grades" of scurvy, corresponding to different degrees of vitamin C deprivation. Scurvy, when it occurred among land dwellers, was presumably often a case of chronic partial vitamin C deficiency (hypovitaminosis C) rather than the "full" scurvy (avitaminosis C) that afflicted sailors after their much longer periods of complete deprivation of the vitamin. Hence the confusion between the clear-cut symptoms of complete deficiency among sailors and the chronic (and often seasonal) hypovitaminosis C that could befall land dwellers.

The "Antiscorbutic" Plants

The classical interpretation that diseases and ill health reflected a change in the humoral balance of the body was a powerful element in seventeenth- and eighteenth-century medical thought. Dietary and pharmacological treatments advocated for diseases were frequently devised primarily to counteract or correct the supposed deviant humoral patterns. Edward Strother, in introducing his influential *An Essay on Sickness and Health* in 1725, was quite categorical on this point: "It is therefore a standing Rule that our Meats and Drinks ought to consist, as nearly as can be, of Particles contrary to the Cause of the Disease reigning . . ." (1725: 30).

Correspondingly, eighteenth-century texts on diet and nutrition attached considerable importance to a categorization of foods in terms of their supposed humoral properties so that physicians could select appropriate foods to counteract specific diseases. "The best way of curing the Gout," wrote W. Stephens (1732: 60) "is to hinder the Generation of this gouty Humour in the Body; this is to be effected no other way, that I know of, but by Diet."

The same was to hold true in the case of scurvy. For "hot," "alkaline," "sea," scurvy, cooling acidic foods, such as oranges and lemons, were advocated; "cold," "acid," "land," scurvy, in contrast, could be treated by the "hot" antiscorbutic plants such as scurvy grass, brooklime, and the cresses. Thus there developed a tradition, reinforced by empirical observations, that "sea-scurvy" could be treated by oranges and lemons, whereas the methods of choice for scurvy among land dwellers centered on the antiscorbutic herbs. When John Woodall extolled the virtues of lemon juice as a cure for scurvy among sailors he carefully contrasted its value with that of the traditional antiscorbutics "namely Scurvy-grasse, Horse reddish roots, Nasturtia Aquatica . . . and many other good meanes" whose virtues extended, however, "only to the Cure of those which live at home . . ." (Woodall 1639: 61).

Turner, in describing the virtues of brooklime in his *Herbal* of 1568, penned what must be one of the earliest references to scurvy in an English herbal: ". . . I have proved it my selfe by experience that brooklyme is very good for a decease that reigneth much in Freseland called the Scourbuch. I sod the herbe in butter milke, the cheese and butter taken away, and gave the patientes it so" (128). Clearly, this statement lends further support to the belief that scurvy was either comparatively rare or unrecognized in sixteenth-century Britain.

As it happens, the concentration of foliar ascorbic acid in the three antiscorbutic herbs (*Cochlearia officinalis* [scurvy grass], *Veronica beccabunga* [brooklime], and *Nasturtium officinale* [watercress]) – and particularly in scurvy grass – is low when compared with other angiosperms. Although fresh preparations of the "antiscorbutics" would, in sufficient amounts, certainly have cured scurvy, it seems likely that their entry into, and retention by, sixteenth-century medical literature probably reflected a priori thoughts on the humoral nature of "land scurvy" more than any observed genuine therapeutic value.

James Cook provided his crew with a wide range of vegetables and fruit and scurvy grass collected whenever available, and this, no doubt, protected them from the disease. Had Cook, however, relied on fresh scurvy grass alone, a weekly supply of some 100 pounds of scurvy grass leaf would have been required for a ship with a complement of 100, to provide the Dietary Reference Value of vitamin C (40 mg daily) for the prevention of scurvy.

Nevertheless, the antiscorbutic triumvirate retained a position of importance in the herbals of the sixteenth, seventeenth, and eighteenth centuries, although, as has recently been shown, almost all of the original ascorbic acid would have been lost because of the form in which the preparations were ultimately administered – a finding that must cast considerable doubt on their overall effectiveness (Hughes 1990).

A Nosological Safety Net

The picture was further confused in the eighteenth century by a readiness of physicians to describe a whole range of unrelated conditions as "scurvy"; and the term became a convenient nosological safety net for the not inconsiderable number of diagnostic failures of the century. In the words of one physician: "It is yet a suficient Answer to Patients when they enquire into their ailments to give this Return to a troublesome Enquirer, that their Disease is the Scurvy, they rest satisfied that they are devoured with a Complication of bad Symptoms . . ." (Strother 1725: 150). At the end of the century the maverick Sir John Hill declared on the title page of his *The Power of the Water Dock against the Scurvy* (1777) that "If any one is ill, and knows not his Disease, Let him suspect the Scurvy."[1]

With such confusion surrounding scurvy, one cannot with any certitude delineate the true importance of the ailment among land dwellers in the seventeenth and eighteenth centuries, and in the absence of details of dietary patterns (and particularly of the consumption of vegetables by the population in general), there must remain considerable doubts about its true incidence. About all that is clear is that the use of the term "scurvy" was almost certainly more common than the disease itself.[2]

Nevertheless, epidemics did occur; Hirsch lists some 30 such outbreaks during the eighteenth century in such diverse areas as Canada, Denmark, and Russia (1885: 521–3). Among the seafaring population, however, the picture was much more clearly delineated, and right through the seventeenth and eighteenth centuries scurvy was the most feared of all the hazards associated with long sea voyages, and with good cause. As we have already noted, it has been estimated that between 1600 and 1800 scurvy accounted for some million deaths at sea and that in almost every naval campaign of any length during this period scurvy played an important role (Roddis 1951: 72).

James Lind

The name of James Lind is deservedly associated with a substantial advance in the understanding of scurvy. A ship's surgeon, he soon came face-to-face with the ravages of the disease among sailors. Others before him had successfully used empirically discovered remedies in the cure of scurvy, and their use of citrus fruits as the antiscorbutic remedy par excellence was well established (see, for example, Zulueta and Higueras 1981). This was presumably known to Lind, who himself quoted J. G. H. Kramer's observation ". . . if you have oranges, lemons or citrons . . . you will, without other assistance cure this dreadful disease" (Stewart and Guthrie 1953: 154).

John Woodall in his *The Surgions Mate* (1617) quite clearly drew attention to the prophylactic value of lemon juice – which had, in any case, already been successfully used by James Lancaster in his East Indian voyage at the beginning of the century. In 1696 William Cockburn underlined the importance of fresh fruit and vegetables to sailors in his *Sea Disease, or Treatise of their Nature, Cause and Cure* and in his *Essay on Sickness and Health* (1725). Edward Strother also had pointed out that "eating Lemons and Oranges" would cure scurvy in sailors.

But Lind's achievement was that he subjected these empirically derived claims, and others, to the test of scientific experimentation in what has been claimed to be the first controlled clinical study in the history of medicine. Here is a description of it in Lind's own words:

> On the 20th of May, 1747, I took twelve patients in the scurvy, on board the *Salisbury* at sea. Their cases were as similar as I could have them. They all in general had putrid gums, the spots and lassitude, with weakness of the knees. They lay together in one place, being a proper appartment for the sick in the fore-hold; and had one diet common to all, viz. water-gruel sweetened with sugar in the morning; fresh mutton-broth often times for dinner; at other times puddings, boiled biscuit with sugar etc. and for supper, barley and raison, rice and currants, sago and wine, or the like. Two of these were ordered each a quart of cyder a day. Two others took twenty-five gutts [drops] of *elixir vitriol* three times a day, upon an empty stomach; using a garble strongly acidulated with it for their mouths. Two others took two spoonsfuls of vinegar three times a day upon an empty stomach having their gruels and other food well acidulated with it, as also the gargle for the mouth. Two of the worst patients, with the tendons in the L arm rigid (a symptom none of the rest had) were put under a course of sea water. Of this they drank half a pint every day, and sometimes more or less as it operated, by way of gentle physic. Two others had each two oranges and one lemon given them each day. These they [ate] with greediness at different times, upon an empty stomach. They continued but six days under this course, having consumed the quantity that could be spared. The two remaining patients took the bigness of a nutmeg three times a day, of an electuary recommended by an hospital-surgeon, made of garlic, mustard seed, *rad. raphan.*, Balsam of Peru, and gum myrrh; using for common drink, barley water well acidulated with tamarinds; by a decoction of which with the addition of *cremor tartar,* they were gently purged three or four times during the course.
>
> The consequence was that the most sudden and visible good effects were perceived from the use of the oranges and lemons; one of those who had taken them, being at the end of six days fit for duty. The spots were not indeed at that time quite off his body, nor his gums sound; but without any other medicine, than a gargarism of *elixir vitriol* he became quite healthy before we came into Plymouth which was on the 16th of June. The other was the best recovered of any in his condition; and being now deemed pretty well, was appointed nurse to the rest of the sick. Next to the oranges, I thought the cyder had the best effects. . . . (Stewart and Guthrie 1953: 145–7)

Lind's note on the partial efficacy of cider has been quoted in support of the thesis that cider, as prepared traditionally in the eighteenth century, would have contained significant amounts of vitamin C and that it could have played a significant role in the prevention of scurvy (French 1982: 59–66). Although this may have been the case, such evidence as is available would suggest that in general, very little of the original vitamin C would survive a fermentation procedure (Hughes 1975, 1990).

Lind's book *A Treatise of the Scurvy* appeared in 1753; a second edition was published in 1757 and a third and "updated" version in 1772 (a bicentenary reprint of the first edition was published in 1953 [Stewart and Guthrie 1953]). A French translation appeared in 1756 with subsequent reprints, and an Italian translation was published in 1766.

Not all of Lind's conclusions, however, were characterized by the same degree of scientific acumen that he displayed in his famous "scurvy trial," and it is clear that he claimed "antiscorbutic" properties for preparations that modern analysis would suggest are quite devoid of vitamin C (Hughes 1975). Nevertheless, his *experimental* demonstration that oranges and lemons could cure scurvy, his critical assessment of the literature of scurvy, his demonstration that the distinction between "land scurvy" and "sea scurvy" was a spurious one, and his advocacy of the use of various prophylactic foods by ships' crews must place him among the most significant figures in the history of nutrition.

Unfortunately, although subsequent commentators advocated the official adoption of lemon juice by the naval authorities as a prophylactic measure, they met with little success for many decades (Carpenter 1986: 73, 87). The purchase of vegetables by ship captains was sanctioned but the practice soon lapsed, and scurvy among sailors continued unabated. Indeed, when the Channel Fleet returned to port in 1780 after a cruise of only six weeks, there were 2,400 cases of scurvy present (Lloyd 1981: 12).

But in 1795, largely as a result of the advocacy of Gilbert Blane, himself a prominent and influential naval surgeon (actually "physician to the fleet"), the official issue of lemon juice to naval personnel in Britain was sanctioned (the practice was not, however, officially extended to the merchant service until 1844). Within two years, cases of scurvy in naval hospitals were rare occurrences, and there were clinicians who complained that they had never seen a true case of scurvy – a situation that would have been unthinkable a few years previously. J. Turnbull's almost monotonously successful treatment of the few scorbutic sailors arriving at Liverpool in 1848, merely providing them each with two lemons daily, was, perhaps, the final elegant vindication of Lind's pioneer study (Turnbull 1848).

Limes and Scurvy

A minor setback in keeping scurvy at a distance occurred in the 1850s when, for economic reasons, the British Admiralty contracts were changed so that the West Indian lime *(Citrus aurantiifolia)* was substituted for the lemon *(Citrus limon).* The superficial similarity between the two fruits had already led to the use of the terms "lime juicer" and "limey" by Americans in referring to British ships and sailors. Furthermore, the terms "lemon juice" and "lime juice" were used carelessly and often without distinction in referring to the two species. In fact, at the beginning of the century the lime was sometimes referred to as the "sour lemon" (Green 1824: 316).

An unfortunate consequence of this change was the reported failure of stored lime juice to offer protection against scurvy – as in the ill-fated "Nares" expedition to the Arctic in 1875. The apparent failure of lime to prevent scurvy led to the rejection by some observers of the thesis that lack of fresh fruit and vegetables was the only cause of scurvy. A. H. Smith, in a comprehensive article stimulated by outbreaks of scurvy among troops issued lime juice during the First World War, concluded that lime juice (as contrasted with lemon juice) as an antiscorbutic agent was "worthless" (Smith 1919).

The reason for this apparent lack of antiscorbutic potency on the part of lime juice preparations is still incompletely understood. It is true that lime juice has a lower vitamin C content than lemon juice, but it is still high enough to be regarded as a moderately good source of the vitamin. It is possible that the vitamin C molecule is much less stable in lime juice than in lemon juice – a belief that was apparently confirmed by Harriette Chick in 1918 using the guinea pig as an assay system. This observation would suggest that the protective and stabilizing factors present in lemon juice (high acidity, tannins, anthocyanins, etc.) are less potent in lime juice preparations. However, in a recent study, Carpenter found no essential difference between the rate of loss of ascorbic acid in lime and lemon juices (Carpenter 1991, personal communication). Whatever the true explanation, the apparent discrepant protective capacities of the two forms was an important feature in the history of scurvy, introducing a puzzling diversionary element into an otherwise fairly smooth development.

Scurvy in the Nineteenth Century

In general, the importance of scurvy diminished during the nineteenth century. It no longer posed a problem to mariners (the greater rapidity of sea vessels was a contributory factor in this respect), and it no longer occupied a position of importance in the medical texts. The eighteenth-century tendency to use the term "scorbutic" indiscriminately with reference to almost any unidentifiable or challenging condition seemed also to be dying. And an increase in the intake of vegetables (and to a lesser extent, fruit) reduced the possibility of scurvy occurring among the general population.

Nevertheless, sporadic outbreaks of scurvy occurred from time to time, and a number of these led to detailed reports in the medical press – some of them substantial ones, such as that by J. O. Curran in 1847 of cases of scurvy following the potato famine in Ireland (Curran 1847) and that of R. Christison describing a similar outbreak in Scotland in 1846 (Christison 1847).

Scurvy outbreaks occurred most frequently in "closed" communities subjected to the same (inadequate) dietary pattern – hospitals, prisons, and workhouses. The numerous reports presented to Parliament in the nineteenth century on conditions in the prisons and workhouses provide useful information on the adequacy of the diets in these institutions (Johnston 1985). The availability of potatoes – and to a lesser extent, vegetables – was of paramount importance in this respect; fruit was almost totally absent from the normal prison and workhouse diet. Thus, the outbreaks of scurvy among convicts at Millbank in 1822 and in Pentonville in 1847 were a direct result of a lack of vegetables.

W. Baly, in 1843, in a simple type of controlled experiment, was able to show that outbreaks of scurvy at Pentonville Prison could be eliminated by including adequate amounts of potatoes in the diet (Baly 1843). In 1851, R. Boyd described two cases of scurvy (a female aged 38 and a male aged 59) in the Somerset County Pauper Lunatic Asylum resulting from "a continued diet of one meal of bread and cheese daily for three months." Of particular significance to Boyd was the observation that this occurred "despite a plentiful allowance of cider (nearly 3 pints daily), which is supposed to be antiscorbutic" (Boyd 1851: 520; see also French 1982).

In the second half of the century potatoes were a regular feature of such institutional diets and outbreaks of scurvy diminished, although some cases still occurred among sailors despite the official adoption of lemon juice as a prophylactic. "It is very rare for London physicians to see cases of scurvy such as they are presented at our seaports," wrote P. Black in 1876 (12), confirming Boyd's earlier statement that "Scurvy is now seldom seen in ordinary hospital practice in this country except in the [naval] hospital ship *Dreadnought*" (Boyd 1851: 520). Nevertheless, there were still isolated epidemics in communities deprived of fresh food supplies for long periods – as among British soldiers in the Crimean War and among some of the persons on Arctic expeditions.

"Explaining" Scurvy in the Nineteenth Century

Attempts to "explain" the nature of scurvy continued. In particular, efforts were made to relate it to the absence of fresh fruit and vegetables in the diet, and by the middle of the nineteenth century there was a fair consensus that this was the main cause of the disease. Just as in the eighteenth century, when there had been attempts to accommodate scurvy within the then popular humoral theory of disease, so in the nineteenth century there were efforts to explain it by drawing on concepts borrowed from the embryonic nutritional science of the period. This explanation involved an interesting conceptual shift from the conviction that there were positive causes of scurvy (such as coldness or too much dietary salt) to the belief that it resulted from a dietary deficiency – albeit an undefined one.

Two writers were particularly vocal in developing this theme. One was George Budd, a pioneer thinker in the development of the concept that there were clearly definable "Disorders Resulting from Defective Nutriment" (to use the title of his series of articles in the *London Medical Gazette* in 1842 [Budd 1840, 1842]). The second was Robert Barnes, who in 1864 produced his less widely available *On the Occurrence of Sea Scurvy in the Mercantile Navy. . . .* Budd, in a frequently referenced article in Tweedie's *Library of Medicine,* stated quite unambiguously that scurvy was the result of a lack of a single essential dietary principle and of that alone; he furthermore described this antiscorbutic principle as a thermolabile one, present in fresh fruit and vegetables and with uncanny foresight prophesied that it would "be discovered by organic chemistry or the experiments of physiologists in the not too distant future" (Budd 1840: 77; Hughes 1973).

Twenty years later Barnes reaffirmed the essential dietary nature of scurvy in a 10,000-word official report. Basing his arguments on "experiments and facts" he stated, "There is no fact so well attested by the history of mankind as the dependence of scurvy upon the negation of fresh vegetable food . . . the abolition of scurvy is entirely a question of diet, and a very simple question of diet." Barnes, basing his calculations on returns obtained from the Dreadnought (Naval) Hospital, attempted to arrive at a figure for the depletion period necessary for the emergence of scurvy and concluded that "symptoms such as . . . blotches like bruises, swelling of the gums, lassitude and emaciation . . . have generally been manifest in from 60 to 80 days." He acknowledged, however, that there was a strong factor of individual variation (Barnes 1864: 330).

But what was the nature of this deficient element that was absent from scorbutigenic diets yet present in vegetables and fruits? E. A. Parkes, an eminent clinician, presented the problem in four simple sentences, logically and within the currently accepted framework of dietary knowledge in 1869:

> The peculiar state of malnutrition we call scurvy is now known not to be the consequence of general starvation, though it is doubtless aided by this. Men have been fed with an amount of nitrogenous and fatty food sufficient not only to keep them in condition, but to cause them to gain weight, and yet have got scurvy. The starches also have been given in

> quite sufficient amount without preventing it. It seems, indeed clear that it is to the absence of some of the constituents of the fourth dietetic group, the salts, that we must look for the cause. (1869: 492)

And the missing components in Parkes's opinion were the salts of organic acids, such as citric, malic, and tartaric – compounds known to be of vegetable origin. Parkes's advice, included in his army manual *Practical Hygiene,* was that, "In time of war every vegetable should be used which it is safe to use, and, when made into soups, almost all are tolerably pleasant to eat. . . . Good lemon juice should be issued daily (1 oz.) and it should be seen that the men take it" (1869: 494).

Parkes's theory of the nature of scurvy was by no means the only one in the field during the nineteenth century. There were many others, and as late as 1908, J. M. Cowan, writing in the standard Oxford manual *A System of Diet and Dietetics,* while admitting "the undisputed fact that a plentiful diet of fresh vegetables cures the disease" went on to state, "The exact nature of the fault is, however, undetermined" (1908: 645). Cowan referred to a number of theories of scurvy then in vogue. These were a deficiency of potash salts; a deficiency of dietary bases (alkali); ptomaine poisoning; and a specific infection (Cowan 1908: 645). Cowan's uncertainty about the cause of scurvy was echoed in 1911 by the *Encyclopedia Britannica,* which stated, ". . . the modern tendency is to suspect an unknown micro-organism . . . even among the more chemical school of pathologists it is disputed whether the cause is the absence of certain constituents in the food or the presence of some actual poison . . ." (517).

Had Cowan been aware of it, these alternative theories had already been rendered redundant by an experiment reported the previous year from Oslo – in Carpenter's opinion "the most important single paper in the whole history of this subject" (Carpenter 1986: 173). This was the classic study by A. Holst, in which he produced scurvy in guinea pigs by feeding them a grain diet – in an experiment originally designed to study the nature of beriberi.

Holst had fortuitously chosen one of the few species unable to produce vitamin C endogenously and had fed them a diet completely lacking in vitamin C. The guinea pigs died after a month on the diet, and it was noted that the tissues showed degenerative changes similar to those known to occur in human scurvy (Holst and Frohlich 1907). Until the characterization of the "antiscorbutic factor" and the development of chemical methods of assessing it in the 1930s, the prevention of scurvy in guinea pigs was the standard technique for measuring the antiscorbutic potency of a preparation.

The last quarter of the nineteenth century also witnessed a proliferation of interest, both in America and in Europe, in "infantile scurvy" – a form of avitaminosis C occurring in very young children and characterized primarily by defective bone development. It was later referred to as "Barlow's disease," after Thomas Barlow, a London physician, who described its true nature and distinguished it from rickets, with which it was frequently associated and often confused (Evans 1983).

It is interesting to note that the emergence of infantile scurvy, like that of "sailors' scurvy" three centuries previously, was probably a consequence of developments in technology, namely, too great a dependence on processed foodstuffs from which the vitamin C had been destroyed and, in particular, evaporated and condensed milks, the use of which increased significantly during the second half of the nineteenth century (Carpenter 1986: 158–72). The subsequent introduction of orange juice supplements for babies ensured the sudden eradication of "Barlow's disease," although isolated reports from Germany, as late as the 1980s, described its occurrence in babies fed only on oat gruel.

Experimental Scurvy in Humans

Following the identification of ascorbic acid as the "antiscorbutic factor," human volunteers attempted to induce scurvy in themselves by subsisting on a vitamin C–free diet. J. Menshing, in Germany, ate a virtually vitamin C–free diet for 100 days; his blood vitamin C fell to zero but there were no discernible signs of scurvy. H. Rietschel and H. Schick repeated the experiment, extending the period of deprivation to 160 days but again without the appearance of any overt signs of scurvy (Rietschel and Mensching 1939). J. H. Crandon, in the United States, deprived himself of vitamin C and noted the appearance of the first recognizable signs of scurvy after some 5 months (Crandon, Lund, and Dill 1940).

However, the first controlled study designed to produce scurvy in humans was undertaken at Sheffield in England during the latter stages of the Second World War and published in 1953 (eight years after the conclusion of the work) as Medical Research Council Special Report (Medical Research Council 1953). Twenty young volunteers (aged 21 to 34) took part in the experiment; anecdotal reports indicate that they were conscientious objectors to military service, although, understandably perhaps, this information was not included in the official report of the study.

All participants were placed on a vitamin C–free diet. Ten received no supplements; seven were given 10 mg ascorbic acid daily; and three received 70 mg ascorbic acid daily. The general picture to emerge was that the classical signs of scurvy (hyperkeratotic follicles, gum lesions, impaired wound healing – in that order) were experienced by those in the deficient group but not by either of the supplemented groups.

The hair follicle changes occurred after 17 weeks of deprivation and the gum changes after 26 weeks – somewhat later than the corresponding period calculated by Barnes in 1864. The difference presumably reflected differences in the subjects' vitamin C status at the beginning of the deprivation period. Furthermore, a supplement of 10 mg ascorbic acid was sufficient to restore the scorbutic subjects to normal health.

The report recommended that "in order to arrive at a figure for a daily allowance which covers individual variations and includes a safety margin, it is suggested that the minimum protective dose of 10 mg be trebled" (Medical Research Council 1953: 145). For 40 years the United Kingdom Recommended Daily Allowance for vitamin C remained at 30 mg, and the experimental evidence for this amount was the single "Sheffield Study" of 1944 – a study that, in terms of sex and age alone, it may be argued, was based on a completely unrepresentative population group.

A similar investigation, but with fewer participants, was reported from the United States in 1969. The subjects in this instance were prisoners who "bought" remission periods by subjecting themselves to scurvy. The signs of deficiency appeared somewhat earlier than in the "Sheffield Study" – skin lesions in 8 to 13 weeks and gum changes in 11 to 19 weeks (Hodges et al. 1971). Both the Sheffield and the U.S. projects included wide-ranging physiological and pathological examinations, and further projects of this nature are unlikely to add very much to our clinical knowledge of the condition.

There remain, of course, peripheral problems that are of some academic interest but of little practical significance, such as the identification of further species unable to synthesize ascorbic acid and, therefore, susceptible to scurvy – and the mirror image of this, the search for a mutant form of guinea pigs resistant to scurvy. One of the more interesting current problems centers on the apparent refractiveness of the elderly to scurvy; it has been shown that persons over 80 years of age may have extremely low blood levels of ascorbic acid without the emergence of any of the expected clinical features (Hughes 1981: 60).

Scurvy Today

Our current knowledge of the vitamin C requirement of the body allows us, in a perverse way, to assess the validity of some historical claims of dietary interest. L. Cornaro, who reputedly attained a century of life by prudent living, recommended for the poorer and older members of the community a diet of bread, panada, and eggs. A diet so structured, however, would be almost completely lacking in vitamin C and almost certain to produce scurvy in a matter of months (Cornaro 1768: 98). Similarly, the numerous accounts of survival for considerable periods on diets, which simple inspection indicates to be completely vitamin C–free (such as that of John Ferguson, who in the eighteenth century lived, allegedly for 18 years, only on water, whey, and barley water [Umfreville 1743]), must now be regarded as largely apocryphal.

The life, and untimely death, of William Stark was more in keeping with what we now know of scurvy and vitamin C. Stark, perhaps the best known of all dietary masochists, achieved historical immortality by experimenting on his own body. He may be regarded as the founder of the now firmly rooted "Death by Diet" brigade. A 29-year-old unmarried physician living in London, he decided to test whether very simple diets would support health. From July 1769 to February 1770 he subsisted on diets such as meat, bread, and water; or bread and cheese; or honey and bread; or sugar and water. This highly scorbutigenic regime was relieved only by a small amount of fruit on one occasion in December 1769. Stark died on February 23, 1770, almost certainly from scurvy, judging by the entries in his detailed diary of the study. It is interesting to note, despite his general lassitude and fatigue, entries such as "had strong desires," "Venus semel," and "Venus bias," which appeared at least weekly in his diary up to within a fortnight of his death, suggesting little impairment of the procreative capacity even in severe scurvy (Smyth 1788; Drummond and Wilbraham 1935).

Scurvy is today a rare condition – so rare that individual cases usually merit a short note in the medical press. Persons on a mixed, balanced diet would normally be expected to daily ingest more than the amount of ascorbic acid required to protect them against the disease. Thus, in the United Kingdom the mean ascorbic acid intake is some 60 mg daily – 50 percent above the current U.K. Reference Daily Intake of 40 mg. The only persons likely to fall into a scurvy-risk category are those who, for economic or dietary reasons, subsist on a diet deficient in fruit, vegetables, and fresh meat – such as a diet based primarily on nuts and grain and dairy products or the proverbial American scorbutigenic diet of doughnuts and black coffee.

Indeed, even the ingestion of large amounts of fresh meat (particularly liver) will provide sufficient amounts of vitamin C to prevent scurvy in the comparative absence of fruit and vegetables. This explains why Eskimos (the name of which, apparently, means "raw flesh eaters") remain scurvy-free even though their intake of plant sources is minimal. A turn-of-the-century account underlines this fact:

> In 1893, at Kharborova, a Samoyad settlement on the Yugor Straits . . . six Russian priests, whose religion forbade them to eat reindeer or other such meats, but allowed salted fish, were left in a hut by a wealthy mine-owner to pass the winter. . . . A small Russian peasant boy was left to wait on them. The priests lived almost exclusively on tea, bread and salted fish; the boy

> lived upon similar food, except that instead of the salted fish he ate fresh reindeer meat. None of them had any vegetables. In the following May, when the Samoyads and peasant traders returned, they found that all the six priests had died of scurvy, whereas the little boy, who had lived upon fresh meat and had not eaten salted fish was alive and well, and had buried all his late masters in the snow. . . . (Jackson and Harley 1900: 252–3)

Recently reported cases of scurvy include that of a 9-year-old American girl who consumed nothing but tuna sandwiches and iced tea (without lemon) (Ellis, Vanderveen, and Rasmussen 1984), and that of a 24-year-old British male whose main form of sustenance was peanut butter sandwiches (Pozniak and Tomson 1983).

Epidemics of scurvy have been equally rare in the twentieth century. They occurred on a limited scale among soldiers in World War I (Smith 1919) and, particularly, among Indian personnel fighting in Iraq, where some 11,000 cases were reported (Willcox 1920). J. D. Comrie stated that he had personally examined 600 cases of scurvy in 1919 in North Russia (Comrie 1920).

Even today, however, we have the occasional reminder that the history of scurvy is not as completely closed a book as modern science would perhaps lead us to believe. Recently it has been reported that scurvy remains a serious public-health problem for Ethiopian refugees in Sudan and Somalia, where the incidence of scurvy in six camps ranged from 14 percent to 44 percent. It was found that the standard relief food (mainly cereals, legumes, and oil) distributed to the refugees was almost completely deficient in vitamin C (Desenclos et al. 1989).

The condition sometimes described as "chronic scurvy" or hypovitaminosis C (in which a person subsists on a suboptimal intake of vitamin C but without the emergence of the clinical features of overt scurvy) may affect substantial sectors of a population and, in particular, the institutionalized elderly; but its clinical significance, if any, is a matter of continuing dispute that need not concern us here.

R. E. Hughes

Notes

1. The water dock was not the only plant to have been the subject of a monograph devoted to its supposed antiscorbutic properties; Andreas Moellenbrok's *Cochlearia Curiosa* was translated into English in 1676, and a century later John Edwards published his . . . *Goose Grass or Clivers and its Efficacy in the Cure of the most inveterate Scurvy.*
2. Ironically, the situation is today completely reversed. In a recent paper it was pointed out that "Scurvy is a disease which can mimic other more serious disorders such as deep vein thrombosis and systemic bleeding disorders . . . [and] because the clinical features of scurvy are no longer well appreciated scorbutic patients are often extensively evaluated for other disorders" (Reuler, Brondy, and Cooney 1985).

IV.E

Food-Related Disorders

IV.E.1 Anorexia Nervosa

Definition

Anorexia nervosa is a psychophysiological disorder – usually of young females – characterized by a prolonged refusal to eat or maintain normal body weight, an intense fear of becoming obese, a disturbed body image in which the emaciated patient feels overweight, and the absence of any physical illness that would account for extreme weight loss. The term "anorexia" is actually a misnomer, because genuine loss of appetite is rare and usually does not occur until late in the illness. In reality, most anorectics are obsessed with food and constantly struggle to deny natural hunger.

In anorexia nervosa, normal dieting escalates into a preoccupation with being thin, profound changes in eating patterns, and a loss of at least 25 percent of the original body weight. Weight loss is usually accomplished by a severe restriction of caloric intake, with patients subsisting on fewer than 600 calories per day. Contemporary anorectics may couple fasting with self-induced vomiting, use of laxatives and diuretics, and strenuous exercise.

The most consistent medical consequences of anorexia nervosa are amenorrhea (ceasing or irregularity of menstruation) and estrogen deficiency. In most cases amenorrhea follows weight loss, but it is not unusual for amenorrhea to appear before noticeable weight loss has occurred. The decrease in estrogen causes many anorectics to develop osteoporosis, a loss of bone density that is usually seen only in postmenopausal women (Garfinkel and Garner 1982).

By the time the anorectic is profoundly underweight, other physical complications resulting from severe malnutrition begin to appear. These include bradycardia (slowing of the heartbeat), hypotension (loss of normal blood pressure), lethargy, hypothermia, constipation, the appearance of "lanugo" or fine silky hair covering the body, and a variety of other metabolic and systemic changes.

In addition to the physical symptoms associated with chronic starvation, anorectics also display a relatively consistent cluster of emotional and behavioral characteristics, the most prominent of which grows out of the anorectic's deviation from normal eating habits. Severe restriction of food intake is sometimes alternated with bulimic phases, in which the anorectic engages in uncontrolled or excessive eating followed by self-induced vomiting and laxative abuse. Other unusual eating habits may include monotonous or eccentric diets, hoarding or hiding of food, and obsessive preoccupation with food and cooking for others.

Emotionally, anorexic patients are often described as being perfectionist, dependent, introverted, and overly compliant. Although studies have failed to find a consistent psychiatric symptom pattern for the disorder, frequently reported neurotic traits include obsessive-compulsive, hysterical, hypochondriacal, and depressive symptoms. A decrease in or disappearance of sexual interest is also a frequent concomitant of anorexia nervosa.

A distorted body image is an almost universal characteristic of anorectics, with many patients insisting they are overweight even when their bodies are extremely emaciated. As a result, most individuals with anorexia nervosa deny or minimize the severity of their illness and are usually highly resistant to therapy. The anorectic's refusal to acknowledge her nutritional needs, and her steadfast insistence that nothing is wrong, make anorexia nervosa one of the most recalcitrant disorders in contemporary medicine.

Distribution and Incidence

Once considered to be extremely rare, the reported incidence of anorexia nervosa has more than doubled during the past 20 years (Herzog and Copeland 1985). The disorder is especially prevalent among adolescent and young adult women. Ninety to 95 percent of anorectics are young and female, and as many as 1 in 250 females between 12 and 18 years of age may develop the disorder. The exact incidence of anorexia and other eating disorders is difficult to determine, however, because of problems in conducting reliable epidemiological studies and the small samples on which many such studies are based (Crisp, Palmer, and Kalucy 1976).

The onset of anorexia nervosa occurs most often during adolescence, although some patients have become anorexic as early as age 11 and as late as the sixth decade of life. Patients are typically high achievers, with normal or above average intelligence. They also tend to come from middle- or upper-class families, although evidence of anorexia nervosa among working-class and poverty-class women is growing (Bulik 1987; Gowers and McMahon 1989; Dolan 1991).

Anorexia nervosa is comparatively rare in men: Approximately 5 to 10 percent of anorectics are male. The clinical picture for male anorexic patients is also much different from that for women. In general, male anorectics tend to display a greater degree of psychopathology, are often massively obese before acquiring the disorder, are less likely to be affluent, and are even more resistant to therapy than their female counterparts (Garfinkel and Garner 1982). There is growing evidence, however, that anorexia nervosa and bulimia are more common among men than previously believed. This is particularly true among homosexual men, who tend to experience more dissatisfaction with body image than do heterosexual men (Yager et al. 1988; Silberstein et al. 1989; Striegel-Moore, Tucker, and Hsu 1990).

Anorexia nervosa was also once thought to be comparatively rare among American blacks, Hispanics, Native Americans, lesbians, first- and second-generation ethnic immigrants, and individuals from disadvantaged socioeconomic backgrounds (Herzog and Copeland 1985). Recent research in this area, however, has indicated that the incidence of anorexia and other eating disorders among these groups is much higher than previously thought (see the section "Geographic and Demographic Features").

Etiology and Epidemiology

Although the etiology of anorexia nervosa is an area of intense investigation, researchers have yet to reach a consensus about the origin of the disorder. The most sophisticated thinking on the subject regards anorexia nervosa as a multidetermined disorder that involves an interplay of biological, psychological, and cultural factors. Advocates of this model view these three etiological factors as reciprocal and interactive and believe it is simplistic to isolate one component as the single underlying cause of the disorder (Garfinkel and Garner 1982; Brumberg 1988).

Joan Brumberg (1988) has developed a multidetermined etiological model based on a two-staged conceptualization of anorexia nervosa that delineates the relative impact of sociocultural influences and individual biological and psychological variables in precipitating the disorder. In the first stage – the "recruitment" phase of the illness – sociocultural factors play the dominant role. During this period, cultural assumptions that associate thinness with female beauty lead certain women into a pattern of chronic dieting. Indeed, research on the sociocultural causes of anorexia nervosa has linked the increased incidence of anorexia nervosa and other eating disorders with the tremendous cultural attention given to dieting and food, increasingly thinner standards of beauty, and the fitness movement (Schwartz, Thompson, and Johnson 1982; Chernin 1985; Orbach 1986; Bordo 1993). Yet sociocultural variables alone cannot explain why some women but not others move from chronic dieting to anorexia nervosa. Therefore, other individual factors must be implicated in the final development of the illness.

Brumberg's model of anorexia nervosa relies on a second stage – career or acclimation – to correct the shortcomings of sociocultural explanations of the disorder. During the career phase, specific biological and psychological features determine which individuals develop the full-blown psychopathology of anorexia nervosa. In order to explain the transition between the recruitment and career phases of anorexia nervosa, Brumberg relies on recent research in the biological and social sciences, which has sought to uncover the unique physiological and psychological characteristics of anorexic patients.

Since the early 1900s, a number of different endocrinological and neurological abnormalities have been postulated as underlying biological causes of anorexia nervosa: hormonal imbalance, dysfunction in the satiety center of the hypothalamus, lesions in the limbic system of the brain, and irregular output of vasopressin and gonadotropin (Herzog and Copeland 1985). The search for a biomedical cause of anorexia nervosa is made difficult, however, by the fact that chronic starvation itself produces extensive changes in hypothalamic and metabolic function. Researchers in this area have yet to find a common biological characteristic of the anorexic population that is unmistakably a cause rather than a consequence of extreme weight loss and malnutrition (Brumberg 1988).

A more satisfactory explanation of the biological factors that contribute to the "career" phase of anorexia nervosa is the "addiction to starvation" model proffered by the British psychiatrists George I. Szmukler and Digby Tantum (1984). According to Szmukler and Tantum, patients with fully developed anorexia nervosa are physically and psychologically dependent on the state of starvation. Much like alcoholics and other substance abusers, anorectics find something gratifying or tension-relieving about the state of starvation and possess a specific physiological substrate that makes them more susceptible to starvation dependence than individuals who merely engage in chronic dieting. Szmukler and Tantum add, however, that starvation dependence is not the total explanation of anorexia nervosa. Rather, they believe that starvation dependence acts in conjunction with a range of sociocultural, psychological, and familial factors that encourage certain individuals to use anorexic behavior as a means of expressing personal anguish.

Current psychological models of anorexia nervosa fall into three basic categories: psychoanalytic, family systems, and social psychology. In both the psychoanalytic and family systems models, anorexia nervosa is seen as a pathological response to the developmental crisis of adolescence. Orthodox psychoanalysts, drawing on the work of Sigmund Freud, view the anorectic as a girl who fears adult womanhood and who associates eating with oral impregnation (Brumberg 1988). Family systems theory, however, offers a more complex explanation of the relationship between adolescence and anorexia nervosa. On the basis of clinical work with anorectics and their families, family systems therapists have found that the majority of anorexic patients are "enmeshed," meaning that the normal process of individuation is blocked by extreme parental overprotectiveness, control, and rigidity. Anorexia nervosa is therefore seen as a form of adolescent rebellion against parental authority (Minuchin, Rosman, and Baker 1978; Bruch 1988).

Research in social psychology and the field of personality has devised several psychological tests to distinguish the psychological characteristics of anorectics from others in their age-group. One study has shown that although many of the psychological traits of anorectics and other women are indistinguishable, anorectics display a markedly higher degree of ineffectiveness and lower amount of self-esteem. Other studies have proposed that anorectics have actual cognitive problems with body imaging; still others suggest a relationship between anorexia nervosa and sex-role socialization (Garfinkel and Garner 1982).

Some researchers have attempted to fit anorexia nervosa within other established psychiatric categories such as affective disorders and obsessional neurosis. Many anorectics, in fact, display behavior patterns associated with obsessive-compulsive disorders: perfectionism, excessive orderliness and cleanliness, meticulous attention to detail, and self-righteousness. This correlation has led a number of researchers to suggest that anorexia nervosa is itself a form of obsessive-compulsive behavior (Rothenberg 1986). Depressive symptoms are also commonly seen in many patients with anorexia nervosa. Various family, genetic, and endocrine studies have found a correlation between eating disorders and depression. However, the association between anorexia nervosa and other psychiatric disorders remains controversial (Garfinkel and Garner 1982; Herzog and Copeland 1985).

History

The extent to which people suffered from anorexia nervosa in the past has been a subject of much historical debate. Some clinicians and medical historians have suggested that anorexia nervosa was first identified in 1689 by the British doctor Richard Morton, physician to James II (Bliss and Branch 1960; Silverman 1983). The medieval historian Rudolph Bell (1985) has dated the origins of anorexia nervosa even earlier, claiming that the medieval female saints, who were reputed to live without eating anything except the Eucharist, actually suffered from anorexia nervosa.

Other historians, however, have argued that attempts to label all historical instances of food refusal and appetite loss as anorexia nervosa are simplistic and maintain that the historical record is insufficient to make conclusive diagnoses of individual cases (Bynum 1987; Brumberg 1988). Although these historians agree that the final physiological stage of acute starvation may be the same in contemporary anorectics and medieval ascetics, the cultural and psychological reasons behind the refusal to eat are quite different. Thus, to reduce both to a single biomedical cause is to overlook the variety of social and cultural contexts in which certain individuals have chosen to refuse food.

The modern disease classification of anorexia nervosa emerged during the 1860s and 1870s, when the work of public asylum keepers, elite British physicians, and early French neurologists partially distinguished anorexia nervosa from other diseases involving loss of appetite (Brumberg 1988). In 1859, the American asylum physician William Stout Chipley published the first American description of sitomania, a type of insanity characterized by an intense dread or loathing of food (Chipley 1859). Although Chipley found sitophobia in patients from a broad range of social groups and age-groups, he identified a special form of the disease that afflicted adolescent girls.

Chipley's work was ignored by his contemporaries, however, and it was not until the 1870s, when two influential case studies by the British physician William Withey Gull and the French alienist Charles Lasègue (Lasègue 1873; Gull 1874) were published, that physicians began to pay significant attention to anorexia in girlhood. Gull's primary accomplishment was to name and establish anorexia nervosa as a coherent disease entity, distinct from mental illnesses in which appetite loss was a secondary feature and from physical "wasting" diseases such as tuberculosis, diabetes, or cancer. Despite widespread acclaim for Gull's work with anorexic patients, however, late-nineteenth-century clinicians generally rejected the conception of anorexia nervosa as an independent disease. Instead, they viewed it either as a variant of hysteria that affected the gastrointestinal system or as a juvenile form of neurasthenia (Brumberg 1988).

Nineteenth-century physicians also tended to focus on the physical symptom of not eating and ignored the anorexic patient's psychological reasons for refusing food. An important exception was Lasègue, who was the first to suggest the significance of family dynamics in the genesis and perpetuation of anorexia nervosa. Because of the somatic emphasis of nineteenth-century medicine, however, most medical practitioners of that time disregarded Lasègue's therapeutic perspective. Instead, they directed medical intervention toward restoring the anorectic to a reasonable weight and pattern of eating rather than exploring the underlying emotional causes of the patient's alleged lack of appetite (Brumberg 1988).

In the twentieth century, the treatment of anorexia nervosa changed to incorporate new developments within medical and psychiatric practice. Before the Second World War, two distinct and isolated models dominated medical thinking on anorexia nervosa. The first approach was rooted in late-nineteenth-century research in organotherapy, a form of treatment based on the principle that disease resulted from the removal or dysfunction of secreting organs and glands (Brumberg 1988). Between 1900 and 1940, a variety of different endocrinologic deficiencies were proposed as the cause of anorexia nervosa. In 1914, Morris Simmonds, a pathologist at the University of Hamburg, published a clinical description of an extreme cachexia due to destruction of the anterior lobe of the pituitary. Because patients with anorexia nervosa and those with Simmonds's disease shared a set of common symptoms, many clinicians assumed that a deficiency in pituitary hormone was the cause of both conditions (Brumberg 1988).

Other researchers implicated thyroid insufficiency as the cause of anorexia nervosa. Research conducted at the Mayo Clinic in Rochester, Minnesota, during the period between the two world wars established the relationship between thyroid function and body weight and led many physicians to regard anorexia nervosa as a metabolic disorder caused by a deficiency in thyroid hormone. Throughout the 1920s and 1930s, insulin, antuitrin, estrogen, and a host of other hormones were also employed in the treatment of anorexia nervosa (Brumberg 1988).

The second major approach to anorexia nervosa in the early twentieth century grew out of the field of dynamic psychiatry, which emerged during the 1890s and early 1900s. Beginning in the last decade of the nineteenth century, practitioners in dynamic psychiatry increasingly focused on the life history of individual patients and the emotional sources of nervous disease. Two of the leading pioneers in this new field – Sigmund Freud and Pierre Janet – were the first to suggestively link the etiology of anorexia nervosa with the issue of psychosexual development. According to Freud, all appetites were expressions of libido or sexual drive. Thus, not eating represented a repression of normal sexual appetite (Freud 1959). Similarly, Janet asserted that anorexic girls refused food in order to retard normal sexual development and forestall adult sexuality (Janet 1903).

Because of the enormous popularity of endocrinologic explanations, the idea of anorexia nervosa as a psychosexual disturbance was generally overlooked for more than 30 years. By the 1930s, however, the failure of endocrinologic models to establish either a predictable cure or a definitive cause of anorexia nervosa, the growing reputation of the Freudian psychoanalytic movement, and increased attention to the role of emotions in disease led a number of practitioners to assert the value and importance of psychotherapy in the treatment of anorexia nervosa. Although biomedical treatment of the disorder continued, most clinicians argued that successful, permanent recovery depended on uncovering the psychological basis for the anorectic's behavior. Following up on the work of Freud and Janet, orthodox psychiatrists during this time postulated that refusal to eat was related to suppression of the sexual appetite and claimed that anorexic women regarded eating as oral impregnation and obesity as pregnancy (Brumberg 1988).

After World War II, a new psychiatric view of eating disorders, shaped largely by the work of Hilde Bruch, encouraged a more complex interpretation of the psychological underpinnings of anorexia nervosa. Although Bruch agreed that the anorectic was unprepared to cope with the psychological and social consequences of adulthood and sexuality, she also stressed the importance of individual personality formation and factors within the family that contributed to the psychogenesis of anorexia nervosa. Here, Bruch revived Lasègue's work on the role of family dynamics in anorexia nervosa. According to Bruch, the families of most anorexic patients were engaged in a dysfunctional style of familial interaction known as "enmeshment": Such families are characterized by extreme parental overprotectiveness, lack of privacy of individual members, and reluctance or inability to confront intrafamilial conflicts. Although superficially these families appeared to be congenial, Bruch wrote, this harmony was achieved through excessive conformity on the part of the child, which undermined the child's development of an autonomous self. Anorexia nervosa, according to Bruch, was therefore a young woman's attempt to exert control and self-direction within a family environment in which she otherwise felt powerless (Bruch 1973, 1988).

Bruch was also primarily responsible for the tremendous growth in the popular awareness of anorexia nervosa and other eating disorders in the 1970s and 1980s. Through her book, *The Golden Cage: The Enigma of Anorexia Nervosa* (1978), which sold over 150,000 copies, and numerous articles in *Family Circle* and other popular magazines, Bruch brought anorexia nervosa into common American parlance.

At the same time that the American public was becoming increasingly aware of anorexia nervosa, the number of reported cases of the disorder grew tremendously. This phenomenon has led some clinicians and social commentators to suggest that the popularization process itself may promote a "sympathetic host environment" for the disorder (Striegel-Moore, Silberstein, and Rodin 1986). As Bruch herself observed: "Once the discovery of isolated tormented women, it [anorexia nervosa] has now acquired a fashionable reputation, of being something to be competitive about. . . . This is a far cry from the twenty-years-ago anorexic whose goal was to be unique and suggests that social factors may impact the prevalence of the disorder" (Bruch 1988: 3–4).

Geographic and Demographic Features

Until recently, anorexia nervosa was believed to be a disorder largely confined to the United States, Canada, and Western Europe. Researchers also thought that the disease was virtually nonexistent in people of color and/or those from disadvantaged socioeconomic backgrounds. As early as 1880, S. Fenwick observed that anorexia nervosa "is much more common in the wealthier class of society than amongst those who have to procure their bread by daily labor" (Fenwick 1880: 11). This image of anorexia nervosa as a disease of abundance has persisted into the present day. Many researchers suggest that individuals from non-Western societies, minority groups, and impoverished backgrounds are "protected" from eating disorders because thinness is not highly valued in these communities, and fatness is often viewed as a sign of health and prosperity (Andersen and Hay 1985; Gray, Ford, and Kelly 1987; Gowers and McMahon 1989). The apparent absence of the disorder in developing nations and its high incidence among affluent social groups in Westernized countries led many clinicians to classify anorexia nervosa as a "culture bound" syndrome, meaning a disorder that is restricted to certain cultures primarily because of their distinctive psychosocial features (Prince 1985).

As a result of these views, none of the early literature on anorexia nervosa mentioned individuals from minority groups, non-Western countries, or lower socioeconomic classes (Bruch 1966; Kendall et al. 1973; Garfinkel and Garner 1980). The first cases of nonwhite anorectics appeared in a paper by M. P. Warren and R. L. Vande Wiele (1973), which noted 1 Chinese and 1 black person out of 42 patients seen at their New York clinic between 1960 and 1971. Other articles from the late 1970s and early 1980s mentioned one or two cases of nonwhite anorectics but did not offer any explanations of this phenomenon (Jones et al. 1980; Hedblom, Hubbard, and Andersen 1981; Garfinkel and Garner 1982; Roy-Byrne, Lee-Benner, and Yager 1984).

More recently, research on nonwhite and non-Western anorectics has grown significantly: Investigators have identified cases of the disorder in Malaysia (Buhrich 1981), Greece (Fichter, Elton, and Sourdi 1988), Nigeria (Nwaefuna 1981), Zimbabwe (Buchan and Gregory 1984), and Ethiopia (Fahy et al. 1988). The non-Western country to receive the most attention from researchers has been Japan, probably because it is one of the most Westernized East Asian countries. In Japan, anorexia nervosa and a binge-eating syndrome called *Kirbarashi-gui* have been well documented by researchers for a number of years (Nogami and Yabana 1977; Azuma and Henmi 1982; Nogami et al. 1984; Suematsu et al. 1985).

Within the United States and Great Britain, there has been a growing body of research on the incidence of anorexia nervosa in blacks (Pumariega, Edwards, and Mitchell 1984; Andersen and Hay 1985; Nevo 1985; Robinson and Andersen 1985; White, Hudson, and Campbell 1985; Silber 1986; Gray et al. 1987; Hsu 1987; Thomas and James 1988), Hispanics (Silber 1986; Hiebert et al. 1988; Smith and Krejci 1991), Asian-Americans and British-Asians (Nevo 1985; Root 1990), and Native Americans (Rosen et al. 1988; Whitehouse and Mumford 1988; Smith and Krejci 1991), as well as recent immigrants from Eastern Europe (Bulik 1987), the Middle East (Garfinkel and Garner 1982), and the Caribbean (Thomas and Szmukler 1985; Holden and Robinson 1988). Researchers have also challenged the notion that lesbians are "protected" from eating disorders because lesbian ideology challenges culturally prescribed beauty ideals (Striegel-Moore et al. 1990; Thompson 1994).

Although all of this recent research indicates that the number of reported cases of anorexia nervosa and other eating disorders is substantially lower in nonwhites, lesbians, and individuals from non-Western countries, there is a difference of opinion on what this implies about the actual incidence of eating disorders in these groups. Some researchers who have investigated anorexia nervosa in racial minorities have suggested that the disorder is linked more to socioeconomic class than to race and argue that the growing incidence of nonwhite anorectics reflects the growing economic prosperity of certain minority group members. These researchers argue that as nonwhites become more prosperous, their exposure to white, middle-class beauty standards increases, thereby making nonwhites more vulnerable to anorexia and other eating disorders. Because fewer nonwhites than whites belong to the middle and upper economic classes, fewer nonwhites become anorexic (Pumariega et al. 1984; Andersen and Hay 1985; Robinson and Andersen 1985; White et al. 1985; Gray et al. 1987; Hsu 1987; Thomas and James 1988).

Other investigators, however, have exposed methodological and philosophical flaws behind this kind of argument. Some have suggested that the reason there are so relatively few nonwhite anorectics is because people of color do not have the same access to health-care facilities as whites. Because most of the studies of anorexia nervosa record only those sufferers who come to the attention of medical and psychiatric facilities, nonwhites who lack access to these facilities will not be acknowledged by health-care researchers. Moreover, even those minorities who do have access to medical care may feel threatened by a white-dominated medical profession and/or may be embarrassed to seek help for a mental health problem. Thus, the actual number of nonwhites with anorexia nervosa in the general population may be greater than indicated by case reports (Rosen et al. 1988; Root 1990; Dolan 1991; Smith and Krejci 1991; Thompson 1994).

In addition, some have argued that racial stereotypes about who is most vulnerable to anorexia nervosa can explain the apparent rarity of the disorder in minority groups. Anorexia nervosa is frequently referred to in medical and popular literature as a "Golden Girl's Disease" that afflicts only young girls from white, Western European, privileged backgrounds (Root 1990). Consequently, this ethnocentric bias may lead medical personnel to misdiagnose or underdiagnose eating disorders in persons of color (Silber 1986; Hiebert et al. 1988; Rosen et al. 1988; Dolan 1991; Thompson 1994).

Even those who agree that minority group status may "protect" nonwhites from eating disorders also argue that this status does not necessarily protect specific individuals within these groups. As Maria Root (1990: 534) notes in a recent article on eating disorders in women of color: "Individuals within each racial/ethnic group are subject to the standards of the dominant culture, particularly when the culture-of-origin is devalued by the dominant culture." Because thinness in Western and Westernized societies is associated with higher social class, and the attendant social power, resources, and opportunities, some individuals of color may see the pursuit of a slim body-type as a ticket to upward social mobility and acceptance by the dominant culture (Root 1990; see also Silber 1986 and Thompson 1994).

Whatever the explanation, the standard image of anorexia nervosa as a privileged white girl's disease is increasingly being called into question. The disorder has been detected in a variety of racial, ethnic, and socioeconomic groups and in both Western and non-Western societies, although at the moment the number of cases among these groups appears to be relatively rare. Clearly, more research is needed before any definitive statements on the incidence and form of eating disorders in nonwhite and non-Western groups can be made.

IV.E.2 ∾ Celiac Disease

Historical Perspective

Celiac disease has been recognized for centuries (Dowd and Walker-Smith 1974) by physicians aware of its major symptoms of diarrhea and gastrointestinal distress accompanied by a wasting away in adults and a failure to grow in children. The Greek physician Aretaeus (first century A.D.) called the condition *coeliac diathesis* – coeliac deriving from the Greek word *koeliakos,* or abdominal cavity. The British physician Samuel Gee provided what is generally considered the first modern, detailed description of the condition, which he termed the *coeliac affection* in deference to Aretaeus, in a lecture presented at St. Bartholomew's Hospital in London (Gee 1888). At present, celiac disease (or, especially in Britain, coeliac disease) is the most commonly used term for the condition, although various others may be encountered, including celiac syndrome, celiac sprue, nontropical sprue, and gluten-sensitive enteropathy.

There were perceptions, certainly since Gee's time, that celiac disease was a consequence of, or at least affected by, diet. Gee (1888: 20) noted that "[a] child, who was fed upon a quart of the best Dutch mussels daily, throve wonderfully, but relapsed when the season for mussels was over." Such associations with diet led to wide-ranging dietary prescriptions and proscriptions (Haas 1924; Sheldon 1955; Weijers, Van de Kamer, and Dicke 1957; Anderson 1992). Some physicians recommended exclusion of fats – others, exclusion of complex carbohydrates. At times, so many restrictions were applied simultaneously that it became impossible to maintain a satisfactory intake of calories.

Because dietary treatments of celiac disease were of limited effectiveness, the food connection remained a puzzle until the end of the 1940s when a Dutch physician, W. K. Dicke, observed that removal of wheat from the diet of celiac patients led to dramatic improvement (Dicke 1950). It eventually became clear that the efficacy of the various diets recommended prior to Dicke's discovery was in proportion to the extent that wheat was excluded from them. Initial fractionation studies pointed to the gliadin protein fraction as being most harmful to celiac patients (Van de Kamer, Weijers, and Dicke 1953).

Soon after Dicke (1950) reported the harmful effects of wheat on celiac patients, a series of investigations indicated that rye, barley, and oats were also harmful, whereas rice and maize (corn) were not (Dicke, Weijers, and Van de Kamer 1953; Van de Kamer et al. 1953; Weijers et al. 1957). With children, and most adults, the exclusion of wheat, rye, barley, and oats from the diet usually brought about a complete, or largely complete, recovery.

During the 1950s, the development of intestinal biopsy techniques (Shiner 1956; Crosby and Kugler 1957; Brandborg, Rubin, and Quinton 1959) enabled pieces of tissue to be recovered from the intestine for examination and testing, and it was recognized that ingestion of wheat and related grains often resulted in damage to the intestinal mucosa, including the absorptive cells, or enterocytes, lining the interior surface of the intestine. The enterocytes are responsible for the absorption of almost all nutrients; the damage to them provided a basis for the gastrointestinal symptoms and malabsorption.

Familial associations, as well as its rarity among the Chinese, the Japanese, and blacks in sub-Saharan Africa (McNeish et al. 1974), indicated a likely genetic basis for celiac disease. Subsequent findings of strong associations with particular histocompatibility antigens supported this possibility (Kagnoff 1992) and, along with the presence of circulating antibodies to wheat gliadin proteins in patients on a gluten-containing diet, suggested that an abnormal immune response initiated intestinal damage in susceptible individuals.

A detailed understanding of the basis for celiac disease remains to be achieved. Neither the initiating event triggered by wheat gliadin proteins or products derived from them by digestion, nor the mechanisms leading to tissue damage in the small intestine following ingestion of wheat are completely understood. On the basis of current knowledge, it appears that celiac disease has resulted from the convergence of various evolutionary developments: These include human evolution (especially evolution of the immune system), the evolution of wheat and related grasses, the evolution of the protein structures apparently unique to wheat and closely related species, and the evolution of culture – specifically the development of agriculture and the spread of wheat farming (Figure IV.E.2.1).

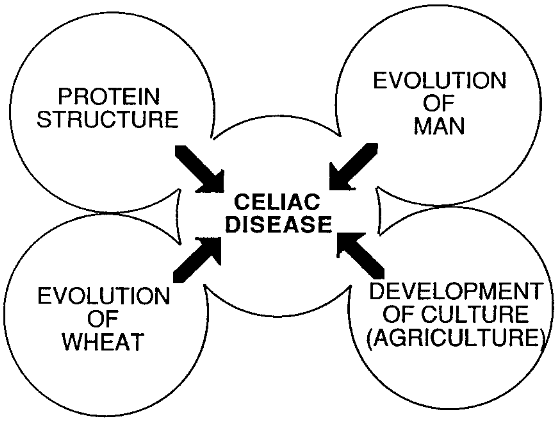

Figure IV.E.2.1. Evolutionary factors combine to produce celiac disease.

Geographical Distribution of Celiac Disease

Celiac disease is commonly thought of as largely afflicting people of European ancestry, and reports of cases among the Chinese, the Japanese (Kihara, Kukida, and Ichikawa 1977), and black Africans are sufficiently rare as to make it unlikely that this assumption is incorrect (also see McNeish et al. 1974; Simoons 1981). However, studies throughout much of the world either are inadequate or have yet to be done.

There are some parts of Asia where rice, a harmless grain (see ahead for definitions of harmful grains), is the predominant cereal grain in the diet, and in some parts of Africa, teff and millet - likely to be harmless cereal grains - predominate. To what extent a low intake of wheat, rye, barley, and oats in Asia and Africa contributes to the apparently low incidence of celiac disease is unknown. Furthermore, in some parts of the world - the United States, for example - medical personnel may have only minimal knowledge of celiac disease and fail to recognize it, whereas in Britain and much of Western Europe, physicians are much more attuned to its signs, which may be highly varied. The likelihood of failure to recognize celiac disease is doubtless substantially greater in some Asian and African countries and may contribute to the perception that it is rare in these places. The difficulties in diagnosing celiac disease and in developing statistical information about its incidence and prevalence have been discussed by R. F. A. Logan (1992a, 1992b).

The incidence of celiac disease varies throughout Europe and with time. For example, crude incidence rates (number of cases per 1,000 births) in various parts of Sweden currently range from about 2.2 to 3.5 per 1,000, whereas in neighboring Denmark, the rate is about 0.1 per 1,000 (Greco et al. 1992). Furthermore, the incidence varies with time, possibly indicating the contribution of some environmental factor. Prior to 1983, incidence of the disease in Sweden was much lower, but it began to increase at about that time, and it has been speculated that an increase in the amount of gluten in infant formulas was responsible for the rise (Maki et al. 1992). The suggestion has also been made (on the basis of screening of blood donors for antigliadin antibodies) that the incidence of celiac disease in Denmark may be similar to that of Sweden although largely undiagnosed (E. Grodzinsky, personal communication, cited by Ascher and Kristiansson 1994).

Ireland was reported to have a high incidence of celiac disease - about 4 per 1,000 births during an 11-year period prior to 1973, particularly in the west near Galway (Mylotte et al. 1973). Since that time, however, the incidence among children under the age of 12 has fallen by 62 percent (Stevens, Egan-Mitchell, et al. 1988), in contrast to the rise experienced in Sweden. The reasons for the decline in Ireland are unclear; they perhaps involve dietary changes such as an increase in the frequency of breast feeding or a decrease in the early introduction of grains to the diet of infants. Or some other undefined factor, perhaps a change in the type of viral infections prevalent in the population, may be involved.

The incidence in the United States has not been established, but a recent study of a Minnesota population (Talley et al. 1994) estimated the incidence as 0.01 per 1,000 person-years and the prevalence at 1 per 5,000. Because of the diversity of the U.S. population, which includes significant numbers of people having African, Chinese, or Southeast Asian ancestry, it might be expected that prevalence would be less than that of Europe as a whole, which is about 1 per 1,000. Whether the prevalence among U.S. residents of European extraction approximates that of European populations remains to be established, but it would be surprising to find that it is different.

Most studies of incidence and prevalence have focused on clearly recognizable disease resulting from significant damage to the absorptive epithelium of the intestine, often diagnosed by intestinal biopsy to show loss of villous structure and followed by removal of wheat and other harmful grains from the diet to demonstrate recovery of mucosal structure and function. It is becoming obvious, however, that there are many people who have subclinical celiac disease (Marsh 1992a), so that the true incidence of celiac disease may be at least two to three times greater than that represented by those with significant damage to the epithelium.

Origins of Agriculture and Wheat Farming

A diploid wheat and barley were likely to have been among the first crops cultivated by humans who were spearheading the Neolithic Revolution about 10,000 years ago. Wild diploid species of wheat, probably *Triticum boeoticum* and *Triticum urartu,* or possibly the wild tetraploid species *Triticum dicoccoides,* had most likely been harvested by hunter-gatherers for some considerable time. These species of *Triticum* were probably extant for perhaps 16 million years (Shewry et al. 1980) before domestication occurred (Harlan 1977) and thus those who pioneered in cultivating it probably had a reasonably good understanding of the plant's life cycle. The origin of wheat cultivation is likely to have been somewhere in the Fertile Crescent area of the Middle East, perhaps near Jericho.

Frederick Simoons (1981) has discussed the possible effects of the spread of wheat farming (from likely centers of origin in the Middle East) on populations with members genetically susceptible to celiac disease. He used a genetic marker for celiac disease and compared the incidence of this marker in populations throughout the world with the incidence of celiac disease. The marker selected was a human leukocyte antigen, HLA-B8 (a class I major histocompatibility complex [MHC] protein). HLA-B8 had been demonstrated to have approximately threefold greater occurrence in celiac patients (Falchuk, Rogentine, and Strober 1972; Stokes et al. 1972) than in normal individuals of the same populations, although it is now known that certain class II MHC proteins show even better correlations and are more likely to play a direct role in the processes of celiac disease (Kagnoff, Morzycka-Wroblewska, and Harwood 1994). The data available to Simoons were, however, limited to HLA-B8.

Simoons reasoned that the greater rate of occurrence of celiac disease among people with the HLA-B8 antigen gave researchers a tool to use in their study of the illness. By determining the distribution of the antigen among human populations, researchers could predict which people were more at risk of developing the disease. Although there are exceptions, such that populations without HLA-B8 may yet have high levels of celiac disease (Logan 1992a), the assumption appears to have general validity.

It turned out that there were two geographic centers in Old World populations with noticeably higher frequencies of HLA-B8, one in western Europe, centered about the British Isles, and one in northwestern India, centered about the Punjab region. These regions also fell within the major areas of wheat cultivation, and in both there had been reports of relatively high incidences of celiac disease. They also represented, to a considerable degree, the boundaries of the spread of wheat farming throughout its geographical range up to relatively recent times (in this analysis, about 1000 B.C.) from its point of origin.

There appeared to be a gradient in the incidence of HLA-B8 throughout the range of wheat cultivation, such that low levels of the antigen were found at the likely origin of wheat cultivation and higher levels at the periphery. Simoons (1981) assumed that high levels of HLA-B8 were once typical of peoples at the origin and suggested that the gradient observed from the center to the periphery might well reflect the effects of a selective genetic disadvantage to members of the population carrying HLA-B8 – along with other genes for susceptibility to celiac disease. Thus, the high levels of HLA-B8 in populations that took up wheat farming late (in the west of Ireland, for example) in its spread from the center of origin, along with high incidences of celiac disease, would reflect the lesser time available for the selective disadvantage to have diminished marker levels.

One obvious discrepancy was northwestern China, where wheat farming was introduced quite late through trade. This major wheat-growing area, although somewhat beyond the contiguous area of the earlier spread of wheat farming, might reasonably be considered its periphery.

There was, however, neither evidence of celiac disease nor high levels of HLA-B8 in the wheat-growing regions of China. A possible explanation for this was the likelihood that immune systems evolved differently in different populations to protect against relatively specific infectious diseases. Geographically distant populations would have been exposed to different stresses, thereby resulting in different complements of histocompatibility antigens. Furthermore, histocompatibility antigens that provided resistance to one disease might, quite coincidentally, enhance susceptibility to another, and this may well be true of genes for susceptibility to celiac disease (Strober 1992). Thus, the absence of celiac disease in the wheat-growing areas of China may well reflect the absence of the susceptibility genes in the Chinese population. Although hampered by a lack of adequate information, the analysis by Simoons (1981) is at least a highly interesting attempt to deal with what must have been selective pressures on populations containing the genes for susceptibility to celiac disease as wheat farming spread from the Middle East throughout Western Europe.

Definition of Harmful Cereal Grains and Components

Wheat, Rye, Barley, and Oats

Early conclusions regarding the toxicity of cereal grains and their constituents were based mainly on the ability of a grain to produce malabsorption of fats in celiac patients. Despite the lack of the more sophisticated approaches available today, early test results generally seem convincing. Currently, examination of mucosal biopsy specimens has become fairly common. When a flattened mucosa is found, with loss of villous structure, wheat and other harmful grains are removed from the diet to see if improvement follows. If it does, a subsequent challenge and biopsy to test for relapse may follow, although subsequent challenge has come to be reserved for special circumstances (Walker-Smith et al. 1990) because supporting antibody tests (tests for circulating antigliadin and antiendomysium antibodies) have lessened the likelihood of misdiagnosis (McMillan et al. 1991). In recent years, however, the situation has become more complicated through recognition that a flattened mucosa may actually be an extreme response and that there are many gluten-sensitive people who show less obvious evidence of the disease (Marsh 1992a). Circulating antigliadin antibodies may be indicative of celiac disease or at least a related gluten-sensitive condition in the absence of any evidence of mucosal changes, particularly when symptoms are present (O'Farrelly 1994).

Relatively few subjects were used in the testing of some grains or grain fractions in early work. This has been a continuing problem, resulting largely from the difficulties inherent in the requirement for human subjects in celiac disease research. It has become fairly clear that response to challenge may vary greatly from one patient to another and for a single patient over time. Furthermore, a considerably delayed response to challenge is not unusual, even when the challenge is with wheat, presumably the most toxic of the cereal grains (Egan-Mitchell, Fottrell, and McNicholl 1978; Walker-Smith, Kilby, and France 1978).

The variations in response known to occur might explain the opposing conclusions arrived at by various investigators regarding the harmful effects of oats. For example, Dicke, H. A. Weijers, and J. H. Van de Kamer (1953) asserted that oats are toxic, whereas W. Sheldon (1955) concluded that they are not. Part of the problem apparently arises from the relatively small proportion of avenins, the likely toxic fraction, in oat grain proteins (Peterson and Brinegar 1986): Avenins may make up only about 10 percent of the total protein in oats. Furthermore, when small numbers of subjects are involved, the average response of one group can be quite different from that of another. Because a negative response in one or a few patients might indicate only that the feeding time was too short, a clear positive response, as in the studies of oat protein toxicity by P. G. Baker and A. E. Read (1976), should perhaps be given more weight than a negative response, as in the study by A. S. Dissanayake, S. C. Truelove, and R. Whitehead (1974). The latter effort, however, included testing by intestinal biopsy – the more rigorous test – whereas the former did not.

A recent feeding trial using oats with 10 confirmed celiac patients produced no harmful effects as indicated by changes in mucosal architecture, endomysial antibody development, and infiltration of intraepithelial lymphocytes (Srinivasan et al. 1996). The relatively low percentage of avenins in oats may complicate this study in that a daily dosage of 50 grams (g) of oats was fed for 3 months. This would correspond to about 5 g of avenins per day. If 50 g of wheat had been fed instead, the patients would be eating at least 40 g of gliadins per day. Nevertheless, subsequent challenge of two of the patients with only 0.5 g of gluten per day produced evidence of intestinal damage. Thus, the toxicity of oats must be considered questionable on the basis of this latest study, as there are now two careful studies that showed no evidence of toxicity and only one study that was positive. It should also be emphasized that the supposedly positive study did not include biopsies.

In other cases, the test materials may not have been well defined. It is possible that the maize (corn) flour used in early testing was actually maize starch and relatively free of protein (Simoons 1981); the conclusion that maize proteins are not harmful may not have as rigorous a scientific base as is generally thought. There is, however, no obvious reason to question the apparent safety of maize.

A lack of sensitivity of the available testing methods, combined with inadequate test length, may have been responsible for the early conclusions that wheat starch is safe for celiac patients (Dicke et al. 1953). These conclusions, however, were challenged in later work (Ciclitira, Ellis, and Flagg 1984; Freedman et al. 1987a, 1987b; Skerritt and Hill 1990, 1991) as a consequence of the development of sensitive monoclonal antibody tests for gliadins (but also see Booth et al. 1991). Such tests have demonstrated the presence of small amounts of gliadins in wheat starch preparations, although the question of how harmful these small amounts may be to celiac patients is controversial (Ejderhamn, Veress, and Strandvik 1988; Hekkens and van Twist-de Graaf 1990; Campbell 1992).

It may be that rigorous scientific studies have proved toxicity in celiac disease only for wheat (and wheat proteins). To a considerable extent, conclusions regarding the toxicity of rye and barley – and, conversely, the lack of toxicity for rice and maize – are not based on an adequate amount of rigorous scientific testing. (Rigorous studies of oats are beginning to appear, and these support an absence of toxicity for this grain.)

Wheat Evolution

Wheat is a member of the grass family (Gramineae), as are the other grains – rye, barley, and oats – that are suspected of harming people with celiac disease. Of course, triticale, a cross between wheat and rye, is toxic, as would be expected for any other similar crosses that included genetic material from one or more of the toxic grains.

The grasses are a relatively recent evolutionary development. They are angiosperms, flowering plants, that developed somewhere between 100 and 200 million years ago (Cronquist 1968). Fossil evidence for grasses goes back only about 65 million years. They became widespread during the Oligocene epoch about 25 to 40 million years ago (Thomasson 1980), which, when it is considered that life has been evolving on earth for about 4 billion years, is a relatively short time. Cereal grains presumably evolved more recently within the time frame of grass evolution.

The ancestors of wheat, barley, and rye were diploid species with 7 chromosomes in the haploid state, or 14 chromosomes in vegetative cells. Barley first diverged from the common ancestral line, followed by rye. The line eventually gave rise to a series of diploid species that may be classed as *Triticum* species (Morris and Sears 1967). A natural cross occurred at some unknown time between two slightly diverged *Triticum* species, presumably *Triticum urartu* and *Triticum speltoides,* that gave rise to a new species through a process of polyploid formation in which chromosomes become doubled.

Without chromosome doubling, a cross between related species, such as those of *Triticum,* can take place, but the offspring is infertile because of a failure by the chromosomes to pair during meiosis. Polyploid formation occurs naturally, albeit rarely, perhaps through a process involving unreduced gametes (Harlan and de Wet 1975). This process can also be achieved in the laboratory through the use of chemicals (such as colchicine) that interfere with spindle formation to block chromosomal separation at anaphase. Either way, the result is a doubled set of chromosomes, a condition that allows for each original chromosome set to pair with its identical replicated set, thus avoiding the chromosome pairing problems that occur in crosses between species. The result of allopolyploid formation between *T. urartu* and *T. speltoides* was a new fertile species, called a tetraploid because it incorporated four sets of chromosomes in vegetative cells (designated AABB). Durum wheats (*Triticum turgidum* var. *durum*), used for pasta making, belong to one of the varietal groups of the AABB tetraploids.

Some time after wheat cultivation began, a tetraploid wheat crossed accidentally with a weed growing in the same field (*Triticum tauschii* var. *strangulata*), followed by chromosome doubling to give rise to a hexaploid species, which, because the genome of *T. tauschii* was designated D, had the composition AABBDD. Bread wheats (*Triticum aestivum* var. *aestivum*) produce a more elastic dough than durum wheats and have properties that lend themselves to the retention of gases produced during yeast fermentation (leavening) of doughs. It was in the context of the evolution of wheat and closely related species that proteins arose with amino acid sequences capable of initiating damage in persons with celiac disease.

Gluten Protein Evolution

The gluten proteins of wheat (a monocotyledonous plant) and certain closely related species – including rye, barley, and, with qualifications, oats – are unique among plant storage proteins in having exceptionally high proportions of the amino acids glutamine and proline. It was suggested (Kasarda 1980, 1981) that because of their unique composition, the extensive occurrence of repeating sequences based largely on glutamine and proline, and their occurrence only in recently evolved grass species, wheat prolamins are a late evolutionary development. Subsequently, with the development of molecular biological techniques, gene sequencing provided evidence of short amino acid sequences in most wheat prolamins, homologous to sequences found in storage globulins of more distantly related dicotyledonous plant species (Kreis et al. 1985). This discovery pushes the possible age of the ancestral genes back to within the period during which the flowering plants have existed – perhaps 100 million years.

However, repetitive sequences make up major parts of all gluten proteins, whereas the homologous sequences just mentioned occurred only in nonrepetitive regions. These repetitive sequences, having major proportions of glutamine and proline, apparently do not have counterparts in proteins of species outside the grass family. Accordingly, it seems likely that at least the repetitive domains of gluten proteins, which have slightly differing repeat motifs according to type, are of more recent (<~65 million years) origin. All of the various repeating sequences include glutamine and proline residues, and although the repeats are often imperfect, comparison allows a consensus repeating sequence to be recognized. It is at least possible that the most active (in celiac disease) peptides may result from variations on the themes represented by the consensus sequences, as a consequence of these imperfections, rather than from the consensus sequences themselves, but that remains to be established.

There is reasonably strong evidence that the peptides with sequences found in the repeat domain of alpha-gliadin are capable of triggering the intestinal damage characteristic of celiac disease. Furthermore, significant sequence similarities between gluten proteins and other proteins are rare. The first important similarity found was between alpha-gliadin and the E1b protein (Kagnoff et al. 1984), produced in conjunction with infection by adenovirus 12, which infects the human gastrointestinal tract. Recently, similarities have been found for peptides produced in conjunction with infection by other types of adenovirus (Lähdeaho et al. 1993).

The recent evolution of repeating sequence domains in gluten proteins through extensive duplication of the DNA codons (for glutamine and proline, along with a few other amino acids) corresponding to the repeat motifs may be the basis for the lack of homologies or similarities with other proteins. Most proteins do not have large amounts of glutamine and proline. Hence, the sequences active in celiac disease are likely to be confined to the grass family.

Fractionation of Wheat

Gluten

The wheat kernel is made up largely of the endosperm, the interior part of the grain, which constitutes about 85 percent of the kernel. In the milling process, the crushed kernels are fractionated by sieving. The crushed endosperm is the source of white flour, and the outer layers of the kernel yield the bran and germ fractions. Endosperm cells are largely made up of starch granules (about 75 percent) surrounded by a proteinaceous matrix. The proteins of this surrounding matrix are mainly storage proteins; upon germination of the seed, they are broken down to provide a source of nitrogen for use by the new plant. The storage proteins are to a large extent the same as the proteins of gluten, which contribute elasticity, yet at the same time extensibility, to flour–water doughs.

Gluten (Beccari 1745), prepared by washing away the starch granules from dough, constitutes the resulting cohesive, elastic mass of protein. It usually retains about 15 percent albumins and globulins, which are water- and salt-soluble proteins, respectively, according to the classification system of T. B. Osborne (1907). The remainder of the protein may be considered to constitute true gluten proteins, notable for their high percentages of two amino acids, glutamine and proline, which provided the basis for the name prolamins (Osborne 1907). Glutamine usually makes up 30 to 55 percent, and proline 15 to 30 percent, of the amino acids in gluten proteins. These two amino acids seem fairly certain to be included in the amino acid sequences of gluten proteins that are active in celiac disease.

The Meaning of "Gluten-Free"

Celiac patients, the physicians who treat them, and the various organizations that represent celiac patients usually indicate that a food safe for someone with celiac disease is "gluten-free." This use of the term "gluten" is sometimes confusing. Traditionally, gluten, as just mentioned, is the cohesive, elastic protein obtained when a wheat flour dough is kneaded in excess water to wash away the starch granules (Beccari 1745). The resultant gluten ball can only be obtained readily from wheat-flour doughs, with difficulty from rye, and probably not at all from barley or oats. Cereal chemists would not ordinarily refer to "rye gluten" or "barley gluten," let alone "oat gluten," but would refer specifically to the equivalent storage proteins in these grains (for example, the proteins equivalent to the gliadin proteins of wheat are called hordeins in barley, secalins in rye, and avenins in oats). The term gluten has become corrupted in recent times, however, occasionally being used in industry to refer to the protein residues from other grains. For example, when maize is separated into starch and protein fractions, the protein fraction is often referred to as "corn gluten."

What celiac patients wish to know about a food when they ask if it contains gluten is: Does it contain wheat, rye, barley, or oat proteins or any of the harmful peptides that are derived from the storage proteins of these grains during food processing or through the action of the digestive enzymes? Use of the term gluten-free is particularly awkward when applied to seeds of rather distantly related plants, such as the dicots amaranth and quinoa. These plants are not known to have proteins at all similar to gluten proteins. However, because quite small peptides of specific amino acid sequence may be active in celiac disease, it is not beyond possibility that equivalent sequences might occur in generally quite different proteins of distantly related species. Despite its ambiguities, the term gluten-free in relation to foods for celiac patients is already well established, and finding a satisfactory and short alternative may be difficult.

Digestion and Nutrient Absorption

Digestion of proteins commences in the stomach with partial denaturation (unfolding) of the large protein polypeptide chains by hydrochloric acid, which enhances their breakdown into smaller polypeptide chains by the proteolytic enzyme pepsin. In the highly acidic conditions of the stomach, pepsin is very active, cleaving a number of different peptide bonds. Breakdown of food proteins in the stomach is incomplete (Gray 1991), and relatively large peptides pass from the stomach into the duodenal part of the small intestine. Enzymes secreted by the pancreas – trypsin and carboxypeptidases – enter the interior (lumen) of the small intestine to continue digestion of proteins until they are broken down into amino acids or small peptides. Peptides this small are unlikely to be active in celiac disease.

Breakdown of proteins to amino acids or short peptides, both of which can be absorbed, is probably complete in the distal small bowel, even in celiac patients, as evidenced by a gradient of intestinal damage from the duodenum through the jejunum in active celiac disease. The ileum may remain free of tissue damage (Rubin et al. 1962). Instillation of wheat proteins into the ileum (Rubin et al. 1962) or the rectum (Dobbins and Rubin 1964; Loft, Marsh, and Crowe 1990) produces similar damage to that seen in the small intestine, indicating that the entire epithelial surface is susceptible to the damaging effects of wheat proteins or peptides. The final breakdown of food particles to relatively small molecules, and their active or passive absorption for use by the body, takes place at the membranes of cells lining the surface of the small intestine.

Almost all nutrients, ranging through amino acids, sugars, fatty acids, vitamins, and minerals are absorbed from the small intestine so that damage to this absorptive surface may have many manifestations in celiac disease. Obviously, a deficiency of calories from carbohydrates and fats and a deficiency of amino acids needed for protein synthesis can be responsible for a loss of weight or a failure to thrive, but the effects of malabsorption are often more diverse, ranging from osteoporosis in later life as a consequence of a failure to absorb calcium adequately to nerve degeneration as a consequence of a failure to absorb vitamins. The large intestine, or colon, extracts water and electrolytes from the food residues while bacterial action on these residues reduces the bulk of indigestible materials, such as cellulose. Relatively little absorption of nutrients occurs in the colon.

When intestinal biopsy was introduced in the 1950s, it was demonstrated that the surface of the intestinal mucosa in patients with active celiac disease appeared flattened as a consequence of the loss of villous structure and enhanced proliferation of immature cells in the crypts. Subsequently it was recognized that the microvilli of mature enterocytes were often damaged as well. Together, these losses significantly diminish the absorptive surface area and give rise to an increased crypt layer with an immature population of enterocytes having incompletely developed enzyme and transport activities. The net result is a diminished capability to absorb nutrients, although it should be noted that malabsorption may occur even in patients with little or no obvious damage to the epithelium.

It has been noted that initial responses to gluten challenge included infiltration by lymphocytes of the epithelium and lamina propria and thickening of the basement membrane and that these changes preceded major changes in mucosal structure (Shmerling and Shiner 1970; Marsh 1992a), providing strong support for the involvement of immunological processes in the destruction of the absorptive epithelium. A highly significant association of celiac disease with certain proteins of the major histocompatibility complex (histocompatibility antigens) also provides evidence for involvement of the immune system and a genetic predisposition to the disease. The inheritance of celiac disease appears to be complex, however, involving two or more genes (Strober 1992), and an environmental contribution, such as a viral infection or stress, may be necessary before the genetic predisposition comes into play (Kagnoff et al. 1984). What remains to be clarified is how these immune processes are triggered by gliadin peptides and how they ultimately result in the loss of epithelial absorptive cells.

Mechanisms of Tissue Damage

The way in which ingested gluten protein triggers events in the body that may ultimately bring about damage to the absorptive epithelium of the small intestine is unknown. The first important hypothesis put forward postulated that a key enzyme, a protease that could degrade proteins, was absent in celiac patients. As a consequence, certain harmful gliadin peptides that would, in the normal person, have been broken down and rendered harmless, continued to exist with a consequence of either direct toxicity on the absorptive epithelial cells or initiation of immune responses that secondarily damaged the epithelium (Cornell 1988). Although it is difficult to disprove this hypothesis beyond any reasonable doubt, no missing enzyme has ever been found despite considerable research effort to locate it. Furthermore, the likelihood that limited digestion of proteins in the stomach results in exposure of at least the proximal small intestine (duodenum) to fairly large peptides raises the question of why most people do not suffer some damage from such peptides.

The missing enzyme hypothesis was largely supplanted by the proposal that binding of gluten proteins or peptides to the enterocytes targeted them specifically for destruction and that enhanced proliferation of crypt cells, in response to destruction of the villous enterocytes, resulted in flattening of the mucosal surface, one of the major characteristics of advanced disease. Unfortunately, no evidence for the binding of gluten proteins or peptides to enterocytes in vivo has been found. The finding that enterocytes were capable of expressing MHC class II antigens that might be capable of presenting small gluten peptides of perhaps 10 to 20 amino acid residues to T cells raises the question of how effective the search for the binding of peptides to enterocytes has been, insofar as the methods used (often based on antibody probes produced in response to stimulation with intact proteins) were unlikely to recognize such small gluten peptides.

The strong correlation of celiac disease with particular class II histocompatibility antigens, which present peptides to T cells (lymphocytes), thereby activating them, has resulted in a currently favored hypothesis in which this presentation to T cells and binding of gliadin/gluten peptides to T cells is the initiating process that results in damage to the mucosal tissues, especially those underlying the epithelial cells (enterocytes). Binding of peptides by T cells may, however, activate a number of pathways, and beyond the activation step, the details of the hypothesis become rather vague.

Genes and Proteins of the Major Histocompatibility Complex

It is clear that there is an increased incidence of celiac disease in certain families, providing support for the hypothesis that there is a genetic predisposition to the disease. We continue to stress, however, that this predisposition may be insufficient for development of the disease without the intervention of some environmental factor – other than gluten proteins.

Celiac disease occurs in about 14 percent of siblings, 8 percent of parents, and 15 percent of children of celiac patients (Strober 1992). Although dizygotic (fraternal) twins do not show major differences from normal siblings in their tendency to develop celiac disease, monozygotic (identical) twins are about 70 percent concordant for the disease. The fact that 30 percent of the identical twins are discordant, with one having the disease and the other being free of it, is strong support for the necessary role of an environmental factor, such as viral infection (Kagnoff et al. 1984) or some other stressful event.

It was recognized in conjunction with attempts to transplant tissues from one individual to another, that certain protein antigens (human leukocyte antigens, or HLA molecules) had to be matched to avoid rejection of the foreign tissue. These proteins, now often called the proteins of the major histocompatibility complex (MHC proteins, MHC antigens), are coded by a cluster of genes on human chromosome 6. MHC proteins are cell-surface receptors, proteins that bind peptides at specific binding sites for presentation to a receptor site on T cells. The T-cell receptor must interact simultaneously with both the MHC molecule and the peptide presented by the MHC molecule before the presentation is recognized as a signal for the T cell to carry out some other function. An activated T cell might go on, for example, to activate B lymphocytes to produce antibodies, or it must suppress the normal immune response to antigens encountered as part of our food intake (development of oral tolerance). The latter function may be especially important because, presumably, in most people the immune response to gluten peptides has been suppressed, whereas in celiac patients, certain gluten peptides trigger an immune response capable of damaging the small intestine.

The MHC proteins of concern to us here are divided into class I and class II on the basis of a number of distinguishing characteristics, one of which is the type of cell on which they are expressed. Class I antigens appear on most cells, whereas class II antigens are found mainly on cells of the immune system, although class II antigens are expressed on the surfaces of enterocytes as well. The first demonstrations of associations between MHC proteins and celiac disease indicated that a class I antigen, designated HLA-B8, was found in nearly 90 percent of celiac patients but in only about 20 percent of controls (Falchuk, Rogentine, and Strober 1972). This antigen, HLA-8, was the genetic marker that, as was discussed earlier by Simoons, was thought to determine the incidence of celiac disease throughout the world.

However, subsequently it became clear that associations of celiac disease with class II antigens were even stronger than those of the class I antigen HLA-B8. Particularly strong associations have been found for the HLA class II alleles DR3 and DQ2. The association with HLA-B8 apparently resulted from linkage disequilibrium in which certain closely linked genes tend to remain associated during genetic recombinations to a greater extent than would be expected.

The associations of celiac disease with various MHC proteins observed throughout the world are quite complex (see reviews of Kagnoff 1992; Tighe and Ciclitira 1993), but they are sufficiently strong to make it seem likely that class II antigens are directly involved in the mechanisms responsible for tissue damage in celiac disease – possibly by presenting peptides derived from gluten proteins to T cells.

In support of the possibility that gliadin peptide binding by T cells is involved in celiac disease, K. E. A. Lundin and colleagues (1993) have found that T-cell lines derived from intestinal biopsies recognized gliadin peptides, and the cell lines were mainly stimulated by antigen presentation in the context of the DQ heterodimer. In addition, H. A. Gjertson, Lundin, and colleagues (1994) found that a peripheral blood lymphocyte clone from a celiac patient specifically recognized a synthetic peptide corresponding to alpha-gliadin residues 31-47. Further interest in the role of class II MHC proteins derives from studies showing that HLA-DR molecules, which are expressed by enterocytes of normal individuals or of celiac patients on a wheat-free diet (Arnaud-Battandier et al. 1986; Ciclitira et al. 1986), became differentially expressed in the crypt cells of celiac patients (but not in those of normal controls). This occurred when gluten proteins or peptides were added to biopsied tissues in culture that had been obtained from treated patients on a wheat-free diet (Fais et al. 1992).

W. Strober (1992) has pointed out that because discordance for celiac disease is much less common in identical twins than in siblings who have apparently identical complements of histocompatibility antigens (MHC proteins), it seems likely that the difference cannot be explained by an environmental factor because the contribution of environmental effects should have been about the same for the sets of twins and siblings. Strober considers this as strong evidence for a contribution by some non-MHC-defined disease gene. Whether or not this gene turns out to lie outside the MHC complex, celiac disease is likely to have a two-locus basis. D. A. Greenberg, S. E. Hodge, and J. I. Rotter (1982) considered that the available data fit best with a recessive-recessive two-gene model, but studies in the west of Ireland (Hernandez et al. 1991) favored dominance for the gene associated with the HLA locus. Conclusions may be somewhat dependent on the population studied, as many diseases show variation in their genetic basis.

Associated Diseases

Many different diseases have been reported to occur concurrently with celiac disease, including dermatitis herpetiformis, insulin-dependent diabetes, Down syndrome, IgA nephropathy, and epilepsy associated with cerebral calcifications (Bayless, Yardley, and Hendrix 1974; Gobbi et al. 1992; Collin and Maki 1994). In only a few diseases are statistically significant data available for the establishment of an association with celiac disease.

Dermatitis herpetiformis is a disease manifested by a rash with small blisters and IgA deposits even in uninvolved skin (Fry 1992). It is quite strongly associated with celiac disease. Intestinal lesions similar to those encountered in celiac disease are found upon biopsy of about two-thirds of patients with dermatitis herpetiformis, and a gluten-free diet usually improves both the skin rash and the intestinal lesions. Furthermore, even those patients without significant damage to the intestinal epithelium usually have an increased number of intraepithelial lymphocytes, and patients without obvious mucosal damage have developed such damage when their intake of gluten was increased. Nevertheless, malabsorption is much less common in dermatitis herpetiformis than in celiac disease (Kumar 1994). Indeed, the incidence is rather less than that of celiac disease, with dermatitis herpetiformis occurring about half as frequently as celiac disease in Sweden and perhaps one-fifth as frequently in Scotland (Edinburgh).

Insulin-dependent diabetes mellitus also shows a definite association with celiac disease. Between 5 and 10 percent of children with celiac disease have diabetes mellitus, whereas about 1 to 3 percent of children with diabetes mellitus have celiac disease (Visakorpi 1969; Strober 1992). Both celiac disease and insulin-dependent diabetes mellitus share an association with the histocompatibility antigen HLA-DR3 (Maki et al. 1984), and the common MHC gene(s) may predispose individuals carrying them to both conditions.

Down syndrome may be weakly associated with celiac disease. J. Dias and J. Walker-Smith (1988) found an increased incidence of Down syndrome in celiac patients compared with the incidence in the general population. They considered this as supporting evidence for earlier findings (Nowak, Ghisham, and Schulze-Delrieu 1983). M. Castro and colleagues (1993) have confirmed a significant increase in celiac disease among Down syndrome patients and found that antigliadin antibodies provide a useful screening tool to look for celiac disease among these patients. In addition, there are reports that patients with schizophrenia, autism, and IgA nephropathy have apparently benefited by removing wheat (and related harmful grains) from their diets, although such reports are not universally accepted as valid.

There have been extensive attempts to show a correlation between schizophrenia and celiac disease (Dohan 1966, 1988; Lorenz 1990), but the results have not been convincing. Evidence for intestinal damage in the group of schizophrenics studied by F. M. Stevens and colleagues (1977) was no greater than that for controls, and there was no significant increase in serum antireticulin antibodies. Both intestinal damage and antireticulin antibodies are usually present in celiac patients taking a normal (wheat-containing) diet. Nevertheless, published reports from physicians indicating that removal of wheat from the diet can produce a marked reduction in psychotic symptoms for some schizophrenics were considered sufficiently convincing by K. Lorenz (1990) to indicate that in at least a subset of schizophrenics, wheat has an adverse effect on the disease. Even in studies where no positive correlation was found, investigators noted that some patients did apparently show considerable improvement on a wheat-free ("gluten-free") diet (Rice, Ham, and Gore 1978).

Some celiac patients on a gluten-free diet, perhaps about 25 percent (Ansaldi et al. 1988), have indicated that they feel temporary psychological disturbance upon eating wheat, including symptoms such as irritability, hostility, depression, or a general feeling of mental unease. Although such symptoms may be "normal" in the face of physiological changes produced by eating wheat, investigation of a connection between such responses in celiac patients and the effects of wheat in the diet of carefully selected schizophrenics might be worthwhile. Again, even if wheat in the diet does adversely affect the course of schizophrenia, the mechanisms involved may be quite different from those involved in producing intestinal damage in celiac disease.

The role of wheat in autism is also controversial, but development of the hypothesis that wheat and casein exacerbate the symptoms of autistic patients parallels that for schizophrenia. The hypothesis is based so far on studies that indicate value for a wheat-free diet in improving behavior of patients with autism (Reichelt et al. 1991), although these studies are not well controlled because of the difficulties in carrying them out with patients who may not be able to supply informed consent. It has been discovered that amino acid sequences found in the primary structures of wheat gliadin proteins and casein proteins are similar to those of endorphins and other neuroactive peptides termed exorphins (Zioudrou, Streaty, and Klee 1979). It has been proposed that these, along with other neuroactive peptides from wheat, are responsible for the exacerbation of symptoms claimed for schizophrenic patients on a normal, wheat-containing diet (Zioudrou et al. 1979; Dohan 1988). This working hypothesis is also favored by some researchers investigating the possibility that wheat and casein proteins in the diet exacerbate symptoms in autistic patients (Reichelt et al. 1991). According to the hypothesis, food-protein-derived neuroactive peptides pass through the wall of the intestine and also pass the blood-brain barrier to affect brain function. This results in a variety of abnormal behaviors.

Abnormal peptide patterns appear in the urine of autistic subjects and schizophrenics (Cade et al. 1990; Shattock et al. 1990; Reichelt et al. 1991), and the hypothesis has been put forward that these abnormal patterns reflect to some extent the abnormal absorption and then excretion of exorphin peptides derived from wheat or milk proteins in the diet. This implies either excessive passage through the intestinal wall and/or a failure in some other way to process these peptides into harmless forms. However, that these abnormal urine peptide patterns truly represent excretion of peptides of dietary origin does not seem to have been proved.

IgA nephropathy is a kidney disease characterized by protein and blood in the urine and IgA deposits in the kidney (Stevens, Lavelle, et al. 1988). Although the severity is variable, the disease can lead to chronic renal failure. Reports of concurrence with celiac disease, the presence of circulating IgA antibodies to gluten proteins, and patient improvement (even with nonceliac patients) on a gluten-free diet have led to speculation that there may be a connection between the two diseases (Coppo et al. 1986; Sategna-Guidetti et al. 1992). It has been suggested that IgA nephropathy might be similar to dermatitis herpetiformis, with the main difference being that IgA deposits form in the kidney rather than in the skin. However, the evidence indicates that epithelial damage is uncommon in IgA nephropathy, although the activities of marker enzymes in the brush border were significantly lower (Stevens, Lavelle, 1988). Gliadin proteins or peptides have been found in complex with the IgA deposits in IgA nephropathy (Russel et al. 1986), and similar associations should be sought in dermatitis herpetiformis.

Celiac patients have been found to be at increased risk of developing certain types of cancer (Holmes et al. 1989; Logan et al. 1989; Holmes and Thompson 1992), especially small intestinal lymphoma. Nonetheless, the absolute risk of a celiac patient dying from this cancer is small because the incidence in the normal population is quite low.

G. K. T. Holmes and colleagues (1989) found in a study of 210 patients that those who had been on a strict gluten-free diet for more than 5 years did not have significantly increased risk of developing lymphoma. But the risk of developing lymphoma was reported to be high (1 in 10) for celiac patients who were diagnosed late in life (over the age of 50). The investigators did not discuss what constituted a "strict gluten-free diet," and J. A. Campbell (1992) has pointed out that it would not have been unusual for patients who thought themselves to be on a strict gluten-free diet to be using products containing wheat starch, which has a small amount of gluten in it. It seems prudent for celiac patients to follow a strict gluten-free diet as recommended by Holmes and colleagues (1989), but whether traces of gluten in the diet, such as might result from use of wheat-starch products, contribute to the development of malignancies late in life does not appear to have been established.

Conclusion

Human evolution has produced a complex immune system designed to protect us from harmful parasites, bacteria, viruses, and foreign substances. Human cultural development has led to a dependence on agriculture, and in a large part of the world, a heavy dependence on wheat and related grain crops as part of that agriculture. The proteins of these grain crops have evolved in a somewhat isolated manner (in part because they are recently evolved) such that particular amino acid sequences have appeared in these proteins that can induce the immune system in a susceptible subset of people into damaging the absorptive layer of cells lining the small intestine. The mechanisms are not very well understood, but they seem to involve a failure of the suppression mechanisms by which oral tolerance to food-protein antigens is developed in normal individuals.

IV.E.3 ~ Food Allergies

Adverse Food Reactions and Allergies

An adverse food reaction is defined as any untoward reaction following the ingestion of food (Lifshitz 1988). These reactions generally fall into two categories: food intolerance and food hypersensitivity. Intolerances are nonimmunologic (Sampson and Cooke 1990) and are responsible for most adverse food reactions. They may be idiosyncratic, due to metabolic disorders, or caused by pharmacological substances such as toxins or drugs present in food. Food additives can also be a cause of food intolerance or hypersensitivity and can produce respiratory and gastrointestinal complaints (Lifshitz 1988).

True food hypersensitivity, or allergy, is an adverse food reaction involving immunologic mechanisms. It is initiated by production of specific antibodies, otherwise known as immunoglobulins, in reaction to food constituents. The body manufactures antibodies as part of its regular defense system against foreign invaders such as viruses and bacteria. In certain individuals, the immune system is triggered to elicit a specific antibody, called immunoglobulin E (IgE), against various environmental substances like pollens, pet dander, insect venoms, and foods. The common immunologic mechanisms involved can cause food-allergic reactions to resemble allergic reactions to honeybee stings or penicillin.

Mechanism

In food-allergic individuals, IgE antibodies are produced against food components and circulate in the blood. Upon reaching certain cells, known as mast cells and basophils, the IgE becomes fixed to the cell surface and remains there. These cells contain high quantities of special receptors for IgE; rat mast cells have been found to contain 2-5 × 10^5 receptors per cell (Mendoza and Metzger 1976). A large portion of the IgE in the body is fixed to these cells, and when they become armed with IgE, they are said to be "sensitized."

Mast cells are present in many tissues of the body, and basophils are present in the blood. When certain food components, or allergens, are ingested and circulate in the blood, they come in contact with the IgE bound to the mast cell or basophil surface. This contact causes a chain of events to occur in the cells, leading to the release of granules containing certain mediators that are responsible for the clinical manifestations of the allergic reaction. This immediate allergic reaction is classified as a Type I hypersensitivity reaction according to the Gell and Coombs classification (Coombs and Gell 1975). Most food-allergic reactions are of this type (Moneret-Vautrin 1986), although other mechanisms have been shown to be responsible in some cases (Chandra and Shah 1984).

The substances released from the cells include histamine and serotonin, but many other mediators are also released (Barrett and Metcalfe 1988). The major influences of these mediators are vasodilation, smooth muscle contraction, and a general increase in vascular permeability.

A small amount of any food protein remains undigested and passes through the gut wall and into the circulatory system (Steinmann, Wottge, and Muller-Ruchholz 1990). During the neonatal period the gastrointestinal barrier to protein uptake and transport is immature. Therefore, excessive amounts of food proteins may be transported into the circulatory system. In addition, it is possible that a large quantity of protein is not broken down intracellularly due to immature cell function. During this period, infants may become sensitized to ingested allergens; and later, when the mucosal barrier is mature, small amounts of allergen absorbed by the gut can cause a reaction.

It has been suggested that food-allergic reactions are caused by pathologically increased gut permeability (Sampson 1990a); this claim has been refuted by studies with cow's milk–allergic children in which the gut was not shown to be more permeable than in control children (Walker 1984; Powell et al. 1989). However, the permeability of the gastrointestinal barrier does increase following mast cell activation, thereby allowing more allergen through the barrier and, perhaps, increasing the allergic response (Barrett and Metcalfe 1988).

Mast cells located on the mucous surfaces of the gastrointestinal tract are thought to play a major role in IgE-mediated food hypersensitivity reactions (Barrett and Metcalfe 1988). The gastrointestinal tract contains comparatively large numbers of mast cells – for example, the human duodenum contains 20,000 per cubic millimeter (Norris, Zamchek, and Gottlieb 1962), whereas human skin contains 7,000 per cubic millimeter (Mikhail and Miller-Milinska 1964).

Food allergy can develop only if the allergen crosses the gastrointestinal barrier. The clinical manifestations of food allergy depend on the transport of allergens across the barrier, giving rise either to local allergic reactions or, from the systemic circulation, to systemic responses. Penetration of the gut depends on the size and structure of the allergen, changes occurring as a result of digestion, gut permeability (depending on age and preexisting disease), and interaction with other antibodies located in the gut. More factors to be considered are individual responses to various amounts of allergen, sufficient IgE binding at the mast cell or basophil, and the susceptibility of the affected organs to the mediators that are released.

Symptoms

Clinical manifestations of mediator release depend on the part of the body that is affected. Table IV.E.3.1 lists symptoms associated with food-allergic reactions. The most common manifestations are gastrointestinal, dermal, and respiratory (Sampson and Cooke 1990), and they represent contact of allergen with populations of sensitized mast cells present in the affected tissues.

Gastrointestinal symptoms, including nausea and vomiting, cramping, abdominal distension, flatulence, and diarrhea, are especially frequent in infants and young children (Barrett and Metcalfe 1988). Chronic ingestion of offending foods by sensitive people may cause fecal blood loss, malabsorption, and other long-term manifestations (Buckley and Metcalfe 1982). Skin reactions to food allergens in such individuals can include pruritus, edema of the lips, tongue, gums, oral mucosa, and pharynx. Urticaria (hives) is the most common skin manifestation and can be diffuse or localized.

Table IV.E.3.1. *Symptoms of food allergy*

Gastrointestinal	Respiratory	Cutaneous
Abdominal cramps	Asthma	Urticaria
Diarrhea	Laryngeal edema	Angioedema
Nausea	Rhinitis	Atopic dermatitis
Vomiting	Wheezing	

The reactions are very individualistic and diverse (Collins-Williams and Levy 1984). Initially, some individuals may experience immediate contact reactions on their lips and tongue, whereas others do not experience a reaction until the offending food has moved farther down the gastrointestinal tract.

Respiratory symptoms can be divided into two categories: upper airway distress, which in food-allergic reactions is usually caused by laryngeal edema, and middle airway distress, produced as a consequence of bronchoconstriction, with resulting edema and pulmonary mucus production (Collins-Williams and Levy 1984). Respiratory symptoms are infrequent with food allergies, although asthma has been associated with allergies to cow's milk, soybeans, and peanuts (Minford, MacDonald, and Littlewood 1982; Chiaramonte and Rao 1988).

Atopic dermatitis, a chronic inflammatory skin disease, is characterized by dry, easily irritated, intensely pruritic skin. The role of food hypersensitivity in atopic dermatitis has been debated for decades (Burks et al. 1988). IgE-mediated reactions to foods may contribute to the pathogenesis of atopic dermatitis (Sampson and McCaskill 1985); A. W. Burks and coworkers (1988) reported that 96 percent of atopic dermatitis subjects examined in their study developed skin reactions after food challenge.

Anaphylactic shock is a rare, acute, and potentially fatal form of food-allergic response. It is a generalized vasodilation triggered by significant mast cell degranulation and can involve a number of organ systems. If the cardiovascular system is affected, shock and low cardiac output result, and involvement of the respiratory tract can induce bronchospasm, pulmonary edema, and laryngeal edema. In food-induced anaphylactic shock, the gastrointestinal tract can respond with abdominal cramping and vomiting. Anaphylactic reactions may advance rapidly, beginning with mild symptoms that can progress to cardiorespiratory arrest and shock over a one- to three-hour period.

For example, an individual experiencing an anaphylactic food-allergic reaction may notice tongue itching and swelling, or palatal itching at first, then throat tightening, perhaps followed by wheezing and cyanosis. Chest pain and urticaria may be noted, and the individual may have gastrointestinal symptoms such as abdominal pain, vomiting, or diarrhea. A progression of symptoms can lead to potentially life-threatening hypotension and shock.

As there are no official means of reporting anaphylactic episodes, the actual frequency of these reactions is unknown, although J. W. Yunginger and colleagues at the Mayo Clinic (1988) documented 8 cases of fatal food-induced anaphylaxis in a period of 16 months. Exercise-induced food anaphylaxis is a type of reaction that develops during or shortly after exercise following the ingestion of certain foods. In documented cases, exercise most often occurred within 2 hours of ingestion. The foods implicated have included celery, lentils, peaches, shellfish, and wheat. Neither exercise alone nor food alone were sufficient to induce anaphylaxis (Maulitz, Pratt, and Schocket, 1979; Buchbinder et al. 1983; Kushimoto and Aoki 1985; Silverstein et al. 1986).

Symptoms of food-induced anaphylaxis may include cutaneous erythema, itching, and urticaria, which can progress to vascular collapse or upper respiratory obstruction (Schocket 1991). The pathophysiological mechanism of these reactions has not been elucidated, but heightened mast cell responsiveness to physical stimuli may be involved (Sheffer et al. 1983). It has been shown that avoidance of the offending food 8 to 12 hours prior to exercise usually eliminates difficulties.

Incidence and Natural History

The incidence of true food allergy is probably less than the general population perceives. Although studies have shown that at least one in four adults with allergies believe that they have experienced adverse reactions following ingestion or handling of foods (Sampson and Metcalfe 1992), it is estimated that just 2 to 3 percent (Bock 1987; Sampson and Cooke 1990) of the pediatric population and 1 to 2 percent of the adult population suffer from allergic reactions to food (Sampson and Cooke 1990). The true prevalence is unknown, however, and other estimates range from 0.3 to 10 percent of the total population (Taylor 1980; Johnstone 1981; Taylor 1985; Barrett and Metcalfe 1988; Schreiber and Walker 1989).

Food allergy is also influenced by culture and eating habits. For example, allergies to fish are more common in Japan and Norway than elsewhere because consumption of fish is higher in those countries (Aas 1966). The frequency of food hypersensitivity varies by ethnic group and socioeconomic class (Lieberman and Barnes 1990). Its etiology includes many factors, but genetics seem to play a large role. Studies with children have shown that the risk for allergy with one allergic parent is approximately 50 percent and for bilateral parental allergy 67 to 100 percent (Schatz et al. 1983).

Frequency of food allergy is highest in infancy and early childhood and diminishes with increasing age (Collins-Williams and Levy 1984). It is most prevalent between 1.5 and 3 years of age (Kjellman 1991). Although young children appear more likely to outgrow their food allergies, older children and adults may also lose their sensitivity if the offending food is removed from the diet. Investigations have shown that one-third of children and adults lose their clinical reactivity after one to two years of allergen avoidance (Sampson and Scanlon 1989).

Differences in disappearance rates depend on the allergen and the individual; for example, many children with allergy to cow's milk can tolerate small amounts of milk by the time they are 3 years old, and egg allergy tends to decline before age 7. But allergies to nuts, legumes, fish, and shellfish tend to remain a problem for a much longer time (Bock 1982; Collins-Williams and Levy 1984).

Although exposure to food allergens can occur in utero through placental passage, most studies have shown that prenatal sensitization to food is infrequent (Halpern et al. 1973; Croner et al. 1982; Hamburger et al. 1983; Kjellman and Croner 1984). However, the case of an infant with strong skin-test reactivity to wheat and milk at the age of 5 hours has been reported (Kaufman 1971). Some fully breast-fed infants have been observed to have allergies to egg and cow's milk (Warner et al. 1980), and significant amounts of cow's milk casein have been detected in breast milk for up to 12 hours after maternal ingestion (Stuart et al. 1984).

There have been a number of studies on breast feeding to determine what benefit it might have in preventing food sensitization (Halpern et al. 1973; Saarinen et al. 1979; Juto and Bjorkstein 1980; Hide and Guyer 1981; Buscino et al. 1983). The results are conflicting, and the only consistent observation is that prolonged breast feeding (greater than four months and preferably six) and delayed introduction of solid food seem to be beneficial in the prevention of food allergy (Zeiger 1988). Breast feeding and maternal avoidance of common allergenic foods is suggested if there is a family history of allergy and a high serum IgE level at birth (Michel et al. 1980).

Causative Agents

Traditional Foods

The most commonly implicated foods in food allergy are listed in Table IV.E.3.2. The allergenic substances are usually proteins (Aas 1978b). Adults tend to be allergic to shellfish, legumes (especially peanuts), crustacea, tree nuts, and wheat (Bock and Atkins 1990; Sampson 1990a; Sampson and Cooke 1990). Children tend to be allergic to milk and eggs more frequently. Any food, however, has the potential to cause an IgE-mediated reaction. Very severe reactions are most often seen with peanuts, eggs, fish, and nuts (Collins-Williams and Levy 1984). In fact, peanuts are the most common cause of life-threatening reactions (Sampson 1990b). In a period of 16 months, a

Table IV.E.3.2. *Common allergenic foods*

Cow's milk
Crustacea – shrimp, crab, lobster
Eggs
Fish
Legumes – peanuts and soybeans
Shellfish – clams, oysters, scallops
Tree nuts
Wheat

research team at the Mayo Clinic reported 4 cases of death due to peanut-induced anaphylactic shock (Yunginger et al. 1988).

With the widespread introduction of new and "exotic" foods into our diets, it is anticipated that newly described allergic reactions will be reported. D. A. Moneret-Vautrin (1986), for example, has noted that with the relatively recent introduction of soybeans to the diet in France, the incidence of observed soybean allergy has increased to the point where it has become the third most common food allergy. Another example is kiwi fruit, which is not indigenous to the United States and became available as a result of importation in the 1980s. Following its introduction, allergic reactions to kiwi fruit were suddenly reported (Fine 1981; Fallier 1983).

Genetically Engineered Foods

Some concerns are being raised regarding nontraditional foods produced using genetic engineering techniques. These techniques allow for the fast and easy transfer of proteins from one food into another and for increased nutritional or other benefits, such as viral resistance. But there also is the potential for allergenic proteins from some foods to be transferred into other foods; how or whether these foods should be labeled is still being debated. Another compelling issue is whether genetic engineering techniques could potentially change the protein structure so that it could become allergenic once transferred and reproduced in the engineered food. The United States Food and Drug Administration has been and will continue to be working on policies governing the regulation of bioengineered foods, with allergenicity a key issue (Kessler et al. 1992).

Food Allergens

Most allergenic foods contain multiple allergens. For example, egg white is a complex mixture of at least 20 proteins, of which 5 or 6 are allergenic (Langeland 1982). The existence of multiple allergens in cow's milk (Goldman 1963; Bleumink and Young 1968) and peanuts (Barnett, Baldo, and Howden 1983) is well known. Most major food allergens range from 14 to 70 kilodaltons (1,000 atomic mass units) in molecular weight (Aas 1976; King 1976; Chiaramonte and Rao 1988). The upper molecular size observed for these allergens may be due to the permeability limits involved in the gastrointestinal barrier of the host. The allergen must be of adequate molecular intricacy to interact with the elements of the immune system, but quite low limits of molecular size exist; for example, small fragments of the codfish allergen, 6,500 and 8,500 daltons in size, possess pronounced allergenic activity (Elsayad et al. 1972). T. Ishizaka and K. Ishizaka (1984) have shown that the release of mast cell mediators depends on the bridging of two cell-fixed IgE molecules by the allergen. If such bridging is critical, the allergic response should, in fact, depend on the number of allergenic determinants and their distribution on the surface of the allergen and not necessarily their size.

Common food allergens that have been fully or partially purified or characterized include codfish (Elsayad and Aas 1971), cow's milk (Goldman et al. 1963; Bleumink and Young 1968), eggs (Anet et al. 1985), peanuts (Barnett and Howden 1986; Burks et al. 1991; Burks et al. 1992), soybeans (Shibaski et al. 1980; Herian, Taylor, and Bush 1990), and shrimp (Hoffman, Day, and Miller 1981; Daul et al. 1992).

Most common allergenic food proteins appear to be heat-stable and resistant to proteolytic processes, such as peanut, shrimp, and codfish allergens, although many lose their allergenic activity during digestion or cooking (Aas 1984). Therefore, the allergenicity of a food may be influenced by the way in which the food is prepared, processed, or stored. For example, ovalbumin, the third most important allergen of eggs, is moderately heat-labile and is found only in small amounts in cooked egg (Hoffman 1979). Similarly, heating denatures some cow's milk allergens and makes them less allergenic (Bahna and Gandhi 1983). Individuals allergic to fresh fruits and vegetables can often tolerate these foods after they are cooked, canned, or frozen (Hannuksela and Lahti 1977; Eriksson 1978).

Cross-Reactivity

When a sensitive individual produces IgE antibodies directed against a certain food component and then encounters another food with similar components, an allergic response may occur. Structural allergenic similarities may exist within families of biologically related foods. Since dietary elimination of the offending food is the only "tried-and-true" method of preventing an allergic reaction, cross-allergenicity among related foods is of concern to allergists and patients. Food-allergic individuals often report cross-reactivity among other foods in the same families and are cautioned to avoid eating other closely related foods.

The most common food families associated with cross-reactions are fish, citrus fruits, legumes, shellfish, mollusks, and crustaceans (Chiaramonte and Rao 1988). Certain allergens are also apparently common to both foods and pollens. Common allergens have been reported in melon, banana, and ragweed pollen (Anderson et al. 1970), celery and mugwort pollen (Pauli et al. 1985), and apple and birch pollen (Lahti, Bjorkstein, and Hannuksela 1980).

"True" clinical cross-reactivity, however, is often difficult to establish without performing oral challenge studies. Reports in the literature seem to indicate that the occurrence of clinical cross-reaction is infrequent (Bock 1991). Extensive in vitro "allergenic cross-reactivity" (binding of IgE antibody that is specific for a different food allergen) has been documented. For example, D. Barnett, B. Bonham, and M. E. H. Howden

(1987) found that 25 percent of sera from legume-sensitive patients reacted strongly with peanut, garden pea, soybean, and chickpea extracts. Another research team also found extensive in vitro cross-allergenicity with peanuts, soybeans, peas, and lima beans in patients with legume sensitivity (Bernhisel-Broadbent, Taylor, and Sampson 1989).

However, an earlier study by the same researchers indicated that clinical results and in vitro results did not correlate well in evaluating allergenic cross-reactivity in the legume family (Bernhisel-Broadbent and Sampson 1989). Fifty-nine percent of skin-test-positive patients reacted to oral challenge, but only (approximately) 3 percent reacted in oral challenges to more than one legume. These studies show that although IgE antibodies can cross-react with related foods and cause positive skin tests in some cases, clinical manifestations are rare, and being allergic to one food does not necessarily rule out the consumption of biologically related foods.

Occupational Food Allergy

Development of allergic disease can be associated with occupational exposure to food proteins, and most occupational sensitizing agents are food-derived protein allergens (O'Neil and Lehrer 1991). Exposure is facilitated through inhalation and contact, and syndromes include occupational asthma, hypersensitivity pneumonitis, and skin reactions, including contact dermatitis and contact urticaria.

But although allergen levels in the workplace can be very high, only a small percentage of exposed workers develop occupational responses, suggesting that host factors play an influential role. For example, a history of allergy seems to influence development of sensitivity in some instances of occupational allergic disease, such as occupational asthma caused by exposure to green coffee beans (Jones et al. 1982). By contrast, however, family or individual history of allergy has not been shown to be a factor in the development of occupational asthma due to exposure to snow crab (Cartier et al. 1984).

Although the pathophysiology of many occupational food reactions has not been ascertained, the role of IgE in occupational asthma in bakers is well known (Hendrick, Davies, and Pepys 1976; Block et al. 1983). Most occupational allergens that are also foods have not been shown to induce symptoms following ingestion by workers sensitized via inhalation. Occupational asthma related to food products has been most often associated with seafood, eggs, grains, spices, herbs, coffee, tea, and mushrooms, whereas hypersensitivity pneumonitis, although low in occurrence, has been associated with molds used in cheese production, poultry proteins, fish meal, and mushroom spores. Dermatological reactions precipitated by food have been most often linked with fish, seafood, mustard, garlic, onion, cashews, and lettuce.

Diagnosis of Food Allergy

The diagnosis of food allergy is complicated. As we have seen, adverse food reactions can be caused by immunologic, nonimmunologic, and unknown factors (Hawrylko and Murali 1988). Substantiation of food allergy involves meticulous medical evaluation, since self-diagnosis is often unreliable. Elimination diets are frequently the initial approach to diagnosis of food allergy. The suspected offending food is first eliminated for two to four weeks, then reintroduced in small quantities and the patient's response is recorded (Cummings and Bock 1988).

Skin Testing

Skin testing is the most popular diagnostic tool for evaluating food allergy. It was first used in 1966 to identify children allergic to codfish (Aas 1966). The techniques for skin tests are varied and include puncture, prick, scratch, and intradermal methods. A positive response results in a skin reaction forming a "wheal-and-flare." Results are recorded by measuring the wheal-and-flare diameter and comparing them to negative (saline solution) and positive (histamine) controls. Clinically significant wheals are 3 millimeters or more in diameter (Cummings and Bock 1988). But the use of skin testing is precluded in the face of anaphylactic or other severe reactions, as well as generalized dermatitis, and positive skin tests may be inhibited by the use of some medications, especially certain antihistamines and drugs with antihistamine effects (Chodirker 1985).

A major problem with skin testing is that food allergen extracts have not been standardized. Food skin-test extracts are usually crude preparations of unknown composition, and accurate diagnosis of food allergy has, in part, been impeded by the lack of standardized extracts. This may ultimately be responsible for the variability in the predictive accuracy of food skin tests. H. A. Sampson (1988), for example, compared extracts from three commercial firms for their positive predictive accuracy against oral-food-challenge results and discovered that they ranged from 0 to 79 percent. Negative predictive accuracies were much better, ranging from 85 to 100 percent. C. Ortolani and co-workers (1989) found that skin-test extracts prepared with fresh foods produced more sensitive results when compared to commercial extracts. As an increasing number of food allergens are isolated and fully characterized, the potential for use of standardized food extracts increases.

Double-Blind, Placebo-Controlled Food Challenge

The double-blind, placebo-controlled food challenge (DBPCFC), in which a suspected offending food or placebo is administered in capsules or masked in other food, has been called the "gold standard" for the diagnosis of food allergy (Collins-Williams and Levy

1984; Cummings and Bock 1988; Sampson 1988; Bock 1991). This method was initially used in the investigation of immediate hypersensitivity reactions to foods in asthmatic children (May 1976). But S. A. Bock and F. M. Atkins (1990) recently reported a study of a group of food-allergic children over a period of 16 years. Fully 39 percent had positive DBPCFC results. Other investigators have reported good correlation of DBPCFC results with other laboratory methods for diagnosing food allergy (Bernstein, Day, and Welsh 1982; Sampson 1988; Parker et al. 1990).

Although controversy exists regarding the use of skin tests alone for diagnosis (Bernstein, Day, and Welsh 1982; Bock and Atkins 1990), some investigators have found good correlation between food-challenge studies and skin-test results. For example, one such study, which focused on a group of adults with histories of immediate adverse reactions to foods, discovered that 90 percent of those in the group who were food-challenge-positive were also skin-test-positive (Atkins, Steinberg, and Metcalfe 1985). Similarly, Bock and Atkins (1990) noted that 98 percent of positive food reactions to oral challenge were accompanied by a positive skin test in children past their third birthday. But in younger children the correlation dropped to 83 percent.

Nonetheless, other investigators have found false-positive skin tests in patients who were food-challenge-negative (Bernstein et al. 1982; Sampson and Albergo 1984). In general, a negative skin-test result is a good indicator of absence of IgE-mediated hypersensitivity (Sampson 1988; Parker et al. 1990).

Radioallergosorbent Assay

The first assay developed for measuring IgE blood levels was the radioallergosorbent assay (RAST), which was initially described in 1967 (Wide, Bennich, and Johansson 1967). RAST is specific and reproducible (Hawrylko and Murali 1988); however, it measures only circulating, and not tissue-bound, IgE. For this reason, it is less sensitive than skin tests for the detection of specific IgE. In addition, a RAST test is not necessary if the skin test is negative, as circulating IgE will not be present if there is no tissue-bound IgE (May 1976; Sampson and Albergo 1984; Chodirker 1985; Bock and Atkins 1990). Generally, sensitivity of RAST for food allergens varies from 50 percent to more than 90 percent (May 1976). RAST is still widely used in the allergy field to augment skin testing in diagnosis. Sensitivity of RAST for food allergens could be improved, as could skin-test reliability, if there were technical advances in the purification of food allergens.

Basophil Histamine Release

In this technique, blood basophils are obtained from an allergic patient. They are incubated with an allergen for a specified time, and the release of mediating histamine, caused by the presence of the allergen, is measured (May et al. 1970; Hirsch and Zastrow 1972). In one study employing purified cow's milk proteins, wheat, soybean, and ovalbumin extracts, release of histamine from cells was found in 25 to 50 percent of pediatric subjects who also had positive skin tests, and no histamine was released in skin-test-negative patients (May and Alberto 1972).

In another study, however, food extracts did not induce release of histamine in patients with food allergy (Dockhorn 1969). H. Nolte and colleagues (1989), using gut mast cells obtained during biopsies of food-allergic patients, found that histamine release from intestinal mast cells could not be correlated with histamine release by blood basophils. Therefore, there are differences in the ability of food extracts to elicit a response in mast cells from different organs.

As with other diagnostic allergy assays, the sensitivity of the basophil histamine release assay could probably be improved by the use of purified food-allergen preparations. In addition, the technique is neither convenient nor easy to perform and, therefore, is not used widely for diagnosis.

Treatment and Prevention of Food Allergy

Elimination Diets

Elimination diets are the only proven effective therapy for food allergy, once the offending food is identified (Chodirker 1985; Schreiber and Walker 1989). In patients with severe reactions to foods, strict avoidance is indicated, which may include cross-reacting foods, prepared foods (unless one is absolutely certain of all ingredients), and the inhalation of aerosols of the implicated food (Rao and Bahna 1988).

Despite the apparent low incidence of clinical cross-reactivity, food-allergic persons are encouraged to use caution when eating a biologically related food for the first time. The recommendation is usually to avoid the offending food for a number of years, if not for the remainder of the patient's life. However, this advice may be adjusted for children, as they tend to outgrow certain food allergies, such as those to eggs and milk.

Avoidance

Food-allergic individuals must read food labels and ingredient listings diligently, as these usually reveal the presence of the offending ingredient. This task can be difficult, and a certain amount of "education" in reading labels is necessary, because particular terms used by food processors can camouflage the presence of allergenic proteins. "Natural flavorings" may include soybean and/or milk proteins, and "caramel flavoring" may contain milk proteins. "Hydrogenated vegetable protein" commonly contains soybean proteins but can be comprised of other types of vegetable protein. In addition, it can be difficult to identify and avoid some types of allergenic foods. An example is peanuts, which after pressing and deflavoring, are then reflavored and sold as other types of nuts, such as almonds. Though they smell, taste, and look like tree nuts, these deflavored peanuts have been found to retain their allergenic qualities (Nordlee et al. 1981) and can pose a serious threat to unsuspecting peanut-allergic people.

Sensitive individuals may also be inadvertently exposed to foods contaminated with allergenic proteins during processing. In one documented case, for example, the inadequate cleaning of common equipment caused sunflower butter to become contaminated with peanut butter and elicited an allergic reaction in a peanut-sensitive patient (Yunginger et al. 1983).

Antihistamines

Antihistamines have been suggested for use in children with mild food allergies before mealtime (Bahna and Furukawa 1983). However, since antihistamines work by competitive inhibition (Furukawa 1988), they cannot completely prevent allergic reactions, and individuals with severe reactions should not rely on them.

Perspective on the Development of Allergy

Allergic disease is difficult to trace in archaeological or historical records. Evidence of foods or medicines used in the past is very limited (Lieberman and Barnes 1990), and the symptoms of allergy can mimic those of other diseases, thereby concealing accounts of allergic reactions in records and notes.

It has been theorized that allergy is a fairly recent development in the history of the human race. A prominent characteristic of parasitic infections in humans is an elevated level of IgE (Johansson, Bennich, and Berg 1972). But because parasitic infections and allergic disease seem to be mutually exclusive (Merrett, Merrett, and Cookson 1976), allergy could be the result of an ecological transition from endemic parasitosis to improved sanitary conditions that eliminate or reduce parasitic exposure (Lieberman and Barnes 1990). An interesting discovery is a higher frequency of allergies among urban than rural residents in developing countries, but higher IgE levels in rural people than among urban asthmatics and individuals with allergies (Godfrey 1975; Merrett et al. 1976). The advent of modern, hygienic conditions and the elimination of parasitic infection could, therefore, be responsible for spawning production of IgE against other substances in our environment.

IV.E.4 Food-Borne Infection

Numerous infectious diseases are acquired by the ingestion of contaminated food, milk, or water. Such illnesses have a worldwide distribution, although, predictably, the incidence is greatest in those countries where deficiencies exist in the provision of adequate sanitation and hygiene.

Yet outbreaks of food poisoning and other food-borne infections occur with frequency even in the most developed countries of the world. Here increasing demand for vast quantities of readily available food has been met by increased reliance on intensive farming techniques, industrialization of food production, introduction of various methods for preservation, and expanding networks for transport, storage, and distribution.

Many of the stages involved in the commercial processing and production of food provide ideal opportunities for the entry, maintenance, and multiplication of microbes. Consequently, several outbreaks of food-borne infection occur each year in developed nations, with the size of the outbreak reflecting the extent of the distribution of the product. Containment measures rely heavily upon early diagnosis and close cooperation between clinicians, medical microbiologists, and officials of public-health departments and are aimed at rapid detection of the source of infection and prompt action to curtail the outbreak. The measures taken must include immediate withdrawal of the incriminated article of food from sale to the public, dissemination of clearly worded information to consumers defining the source and mode of spread of the infection, and – where appropriate – guidelines on methods of preventing cross-infection between individuals.

Outbreaks of food-borne diseases occurring in Britain in recent years have included (1) salmonellosis spread via infected poultry meat, powdered baby milk, hens' eggs, imported chocolates, and spaghetti; (2) *Escherichia coli* infection transmitted through hamburger meat; (3) botulism from yoghurt that was flavored with contaminated hazelnut puree; and (4) listeriosis from soft cheeses. Recognition of the phenomenal cost entailed in the investigation and control of such outbreaks has led to a heightened awareness of the need for effective measures to curtail the incidence of food-borne diseases. Accordingly, recommendations have been formulated for improving the microbiological quality of food. However, the subject is a complex one and problems continue to arise.

Natural History of Infection

Food and water may transmit infectious diseases when they contain critical numbers of live pathogenic microorganisms that are adapted to invade and colonize the body of the victim through the gastrointestinal tract (see Table IV.E.4.1). Typhoid fever and viral hepatitis are typical examples of such diseases. In some cases the mere presence in food of products of microbial growth, such as toxins, is sufficient to induce disease even though the microbes themselves may have been destroyed. These microbial toxins are relatively heat-stable, retaining their activity even after the food has been heated before consumption, as, for example, staphylococcal enterotoxin and botulinum toxin. Strictly speaking, these are examples of food-borne intoxications in contrast to infections, but it is customary among microbiologists to include them under the rubric of infections.

A characteristic feature of food-borne infection is that, in general, the food concerned looks and tastes appetizing, with no obvious signs of spoilage. This is because the large numbers of bacteria required to cause symptoms in humans would also cause visible signs of spoilage in the food. And that food is unlikely to be consumed.

Thus, in most cases of food-borne infection, the causative agent does not come from spoiled food but from contaminated food and water that have been infected by traveling from host to host via the fecal–oral route. That is to say, the microbes discharged in the feces of an infected human or animal find their way via food, water, or unwashed hands into the mouth of a new host. The organisms are swallowed and proceed to establish themselves on, or in, the mucus membrane lining the gut, or they may pen-

Table IV.E.4.1. *Organisms causing food-borne disease*

Cestodes (Tapeworms)	*Taenia saginata, Taenia solium*
	Diphyllobothrium latum
	Echinococcus granulosus
	Hymenolepis nana
Nematodes (Roundworms)	*Trichinella spiralis*
	Ascaris lumbricoides
	Enterobius vermicularis
	Trichuris trichiura
	Angiostrongylus species
	Gnathostoma spinigerum
Trematodes (Flukes)	*Fasciola hepatica*
	Fasciolopsis buski
	Opisthorchis species
	Heterophyes heterophyes

	Small round structured viruses (Norwalk and Norwalk-like agents)
	Astrovirus
	Calicivirus
Prion (?)	Agent causing bovine spongiform encephalopathy, which may infect humans who eat diseased meat (not proven but suspected)

etrate the gut wall to invade other parts of the body, traveling in the bloodstream and lymphatic channels.

Multiplication of the organisms in their chosen sites is often followed by symptoms of the disease, although symptomless or subclinical infection may also occur. In either case, large numbers of the organism leave the patient (voided in feces, vomit, urine) ready to repeat the cycle in a new and susceptible host. Such diseases may belong to one of two categories: (1) diseases of the gastrointestinal tract, in which the symptoms may include diarrhea, vomiting, and abdominal pain, such as cholera, dysentery, or bacterial and viral gastroenteritis; and (2) diseases with symptoms not necessarily related to the gastrointestinal tract, such as toxoplasmosis, poliomyelitis, brucellosis, and typhoid fever.

Source of Infection

Infection at the Source

The meat of an animal infected with the parasite causing toxoplasmosis, sarcocystis, or tapeworm is infective when eaten undercooked or raw. Eggs laid by hens that are infected with *Salmonella enteritidis* often transmit infection when the egg is eaten raw or undercooked. The question of whether bovine spongiform encephalopathy may be readily transmitted to people eating beef from infected cattle is still hotly debated, but it is becoming more widely accepted that this transmission can occur. Milk from infected animals, when consumed without prior heat treatment, transmits diseases like tuberculosis, brucellosis, and Q fever.

Infected fish may also transmit infection (fish tapeworm) when eaten raw or undercooked. Shellfish contaminated with the organism *Vibrio parahaemolyticus,* which normally grows in the salty water of warm seas, cause food poisoning when ingested. Some fish and mollusks acquire powerful heat-stable toxins through their food and are then able to transmit diseases like ciguatera fish poisoning and paralytic or neurotoxigenic shellfish poisoning to people eating them. These animals feed on toxin-containing dinoflagellates and concentrate the toxins in their flesh. The fish, however, appear to be unharmed by the toxin. In contrast, scombroid fish poisoning is acquired by eating a preparation of the scombroid group of fish, like smoked mackerel, that has been subjected to substandard processing and/or improper storage conditions prior to smoking. Here, bacteria that are commonly present – such as species of *Proteus* and *Klebsiella* – act on, and break down, the histidine present in the musculature to yield histamine and other substances (scombrotoxin). The symptoms produced on ingestion mimic those of histamine poisoning.

Contamination in the Slaughterhouse

Meat is often contaminated with organisms that normally inhabit only the lumen of the gut of animals but escape when the intestinal wall is damaged during slaughter and evisceration. This occurrence seems to be the most common route of transmission of such infections in Britain. Typical of this group of pathogens are *Clostridium perfringens* and species of *Salmonella, Campylobacter,* and *Yersinia.* Some species of *Salmonella* are able to cause a disseminated septicemic illness in their hosts, as, for example, *S. enteritidis* in poultry, which spreads to the heart and other organs that are used as giblets.

Food that is contaminated in this way may then contaminate other clean food by direct contact, as happens when raw meat comes into contact with cooked food, either directly as in refrigerators, or indirectly through use of the same preparation surface or knife.

Fecal Contamination of Food and Water

Both human and animal feces, which contaminate food and water, are major causes of diarrheal diseases. These diseases are especially prevalent in countries lacking adequate facilities for the safe disposal of sewage or protected water supplies. The role of flies, rodents, and birds in the transfer of pathogens from infected feces to food is well documented. Moreover, the washing of salad vegetables or fruit in water contaminated with human or animal sewage results in the transfer of diseases like typhoid, cholera, and bacillary or amoebic dysentery, as well as gastroenteritis caused by *E. coli,* Campylobacter, and Salmonella infections.

Bivalve shellfish (oysters, clams, and mussels) that are harvested from shallow inshore coastal waters adjacent to an outflow of sewage often contain large numbers of fecal pathogens. These animals are filter feeders, filtering large amounts of water each day to extract their food. The microbes present in fecal particles are concentrated in the flesh of the mollusk, which – when eaten raw or undercooked – may transmit diseases like typhoid fever, hepatitis A and E, and viral gastroenteritis. In addition, whereas the process of depuration (leaving the shellfish in tanks of purified water for over 24 hours prior to sale) removes most of the bacteria from the mollusks, viruses remain intact. Heat treatment is therefore required to inactivate them.

Waterborne infections commonly occur in areas lacking chlorinated water supplies. They are also associated with wars and other causes of sudden, uncontrolled movement of populations that disrupt normal services. Waterborne infections occur from time to time in developed countries, resulting in explosive outbreaks in the area of distribution of the water supply concerned.

Generally, such outbreaks follow a sudden or unforeseen breakdown of chlorination or filtration in the water purification plant, but they are also seen in institutions that are situated in remote areas and maintain their own water supply. It is notable that the cysts of some gastrointestinal protozoan parasites, such as species of *Giardia,* along with *Entamoeba histolytica,* are resistant to the standard chlorination process used for drinking water. Improperly filtered but adequately chlorinated tap water has resulted in several recent outbreaks of cryptosporidiosis in Britain and the United States.

In developing countries, where infective diarrheal diseases are common, debility arising from the illness compounds the effects of malnutrition, and childhood mortality rates are excessive. Up to 15 out of every 1,000 children in some areas die before the age of 5 from diarrheal disease transmitted by water.

Food Handlers

Food may be contaminated due to poor standards of hygiene among those who handle and prepare it. These food handlers may be: (1) "carriers" who harbor and continue to excrete pathogenic microorganisms and are thereby able to transmit them to others, even if they themselves no longer suffer from symptoms of the disease or have never had any symptoms; (2) people who are not yet symptom-free following gastrointestinal illness; and (3) those who are caring for patients with such diseases. The danger lies in the transmission of microorganisms to food via unwashed hands and poor toilet hygiene, or by aerosols caused by sick food handlers vomiting in preparation areas. Food handlers typically cause outbreaks of staphylococcal food poisoning, viral gastroenteritis, and enteric fever, which is particularly significant in the commercial or bulk preparation of food. Staphylococcal food poisoning is especially relevant here since the toxin produced can resist heat treatment.

Contamination from the Environment

Microorganisms found in the environment may contaminate food and water. The spores (resistant forms) of *Clostridium botulinum* survive for long periods of time in the soil and mud of lakes and rivers. They may contaminate vegetables and fish and secrete a powerful neurotoxin into the food. *Listeria monocytogenes,* found in the gut of cattle, sheep, and other animals and in soil and grass, may contaminate foods such as unpasteurized milk products. Moreover, the ability of listeriae to grow and multiply at temperatures prevailing in most domestic refrigerators contributes to the problem of preventing infection.

Canned food has often been found contaminated with organisms that have gained entry through tiny undetected faults in the seal. During manufacture, cans of food are first heat-sterilized, then cooled by immersion in water before the labels are attached. When the cans undergo sudden cooling, material from the outside gets sucked into the interior, and infective agents gaining entry at this stage may then multiply freely in the food. If the food is to be eaten uncooked or only lightly cooked, it presents a hazard. A can of imported corned beef was implicated as the source of the outbreak of enteric fever in Aberdeen in 1964. At the canning factory in South America, the cans were cooled in untreated water taken from a river close to the factory. Further investigation revealed that raw sewage from a neighboring settlement was discharged directly into the river upstream from the factory. Enteric fever was endemic in this community.

Back in Aberdeen, the infected corned beef was sliced and sold to the public through a retail outlet, resulting in the outbreak. The causative agent was identified and traced back to the retail premises, revealing the corned beef as the source of the outbreak. All cans belonging to the same batch as that causing the outbreak were withdrawn from sale. However, in spite of this action, the outbreak was observed to continue, with the diagnosis of more new cases in the area. It later became apparent that other items of precooked food sold in the shop, like ham, had been cross-contaminated when they were sliced on the same machine as the contaminated meat. Following this observation, the outbreak was brought under control by enforcing measures for (1) preventing further sale of contaminated food and (2) thorough cleaning and decontamination of all equipment and work surfaces involved. Canned food has also been implicated in outbreaks of botulism, staphylococcal food poisoning, and other diseases. In Great Britain, the most common food-borne infections today are campylobacter and salmonella gastroenteritis acquired from poultry and meat. Among the salmonellae, the incidence of *S. enteritidis* phage type 4 is now increasing steadily in England and many other countries.

Bacterial Food Poisoning

The food-poisoning group of organisms include *Staphylococcus aureus, Salmonella* species, *Clostridium perfringens, Bacillus cereus, Clostridium botulinum,* and *Vibrio parahaemolyticus.*

The term "food poisoning" is generally used in a restricted way to exclude clinical entities like typhoid and cholera, but it includes those conditions in which intestinal disturbances commonly occur, resulting in diarrhea and vomiting (with or without other symptoms). It is caused by ingesting either live bacteria or products of bacterial growth – the latter arising after the microbes have multiplied in the food for some hours before it is eaten.

This vital initial period of bacterial multiplication in food is an essential feature in the natural history of all bacterial food poisoning, as it ensures that a vastly increased number of bacteria are present in the food. The "challenge dose" of bacteria (the number that have to be ingested in order to cause disease) is much higher in the food-poisoning group than it is with other diseases, like typhoid and shigellosis, where food merely acts as a vehicle for transmission of the infection. *C. botulinum* is included in the food-poisoning group, although the symptoms produced here are neurological rather than gastrointestinal, because this pathogen from the soil must grow and multiply for several hours in food before it is able to cause disease.

Crucial factors in the evolution of an outbreak of food poisoning include the type of food involved, the way in which it has been prepared, and the duration and temperature of storage prior to eating. As with most other food-borne infections, the food looks and tastes normal.

Bacterial food poisoning may belong to three different types, depending on the mechanism of pathogenesis observed:

1. In the *infective type,* as caused by *Salmonella,* large numbers of live organisms must be consumed. They then invade the cells lining the small intestine, where further multiplication occurs, causing inflammation, diarrhea, and vomiting. The time interval between ingesting the food and developing symptoms (the incubation period) is between 14 and 36 hours.
2. In the *toxic type,* caused by *S. aureus, B. cereus,* and *C. botulinum,* the phase of multiplication in food results in the release of toxins. When ingested, these toxins (preformed in the food) are responsible for producing the symptoms. It is not necessary to ingest the live organisms. Rapid heating of the food may destroy the bacteria but allow heat-stable toxins to remain active. In contrast to the previous type, the incubation period here is fairly short – a few hours – because the preformed toxin is able to act immediately on the gut.
3. The *intermediate type,* caused by *C. perfringens,* has an incubation period of 8 to 20 hours. The toxin is released not in the food but in the gut of the host, following ingestion. The release of toxins here coincides with the formation of spores (a resistant form of the bacterium). Prolonged low-temperature cooking or inadequate reheating of infected, leftover meat stews and casseroles increases the occurrence of this disease, because it stimulates sporulation of the *C. perfringens* in the gut of the host.

It is apparent that three important criteria have to be satisfied for the successful development of food poisoning. These are as follows:

1. Introduction of organisms into the food at some stage during its preparation.
2. Inadequate cooking. Most microbial agents in food are destroyed by cooking at high temperatures for the prescribed length of time. When frozen food, like meat, is cooked before it is completely thawed out, the temperature reached in the center of the meat may not be sufficient to kill the bacteria even when the outside looks well done.
3. Leaving food standing at an ambient temperature for several hours, enabling the bacteria to multiply

> and attain the infective dose. Refrigeration of food stops multiplication of most of the harmful pathogens, with the exception of species like *Yersinia enterocolitica* and *L. monocytogenes,* which are particularly adapted for growth at temperatures of 0 to 4 degrees Celsius (°C). Freezing suspends replication of all pathogens but fails to kill them. After frozen food is allowed to thaw, bacteria may start to multiply again if kept standing at room temperature. Hence, careful attention is important at all stages of food preparation to ensure adequate cooking and prevent contamination. Furthermore, if food is not to be eaten without delay, it should be rapidly chilled before freezing for storage.

Clearly, even contaminated food is not harmful if properly cooked and eaten right away. But when eaten raw, inadequately cooked, or after remaining for a long time in a warm environment, contamined food may transmit disease. Bacteria in food replicate rapidly by binary fission, doubling their numbers progressively at intervals of less than 20 minutes by a simple process of division in which each cell gives rise to two daughter cells. Food provides the ideal nutrient for bacteria, which continue to multiply, so that in just over 3 hours a starting population of 1,000 organisms (which is too low a dose to cause food poisoning) may reach the level of millions and constitute an effective challenge dose. In most outbreaks, food has been left for longer than 3 hours and the starting population may be higher than 1,000. Organisms like *Campylobacter, Shigella,* and the typhoid bacillus are infective at a much smaller dose level than the food-poisoning group, and in this case it is not necessary for the infected food to remain at room temperature for several hours in order to be able to transmit infection. Indeed, organisms like *Campylobacter* and viruses do not multiply in food. As already mentioned, in this case, food merely acts as a vehicle for transmission of these agents.

Most pathogenic bacteria are unable to grow in acidic food (pH less than 4.5) or in food with a low moisture content. Similarly, high salt or sugar concentration in preserved food inhibits many bacteria. However, they may survive for long periods of time in dried food products.

Staphylococcal Food Poisoning

The food-poisoning strains of *S. aureus* are usually harbored by human food handlers, either in septic skin lesions (boils and whitlows) or as a part of the normal resident microbial flora of the nose or skin. Transfer of such organisms to food may be restricted by the use of a no-touch technique in its preparation. This is especially relevant for large-scale processing of food. Food poisoning does not occur if the contaminated food is either eaten before the bacteria have a chance to multiply, heated before the bacteria multiply and produce toxins (*S. aureus* are readily killed by heat), or refrigerated promptly and served chilled, to prevent multiplication of surviving bacteria.

If contaminated food is first refrigerated and then left standing for a considerable length of time in a warm room, the bacteria are able to multiply again. *S. aureus* multiplies rapidly over a wide range of temperatures, liberating its heat-stable enterotoxin. The type of food involved here is usually that which requires little or no cooking and has a high fat content, like cream cakes, trifles, and ham sandwiches. When eaten, the toxin acts on the host, causing symptoms of nausea, vomiting, and abdominal pain (but rarely with diarrhea) within 1 to 6 hours of ingestion. The toxin appears to act on nerve endings in the gut, transmitting its message to the center in the brain that controls vomiting.

Most cases are self-limiting. Recovery occurs rapidly, usually within 12 hours, and no treatment is required. If the infected food is heated to 70° C before serving, the *S. aureus* will be killed, but the toxin is still active, and even boiling for 30 to 60 minutes may not inactivate it. Moreover, *S. aureus* is not inhibited by a high concentration of salt. Therefore, foods like ham and other semipreserved meat with a high salt and high fat content make an ideal medium for staphylococcal growth and multiplication. Prevention involves stringent measures for personal and environmental hygiene in the food preparation area, the covering of skin lesions with waterproof dressings, rapid refrigeration of prepared food that is not to be eaten right away, and thorough cooking of soups and meats before eating. Control of food handlers and use of the no-touch technique are important in the food manufacturing industry.

Salmonella Food Poisoning

Salmonellosis is a disease affecting both humans and animals and may be transmitted between them (a zoonosis). There are over 200 species of salmonellae, and they are widely distributed in nature, inhabiting the intestines of wild as well as domestic animals and household pets. They frequently contaminate meats, especially chicken, along with eggs, milk, and other products. Intensive farming techniques have resulted in widespread infection in the food chain, and mechanized mass processing of poultry carcasses ensures the cross-contamination of most poultry sold in shops.

Chickens infected with *S. enteritidis* are able to pass the infection on in their eggs. Infected humans acting as food handlers may also transmit infection unless scrupulous attention to hygiene is observed with regard to hand-washing after using the toilet and before handling food. Milk that is not heat-treated may also transmit salmonellae. The organism is readily killed by boiling for half an hour, so poor culinary practices are largely to blame for outbreaks of salmonellosis in humans. Examples of such practices include cooking inadequately thawed large frozen joints of meat, low-temperature cooking, allowing cooked food to come in contact with uncooked meat or its juices, and prolonged storage at room temperature after inadequate cooking.

This last factor is the most important one because it enables an effective infective dose of salmonellae to develop in the food. Normal gastric acidity is sufficient to kill many ingested pathogens, but this defense may be breached when the microbe is taken in large numbers along with food that temporarily neutralizes the protective mechanism. Frequent outbreaks of salmonella food poisoning continue to occur in many developed nations because of (1) infected manufactured food; (2) the practice of adding raw egg to food that is to be eaten uncooked; and (3) importation of food products from areas with a high disease prevalence.

The strain of *Salmonella* responsible for an outbreak of gastroenteritis often points to the species of animal from which the food derived, as many strains have preferred hosts. *S. enteritidis* and *Salmonella typhimurium* are commonly found in poultry and cattle, *Salmonella dublin* in cattle, and *Salmonella hadar* in turkeys. However, at times, certain strains appear to sweep through an entire population of livestock, probably because of contaminated feed and intensive farming techniques involving overcrowding and animal stress. The infection is often asymptomatic in humans and other animals, but continued excretion of the pathogen in feces enables transmission to occur.

This excretion is especially marked when animals are maintained in overcrowded situations and is reflected in the high incidence of infection in flocks of poultry and in beef cattle. During slaughter and evisceration, gut contents often contaminate the meat. Cross-contamination of other carcasses then occurs either through direct contact with the meat or by contact with contaminated surfaces and equipment. Thus, all retailed meat may be regarded as potentially contaminated.

Consumption of an infecting dose of 10^5 to 10^6 organisms is required in order to establish infection. This amount is readily achieved if improperly cooked meat is left to cool at room temperature for 3 or more hours. Fewer cells (10 to 100) may cause illness in very young children or in the elderly, especially if the pathogens are carried in high-fat foods such as cheese, cheesecake, salami, or hamburgers. Low numbers may also be infective when waterborne. A high fat content in food is believed to protect the salmonellae to some extent during cooking. This may be relevant to the survival of *S. enteritidis* phage type 4 in eggs and meat.

Since 1985, this particular strain has appeared with increasing frequency among the poultry population and has now spread to epidemic levels among them. In birds, the infection is not confined to the gut but passes into the bloodstream to give a severe septicemia, and the eggs are infected before they are laid. Thorough cooking of the eggs or pasteurization of bulked eggs would destroy the pathogen. Pasteurization entails heating the product to a temperature of either 63 to 66° C for a period of 30 minutes or 71° C for 15 seconds. This form of heat treatment kills all vegetative pathogens like salmonellae in milk and eggs.

Human infection follows the ingestion of approximately 1 million organisms, which then invade the intestinal mucosal cells and cause local inflammation. The incubation period lasts for 14 to 36 hours and is followed by diarrhea and vomiting, with or without abdominal pain. Most infections are self-limiting and do not require any treatment, but in more severe cases, supportive therapy with rehydration is implemented. In very young babies or in elderly or debilitated patients, for instance, the disease may follow a septicemic course, giving rise to a serious life-threatening condition that necessitates the administration of appropriate antibiotics as well as rehydration. Following recovery, a small proportion of people may retain organisms in the gut for a varying period of time and continue to excrete them intermittently in the feces. If these "carriers" are employed as food handlers, they may transmit the organism to foods unless scrupulous attention to hygiene is observed.

Salmonella organisms may be introduced into manufactured food products at various stages in the production line. For example, they may enter after the heating stage and cause widespread outbreaks. Intercontinental outbreaks have been traced to chocolates and cheeses. Critical monitoring of production procedures to detect and control the possibility of microbiological contamination at every stage is of vital importance. Although it would be ideal to reduce salmonellosis in the livestock by measures like heat treatment of all animal feed and improvement of farming techniques, this aim is not readily achievable.

Legislation to enforce heat treatment of all milk sold from retail outlets has helped reduce milk-borne outbreaks in humans. However, the occasional undetected breakdown of a pasteurization unit has resulted in the sale of contaminated milk that has caused outbreaks. Countries lacking basic sanitation and hygiene tend to have a higher prevalence and transmission rate of salmonellosis. Foodstuffs imported from such areas (for example, spices like pepper) may require more than the usual decontamination. Alternatively, spices and the like can be added to food before it is cooked rather than afterward; this, too, prevents the problem.

Clostridium Perfringens Food Poisoning

This food poisoning is associated with reheated leftover meat dishes, like stews. The causative organism is a normal commensal of the gut of humans and other animals. It is a strict anaerobe able to grow and multiply only in an environment devoid of oxygen. Clostridia are able to produce tough, resistant spores that survive in adverse environments, and these spores germinate into vegetative cells. Multiplication can occur only in the vegetative state and not in spore form.

Inadequate cooking of meat enables the spores to survive. *C. perfringens* type A has particularly heat-resistant spores that can survive prolonged boiling, and these strains are associated with outbreaks of food poisoning, usually in institutions such as nursing homes. The type of food involved is, generally, meat dishes such as large joints cooked at a low temperature, or stews and broth when there is insufficient heat penetration to kill off all the spores.

Furthermore, the spores are protected by the protein-rich food. If the cooked food is eaten right away, it is generally safe, but when such food is left for between 3 and 5 hours at room temperature, it provides the ideal anaerobic conditions for the spores to germinate and the vegetative cells to multiply. Multiplication is rapid, with a mean doubling time of only 7 minutes at 41° C. The infecting dose of 10^8 organisms per gram of food is soon attained. If, at this stage, the food is thoroughly reheated (to over 70° C), the vegetative cells are killed and the food is rendered safe.

If the food is only partially reheated (up to or below 60° C), though, the cells survive, and when ingested, they sporulate in the gut and shed the vegetative fragment, which releases a heat-labile enterotoxin. This acts on the small intestinal mucosa, damaging the brush border of epithelial cells at the tip of the villous processes. There is an outpouring of fluid and electrolytes resulting in violent, watery diarrhea and abdominal colic, occurring 8 to 20 hours after ingestion of the food. Vomiting and fever are uncommon, but nausea may be present. Recovery occurs within 24 hours in most cases, and no specific treatment is required. However, in elderly, debilitated individuals, severe dehydration may result, necessitating supportive therapy with rehydration.

Prevention involves the high-temperature cooking of meat in small amounts, rapid refrigeration if it is not eaten immediately, and reheating of all leftover meat dishes to a temperature higher than 70° C to destroy the vegetative cells. Cooking methods like frying and grilling have an advantage in that they deliver very high temperatures directly to contaminated meat surfaces.

Bacillus Cereus Food Poisoning

B. cereus produces spores that help it to survive in adverse conditions such as drying and heat. Unlike the clostridia, this organism is an aerobe (growing in the presence of oxygen). It is found widely distributed as a saprophyte in the environment and on cereals like rice. In fact, outbreaks of *B. cereus* food poisoning are frequently associated with reheated rice dishes such as fried rice and take-out fast food from Chinese restaurants. Bacterial spores survive the short cooking period involved, and if the rice is left at an ambient temperature for several hours to dry, germination of the spores occurs. The bacterial cells then multiply rapidly in the rice and liberate various enterotoxins. When the precooked rice is stir-fried to make fried rice, the heat-stable toxin is not destroyed by the short exposure to heat and may cause symptoms shortly after ingestion. When boiled rice is stored in a refrigerator, it goes lumpy, and when subsequently stir-fried, it fails to present the aesthetically acceptable appearance of well-separated grains of rice. This probably accounts for the tendency, especially in fast-food outlets, to leave precooked rice at room temperature for several hours and reheat it as required.

Two distinct types of disease symptoms are observed with *B. cereus* infection, depending on the type of toxin formed:

1. In the emetic type, vomiting is common. The incubation period here is 1 to 5 hours, and symptoms include nausea, vomiting, malaise, and, sometimes, diarrhea, lasting for 6 to 24 hours. This type is caused by a heat-stable toxin and is associated with cereals, especially the cooked rice just mentioned. The condition may, of course, be prevented by eating freshly cooked rice while it is hot; but if this is not possible, then the food should be maintained at over 60° C or stored at temperatures of about 8° C.
2. The diarrheal type is the rarer of the two and is due to the production of a heat-labile enterotoxin associated with lightly reheated meat sauces, puddings, and vegetables. Symptoms include profuse watery diarrhea, abdominal cramps, and, sometimes, vomiting occurring 8 to 16 hours after eating the food. Recovery is generally complete in 12 to 24 hours.

Botulism

Botulism is a neuroparalytic disease caused by the ingestion of very small amounts of botulinum toxin. An oral dose of 0.005 µg may be lethal for humans. *C. botulinum* is a spore-producing organism that can grow only in the absence of oxygen. The tough spores are found worldwide in the soil and in the mud of lakes and rivers. When food like fish, vegetables, and meat is contaminated with soil containing the spores and is then left at room temperature, the spores germinate and multiplication of the organism occurs.

Some strains grow in temperatures as low as 3.3° C. During the growth process, a powerful neurotoxin is produced, which, when ingested, results in symptoms of botulism, following an incubation period of 18 to 36 hours. The preformed toxin causes a muscular paralysis with hoarseness, visual disturbances, headache, nausea, vomiting, and difficulty in swallowing and speaking. If left untreated, death from respiratory or cardiac arrest is a real danger. Symptoms may last from several weeks to many months.

A less severe disease is caused in infants ingesting spores of *C. botulinum.* These spores germinate in the infant's gut, releasing toxin in the intestine. Symptoms of flaccidity and weakness, with difficulty in feeding, are the presenting symptoms of infantile botulism. Treatment includes administration of antitoxin antibodies to attempt to neutralize the toxins.

Prevention relies on the destruction of spores by thorough heating of all preserved food. This is especially relevant to home-preserved food – the cause of many outbreaks. The high acid content of certain foods prevents the growth of this organism, but preformed toxin retains its activity when added to acid food. As mentioned previously, in an outbreak in England in 1989, the source was contaminated hazelnut puree used to flavor yoghurt. The toxin in food may be destroyed by heating at 85° C for 5 minutes.

Vibrio Parahaemolyticus Food Poisoning

This form of food poisoning is related to the ingestion of undercooked or raw shellfish or fish. *V. parahaemolyticus* has a predilection for high salinity and grows well in the warmer seas. The shellfish and fish taken from such sites may be contaminated with the organism. When undercooked shellfish are eaten, symptoms of diarrhea and vomiting, fever, and abdominal cramps appear within 16 to 48 hours, resolving in 2 to 7 days. Other halophilic (salt-loving) bacteria, like *Vibrio vulnificus,* may cause a septicemic infection in people eating raw oysters. Prevention depends on the adequate cooking of seafood.

Other Bacterial Food-Borne Infections

Apart from the food-poisoning group of organisms, many other bacteria transmitted in food may also cause infection.

Campylobacteriosis

Campylobacteriosis occurs throughout the world and is the most common cause of acute infective diarrhea in most developed countries. The organisms *Campylobacter coli* and *Campylobacter jejuni* are widely distributed in nature, infecting the gut of domestic and wild animals, poultry and wild birds, and also humans. Poultry and cattle are important sources of human infection, because in addition to developing acute infection, they may become symptomless excreters of the organism with long-term carrier status. This is a classic example of a zoonosis (a disease transmitted between animals and humans) and, therefore, as is the case with nontyphoid salmonella, cannot easily be eradicated.

The curved, spiral-shaped organism is found in large numbers in the gut contents of infected animals and is commonly transferred to poultry and animal meat during slaughter and evisceration. Most poultry carcasses sold in shops are consequently contaminated with the organisms. They may also be transferred from the feces of infected animals, wild birds, or humans to unprotected drinking water supplies or to food. Outbreaks occur most frequently after the consumption of improperly cooked poultry but have also taken place after the drinking of milk that was not heat-treated and unchlorinated water.

The infective dose is small (a few hundred bacteria), and the incubation period is approximately 3 days. The disease produced is an acute enterocolitis, and lesions are seen in the intestinal mucosa similar to those produced by shigellae or salmonellae. A characteristic feature of campylobacter is that the incubation period is followed by a period of a few days when the patient feels ill with headache, malaise, fever, and abdominal pain (the prodromal period). This is followed by a dysentery-like illness with frequent stools, sometimes containing blood and mucus. The prodromal symptoms help differentiate this illness from that caused by salmonellae or shigellae. Furthermore, the symptoms of abdominal pain and diarrhea seen here may be more prolonged. In fact, the pain may be so severe as to lead to a misdiagnosis of acute appendicitis and to the patient undergoing unnecessary abdominal surgery.

In most cases, recovery occurs within a week, and there is no need for antibiotic therapy. However, in debilitated or immunodeficient patients the organism may spread through the blood to cause a severe systemic infection, requiring appropriate antibiotic therapy.

Prevention of infection is achieved by measures that break the routes of transmission, such as the following:

1. Thorough cooking of all meat.
2. Observance of good principles of kitchen hygiene, like preventing contact between cooked food and raw meat, including contact with surfaces on which the raw food was placed first.
3. Heat treatment of milk by pasteurization or sterilization.
4. Adequate chlorination of the water supply or boiling of untreated drinking water.

Because the campylobacter organisms are so widespread in the animal kingdom, it would be unrealistic to hope to eradicate them entirely. It would, however, be useful to reduce the incidence of campylobacteriosis in poultry stocks and farm animals by good principles of farming and processing, while preventing human infection by observance of the simple measures recommended. This is also true of nontyphoid salmonellosis. Unlike salmonellae however, the campylobacter do not appear to multiply in food that is kept warm. The infective dose is low, and heavy contamination of food ensures transmission. Any food may be contaminated by direct or indirect contact with the feces of infected domestic pets, other animals, birds, or humans.

Shigellosis (Bacillary Dysentery)

Shigellosis is a common disease seen throughout the world, but unlike nontyphoid salmonellae and campylobacter, shigellae infect only humans – there is no known animal host. The species involved are *Shigella dysenteriae, Shigella flexneri, Shigella boydi* and *Shigella sonnei,* and the severity of the diseases they produce decreases in this order.

Shigella sonnei, the mildest of the four forms, causes outbreaks mainly among young children in institutions like daycare centers and elementary schools. Poor toilet hygiene is the main cause of transmission in such cases. Outbreaks also occur in military barracks, institutions for the mentally handicapped, and in populations subjected to major social upheavals with a breakdown in the normal pattern of life.

Shigella dysenteriae, which causes the most severe of the four infections, is commonly seen in Asia. A high level of transmission is maintained in those countries with unprotected water supplies, a lack of facilities for the safe disposal of sewage and poor environmental conditions and personal hygiene practices.

The infective dose is small, and the disease is readily transmitted from person to person. There is no need for the organism to multiply in food in order to cause disease, as is the case with salmonella food poisoning. Following ingestion, the organism invades superficial layers of the cells lining the intestinal lumen, causing ulceration and inflammation that results in bleeding, secretion of mucus, and exudation of pus. The symptoms are diarrhea with loose stools containing blood, mucus, and pus. The severity of the illness varies with the species involved. The infection is localized to the intestine and does not invade deep tissues or the bloodstream except in very severe forms.

Antibiotic therapy is restricted to the serious forms of illness, like *S. dysenteriae,* or any severe form of dysentery occurring in the very young or debilitated patient. In most cases antibiotics are contraindicated as they may prolong symptoms and excretion of shigellae in the feces.

Prevention in the developed countries involves improving toilet hygiene, especially among children in institutions and schools. In developing countries lacking environmental hygiene and safe water supplies, travelers are well advised to drink only bottled or boiled water and to avoid uncooked or salad vegetables and fruit that is to be eaten unpeeled.

Typhoid Fever (Enteric Fever)

Tyhoid fever is a severe febrile septicemic illness that is endemic in countries with poor sanitation and affects only human hosts – animals are not involved. The causative organism, *Salmonella typhi,* is transmitted from one host to the next, usually through water supplies contaminated with human sewage. Food handlers also play an important role in the transmission. Recovery from this fever may be associated with the carrier state, which may last for a lifetime, with intermittent excretion of *S. typhi* in feces and urine. Such a state occurs when the organism continues to live in the gallbladder or kidneys of the host but no longer causes adverse symptoms. However, it is excreted from time to time in the feces of the carrier and may, therefore, be transmitted to other hosts. It is important to identify such carriers, educate them on food hygiene, and exclude them from following a career in the food industry.

Food may act as a vehicle for the transmission of this disease, which is by the fecal–oral route. Symptoms appear after an incubation period of about 10 to 14 days, with fever, headache, malaise, and, sometimes, diarrhea or constipation. Such symptoms are severe, and fatal complications may occur if untreated. Treatment with an appropriate antibiotic is important in all cases of enteric fever. Prevention requires the provision of protected, chlorinated water supplies and safe sewage disposal. In endemic areas it is wise to boil all drinking water or to treat it with chlorine tablets. Travelers to endemic zones are advised to drink only bottled water and not to eat salad vegetables, uncooked food, or unpeeled fruit. A vaccine containing heat-killed *S. typhi* is available but gives only partial protection, so the prevention of infection remains the main aim.

Paratyphoid fever caused by *Salmonella paratyphi* A, B, or C is a milder form of the infection just discussed. *Salmonella paratyphi* B is the strain transmitted in Europe, whereas *S. paratyphi* A and C are endemic in other areas.

Escherichia coli Gastroenteritis

This form of infection is possibly the most common cause of diarrhea in the world. Specific strains of this large family of organisms are involved in causing human gastroenteritis. Their natural habitat is the gut of humans and animals, and transmission is from person to person or by the intake of contaminated water or food. The infective dose is small, and there is no need for the organism to multiply in food for several hours before becoming infective.

The disease is prevalent in areas with poor environmental hygiene and frequently causes diarrhea in travelers to these areas (appropriately termed Aztec two-step, Rangoon runs, Delhi belly, Tokyo trots, and gippy tummy). In developed countries, outbreaks of infantile gastroenteritis have occurred in hospitals, and more recently, outbreaks of hemorrhagic colitis and hemolytic uremic syndrome have been reported where the causative organism was *E. coli* serotype 0157, transmitted in undercooked hamburgers. It is possible that some strains cause zoonotic infection, whereas with others, human hosts are the sole source of infection.

The organisms have been classified according to the way in which disease is produced: Hence there is enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), and verotoxin-producing or enterohemorrhagic *E. coli* (VTEC or EHEC).

In developing countries, diarrhea and dehydration brought on by such infection is a major cause of infant mortality. Adults are also affected from time to time, but they appear to develop a measure of immunity from constant exposure to all the different strains in the community. Travelers to infected areas, however, are unprotected and extremely susceptible to all the new organisms in the environment.

EPEC strains belong to certain known serogroups and, in the past, have caused outbreaks of gastroenteritis in infants and young children. Symptoms include diarrhea and vomiting, and severe dehydration may occur. Thus, unless supportive treatment is initiated rapidly, mortality rates can be high. Adults may also be occasionally infected. The mechanism of pathogenesis of EPEC strains is not clearly understood, but the organisms remain within the lumen of the gut and produce changes in the appearance of the cells lining the small intestine. Antibiotic therapy is restricted to the severely ill and debilitated cases.

All ETEC strains secrete enterotoxins, of which there are two types: heat-labile toxin (LT) and heat-stable toxin (ST). These toxins act locally on the cells of the intestinal mucosa, stimulating them in such a way as to result in a net outpouring of fluid and electrolytes from the bowel wall into the lumen.

The disease rarely occurs in temperate climates. In developing countries, however, it is common in children and is an important cause of travelers' diarrhea. Sewage contamination of water supplies is important in transmission. ETEC strains do not invade the body but remain in the gut lumen closely attached to the surface of the mucosal cells by means of short fibrillar processes (colonization factors). The toxin is secreted in the gut lumen and is internalized by the mucosal cells. Recovery occurs in a few days when the cells of the small intestine are replaced by fresh ones. Cells in the small intestinal mucosa are normally shed and replaced very rapidly. Because there is no inflammation in the gut wall, the stools contain no inflammatory cells. This is in sharp contrast to shigellosis and salmonellosis. Treatment is strictly supportive, with rapid correction of dehydration a lifesaving remedy.

EIEC strains (like *E. coli* serotype 0124) cause invasive disease similar to shigella dysentery, with ulceration of the intestinal mucosa that results in diarrhea with blood, mucus, and pus in stools. Food-borne infection is common, and cross-infection can occur.

EHEC (VTEC) strains have caused outbreaks of bloody diarrhea in people eating undercooked hamburgers. When meat is ground, it enables the organisms to grow better and cause greater contamination. The hemorrhagic colitis may be followed by hemolytic uremic syndrome (kidney failure and anemia due to the destruction of the red blood cells and destruction of thrombocytes). Many patients suffer only mild diarrhea, whereas others are seriously ill. *Escherichia coli* serotype 0157 is particularly associated with such outbreaks. The incubation period is 2 to 9 days. A contagious spread of the disease may also occur and is important in hospital outbreaks. Prevention is similar to the prevention of shigellosis with the added incentive to ensure that hamburgers are properly cooked.

Cholera

Cholera is a purely human, intestinal form of disease, characterized by profuse watery diarrhea (rice-water stools), that frequently leads to dehydration and death in untreated cases. It spreads along the fecal–oral route, with waterborne transmission most responsible for explosive outbreaks. Transmission from person to person also occurs. Flies can spread it, and the disease may also be food-borne. Fecal pollution of seawater can contaminate seafood which, if eaten raw or undercooked, may transmit the disease. No animal host has been detected for the cholera vibrio. Normal levels of gastric acid provide some defense against such infections in humans. The disease is more likely to occur in those with no or low levels of gastric acid.

Vibrio cholerae remains in the lumen of the gut attached to the surface of mucosal cells. The pathogenesis is mediated by a toxin that is secreted into the gut by the organism. This toxin is internalized by the cells and stimulates an outpouring of fluid and electrolytes, resulting in profuse diarrhea with the potential of causing death from dehydration (up to 20 liters per day of fluid loss). The mode of action of the cholera toxin is similar to that of *E. coli* LT. Indeed, the two toxins are similar in structure. There is no damage to the mucosa, and with modern medical treatment, recovery occurs in a week's time in most cases.

That treatment involves rapid rehydration. Oral rehydration with frequent small drinks of an electrolyte and glucose solution is usually used. In severe cases intravenous fluid infusion is necessary. Orally administered tetracycline is useful in reducing the period of excretion of the vibrio and also the severity of symptoms.

The latest cholera pandemic is due to the El Tor variant of *V. cholerae,* which causes a milder form of cholera than that seen in the nineteenth-century pandemics that swept the globe. It began in the 1960s in Southeast Asia and was spread by travelers, first to the Middle East and Africa and then to South America. Outbreaks, common where water supplies and environmental sanitation are poor or nonexistent, are especially likely in camps for refugees from wars or natural disasters.

Cholera prevention. Careful disposal of human sewage is essential, along with the provision of safe chlorinated water supplies or, failing that, boiled or bottled water. *Vibrio eltor* is more difficult to control because it causes a milder disease, meaning there are more ambulant cases to disseminate it more widely. A vaccine is available, but its protection is of short duration, and there is considerable doubt as to its efficacy.

Yersiniosis

Yersiniae are part of the normal gut flora of domestic and wild animals. Human infection is acquired by the ingestion of inadequately cooked meat containing sufficient numbers of the organism. *Y. enterocolitica* induces a typical food-poisoning-type syndrome with mild or moderate diarrhea, fever, and abdominal pain. Nausea and vomiting are rare, but mesenteric adenitis (inflammation of the abdominal lymph nodes) may occur and lead to misdiagnosis as acute appendicitis. Symptoms appear within 16 to 48 hours after the meal and may last for a period ranging from 24 hours to 4 weeks. Reactive arthritis is a complication that may occur following this infection, especially in people of HLA type B27. A heat-stable enterotoxin is produced by the organism that may contribute to the pathogenesis in the gut. However, the infection is not confined to the gut, as the organism invades the body to cause inflammation in the mesenteric lymph nodes.

A characteristic feature of this organism is its ability to grow and multiply in the cold at 0° C; consequently, refrigeration of contaminated food does not prevent the development of an infective dose. The bacteria, however, are readily inactivated by adequate cooking. Another strain, *Yersinia pseudotuberculosis,* is also found in the gut of animals and infects humans eating contaminated meat. It often causes a febrile illness with mesenteric adenitis, and sometimes a fulminant typhoid-like condition ensues. The yersiniae are associated with outbreaks of apparent acute appendicitis among young schoolchildren.

Listeriosis

The listeriae are pathogens of humans and animals that have the unusual property of being able to grow well at refrigerator temperatures as low as 4° C. They are widely distributed in the environment as well as in the guts of animals and humans. Contamination of food is therefore likely unless particular care is taken at all stages of food preparation and production to prevent contamination. The types of food associated with recent large outbreaks include unpasteurized milk products (like soft cheeses), cook-chilled chicken from supermarkets, and coleslaw made with cabbage that was fertilized by sheep manure. The organism frequently contaminates animal feeds, increasing its prevalence in the environment, but it does not grow at a low pH in the presence of organic acids.

When ingested by humans, listeriae may bring on a mild form of influenza-like illness, but in neonates, the elderly, and debilitated persons they may cause severe septicemia or meningitis. In pregnant women a mild influenza-like illness, followed by abortion or stillbirth, is often reported. Newborn babies may acquire the organism from the maternal birth passage and develop a fulminating septicemia or meningitis.

The organism is destroyed by the pasteurization of milk or the thorough cooking of food. Prevention of the contamination of food with environmental organisms is an important consideration.

Plesiomonas Shigelloides

This organism is another environmental bacterium that is widely distributed in nature and has been occasionally implicated in sporadic cases and outbreaks of diarrhea in many countries. It is found in freshwater (rivers and ponds), mud, fish, dogs, cats, and other animals. Adequate cooking of food destroys the organism.

Brucellosis (Undulant Fever)

Brucellosis is also called undulant fever because the disease often presents with bouts of fever alternating with afebrile periods. It is a zoonosis and is primarily a pathogen of goats, cattle, pigs, and camels. Humans acquire the infection by ingesting live brucellae in unpasteurized milk from infected animals, as well as through infective secretions from animals. Veterinary surgeons, farmers, and abattoir workers are especially at risk.

The main species of importance to humans are *Brucella abortus* from cattle, *Brucella melitensis* from goats, and *Brucella suis* from pigs. *Brucella melitensis* causes a more severe infection (Malta fever) than the other two species. The symptoms follow the ingestion of infected goats' milk or goats' cheese, and the condition is endemic in Europe, Africa, and the Far East. *Brucella suis* causes infection in America. In cattle, *B. abortus* causes abortion because of the organism's predilection for the placenta due to the high concentration of erythritol in bovine placenta and in the fetal fluids. Vigorous multiplication, therefore, occurs at this site, and the cow's milk will contain live brucellae, making it highly infectious, as are products made from it like butter, cheese, and cream.

In humans, the infection causes a protracted systemic illness. The organism is distributed in the bloodstream to various tissues, causing joint and muscle pains, headache, malaise, and depression. In many cases the disease runs a mild course, but in others a prolonged and disabling form of presentation is seen, especially when untreated.

Routine pasteurization of milk stops this mode of transmission so that only those in direct contact with infected animals remain at risk because the bacillus lives inside the cells of the host. Treatment with antibiotics must be continued over a long period and repeated to ensure recovery.

Tuberculosis

Tuberculosis is generally transmitted by a respiratory route, but it can also be acquired by drinking unpasteurized cows' milk. The organism *Mycobacterium bovis* infects cows and passes in the milk to humans. It usually causes enlargement of lymph nodes in the neck or abdomen; fever, loss of weight, and can cause pulmonary symptoms. Treatment with several antibiotics is required. The infection may also spread in the bloodstream to involve other sites like meninges, bone, joints, and other organs.

Tuberculosis prevention. Pasteurization, boiling, or heat sterilization of milk renders it safe for use. Infected animals may be identified by tuberculin skin testing. They are then slaughtered to prevent spread to other herds. In humans, the BCG vaccine may be used to confer protection against this disease.

Q Fever

Q fever is an influenza-like febrile illness associated with patchy pneumonic consolidation of the lungs that humans acquire from animals by drinking untreated milk or by inhaling their infective secretions. The causative organism *Coxiella burnetti* has a worldwide distribution, affecting various domestic and wild animals and birds.

This organism is particularly resistant to desiccation and can survive heat-treatment temperatures only slightly less than those recommended for pasteurization of milk. The infection in humans may occasionally be severe, with complications like osteomyelitis, endocarditis, meningoencephalitis, and hepatitis. Treatment requires antibiotics, and prevention involves adequate pasteurization or heat treatment of all milk.

Food-Borne Viruses

Any virus transmitted by the fecal–oral route may be transmitted in food. Viruses can contaminate food at its source or during preparation. Mollusks and shellfish growing in coastal waters that are polluted with fecal material often contain human intestinal viruses. Oysters, clams, and mussels, eaten raw or incompletely cooked, can result in outbreaks of infection by the hepatitis A virus and small round structured viruses (SRSVs) such as those seen recently around the Gulf of Mexico. Outbreaks of virus infection acquired by drinking unchlorinated water have also been reported in other countries (poliomyelitis and hepatitis A and E). Chlorination of water prevents waterborne virus infection. Depuration of oysters and bivalve mollusks in clean water does not remove viruses as easily as it removes bacteria. Therefore, adequate cooking, by raising the temperature to 85 to 90° C and maintaining it there for between 1 and 5 minutes, is recommended.

Viral infections may also be transmitted to food by food handlers who are excreting the virus. A characteristic feature of these viral food-borne infections is the frequent occurrence of secondary cases following the outbreak. Here, person-to-person transmission occurs after the initial food-borne outbreak.

Viral Gastroenteritis

The viral agent most frequently found to cause food-borne outbreaks of gastroenteritis in Great Britain belongs to the group of SRSVs also known as Norwalk and Norwalk-like agents. SRSVs cause an acute short-lived attack in which vomiting is a prominent feature. The disease usually affects adults and is associated with outbreaks of gastroenteritis in restaurants, canteens, and institutions like hospitals. Food handlers are implicated in the transmission, especially when they have had a bout of projectile vomiting in the food preparation area. But any kind of food may also be involved in this form of transmission; raw oysters, for example, have been the source of outbreaks in recent years. Secondary cases usually follow the primary cases and are a result of transmission by airborne aerosols. The clinical picture presented is of a flulike illness with nausea, vomiting, diarrhea, and abdominal pain, following an incubation period of 1 to 2 days. Symptoms resolve within a further 1 to 2 days.

Control measures include scrupulous personal and environmental hygiene, the use of chlorine-based compounds to disinfect contaminated surfaces, and adequate cooking of shellfish.

Rotavirus

Rotavirus infection affects mainly schoolchildren, though adults may also be infected. It has a worldwide distribution, causing enteritis following a fecal–oral or airborne spread – usually in winter months. The incubation period is 48 to 72 hours. The symptoms presented are diarrhea and vomiting. The disease is acute and self-limiting, but moderate dehydration may result. Malnourished and debilitated children in developing countries may be severely affected. Treatment is mainly supportive (rehydration), and recovery is seen in a few days.

Viral Hepatitis

Hepatitis A virus. Hepatitis A affects mainly children and young adults in schools, colleges, and military camps. The virus is excreted in feces 7 to 10 days before the onset of symptoms and for a few days after that. Transmission occurs by the fecal–oral route during this period. Food handlers are important in this transmission since they are infectious before they become ill. Transmission also occurs by water, from flies, and in food, especially shellfish. The incubation period is from 3 to 6 weeks and is followed by symptoms of anorexia, fever, nausea, vomiting, and abdominal pain. Jaundice appears 3 to 10 days later, and the patient then starts to feel better. Prevention includes standard measures of hygiene and well-cooked food. A vaccine is now available to protect against hepatitis A infection. Normal human immunoglobulin, to provide passive protection over a period of 4 to 6 months, has been given to those traveling to endemic areas.

Hepatitis E virus. Waterborne outbreaks of hepatitis E virus infection (a recently recognized entity) have been reported from many countries. It is transmitted by the oral–fecal route, and food-borne infection (especially by shellfish) is a distinct possibility. Preventive measures include the provision of safe water supplies and protection of food from fecal contamination.

Poliomyelitis

Poliomyelitis is a disease affecting only the human host and is transmitted by the fecal–oral route, mainly through contaminated drinking water, although food may also act as a vehicle of infection. The infection usually causes only mild intestinal or systemic disturbances. Occasionally, however, a serious form of the illness is seen with involvement of the meninges, severe paralysis, and even death. In these cases recovery may leave permanent disabilities. A good vaccine is available to prevent the disease, which, it is hoped, will mean its eradication all over the world through a mass vaccination campaign. Meanwhile, improvement in environmental and personal hygiene reduces its transmission.

Bovine Spongiform Encephalopathy (BSE)

BSE is a recently recognized disease of cattle caused by a transmissible agent (prion) that resembles the agent of scrapie in sheep. Cattle develop spongelike areas in the brain, with vacuoles appearing in the gray matter. The infectious agent is extremely resistant to heating and standard sterilizing temperatures, and its incubation period is very long, ranging from 2 to 8 years. It is thought that the scrapie agent from infected sheep may have adapted itself to a new host (cattle), possibly as a result of the practice of feeding sheep protein to cattle. Whether BSE can be transmitted to humans eating infected meat has been a topic of debate for some time, but recent concern over outbreaks of "mad-cow disease" in Britain has prompted a wide belief that this is so. Although as yet unproven, BSE infection from food is suspected to be the cause of a number of human cases of a new type of the rare, deadly brain malady known as Creutzfeldt-Jakob disease.

BSE prevention. Precautions to be taken include the destruction of all BSE-infected animals and their milk, banning the feeding of ruminant-derived protein to cattle, and prohibiting the sale of bovine offal from organs like the brain, intestine, and spinal cord, where the agent may replicate. In recent years, the British beef industry has been badly hurt by these and other efforts to control the disease.

Protozoal Infections

Amebiasis

Amebiasis is a disease with a worldwide distribution that occurs mainly where sanitation and hygiene are lacking. Transmission is mediated by the viable cysts of *Entamoeba histolytica,* which are tough-coated, rounded forms of the parasite, excreted in the feces of infected humans. The incubation period is between 2 and 6 weeks. Following ingestion of the cysts in contaminated water or food, excystation occurs in the intestines, and the liberated vegetative cells or trophozoites establish themselves in the large bowel. Ulcers are produced in the bowel wall, resulting in symptoms of amebic dysentery, namely diarrhea with blood and mucus in the stools. Infection may spread in the blood to cause abscesses in other organs like the liver, lung, and brain.

In many cases, noninvasive, symptomless infection continues for years, making carriers of people who excrete cysts in their feces and who are, thus, a potential threat to others, but these cases may convert to the symptomatic state when conditions are appropriate – as, for example, in the immunocompromised patient. The vegetative form, called trophozoite (feeding stage), is only occasionally seen in the feces (in diarrheal stool), is noninfective, and is rapidly destroyed in the environment. But the presence of a tough wall around the cyst (resting stage) renders it highly resistant to adverse environmental conditions. Cysts can survive for 2 to 4 weeks outside the host. They develop from trophozoites in the lumen of the gut and are passed out in the feces. Nuclear division and further development occurs within the cyst, even after it has been voided from the body.

Travelers often develop symptoms following ingestion of contaminated food or drink in countries where transmission is high. Oral or anal sex is also a possible route of transmission of this disease (for example, the "gay bowel syndrome" occurring among homosexual people). Prevention is achieved by the provision of good-quality water supplies or by boiling all drinking water (cysts are not killed by chlorine), safe disposal of sewage, screening food handlers to exclude cyst passers, and treatment of already infected individuals.

Cryptosporidiosis

Occurring in both humans and animals, infection by *Cryptosporidium parvum* is transmitted to the former mostly in rural areas, following contact with animals or consumption of contaminated milk, water, or food that has not been heat-treated. Explosive outbreaks in urban areas (Milwaukee, for example, where in 1993 more than 400,000 people became infected) are usually the result of waterborne spread. The cysts are not destroyed by chlorination but may be removed from drinking water by filtration. Indeed, a malfunction in the filtration of water in sand beds is believed to have caused several outbreaks of this disease in Great Britain. Outbreaks have also arisen from consumption of unpasteurized milk. The pasteurization process destroys this pathogen.

The incubation period is between 3 and 11 days. Following ingestion, the organism emerges from the cyst and penetrates the epithelial cells lining the intestinal lumen, coming to lie just beneath the membrane within a vacuole. Here, organisms multiply to form the oocysts that are released in the feces. The symptoms include impaired digestion, malabsorption, profuse watery diarrhea, vomiting, and weight loss. In the immunocompetent host, recovery occurs within 7 days. Immunosuppressed patients, however, develop severe and protracted diarrhea with dehydration and prostration, as is seen when AIDS patients are infected.

There is no effective treatment for this infection apart from supportive measures like rehydration. Prevention of infection involves preventing oocysts from coming in contact with food or water, provision of safe drinking water, and proper cooking of all food.

Giardiasis

Giardiasis is an infection principally of the small bowel, with symptoms of diarrhea, passage of bulky, pale, offensive stools, abdominal cramps and distension, malabsorption, weight loss, and fatigue. The malabsorption involves mainly fats and fat-soluble vitamins. The disease is characteristically seen as severe bloodless diarrhea in children. The trophozoite form of *Giardia lamblia/intestinalis* inhabits the duodenum and upper ileum, closely attached to the mucosa. Transmission is by the cyst forms, which are passed in stools that contaminate water and, sometimes, food. Cysts are destroyed by boiling but not by the routine chlorination of drinking water. Hence, the importance, as with cryptosporidium, of providing efficient preliminary sand filtration. The infective dose is said to be as low as 10 cysts. Following ingestion, excystation occurs, and the trophozoites are responsible for the intestinal pathology. Heavy infestation damages the mucosa and atrophies the villous processes, but there is no penetration into intestinal cells. The disease has a worldwide distribution and is found in relation to poor hygiene and the substandard quality of drinking water. The incubation period is between 1 and 3 weeks, and the disease, if untreated, lasts for 4 to 6 weeks. Symptomless carriage is a common feature. Prevention involves the use of boiled or filtered water and protection of food from contamination.

Other Intestinal Protozoa

Balantidium coli. This is a normal inhabitant (commensual organism) of the pig bowel. It has a worldwide distribution but rarely causes disease in humans. Those ingesting the cysts may develop a symptomless carrier status, or invasion of the colonic mucosa may lead to symptoms of colitis.

Isospora belli. This infection is particularly found in association with diarrhea in patients with acquired immunodeficiency disease (AIDS). In normal individuals it is possibly a cause of symptom-free infection or of mild transient diarrhea. Little is known about the life cycle. The organism inhabits the small bowel, cysts are passed in the stools, and transmission is believed to be by direct person-to-person transfer or via food or water.

Microsporidium. This group of organisms is found in a range of host species. The organisms have also occasionally been isolated from patients with AIDS and are now believed to be opportunistic pathogens. They are possibly transmitted during the spore stage, voided in the stools of an infected host, and they contaminate food or water. When swallowed by the new host, the organisms enter the gut mucosal cells and multiply there, producing symptoms of intractable diarrhea.

Toxoplasma gondii

Toxoplasmosis is a food-borne systemic infection with a wide geographical distribution. Serological tests indicate that a large proportion of the human population has been infected at some stage in life.

Toxoplasma gondii has a complex life cycle, with its definitive or final host (in which a sexual stage of development occurs) being the domestic cat and some of its wild relatives. The sexual stage takes place in the intestine of the cat, which then excretes oocysts in its feces, although the cat is rarely ill with the infection. Indeed, this relationship typifies a successful parasitization, where neither the host nor the parasite appears to suffer. The intermediate host, in which the asexual life cycle occurs, may belong to a wide range of species, including *Homo sapiens,* who is infected by ingesting the oocysts from cat feces. The parasites then travel via the bloodstream to infect cells in diverse parts of the body, where they multiply asexually (by fission), producing infective cysts. The incubation period may range from 5 to 20 days.

In the healthy individual, the infection is controlled by the immune response, although the parasite may evade immune surveillance by encysting in various tissue cells, surrounding itself with a tough coat, and continuing to multiply at a slow rate within the cyst. Damage to tissues may occur at these sites in immunocompromised individuals like AIDS patients. Pregnant women acquiring the acute infection may transfer the infection transplacentally to the fetus, which may be seriously damaged as a consequence. As in the immunocompromised patient, lesions may occur in the fetal brain, lung, liver, and other tissues with a fatal outcome.

The majority of people infected (often in childhood) develop no symptoms, but some develop a glandular fever-like syndrome, with fever and generalized enlargement of lymph glands. The disease may sometimes present with inflammatory lesions of the eye (choroidoretinitis). Avoidance of infection involves rigorous attention to hygiene, prevention of contamination of food with cat feces, the cooking of all meat before consumption, and advice to pregnant women to avoid contact with cat litter and feces.

Sacrocysts

Sarcocystis hominis causes a disease in humans (the definitive host), with mild symptoms like nausea, diarrhea, and malaise appearing a few hours after the ingestion of raw, infected meat from animals like cattle, sheep, and pigs (intermediate hosts) that contain the encysted infective forms. It is a common infection in animals but rare in humans. This is perhaps because of low transmissibility, inactivation by cooking or freezing, or the frequent occurrence of subclinical infection. The oocysts are passed in the feces of infected humans, and animals ingesting these oocysts develop the tissue cysts.

Trematodes (Flukes)

Adult trematode worms may inhabit either the intestinal tract, the bile ducts, or the lungs. Trematodes are flat, leaflike organisms having an alternating sexual cycle in the final (definitive) host and an asexual multiplication cycle in the intermediate host. Many trematodes have, in addition, a second intermediate host.

Fascioliasis

The liver fluke, *Fasciola hepatica,* is a common parasite of sheep and cattle kept in damp pastures in many parts of the world, and it is only occasionally found in humans. The adults live in the bile duct of the host and produce eggs that are passed in the feces of sheep and cattle. The developing form (miracidium) leaves the eggs and enters a suitable snail host. Here it multiplies asexually, and in 4 to 5 weeks the infective form leaves the snail and encysts on vegetation such as grass, watercress, or radishes growing at the site. Humans acquire the infection by eating the raw, infected vegetables. The young fluke then excysts and penetrates through the duodenum, goes to the liver, and settles in the bile ducts.

Symptoms of dyspepsia, nausea, fever, and abdominal pain occur in the acute stage. In the chronic stage, pain, enlargement of the liver and obstructive jaundice, and anemia may occur. Prevention involves protecting vegetation to be eaten raw from cattle or sheep feces and eliminating snails by draining pastures or using molluscicides.

Fasciolopsis

Fasciolopsis is the intestinal infection involving snails that occurs in China and some other parts of Asia. The large-sized fluke *Fasciolopsis buski* attaches itself to the wall of the small intestine of its host and passes its eggs in the feces. When the eggs find themselves in freshwater ponds, they hatch, and the larvae infect freshwater snails, in which they develop further. On leaving the snails, they encyst on the fruit and roots of water plants, like the water calthrop, water chestnut, and lotus. Pigs and humans are common hosts of the infection, which they acquire by eating the infective encysted forms on raw aquatic vegetation. Children in endemic areas often peel this material with their teeth, thus enabling entry of the parasite. Following ingestion, the parasite emerges from the cyst, attaches itself to the wall of the intestine, and develops into an adult.

In most cases the infection is asymptomatic, but where there is heavy infestation, symptoms include diarrhea, vomiting, and gripping pain. Diagnosis is confirmed by finding the eggs in the feces. Prevention involves careful peeling or cooking of water-grown vegetables before consumption in endemic areas. The cysts are killed by the drying of water plants or by a few minutes of boiling. It is necessary to keep human or pig feces away from ponds.

Heterophyiasis and Metagonimiasis

Heterophyes and *Metagonimus* species are small flukes that attach themselves to the wall of the small intestine between the villi. Eggs are passed in the feces into water, and larvae emerge to enter freshwater snails. The larvae emerge from the snails in due course to infect freshwater fish. Human infection follows ingestion of infective cysts in raw fish. The larvae excyst and establish themselves in the gut where they grow to adults, causing nausea, diarrhea, and abdominal colic. Adequate cooking of fish and prevention of fecal pollution of freshwater are important preventive measures.

Clonorchiasis and Opisthorchiasis

Infection with *Clonorchis* species occurs mainly in the Far East. Infection with *Opisthorchis* species occurs in the Far East, in Poland, in the Ukraine, and in Siberia. Adults are small flukes that live in the bile duct. Eggs, passed in the feces, infect snails in slow-flowing streams.

After a stage of development, larvae leave the snail and encyst themselves beneath the scales of freshwater fish. When raw or undercooked fish is eaten, the flukes excyst in the intestine and migrate up to the bile duct. Light infection may cause only vague symptoms related to the biliary tract. However, signs of biliary obstruction, portal hypertension, and enlargement of liver and spleen may occur in heavy infection. Dogs can also be infected and act as reservoirs of infection. Prevention involves the cooking of fish and treatment of feces before their use as fertilizers.

Gastrodisciasis

Human infection occurs in India (Assam), Bangladesh, Vietnam, China, and Russia, where adult *Gastrodiscoides hominis* attach themselves to the large intestine (colon or caecum), and eggs pass out in the feces to enter and develop in pond snails. The infective form then leaves to encyst on vegetation, like water calthrop. Eating infected raw vegetables leads to human infection and superficial inflammation of the intestinal mucosa. The presenting symptoms are diarrhea and passage of mucus in stools. Pigs act as a reservoir of infection. Prevention includes the careful peeling and washing of all water vegetables and keeping pig feces away from the water. Dried waterplants can be fed to pigs because drying inactivates the parasite.

Paragonimiasis

Paragonimiasis is seen in Asia, Africa, and America. The lung fluke – *Paragonimus westermani* – infects humans and animals that eat crustaceans like freshwater crabs and crayfish. The fleshy adults live in pairs in the lungs, resembling large coffee beans in size and shape. Eggs may be coughed up in sputum or swallowed and passed in feces. When they reach fresh water, the larvae emerge and penetrate snails. After a stage of development, the larvae leave the snails to penetrate and encyst in crabs and other crustaceans. When these are eaten uncooked, they can transmit the infection. Pickling processes that fail to kill the larvae are also often involved in transmission of the infection. Excystation in the small intestine enables the young fluke to emerge, penetrate the gut wall, and migrate across the diaphragm and into the lungs. Granulomatous changes occur in the lung surrounding the fluke, and symptoms include dry cough, pain in the chest, difficulty in breathing, and the coughing up of blood. Prevention involves the proper cooking of crustaceans and care in handling and washing them so as not to cause cross-contamination with other food.

Cestodes (Tapeworms)

Adult tapeworms all have flat, tape-like bodies and live in the intestinal tract. The body is segmented and the eggs are contained in the terminal segments, which are passed out in the feces. These eggs are infective.

Taeniasis

Taenia saginata (beef tapeworm). Human infection with this tapeworm occurs when raw or slightly cooked beef is eaten. Cattle are infected by eating infective eggs and develop cysticercosis, whereby infective larvae are found encysted in the muscles. When beef is eaten raw by humans, the larvae emerge and attach themselves to the walls of the small intestines and grow into adults of 5 to 20 meters in length. The terminal segments containing eggs drop off, emerging with feces to remain infective on grass and vegetation contaminated by human feces. The eggs are eaten by cattle and hatch out in the duodenum. The parasites then penetrate through the intestinal wall to reach the bloodstream and are carried to the muscles, where they form fluid-filled cysts (cysticerci). Each of these contains an infective larva that, when ingested raw by humans, can grow into an adult tapeworm in the gut. Cysts are killed by cooking at over 56° C.

The symptoms involved are vague abdominal complaints, with segments of worm occasionally wriggling out of the anus. Prevention includes cooking beef adequately, inspecting all meat intended for sale, and the condemnation of any "measly" meat containing tiny pinhead-sized cysts.

Taenia solium (pork tapeworm). People are at risk of contracting this tapeworm in countries where much pork is eaten, including Eastern Europe, China, Indonesia, South Africa, Mexico, and Chile. The infection is carried in pigs as infective cysticerci in the muscles. People acquire the infection by ingesting undercooked or raw pork. The infective form then leaves the cyst and attaches itself to the mucosa of the small intestine, where it proceeds to grow over the next 10 weeks to its full length of between 2 and 10 meters. The terminal segments containing the eggs are passed out in the feces. Pigs eat the infective eggs in soil or feces, and the larvae hatch out, penetrate the gut wall, and travel by the bloodstream to encyst in the musculature, causing cysticerci. As in cysticercus bovis, each cyst contains the infective cephalic end of the worm, which, when ingested by the definitive host (human), excysts and attaches itself to the small intestine, where the worm develops to the adult form. Symptoms are abdominal pain, diarrhea, and passage of segments through the anus.

Humans may also develop cysticercosis when they ingest the eggs of *Taenia solium* along with raw vegetables or drinking water. The larval forms migrate to and encyst in muscles, brain, and other tissues. Autoinfection may possibly cause cysticercosis in humans when reverse peristalsis carries eggs up to the stomach and duodenum, enabling hatching and migration of larval forms. The larvae in the cysticerci die off within a year and become calcified. Symptoms produced are related to the site of the lesion; for example, Jacksonian epilepsy can occur when the cysts form in the brain.

Prevention of transmission is achieved by (1) eating only well-cooked pork; (2) inspection of pig carcasses in the slaughterhouse to eliminate any that show signs of cysticercosis infection; and (3) safe disposal of human feces to interrupt the transmission to pigs.

Hymenolepiasis

Hymenolepiasis is cosmopolitan in distribution. Children in institutions and the immunodeficient or malnourished are particularly prone to it. The dwarf tapeworms of *Hymenolepis* species do not require an intermediate host. The adult worm lives in the small intestine, passing its eggs in the feces. When these eggs are ingested by other humans along with contaminated food or water, infection occurs. Autoinfection also takes place when eggs hatch out in a patient's gut; they develop into adults in 2 weeks.

Hydatidosis (Echinococcosis)

Hydatid disease occurs in the sheep- and cattle-rearing areas of the world, mainly those in South America, Kenya, Vietnam, and China. The adult *Echinococcus granulosus* is small, less than 1 centimeter in length, and inhabits the small intestine of carnivorous animals like dogs – the definitive hosts. The terminal segments of the worm, which contains the eggs, are passed in the dog's feces and can survive for months on pastures. When eaten by the intermediate host (humans, cattle, sheep, goats), the eggs hatch and the larval form penetrates the intestinal wall to be carried by the bloodstream to various parts of the body where hydatid cysts develop. The sites affected are often the liver, lung, brain, or bone, with the slow-growing cyst consisting of a laminated cyst wall filled with fluid and containing many infective forms (hydatid sand). When the tissue form is eaten raw, as happens when dogs are fed infected offal in farming regions, adult worms develop in the dog to repeat the cycle.

Symptoms of a slow-growing, space-occupying cyst are related to the site of the lesion. Treatment often requires careful surgical removal of the cyst. Prevention involves personal hygiene to avoid the ingestion of eggs from dogs, with regular worming of dogs to eliminate the tapeworm, and sanitary disposal of infected offal and viscera of slaughtered animals.

Diphyllobothriasis

Diphyllobothriasis occurs in temperate and subarctic countries where fish is eaten raw, as in Finland, the former Soviet Union, Japan, Canada, the United States, and Chile. The adult *Diphyllobothrium latum* (fish tapeworm) measures 3 to 10 meters long and remains attached by the head end to the mucosa of the small intestine. Eggs are discharged on their own (not within the segments as in taeniasis), pass out in feces, and hatch when they reach fresh water. The parasite now waits to be ingested by a freshwater microcrustacean (cyclops), in which it develops further. If this tiny freshwater cyclops is ingested by a freshwater fish, the larva emerges and penetrates the intestinal wall, developing into its infective form in the muscles of the fish. People ingesting infected raw fish acquire the disease, the symptoms of which include diarrhea, vomiting, fatigue, abdominal pain, dizziness, and megaloblastic anemia. Diagnosis is based on looking for eggs in stools. Prevention means avoiding raw fish, for the infective larvae can be killed by cooking, freezing, or thorough pickling procedures. Human sewage should be treated before discharge into water.

Nematodes (Roundworms)

Ascariasis

Ascariasis is a common disease in areas with poor sanitation, especially in the tropics. Infection with *Ascaris lumbricoides* (roundworms) is achieved by ingesting embryonated eggs on food, like salad vegetables. The larvae hatch, penetrate the wall of the duodenum, and travel in the bloodstream to the lungs, where they develop further. They then penetrate the alveoli and come up the trachea to be swallowed down into the intestines, where they settle in to mature in the ileum. Adults live in the lumen of the gut for up to 2 years, and their eggs are passed in the feces. The eggs are thick-walled and able to resist drying and the standard procedure for sewage treatment. They are, however, killed by heat over 60° C. These eggs require a further period of 10 to 50 days to develop in warm moist soil before they become infective. They may be consumed on raw salad vegetables or unpeeled fruit.

The majority of cases remain symptomless although respiratory symptoms occur when the larvae are traversing the lungs (cough, chest pain, pneumonitis with eosinophilia). When a heavy worm load is present in the intestine or when allergic reactions to the worm occur, symptoms of digestive disorder or intestinal obstruction may be observed. Diagnosis may be made by demonstrating eggs in feces. Prevention is accomplished by thorough washing of all salad vegetables, improvement of sanitation, safe disposal of sewage, and treatment of existing cases.

Trichuriasis

The adult nematode *Trichuris trichiura* (whipworm or thenoworm) has a narrow anterior whiplike portion and a broader posterior end. The whole worm is 40 centimeters long and lives in the colon with the anterior whiplike end embedded in the mucosa. Eggs are passed in feces, develop in warm moist soil, and are ingested by another human host. Larvae hatch to penetrate the wall of the large intestine where they develop into the adult form. They then return to the lumen of the colon, embed their whiplike ends by tunneling through mucosa, and repeat the cycle.

In children, following heavy infestation, the disease may present as retarded growth and malnutrition. Sometimes a prolapsed rectum may occur. Prevention measures are the same as those for ascariasis.

Enterobiasis

Enterobiasis is a common disease in most parts of the world, including temperate countries. The adult *Enterobius vermicularis* (pinworm) is about 11 millimeters long and lives in the lumen of the large bowel. Females lay their eggs on the skin around the anus, which causes intense itching. When scratched, the eggs are transferred on fingers or through dust to food. After they are ingested, larvae emerge to develop into adults in the bowel. The disease is common among children, can affect whole families, and is seen in institutions.

Diagnosis involves the demonstration of eggs in skin around the anus, whereas prevention involves hand washing and treatment of whole families or institutions. The cleaning of bedclothes and rooms to remove eggs is also essential.

Trichinosis

Infection with *Trichinella spiralis* in animals is worldwide, but human infection is mainly seen in Eastern Europe, the Arctic regions, South America, Asia, and East Africa. The domestic pig is the main source of infection, and the infective larval form is found encysted in the muscles. When eaten in raw or undercooked pork, it develops into the adult worm, which lives embedded in the mucosa of the small intestine. The adult is viviparous, producing many live larvae, which penetrate the intestinal wall to be carried in the blood to muscles, where they coil up forming cysts.

Symptoms include diarrhea, abdominal pain, and pain in the muscles. Heavy infection causes severe illness and may be fatal due to the involvement of the nervous or cardiac systems.

Diagnosis is confirmed by looking for larvae in muscle biopsies, and prevention is accomplished by cooking meat at over 60° C or deep freezing it to kill the larva. In addition, improving their feed prevents pigs from contracting the disease.

IV.E.5 Food Sensitivities: Allergies and Intolerances

Foods and beverages contain nutrients that are essential to human life, but they also contain elements that, for some individuals, may be harmful to health or even life-threatening. Foods and beverages may cause adverse reactions when ingested, but humans also can have adverse reactions to foods through inhalation (Edwards, McConnochie, and Davies 1985; Kemp, Van Asperen, and Douglas 1988), skin contact (Mathias 1983), or injection (Flu Shots and Egg Allergy 1992; Schwartz 1992).

Sensitivity to foods may be caused by immunologic abnormalities or by other mechanisms, such as host enzyme deficiency. Food sensitivities caused by immunologic abnormalities are commonly referred to as food allergies, whereas food sensitivities caused by nonimmunologic mechanisms are referred to as food intolerances (Anderson 1990; Beaudette 1991). This chapter reviews major considerations with regard to both classifications of food sensitivities. It should also be noted that a disorder called "pseudo-food allergy syndrome" exists. This syndrome is a psychological disorder in which the sufferer believes in the existence of a food allergy that cannot be confirmed by clinical testing (Pearson and Rix 1983, Pearson 1988).

Food Allergies

Allergic, or immunologically based, reactions to food most commonly involve a Type I or IgE mediated reaction (Anderson, 1990) as classified by R. R. A. Coombs and P. G. H. Gell (1975). The stages of the Type I reaction are illustrated in Table IV.E.5.1. It has been theorized that IgE mediated reactions to food may be related to a reduction in the need to produce IgE in response to intestinal parasitic infection. This theory, known as the "mast cell saturation hypothesis," speculates that when the majority of IgE antibodies are bound to intestinal parasites, fewer antibodies are available to bind with food antigens. Production of high levels of IgE to fight parasitism would be protective, whereas production of high levels of IgE specific for food antigens is counterproductive to health (Godfrey 1975; Merrett, Merrett, and Cookson 1976; Lieberman and Barnes 1990).

In food allergy, the Type I reaction involves production of IgE antibodies that are tailored to food allergens. Food allergens are most commonly proteins but also may be glycoproteins or glycolipids (Bindels and Verwimp 1990). In order for a food allergen to stimulate IgE production, it must be absorbed and be of the appropriate size and shape to bridge IgE antibodies on the mast cell surface (Perkin 1990; Taylor 1990). Although most individuals are able to digest food proteins without eliciting an allergic response, individu-

Table IV.E.5.1. *The Type I allergic reaction*

Stage	Description
1st	Familial predisposition: To make IgE allergen-specific antibodies–Atopy.
2d	Sensitization and fixation: Specific allergen exposure, sensitization to form IgE allergen-specific antibodies followed by mast cell (or basophil effector cells) fixation.
3d	An-Ab interaction, mediator release/formation: reexposure to specific allergen, allergen +IgE antibody interaction followed by both preformed chemical mediator release from mast cells (or basophils) or activation of other mediator pathways outside the effector cells.
4th	Immune inflammation: Influx of leukocytes and monocytes. Release of other chemical mediators from all types of cells, plus tissue reactive substances from eosinophils. Release of cytokine histamine releasing factor (HRF) to promote nonspecific reactivity.
5th	Clinical reactions: (1) Early phase–within minutes to hours an allergic reaction occurs, including vasodilation, smooth muscle contraction, and hyperglandulin secretion. (2) Late phase – in one-third to one-half of all cases, in 6 to 12 hours a late inflammatory reaction occurs that is characterized by eosinophil (and other leukocytes and monocytes) infiltration – tissue damage and other mediator release (from all cells). (3) Prolonged phase – clinical hyperreactivity induced by nonspecific chemical mediator release, following nonallergic stimuli and modified by HRF.

als who are atopic seem to absorb food antigens in a form that causes their cells to produce IgE. When food allergens are of the appropriate size, they are capable of binding with IgE and triggering the release of chemicals that cause the clinical manifestations of food allergy. Chemicals commonly implicated in the allergic process include histamine, leukotriences and cytokines (Metcalfe, 1991).

In some individuals, exercise may play a role in stimulating the food allergy response (Sheffer et al. 1983). Food-dependent anaphylaxis related to exercise is thought to be associated with chemical mediator release from mast cells in conjunction with an abnormal functioning autonomic nervous system, specifically increased parasympathetic activity and decreased sympathetic activity (Fukutomi et al. 1992). Abnormalities of IgE synthesis associated with other disorders may result in the secondary appearance of food allergy. D. S. Mazza, M. O'Sullivan, and M. H. Grieco (1991) have published a case report of food allergy that developed secondary to infection with the human immunodeficiency virus.

There are types of food-related immunologic reactions that are not believed to be Type I. Heiner's syndrome (a bovine milk-associated respiratory disorder) and celiac sprue are two examples of adverse food reactions believed to be associated with other types of immunologic reactions (Anderson 1990).

Food allergy is more common in children than adults although food allergy can develop at any age. One study that surveyed physicians estimated that allergy prevalence was 7 percent for adults and 13 percent for children (Anderson 1991). Another often-cited study estimates the prevalence of allergy in children to be from 0.3 to 7.5 percent, with adults having a lower prevalence (Buckley and Metcalfe 1982). One theory used to explain the relatively higher level of allergy prevalence in children relates to infancy-associated intestinal immaturity, which, some believe, results in greater passage of larger proteins across the gut with resultant stimulation of IgE production (Walker 1975; Udall et al. 1981). But the primacy of a more permeable intestine in terms of allergy causation has recently been questioned by T. Jalonen (1991), who has postulated that greater intestinal permeability is a secondary phenomena for food allergy rather than an initiating event.

Infants may become sensitized to food allergens in utero since IgE can be synthesized before birth and large food proteins can cross the placenta. It should be noted, however, that although prenatal sensitization occurs, it is a relatively rare event (Strimas and Chi 1988). P. G. Calkhoven, M. Aalbers, V. L. Koshte, and colleagues (1991) have postulated the existence of a "high food responder phenotype" based on their findings that certain children seem to demonstrate allergic responses to a wide variety of foods. High cord IgE levels or high levels of serum IgE measured seven days after birth are considered to be predictive of subsequent food allergy development in an infant (Chandra, Puri, and Cheema 1985; Strimas and Chi 1988; Ruiz et al. 1991). A low level of CD8+ suppressor cells in the neonatal period is also predictive of the potential for allergy development (Chandra and Prasad 1991).

Breast feeding is often cited as being allergy protective, but this is an extremely controversial subject (Kramer 1988; Perkin 1990). Certainly there are physiological reasons to suggest that breast feeding may be protective against food allergies or at least may delay food allergy development. These reasons include (1) the relative lack of exposure to food antigens associated with breast feeding; (2) the presence of secretory IgA in breast milk, which is believed to aid in reducing the intestinal entry of large food protein molecules; (3) the stimulation of infantile IgA production by breast milk; (4) the opportunity for less intestinal antigen uptake because of the decreased incidence of gastrointestinal infections associated with breast feeding; (5) the presence in breast milk of anti-inflammatory properties, such as histaminase and arylsulfatase, and (6) the provision of IgG antibodies in breast milk that are targeted at food antigens (Pittard and Bill 1979; Atherton 1983; Businco et al. 1983 ; Ogra et al. 1984; Goldman et al. 1986; Michael et al. 1986). Low breast milk IgA levels have been associated with an increased likelihood of developing infantile cow's milk allergy (Savilahti et al. 1991).

Clinical studies that have examined breast feeding in relation to food allergy have not demonstrated a clear-cut protective or delaying effect (Kramer 1988; Perkin 1990), perhaps because of numerous methodological problems involved in this type of research. If breast feeding is protective, it is generally believed that exclusive breast feeding (no solid foods and no formula) should be practiced for at least six months (Bahna 1991; Kajosaari 1991). Since this is seldom done in the United States, the measurement of any allergy-prevention benefits of breast feeding is difficult.

Food allergies may disappear over time. Young age at food allergy onset coupled with a mild clinical reaction may mean that an individual will ultimately develop tolerance for an offending food. A more severe clinical reaction profile and older age of food allergy onset are associated with greater likelihood of allergy persistence. Allergies to certain foods, such as peanuts or crustacea, also tend to be allergies that persist through time (Anderson 1991). Food allergy developing in adulthood may be related to occupational exposure to food antigens (Anderson 1991; Metcalfe 1991). Baker's asthma, caused by allergic reactions to several wheat proteins, is one of the most studied occupational allergies (Prichard et al. 1985; Anderson 1991).

Certain foods have been commonly identified as implicated in the causation of food allergies. Among these are cow's milk, soybeans, wheat, eggs, nuts, and seeds (including cottonseed, which can be highly allergenic), crustacea (shrimp, lobster, crawfish), and fish. Also implicated are noncitrus fruits and vegetables (for example, tomato, celery, watermelon, pear, cherry, apple), citrus fruits, and spices (Perkin 1990). Table IV.E.5.2 outlines currently identified food allergens in some of the major food categories linked to allergy (Perkin 1990). Food types linked to allergy reflect cultural dietary patterns (Esteban 1992; Walker 1992).

The literature continues to identify new food categories that may cause allergic reactions in some individuals. Foods recently identified include squid (Carrillo et al. 1992), grand keyhole limpet and abalone (Morikawa et al. 1990), annatto dye (Nish et al. 1991), jícama (Fine 1991), and Swiss chard (de la Hoz et al. 1991). Progress has also been made in terms of identifying other factors, such as mites, that may be related to food allergies. For example, A. Armentia, J. Tapias, D. Barber, and colleagues (1992) have demonstrated that an allergic reaction may be precipitated by exposure to the wheat flour storage mite *Lepidoglyphus destructor.* Foods or beverages used as folk remedies may also elicit allergic reactions. J. Subiza, J. L. Subiza, M. Alonzo, and co-workers (1990) have described allergic responses that were initiated by washing the eyes with chamomile tea. Even human breast milk may contain allergenic food proteins (Gerrard and Shenassa 1983; Kilshaw and Cant 1984; Gerrard and Perelmutter 1986).

Table IV.E.5.2. *Major food allergens*

Food	Identified allergens
Cow's milk	Beta-lactoglobulin, alpha-lactalbumin, casein
Soybeans	Globulin 2S, Globulin 7S, Globulin 11S, hemagglutinin
Shrimp	Sa-I, Sa-II, antigen I, antigen II
Fish	Allergen M, protamine sulfate
Egg white	Ovalalbumin, ovotransferrin, ovomucoid
Egg yolk	Apovitellenin I, Apovitellenin VI

The determination of the extent to which foods related to one another in botanically defined plant families trigger allergies has long been of interest. When such a reaction occurs, it is called cross-reactivity. Legumes (Barnett, Bonham, and Howden 1987) and crustacea (Sachs and O'Connell 1988) are often studied in this regard. Cross-reaction between environmental and food allergens has also been reported. Birch pollen has been noted to be cross-reactive with the carrot and apple (Ortolani et al. 1988), and banana and latex have recently been reported as cross-reactive (M'Raihi et al. 1991). The phenomenon of cross-reactivity is one that is currently ill defined and is a subject of debate in terms of its clinical relevance.

Clinical signs and symptoms of food allergy are numerous, and diagnosis of food allergy is a complex process. Clinical manifestations may occur in selected body systems, such as the respiratory system or the skin, or may be a more generalized phenomenon, such as anaphylaxis. There are also specific syndrome symptom complexes that have been linked to food allergy.

Skin symptoms of food allergy may include hives, angioedema, eczema, and itching and/or redness (Anderson 1991). Eczema is particularly common in children and usually occurs on the elbows, knees, and perhaps the face (Burks 1992). Respiratory symptoms may include rhinitis, wheezing, and asthma.

Certain food allergies also produce gastrointestinal symptoms, such as nausea, vomiting, and diarrhea (Anderson 1991; Beaudette 1991; Metcalfe 1991). Cow's milk allergy is particularly noted for its association with gastrointestinal symptoms. It may also be associated with low-grade gastrointestinal bleeding and, thus, may be a cause of anemia (Wilson and Hamburger 1988).

Anaphylaxis is a systemic manifestation of food allergy. It is also potentially deadly, although it may be mild and simply characterized by simultaneous allergic manifestations in several organ systems. But the term is commonly used to refer to the more serious form of multiorgan system reaction that includes the development of cardiovascular shock, severe respiratory distress, and even death (Anderson 1990). Symptoms of classic food allergy generally appear within one to two hours after ingestion of the offending food, although in some cases, symptoms can appear as much as 12 hours following consumption (Anderson 1990).

Several clinical syndromes have also been associated with food allergy. These include oral allergy syndrome, eosinophilic gastroenteritis, food protein-induced enterocolitis syndromes, and hypersensitive furrowed mouth (Anderson 1991; Metcalfe 1991).

Oral allergy syndrome, as described by C. Ortolani, M. Ispano, E. Pastorello, and colleagues (1988), is initially manifested by irritation and swelling of the lips, which is then followed by hives, respiratory problems, and, in some cases, the development of anaphylactic shock. The oral allergy syndrome is associated with allergies to certain fruits and vegetables, notably celery (Ortolani et al. 1988; Pauli et al. 1988). J. A. Anderson (1991) has estimated that 0.1 to 0.2 percent of the general population may experience oral allergy syndrome. The syndrome is more frequently seen in persons who are sensitive to ragweed pollen.

Eosinophilic gastroenteritis associated with food allergy is characterized clinically by gastrointestinal disturbance, elevated levels of eosinophils, the presence of eosinophils in the stomach and intestine, and elevated levels of IgE (Anderson 1991; Metcalfe 1991). The syndrome of food protein-induced enterocolitis is seen in infants and is characterized by diarrhea, malabsorption, and high levels of eosinophils (Metcalfe 1991).

Hypersensitive furrowed mouth syndrome is characterized by mouth swelling and the development of cracks and furrows in the mouth. Anderson (1991), who described this problem, has associated it with consumption of large amounts of foods rich in protein.

Diagnosis of food allergy can be complex. It involves analysis of the clinical history, epicutaneous skin testing, and/or the use of in vitro assays, such as the radioallergosorbent test (RAST) or the enzyme-linked immunosorbent assay (ELISA) (Anderson 1990).

Elimination diets and the analysis of diet-symptom diaries may also be used in the diagnostic effort (Olejer 1990; Burks and Sampson 1992). The "gold" standard for diagnosis of food allergy is the double blind placebo-controlled food challenge (Olejer 1990). In children under the age of three years, skin testing is not a reliable indicator of food allergy, and single blind food challenge is more commonly employed to determine foods to which a child has an adverse reaction (Olejer 1990; Beaudette 1991). Diagnostic procedures used for research purposes are being studied for potential clinical application. These include basophil histamine release assay and assay of intestinal mast cell histamine release (Burks and Sampson 1992).

Once a food allergy is diagnosed, treatment primarily involves instructing the patient to eliminate the offending substance from the diet. This requires that the allergic individual pay careful attention to food preparation techniques and food labeling. Unfortunately, food labels are not always helpful and can even be misleading. A label of kosher-parve, for example, generally denotes a milk-free product, but a recent report indicated that a dessert labeled as kosher-parve was found to contain milk protein (Jones, Squillace, and Yunginger 1992). In this instance, the milk proteins were present in the product as the result of a faulty production process that permitted milk contamination from previous use of the equipment.

In some cases, individuals may not understand the wording on food labels. R. N. Hamburger (1992) noted that one of his patients did not recognize that the term "calcium caseinate" meant the presence of milk protein. Eating outside of the home also presents special problems. The National Restaurant Association has recently launched an allergy awareness program and is attempting to make restaurant owners more aware of the needs of patrons with food allergies (Restaurant Food Allergy Awareness 1992).

Special attention must be paid to the nutritional adequacy of diets when foods are eliminated. Nutritional deficits, such as insufficiencies of calories, protein, and calcium, have been noted in children following restricted diets for food allergies (Lloyd-Still 1979; Sinatra and Merritt 1981; David, Waddington, and Stanton 1984).

For limited periods of time, elemental diet formulas may be useful for managing food allergies. These formulas contain protein that has been extensively hydrolyzed. However, the relatively poor taste and high cost of these products generally make them a poor long-term solution for food allergies. They can, however, help symptoms resolve and can bring relief prior to the development of a restricted dietary program of traditional foods.

Formula-fed infants who are allergic to cow's milk protein are placed on alternative formulas. These may include a soy-based formula or one of casein hydrolysate (Olejer 1990). The use of soy formulas, however, to treat infants with cow's milk allergy is controversial, and whey hydrolysate formulas are currently not recommended as treatment for such infants (American Academy of Pediatrics 1983; Businco et al. 1992).

Hypoallergenic formulas are defined as those that can be tolerated by children with cow's milk allergy, such that 90 percent will experience no symptoms at a 95 percent level of confidence (Sampson 1992). Casein hydrolysate formulas are currently regarded as hypoallergenic (Oldaeus et al. 1992; Rugo, Wahl, and Wahn 1992). Breast-fed infants who are allergic to food proteins transferred through breast milk may be treated by the mother's restriction of the offending foods from her diet (Perkin 1990).

Traditionally, pharmacological approaches have had limited application in the treatment of food allergies. Epinephrine is used as an antianaphylactic agent, and antihistamines and corticosteroids are employed to alleviate allergy symptoms (Doering 1990). Oral cromolyn is effective in some cases for treating food allergy or other food-related problems, such as migraine (Doering 1990; Knottnerus and Pelikan 1993). Injection treatment with peanut extract is currently being investigated (Oppenheimer et al. 1992), as are such drugs as loratadine (Molkhou and Czarlewski 1993) and pancreatic enzyme supplements (Bahna and McCann 1993).

Research efforts are attempting to find ways that food allergies can be prevented or delayed. One thrust of the research is to examine infant formulas for those types that can delay or prevent allergies. Although not currently recommended for cow's milk allergy treatment, whey hydrolysates have been demonstrated by some studies to be protective (Chandra and Prasad 1991; Vandenplas et al. 1992); other studies have found that casein hydrolysate formula can decrease the occurrence of atopic dermatitis (Bahna 1991) and eczema (Mallet and Henocq 1992).

The majority of food allergy prevention focuses on alterations of both maternal and infant diet. As early as 1983, Hamburger, S. Heller, M. H. Mellon, and colleagues began testing the efficacy of a maternal elimination diet (no eggs, peanuts, and milk during the last trimester of pregnancy and during lactation) in conjunction with modifications in the infant's diet, such as delayed introduction of solids and breast feeding supplemented only by casein hydrolysate formula. But this type of regimen has yet to prove successful even though it may help to delay allergy appearance (Zeiger et al. 1986; Zeiger et al. 1989). Preventive strategies, such as the restrictive regimen just described, are used with infants who are considered at high allergy risk as determined by cord blood IgE levels (greater than 2 micrograms per liter) and a positive family history of allergy (Beaudette 1991). M. Kajosaari (1991) has demonstrated that delay of solid feeding until the age of six months can help prevent food allergy, and such a delay is currently standard dietary advice.

Food Intolerances

Some individuals experience adverse reactions to foods that cannot be explained by an immunologic mechanism. Several substances seem to elicit clinical problems through these alternative pathways that include enzyme deficiencies and pharmacological mechanisms (Schwartz 1992). Examples of food components associated with intolerance include lactose, histamine, gliadin, aspartame, sulfites, tartrazine, and monosodium glutamate. Some of these components are naturally present in foods, whereas others occur as food additives.

Lactose (or milk sugar) consumption causes problems because of inadequate amounts of intestinal lactase activity (MacDonald 1988). Symptoms of lactose intolerance include diarrhea, pain, and abdominal bloating (Scrimshaw and Murray 1988). The most common type of lactose intolerance is termed primary lactase deficiency. It occurs sometime following weaning and is found in varying degrees from mild to severe. It is a common condition among the majority of the world's populations (Savaiano and Kotz 1988). Lactose intolerance can also occur as a secondary event subsequent to intestinal damage (Penny and Brown 1992).

Histamine, a preformed chemical mediator for allergic reactions, is naturally present in some foods and wines (Malone and Metcalfe 1986; Anderson 1990). Most of the time, histamine in foods does not cause problems because it is quickly broken down by enzymes in the digestive process. Some individuals do experience symptoms of histamine sensitivity, which include headache and reddening of various body parts, such as the eyes, face, and hands. Histamine sensitivity problems may also be seen when histidine is degraded to become histamine in fish and cheeses (Burnett 1990). Scombroid fish poisoning is the name given to the clinical complex (headache, flushing, and neck pain) caused by eating dark fish meat in which histidine has broken down to histamine because of improper storage and high temperatures. This syndrome can be treated with histamine antagonist drugs (Morrow et al. 1991).

Gliadin, a component of gluten, is a natural food substance that can cause adverse reactions in some individuals. It occurs in grain products such as wheat, rye, and barley. Celiac sprue, an intestinal disorder, and dermatitis herpetiformis, a skin disorder, are the clinical manifestations of intolerance to gliadin. A transient, rare form of gluten hypersensitivity, similar to celiac sprue, has also been reported in very young children (Iacono et al. 1991).

Celiac sprue, the intestinal form of gliadin intolerance, is characterized by iron deficiency, weight loss, diarrhea, malabsorption, abdominal distension, and altered mental capabilities. Persons suffering chronically from celiac sprue appear to be at increased risk for the development of cancer (Holmes et al. 1989) and osteoporosis later in life (Mora et al. 1993). Recent work has focused on identifying and describing peptides of gliadin that cause the damage in celiac sprue (Cornell, Weiser, and Belitz 1992). The disease may have an immunologic basis, but this has not been fully described; and for the moment at least, celiac sprue is classified as a food intolerance rather than a food allergy.

Dermatitis herpetiformis, the skin form of gliadin intolerance, is characterized by a rash with itching and blistering. Granular deposits of the immunoglobulin IgA between skin layers are also characteristic of dermatitis herpetiformis (Beaudette 1991).

Aspartame is a nutritive artificial sweetener added to a variety of foods. It was introduced into the marketplace in 1981 (Tollefson and Barnard 1992). Adverse reactions reported in conjunction with aspartame ingestion include headache, memory loss, depression, dizziness, changes in vision, and seizures (Bradstock et al. 1986; Roberts 1990). L. Tollefson and R. J. Barnard (1992) have indicated, however, that an analysis by the United States Food and Drug Administration does not support the assertion that aspartame causes seizures. The postulated mechanism for aspartame's link to headache is via increasing serum tyrosine levels (Schiffman et al. 1987). One study has cited an immune basis for aspartame sensitivity manifested by hives (Kulczycki 1986). Aspartame, however, has not been shown to degranulate basophils or mast cells (Garriga and Metcalfe 1988). Therefore, in general, adverse reactions in conjunction with aspartame tend to be reported under food intolerance because of an unknown mechanism or mechanisms. After failing to reproduce hypersensitivity reactions to aspartame, M. M. Garriga, C. Berkebile, and D. D. Metcalfe (1991) noted that aspartame should not induce an IgE mediated response because it is easily broken down in the brush border of the intestine.

Sulfites are another category of food additive associated with adverse reactions in selected individuals. About one percent of the general United States population is estimated to be sulfite sensitive (Folkenberg 1988); this figure rises to about 5 percent of the asthmatic population (Nagy et al. 1993). As in the case of aspartame, most sulfite-associated adverse reactions cannot be linked to an immune mechanism, although an immune abnormality may be responsible for a reaction in a small number of individuals. W. N. Sokol and I. B. Hydick (1990) demonstrated basophil histamine release and obtained a positive skin test in a patient who had symptoms of angioedema, nasal congestion, and hives. Examples of clinical problems seen in conjunction with sulfite sensitivity include low blood pressure, hives, angioedema, intestinal cramping and chest tightness (Perkin 1990).

Sulfite sensitivity seems to have different clinical manifestations with asthmatics, where it is manifested by bronchial dysfunction (spasm or constriction), dizziness, flushing, wheezing, and perhaps anaphylaxis (Perkin 1990). Recently, sodium bisulfite has also been linked to genetic damage in lymphocytes (Meng and Zhang 1992). One postulated mechanism for sulfite sensitivity is the initiation of a cholinergic reflex by sulfur dioxide's action upon tracheobronchial receptors (Anibarro et al. 1992). With some individuals, it is believed that a deficiency of sulfate oxidase may be responsible (Simon 1987; Perkin 1990). Deaths and severe reactions related to sulfite sensitivity have resulted in strict labeling regulations when sulfites are present in foods in excess of 10 parts per million (ppm) (Schultz 1986). Experimentation is also under way to determine if the use of cyanocobalamin can prevent sulfite-induced respiratory distress (Anibarro et al. 1992).

Tartrazine, or FD&C Yellow 5, is another food additive cited as causing adverse reactions in susceptible individuals. Tartrazine is used to produce various food colors including yellow, green, and maroon (Dong 1984; Schneider and Codispoti 1988), and more than half of the daily food dye consumption in the United States is in the form of tartrazine (Beaudette 1991). Clinical symptoms indicating an adverse reaction to this food additive include hives, asthma, angioedema, photosensitivity, eczema, purpura, and anaphylaxis (Michaelsson, Petterson, and Juhlin 1974; Desmond and Trautlein 1981; Pereyo 1987; Perkin 1990; Devlin and David 1992). J. Devlin and T. J. David (1992) recently indicated that they could confirm tartrazine intolerance in only 1 of 12 children whose parents reported that tartrazine consumption worsened their child's eczema. Although the mechanism of tartrazine sensitivity is unknown, the cause has been postulated as an excess of bradykinin production (Neuman et al. 1978). There is a link between aspirin sensitivity and tartrazine sensitivity with a cross-reactivity of 5 to 25 percent reported (Settipane and Pudupakkam 1975; Condemi 1981).

Monosodium glutamate (MSG) as the cause of adverse food reaction has been a source of great controversy. It is used as a food additive because of its ability to enhance flavors (Beaudette 1991). The most often cited potential adverse reaction to MSG is Chinese Restaurant Syndrome characterized by such symptoms as development of tears in the eyes, facial flushing, tightness and burning, nausea, sweating, headache, and vascular abnormalities (Ghadimi and Kumar 1972; Gann 1977; Goldberg 1982; Zautcke, Schwartz, and Mueller 1986).

Symptoms of this syndrome usually occur shortly after consumption of an MSG-containing food, and problems generally resolve in less than one hour (Beaudette 1991). Some scientists suggest that the role of MSG as the causative agent of the Chinese Restaurant Syndrome remains unproven because of a lack of a demonstrated dose-response effect (Beaudette 1991), and histamine has been proposed as an alternative culprit (Chin, Garriga, and Metcalfe 1989). In addition to Chinese Restaurant Syndrome, other potential adverse reactions to MSG consumption have been reported. These include headache, angioedema, and asthma (Diamond, Prager, and Freitag 1986; Allen, Delohery, and Baker 1987; Squire 1987). It has also been suggested that there may be a subset of the population for whom the potential excitotoxicity of glutamate could be a problem (Barinaga 1990).

Prevention and treatment of food intolerance involves avoidance of the foods and beverages that contain the offending substances. Careful reading of food labels is critical. In the case of lactose intolerance, some individuals can consume small amounts of milk or dairy products, such as yogurt or cheese, which have a low lactose content. In addition, some find it beneficial to employ special dairy products in which the lactose has been partially hydrolyzed or broken down or to use tablets that serve to break down lactose in foods and beverages. Celiac sprue and dermatitis herpetiformis are treated with a gluten-restricted, gliadin-free diet (Beaudette 1991), sometimes referred to as a gluten-free diet. The gluten-free diet has recently been shown to relieve the primary symptoms of these conditions, and also to aid in protecting against bone loss (Mora et al. 1993) and cancer (Holmes et al 1989). Some have advocated the use of a low gluten diet for the treatment of celiac sprue (Kumar et al. 1985; Montgomery et al. 1988), but at present this is in the exploration stage as a potential treatment alternative.

Summary

Foods and beverages may cause clinical problems through immunologic or physiological mechanisms. When immunologic mechanisms are confirmed, the condition is called a food allergy. The term food intolerance is used to denote clinical problems associated with food when an immunologic mechanism cannot be confirmed.

Common food allergens in the United States include cow's milk, soybeans, wheat, eggs, nuts, seeds, and crustacea. Food allergies are more common in children than adults. Most food allergies are of the Type I IgE mediated variety. Avoidance of the foods that cause problems is the mainstay of current prevention and treatment efforts.

Food intolerance may be associated with natural food components or with food additives. Natural food components that cause clinical problems include lactose (milk sugar), histamine, and gliadin. Food additives linked to intolerance include aspartame, sulfites, monosodium glutamate, and tartrazine. Here again, dietary avoidance is the key to preventing and treating food intolerances, although pharmacological agents may be useful in treating symptoms associated with food allergies or intolerances. Several new pharmacological approaches are now being investigated.

Research in the area of food intolerances continues to look at immune mechanisms (particularly those in addition to Type I) and other physiological mechanisms that cause clinical problems related to exposure to foods and beverages. Research efforts are also underway to characterize the specific components that cause food allergies and to find new ways of treating them. In addition, testing of potential preventive or delaying approaches will continue to be a research focus in future years.

IV.E.6 ~ Lactose Intolerance

Lactose is a disaccharide composed of linked molecules of the simple sugars glucose and galactose. Dietary lactose is obtained almost exclusively from milk. Infants and young children digest lactose with an enzyme, lactase, which splits the molecule into the two readily absorbable simple sugars. The majority of adults, however, have lost this ability and are lactose malabsorbers. Those malabsorbers who display clinical symptoms after milk consumption are described as lactose intolerant.

Lactose is a major constituent of the milk of all mammals except sea lions (Kretchmer 1993). Human milk contains the highest lactose concentration, about 7 percent; lactose levels in commonly milked animals, such as camels, goats, sheep, and cows, run between 4 and 5 percent. Adult animals, like most humans, lose the ability to digest lactose. This suggests that adult loss of lactase is a normal mammalian trait and that adult ability to split lactose is an "abnormal" evolutionary innovation.

Definition and History

Lactose malabsorption and intolerance must be distinguished clinically from allergy to milk proteins, which is a rare but serious genetic problem in infants. This essay focuses on primary adult onset lactase deficiency, but two other forms of the syndrome must be noted. Lactase deficiency may be secondary due to damage to the small intestine from heavy parasitic infections (especially the protozoan *Giardia lamblia*); to other severe intestinal infections; to AIDS; and to ionizing radiation, some drugs, and gastric surgery (Castiglia 1994; Tamm 1994). Total inability to synthesize lactase is another rare genetic disorder that was obviously lethal until modern times. If diagnosed promptly, such cases can now be managed with soy-based infant formulas.

Gastrointestinal distress in adults after milk consumption was described in ancient Greek and Roman texts, and there were isolated clinical reports in the late nineteenth and early twentieth centuries, but the problem was not widely studied until the development (in the 1960s) of new techniques to study enzymatic action in the intestine. Consequently, the high prevalence of diminished lactase activity in healthy adults was described only in the early 1960s, with especially important work done by A. Dahlqvist and his associates (Dahlqvist 1977). Worldwide surveys in the 1960s and 1970s showed that loss of lactase activity in adulthood is the common condition in humans and that terms like "lactase deficient" incorrectly imply that this is somehow abnormal (Flatz 1987).

Biology and Clinical Manifestations

Lactase (technically lactase-phlorizin hydrolase), is a protein produced in the cells of the epithelium of the small intestine. It is most concentrated in the mucosal cells of the brush border of the jejunum (Buller and Grand 1990). Production of lactase begins to decline in most children between the ages of 2 to 5, around the time of weaning. Most adults retain only about 10 percent of infant-level lactase activity. But Finnish children who become lactase deficient often do so as teenagers; the reasons for this late onset are unknown (Arola and Tamm 1994).

If lactose-intolerant people consume significant quantities of milk or other dairy products, unmetabolized lactose passes through the small intestine to the large intestine, where it is acted upon by the resident facultative bacterial flora. These bacteria split lactose into acetic, butyric, propionic, and other short-chain fatty acids, which can be absorbed by intestinal cells and used as metabolites. Among the by-products are carbon dioxide, hydrogen, and methane, which can cause a gassy, bloated, and/or nauseous feeling.

It is generally thought that the abundance of short-chain molecules increases osmotic pressure within the intestinal lumen, causing water to pass into the lumen, sometimes in amounts that produce diarrhea (Castiglia 1994), but this has recently been questioned by H. Arola and A. Tamm (1994). They suggest that bacteria that produce larger amounts of iso-fatty acids – those with branched carbon chains in contrast to the normal straight chain forms – may provide protection against diarrhea. Although the intestinal flora of an individual tend to remain relatively stable over time, commensal bacterial populations vary considerably among people. Those persons with large colonies of the types of bacteria that efficiently metabolize lactose and produce significant quantities of iso-fatty acids (for example, members of the genus *Bacteriodes*) would be less likely to display symptoms (Arola and Tamm 1994). They would be lactose malabsorbers but not necessarily lactose intolerant.

Genetics

The mechanisms controlling lactase production were disputed for many years. Some researchers, drawing on studies of gene regulation in bacteria, argued in the 1960s that lactase was a substrate-inducible enzyme; that is, that lactase production was believed to be stimulated by the presence of its substrate, lactose. In this view, populations that did not use milk as adults lost the ability to produce lactase, whereas groups that did consume milk and milk products retained lactase capability.

Biochemical studies cast doubt on this theory, and family studies have demonstrated that lactase production is controlled by an autosomal gene, recently located on chromosome 2. Persistence of lactase production is a dominant trait (Buller and Grand 1990; Arola and Tamm 1994). Following the terminology suggested by Gebhard Flatz (1987), the two alleles are designated LAC*P for lactase persistence and LAC*R for normal adult lactase restriction. The LAC locus appears to be a regulatory gene that reduces lactase synthesis by reducing the transcription of messenger RNA (Arola and Tamm 1994). Persons inheriting LAC*P from both parents would have lactase persistence into adulthood; those getting LAC*R alleles from both parents would display lactase restriction as adults. Heterozygotes would get different alleles and be LAC*P/LAC*R, but since LAC*P is dominant, lactase activity and ability to digest milk would persist beyond childhood.

Nutritional Implications

As milk and milk products are such rich sources of protein, calcium, carbohydrates, and other nutrients, the nutritional consequences of lactose intolerance in infants and children can be devastating, even lethal, unless other dietary sources are used. Formulas based on soybeans help many youngsters. Adults can get protein from other animal and vegetable sources or from fermented milk products. Yoghurt with live bacterial cultures may be tolerated well. Calcium can be obtained from dark green vegetables or from the bones of small sardines or anchovies consumed whole (Kretchmer 1993). It has been suggested that low milk consumption in elderly lactose intolerance adults might contribute to osteoporosis (Wheadon et al. 1991), but this has not been demonstrated. Lactose-free dairy products and oral lactase preparations are commercially available and help many people enjoy and gain the nutritional benefits of ice cream and other milk-based foods (Ramirez, Lee, and Graham 1994).

Lactase persistence is uncommon in Africans, Asians, southern Europeans, and the indigenous populations of the Americas and the Pacific. Questions have arisen concerning the use of milk as food for children. The American Academy of Pediatrics (AAP), noting the high nutritional value of milk for growing children, has determined that almost all U. S. children under 10, regardless of family background, can digest reasonable quantities of milk. The AAP recommends that the school-lunch half pint (about 240 milliliters [ml]) of milk be supplied to children up to this age, and notes that intolerance to 240 ml is rare even among older teens (American Academy of Pediatrics 1978). Similar results have been reported for African children in South African orphanages (Wittenberg and Moosa 1991). Malnourished African children, such as famine victims, also tolerate up to 350 ml of milk well, which allows the use of this valuable source of nutrients in emergency situations (O'Keefe, Young, and Rund 1990).

Testing for Lactase Persistence

Clinical diagnosis and population surveys for lactose digestion capabilities present several challenges. Clinical symptoms are discovered by self-reporting; thus, double-blind studies, in which neither the experimenter nor the subject knows if a challenge dose contains lactose or a placebo, are most useful. Direct lactase assay using biopsy specimens of intestinal mucosa is obviously an expensive and invasive method, practical only in particular clinical cases. Indirect assays require subjects to fast for several hours before being given doses of lactose in solution.

Then various tests are used to measure the splitting and subsequent metabolism of the disaccharide. Many of the older methods are cumbersome and imprecise. Blood samples may be tested for glucose before lactose challenge and at intervals afterward. High blood glucose levels after lactose ingestion indicate that lactose is being split in the intestine. A variant of this method is to measure blood galactose. Since the liver metabolizes galactose, a dose of ethanol is given shortly before the experimental lactose to inhibit liver action. Another approach is to measure hydrogen gas excreted through the lungs. Subjects who cannot digest lactose will have hydrogen produced by colonic bacteria. Respiratory hydrogen can be conveniently and efficiently measured by gas chromatography. The ethanol-galactose and hydrogen methods are considered the most reliable; the hydrogen technique is cheaper, easier, and noninvasive (Flatz 1987).

Not only must the population studies of lactase activity be methodologically correct, the subjects must also be truly representative of their populations. Studies done on very small numbers of subjects or on hospital patients or other special groups may be unrepresentative. Indeed, some older studies may be unreliable due to poor techniques or sampling problems. Intermarriage and genetic interchange also complicate analysis of the distribution of lactase persistence. Nonetheless, there has been great interest in the geographical and ethnic distribution of adult lactase persistence and the evolution of this unusual phenotype.

Distribution of Lactase Persistence

Several authors have compiled the results of regional studies (Flatz 1987; Kretchmer 1993; Sahi 1994). Some of the major findings are summarized here in Table IV.E.6.1.

It should be noted that data for northern India and Pakistan are suspect and that figures for Finno-Ugrian groups in northern Russia and western Siberia (Khanty, Mansi, Mari, Mordva, Nentsy) are based on small, possibly unrepresentative, samples and older methods (Valenkevich and Yakhontova 1991; Kozlov, Sheremeteva, and Kondik 1992). There is little hard information for the Balkan or Iberian peninsulas, Slavic territories east of Poland, Siberia, central Asia, or the Indian subcontinent. It would also be interesting to have more data on East African pastoralists, such as the Maasai, and on Baggara Arab and other cattle-keeping groups of the West African Sahel.

A high proportion of lactase persisters was noted in northwestern Europe in the early 1970s, and there were similar reports from northern India, from Bedouin and other pastoral populations in the Middle East and northern Africa, and from the Tutsi pastoralists of the Uganda-Rwanda region of East Africa. Very low rates were found among eastern, and most southern, Asians, most Africans, and native populations of the Americas and the Pacific, and only modest rates were found in southern and eastern Europe. In North and South America, Australia, and New Zealand, adult lactase ability is closely linked to place of origin; for example, white Australians resemble their European counterparts in lactase persistence, whereas Aborigines are almost entirely lactose intolerant. Varying degrees of Spanish and Indian ancestry may explain regional differences in Mexico (Rosado et al. 1994). Similarly, a higher than expected prevalence of lactase persistence among Buryat Mongols of Russia's Lake Baikal region may be due to gene flow from European Russians (Kozlov et al. 1992).

Adult lactase capability appears to have evolved in two, and possibly three, geographic areas. The case is clearest and best documented for northern Europe, where there are very high percentages around the Baltic and North Seas. High levels of lactase persistence seem closely linked to Germanic and Finnic groups. Scandinavia, northern Germany, and Britain have high levels, as do the Finns and Estonians, the Finnic Izhorians west of St. Petersburg, the Mari of the middle Volga basin, and, to a lesser extent, their more distant relations, the Hungarians.

There is a general north–south gradient in Europe, which is evident within Germany, France, Italy, and perhaps Greece. As noted, more information is needed for Spain, Portugal, and eastern Europe, but there may be something of a west–east gradient in the Slavic lands. Varying frequencies of the LAC*P allele among Lapp groups may be related to differing lengths of historical use of reindeer and cow's milk and to admixture with other Scandinavians (Sahi 1994).

The second center of adult lactase persistence lies in the arid lands of Arabia, the Sahara, and eastern Sudan. There, lactase persistence characterizes only nomadic populations heavily dependent on camels and cattle, such as the Bedouin Arabs, the Tuareg of the Sahara, the Fulani of the West African Sahel, and the Beja and Kabbabish of Sudan. Lower rates among Nigerian Fulani may indicate a higher degree of genetic mixing with other peoples than among the Fulani of Senegal. In contrast, surrounding urban and agricultural populations, whether Arab, Turkish, Iranian, or African, have very low rates. It is interesting to note that the Somali sample also had a low frequency of the LAC*P allele. Possibly, pastoral Somali have higher prevalences than their urban compatriots.

A third center of adult lactase persistence has been suggested among the Tutsi population of the Uganda-Rwanda area of the East African interior. The Tutsi are an aristocratic cattle-herding caste of Nilotic descent who have traditionally ruled over agricultural Bantu-speakers. Table IV.E.6.1 shows that only 7 percent of a sample of 65 Tutsi adults were lactase deficient, but the data are old, there certainly has been some mixture with Bantu-speakers, and the study should be replicated. The Nilotic peoples of the southern Sudan, whence the Tutsi originated a few centuries ago, do not display this trait. Unless the Tutsi result can be confirmed, and the Maasai and other East African Nilotic groups can be tested, this third center of the LAC*P allele must be considered doubtful. If it does exist, it probably arose as a fairly recent mutation, as there are no obvious historical mechanisms to account for gene flow between the Tutsi and desert dwellers farther north.

Table IV.E.6.1. *Distribution of lactose phenotypes*

Country	Group	# High LDC	# Low LDC	% Low LDC	Frequency LAC*P allele[a]
Europe					
Sweden	Swedes	396	4	1	.90
Finland	Swedish-speakers	84	7	8	.72
Finland	Finnish-speakers	371	78	17	.58

Evolution of Lactase Persistence

Frederick J. Simoons (1969, 1970) has advanced the thesis that lactase persistence is closely linked to dairying. His culture-evolution hypothesis is that groups that kept cattle and other milk animals would gain a selective advantage if adults retained the ability to use milk and milk products as food. A mutation like LAC*P would be nutritionally beneficial, and the growing number of milk-using adults would then be encouraged to devote more effort toward livestock raising. In general, the distribution of adult lactase persistence and dairying shows a positive relationship. In areas with no dairying tradition, such as China, Oceania, Pre-Columbian America, or tropical Africa, few adults can digest lactose.

Northern Europe presents the opposite case. More data around the periphery of the two postulated centers would be highly desirable, and we know little about most of the stock-raising societies of central Asia. Still, although the correspondence is not perfect, and gene flow through population mixing complicates the picture, the association seems strong. Given the origins of cattle keeping about 4000 to 3500 B.C. in northern Europe, and even earlier in the Middle East, there probably has been enough time for modest selective pressures to have produced observed LAC*P rates (Sahi 1994).

Other selective forces may also have been at work. Flatz (1987) has suggested that calcium absorption was such a factor in northern Europe. Lactose is known to facilitate calcium absorption in the intestine. The cold, cloudy climate frequently discouraged skin exposure to sunlight, thereby reducing the body's production of vitamin D. Relatively little dietary vitamin D was available, and so in its absence, calcium was poorly absorbed. Northern populations were thus vulnerable to rickets and osteomalacia. Pelvic deformities made births more difficult. The gradual extinction of the Greenland Viking colony is an example; skeletal evidence shows that such bone diseases were common among this moribund population. A mutant LAC*P allele would not only allow adults to use an excellent source of calcium, but the lactose would also facilitate its absorption. While not proven, this hypothesis has attracted much attention. It would complement the theory that the pale skin of northern Europeans is a genetic trait maximizing the utility of sunlight in vitamin D production and, hence, calcium absorption.

Similarly, other selective pressures facilitating the survival of mutant LAC*P alleles have been postulated for the Sahara–Arabian Peninsula desert region. There is a high degree of dependency on milk among many groups of desert pastoralists, and so a positive link between lactase persistence and milking seems very plausible. In addition, it has been argued (Cook 1978) that the simple fact that milk is a liquid would give adults who could consume it in large quantities a powerful selective advantage. The theory, while unproven, certainly seems plausible. G. C. Cook's suggestion that lactase persistence conveyed some resistance to gastrointestinal diseases has attracted much less support. At least for cholera, his claim must be rejected, based on what we know of the historical geography of the disease. Cholera seems to have been restricted to the Indian subcontinent until very recent times.

Finally, it seems most likely that the European and Arabia-Sahara centers of LAC*P prevalence, and the Uganda-Rwanda center (if it in fact exists), arose independently. Population movement and gene flow can be very extensive and, no doubt, have played a substantial role around the centers. Despite the efforts of some authors to find a common origin in the ancient Middle East, it is simpler to suggest independent origins than to postulate gene flow from the Middle East to Scandinavia and to the interior of East Africa. The problem might be resolved in the future if gene sequencing could show that the LAC*P alleles in Sweden and Saudi Arabia are, in fact, the same or are distinct forms of the gene with a similar function.

Conclusions

Lactose malabsorption is the normal condition of most adults. Many suffer the clinical symptoms of lactose intolerance if they consume milk, especially in large amounts. In two, or possibly three, places, genetic mutations have arisen that allow adults to gain the nutritional and culinary benefits of milk and many other dairy products. This ability has evolved along with cultural developments with profound implications for livelihood, including, in the northern European case, the development of mixed farming. East Asian, African, Oceanic, and Amerindian peoples, of course, thrived without this genetic trait and its cultural consequences. Their infants and young children enjoyed the nutritional advantages of milk; adults ate other things, including fermented milk products. Milk can be consumed by most lactose-intolerant older children in moderate amounts, and so milk can be a valuable nutrient for the undernourished or famine stricken. Modern commercial lactase products allow most lactose-intolerant adults to consume dairy products; thus, pizza and ice cream need not be forbidden foods.

Finally, the LAC*P and LAC*R genes are interesting far beyond their biomedical significance. Along with linguistics, archaeology, and physical anthropology, further research on lactase genes and other genetic markers will provide clues to the prehistory of peoples, their migrations and interminglings, and the origins and development of major language families.

IV.E.7 ~ Obesity

Obesity is a dimension of body image based on a society's consideration of acceptable body size and, as such, is the focus of anthropological, sociological, and psychological study (de Garine and Pollock 1995). However, most of the research on obesity in Western societies has focused on medical issues ranging from genetic etiology to therapeutic interventions. Overfatness or obesity is a major health problem in countries that are affluent and is increasing in prevalence among the socioeconomic elite of those that are modernizing. An estimated 90 million Americans – one-third of the population – are substantially above their range of desirable body weight; in some other populations more than half of their members fit into this category.

Of course, some fat or adipose tissue is essential for life and serves a number of functions. It provides metabolic fuel; thermal insulation; a reservoir for vitamins, hormones, and other chemicals; and protection for the viscera and dermal constituents, such as blood vessels, nerves, and glands (Beller 1977). However, an excessive accumulation of fat is associated with an increased risk for diabetes, hypertension, cardiovascular and musculoskeletal problems, and in general, a reduced life expectancy. Moreover, in many societies, fatness elicits a psychosocial stigma.

Definitions and Diagnosis

Body weight is the most widely used anthropometric indicator of nutritional reserves, and weight relative to height is an acceptable measure of body size for growth monitoring and for most epidemiological surveys. Overweight and obesity, though often used synonymously, are not the same. S. Abraham and co-workers (1983) clearly made the distinction in analyzing data from the first U.S. National Health and Nutrition Examination (NHANES) survey. Overweight was defined as an excess in body weight relative to a range of weights for height. In this report, individuals over the 85th percentile of weight for height standards are considered overweight. Obesity was defined as an excess of body fat based on the sum of the triceps (upper arm) skinfold and subscapular (back) skinfold. Skinfold measurements using calipers that pinch a fold of skin and subcutaneous fat at specific sites (for example, waist, abdomen, thighs, upper arm, and back) are used in equations to estimate body fat stores and are compared with reference percentile tables (Himes 1991).

Many recent studies have used the Body Mass Index (BMI), which is the weight in kilograms divided by height in meters squared, to categorize body size. This index was devised by the Belgian mathematician Adolphe Quetelet (1796–1874) and is also referred to as the Quetelet index. (The Ponderal Index, which is the quotient of the height in inches divided by the cube root of the weight in pounds, has been similarly used.)

Overweight is defined as a BMI above 27.3 for women and 27.8 for men. These BMIs represent approximately 124 percent of desirable weight for men and 120 percent of desirable weight for women, defined as the midpoint of the range of weight for a medium-size skeletal frame from the 1983 Metropolitan Insurance Company Height and Weight Tables. The World Health Organization uses a similar range of BMIs: below 20 (lean), 20 to 25 (acceptable), 25 to 29.9 (moderately overweight), 30 to 39.9 (severely obese), and greater than 40 (morbidly obese). Epidemiological studies frequently use a BMI of 30 as the delimiter for obesity for both sexes.

Other anthropometric measurements have been used as alternatives to body weight in assessment of obesity. Body girth measurements or circumferences at specific anatomical locations have a high correlation with body mass. A commonly used measure is the circumference of the upper arm. This measurement, in conjunction with the triceps skinfold, has been used to compare the fat and lean components of the arm and thus to provide a measurement of energy and protein stores. More sophisticated, expensive, and time-consuming techniques assess the lean and fat components of the body. These techniques have included densitometry, magnetic resonance imaging (MRI), basic X rays, computerized tomography (CAT) scans, ultrasound, bioelectrical impedance, total body water, and body potassium levels (Lukaski 1987).

Skinfolds, circumferences, and imaging techniques assess the regional distribution of fat deposits. A central distribution of fat is referred to as an apple shape. A lower torso distribution of fat on the hips is referred to as a pear shape. The apple shape, often measured as a high waist-to-hip ratio of circumferences, is associated with internal deposits of abdominal fat and increased risk for coronary artery disease and adult onset diabetes. By contrast, the pear shape is not associated with increased disease risk (Bouchard and Johnston 1988).

Epidemiology

Current estimates of the prevalence of obesity indicate that it has reached epidemic proportions in some populations (Table IV.E.7.1). The most widely cited statistics on weight are those from NHANES III and are based on a random sample of the U.S. population between 1988 and 1991 in which 31 percent of males and 35 percent of females ages 20 to 74 years were considered overweight (Table IV.E.7.1). Table IV.E.7.2 presents the percentages of adults defined as obese with BMIs ≥30. More alarming are the recent estimates of the percent overweight and obese done by the Institute of Medicine of the National Academy of Science (1995). Viewed in light of BMIs that are 25 or greater, 59 percent of American males and 49 percent of females are overweight or obese. Two percent of males and 4 percent of females are considered morbidly obese with BMIs over 40. A 5-foot 4-inch woman with a BMI of 40 weighs 230 pounds.

*Rounded to the nearest percentage point.

Sources: Data are from many sources.

A survey of Micronesian Islanders indicates that 85 percent of males and 93 percent of females are overweight, whereas among native Hawaiians, a Polynesian group, 85 percent of males and 62 percent of females are overweight. Obesity is also prevalent in a number of native North American groups. A survey of Seminoles and Pimas has revealed that more than 50 percent of the adults are obese, whereas among the Canadian Cree and Ojibwa more than 90 percent of females and between 45 and 54 percent of males were so categorized. Among other ethnic groups within the United States there also are high levels of adult obesity: In Texas, fully 66 percent of male Mexican-Americans and 60 percent of females are obese, as were almost 50 percent of female African-Americans and 31 percent of males nationwide. Table IV.E.7.1 and Table IV.E.7.2 present the proportion of obese or overweight adults in a number of countries.

Table IV.E.7.2. *Prevalence of obesity* (Body Mass Index ≥ 30 kg/m^2)*

Country/region	Age	Percentage males	Percentage females

Source: Bouchard (1994), pp. 27–30.

Obesity can begin in early life. Eleven percent of U.S. children (ages 6 to 11 years), 13 percent of adolescent males (ages 10 to 17), and 9 percent of adolescent females are overweight. Outside of the United States, M. Gurney and J. Gorstein (1988), who surveyed the preschool populations of 34 countries, found ranges of obesity from 1 to 11 percent. By way of a few examples, in Jordan and Tahiti 2 percent of the preschoolers were obese, in the United Kingdom 3 percent, in Canada 6 percent, and in Jamaica the figure was 10 percent. There are no comparable multinational studies for school-age children.

Obesity in childhood and adolescence is a good predictor of obesity in adulthood. In one study, a third of the obese adults examined were already overweight or obese at 7 years of age, and two-thirds were overweight or obese by age 14. Studies in the United States and Britain found that between 40 and 74 percent of obese 11- to 14-year-old youngsters became obese young adults.

Secular Trends in Overweight

Since 1960, surveys in the United States have tracked changes in the proportion of those overweight and obese in the population. In general, adult average weight and the proportion of individuals who are overweight have grown larger. Overweight prevalence for adults increased 8 percent between the recording periods of NHANES II (1976–80) and NHANES III (1988–91), as shown in Table IV.E.7.3. The mean BMI jumped from 25.3 to 26.3 and the mean body weight increased by 3.6 kg. The proportion of overweight children and adolescents, in particular, has been augmented, although a countertrend can be seen among the older (over 70 years) segment of the population. Thus for women 60 to 74 years of age, there was a decrease in the percent overweight from 45.6 percent to 41.3 percent. However, among African-American females, corresponding figures for the younger cohort (50 to 59 years) showed an increase from 35 to 52 percent overweight. By contrast, African-American males age 60 to more than 80 years had the lowest percent of overweight individuals in comparison with white and Hispanic Americans. It is notable that during the two decades from 1960 to 1980, no consistent secular trends were found for whites or blacks ages 12 to 17 years and 18 to 34 years. However, this changed significantly with the NHANES III data, which revealed increasing obesity in both of these groups.

Based on self-reports in a Harris Poll, 74 percent of Americans ages 28 and older stated in 1996 that they were overweight. This was an increase from 71 percent in 1995, 69 percent in 1994, and 59 percent in 1986. In the United Kingdom during the decade 1980 to 1990, the percentage of adult males classified as overweight grew from 39 to 48 percent and those who were obese from 6 percent to 8 percent. The proportion of women classified as overweight increased from 32 percent to 40 percent and obese from 8 percent to 13 percent. Overweight percentages were highest for males and females 50 to 64 years of age.

Gender

Childbearing and menopause are associated with weight gain, obesity, and an increasing waist-to-hip ratio. Maternal body fat is gained during pregnancy in response to the hormonal milieu, with a third of women gaining more than 5 kilograms of adipose tissue. In the United States, the mean net weight gain

Table IV.E.7.3. *Age-adjusted and age-specific prevalence of overweight (1960–91)*

Population groups	NHES 1 (1960–2)	NHANES I (1971–4)	NHANES II (1976–80)	NHANES III (1988–91)
White males	23.0	23.8	24.2	32.0
White females	23.6	24.0	24.4	33.5
Black males	22.1	23.9	26.2	31.8
Black females	41.6	43.1	44.5	49.2

Note: NHES = National Health Examination Survey

NHANES = National Health and Nutrition Examination Survey

with each childbearing cycle is 1 kilogram above that normally gained with aging. Americans put on approximately 20 pounds from age 25 to 55. Lactation mobilizes fat, but selectively from the femoral region, and, therefore, there is still an increase in the waist-to-hip ratio. Menopause has also been reported to increase the waist-to-hip ratio and add an average 20 percent body fat mass, compared to the premenopausal state. Both subcutaneous and internal visceral abdominal fat increase in postmenopausal women.

Obesity is approximately twice as prevalent among women as men in the United States, although this disparity is the most striking in certain populations, such as African-Americans, Mexican-Americans, Puerto Ricans, and Western Samoans (Tables IV.E.7.1 and IV.E.7.2). By contrast, Hawaiians, Nauruans, Native Americans, Alaskan natives, and Mexican-Americans have the highest obesity prevalence among males. Obesity is only slightly more prevalent among black, Puerto Rican, and Cuban-American men than among non-Hispanic white men. Asian-Americans (of Chinese, Japanese, Filipino, and Indochinese origin) have a lower obesity prevalence than other minority groups in the United States, although this may be changing. Some groups, such as the California Japanese, have recently developed moderately high BMIs.

P. Brown and M. Konner (1987) have noted that females appear to become obese with modernization. They suggested that the sex ratio of obesity is a marker for a population on a trajectory of economic development and westernization. That is, an excess of female versus male obesity is more likely to be observed in poorer populations in the developing world and less so in affluent Western populations. The data are generally consistent with this interpretation.

Brown's (1991) cross-cultural survey using the Human Relation Area File data found that 81 percent of societies for which there was sufficient data rated "plumpness" or being "filled out" as an attribute of beauty in females. This was particularly true of fat deposits on the hips and legs. Bigness for women in some groups is a sign of power, beauty, and maternity. Indeed, anthropologists have described the practices of populations in Polynesia (Pollock 1995) and West Africa (Brink 1995), where young women are secluded for a year or more in "fattening huts" prior to marriage. Such plumpness is not only considered desirable in a woman but also reflects positively on the socioeconomic status of her family and its ability to feed a daughter without having to rely on her labor.

Modernization

The construct of modernization encompasses a wide variety of lifestyle changes, including physical activity patterns, diet, and psychosocial stress. Many "diseases of civilization" (Trowell and Burkitt 1981) have been associated with westernization or modernization.

For example, the Pimas of Arizona have the highest rate of diabetes of any known population – a condition that is accompanied by a high prevalence of obesity among individuals of all ages. However, this is not the case with a small group of Pima whose ancestors migrated to Mexico some 700 to 1,000 years ago and who live today in a remote, mountainous location with a traditional lifestyle that is in marked contrast to the Arizona Pima. These Mexican Pima are lighter in weight and shorter and have lower BMIs, plasma cholesterol levels, and rates of diabetes. Consequently, it would seem that much of the problem with the Arizona Pima lies in lifestyle. Suggestive as well was a study conducted by K. O'Dea (1984), who took a group of diabetic Australian Aborigines away from an urban lifestyle to live as hunters and gatherers for seven weeks in northwestern Australia. The subjects lost an average of 8 kilograms and experienced improved carbohydrate metabolism.

In another study, the situation was reversed, whereby 13 Tarahumaras living a traditional lifestyle in northern Mexico were fed a diet typical of affluent societies for five weeks. On average, these subjects gained 3.8 kilograms (or 7 percent of their initial body weight) and had dramatic increases in plasma lipids and lipoprotein levels. Clearly, such investigations indicate that aspects of modern lifestyle can significantly contribute to obesity as well as other deleterious metabolic changes. They point to the benefits of a diet low in animal fat and high in complex carbohydrates, as well as the importance of high levels of physical activity (McMurphy et al. 1991).

In addition, migration studies have shown that populations moving from traditional to westernized environments experience large increases in body weight, along with rising rates of diabetes and other metabolic changes (Bindon and Baker 1985; Bindon 1995).

Geography

Derek Roberts's study (1953) of the geography and climate of 220 societies revealed that height and weight ratios are related to mean annual temperatures and that people are fatter the farther away they live from the equator. In other words, populations are fattest where summers are the coldest and leanest where summers are the hottest (Beller 1977). Put another way, if height is held constant, heavier people are found in the world's colder climates. Roberts hypothesized that cold stimulates the adrenal glands which, in turn, increase fat deposits.

In the United States, obesity is most common in the Northeast and Midwest, and rates are significantly higher in metropolitan regions than in rural areas. However, cutting across geographic distinctions are ethnic group concentrations and socioeconomic classes. In modernizing countries, the more affluent segments of populations exhibit a higher prevalence of obesity regardless of rural or urban location. But in industrialized countries, the lower socioeconomic classes have the higher prevalence, and in addition, immigrant populations show increases in body weight compared to their sedentary counterparts or populations of origin. Finally, within a country, migration from rural to urban areas also leads to obesity.

Lifestyle Factors

Physical Activity

Physical inactivity has been related to increases in body weight and to obesity in both children and adults. Research by William Dietz and S. L. Gortmaker (1985) has demonstrated a linear relationship between the number of hours of television watching and body weight among Americans. Moreover, cross-sectional studies indicate that there is a negative relationship between energy expended for physical activity and body fat content. However, these associations do not prove that low levels of physical activity promote high levels of body fat because the association can also mean that individuals with existing high levels of body fat are rendered unable to exercise vigorously or for extended durations.

Both aerobic exercise and resistance training result in decreases in body fat by increasing energy expenditure during the actual period of exercise and subsequent periods of rest. Thus, exercise can promote a negative energy balance provided that there is not compensatory energy intake for those calories expended during and after exercise. Exercise has been found to be moderately successful in promoting and maintaining weight loss, and in some studies, weight loss was sustained with moderate exercise after the cessation of dieting.

Diet

M. Suzuki and N. Hosoya (1988) have succinctly modeled the relationship between obesity in adulthood and dietary changes, by arguing that modernized diets and food habits tend to accelerate the storage of body fat, regardless of the amount of energy that is ingested. Involved are (1) decreased carbohydrate and increased fat proportions in daily energy intake; (2) gorging just before resting; (3) increase of simultaneous intake of fats and sugars; (4) increased consumption of cereals in refined forms, such as flour, rather than unrefined, unprocessed grains; (5) increased consumption of soft, digestible foods rather than hard and more difficult to digest (for example, fibrous) foods; and (6) increased consumption of alcohol.

Although the primary focus has been on caloric intake, data also indicate that the composition of the diet is important in terms of metabolic rate, energy storage, and the production of obesity. Both the amount and the composition of food influence body-weight regulation. In a clinical study by T. Horton and colleagues (1995), carbohydrate overfeeding produced progressive increases in oxidation and total energy expenditure, resulting in 75 to 80 percent of excess energy being stored. Fat overfeeding had a minimal effect on oxidation and total energy expenditure, leading to storage of 90 to 95 percent of excess energy. Excess dietary fat led to a greater fat accumulation than did excess dietary carbohydrates. Other investigations have demonstrated that individuals with a family history of obesity are more likely to suffer the obesity-promoting effects of high-fat diets than individuals without such a family history (Bouchard and Bray 1996).

Epidemiologic data from both the United States and Great Britain have shown that sugar intake is inversely related to obesity prevalence but that BMI and the percent of calories from fat are positively correlated. Indeed, a number of studies indicate that it is dietary fat, rather than sugar intake, that promotes obesity. However, a high-carbohydrate intake may cause hyperinsulinemia that, in turn, promotes fat storage. Excess intake of any macronutrient can contribute to weight gain, especially when associated with low energy expenditure.

The nutritional epidemiological transitions that promote obesity are, in part, fueled by multinational food corporations, which have introduced calorically dense foods that are advertised widely. The U.S. Department of Agriculture estimates that in the United States alone, the food and restaurant industry spends approximately 36 billion dollars annually on advertising, and some campaigns for single items (for example, a new soft drink or a new hamburger) exceeded 50 million dollars in 1996 and 1997. The trend in the United States is to increase the size of fast-food items (for example, "supersize," or "giant size"), which are generally high in fat, carbohydrates, sodium, and calories to begin with. The larger portions tend to be eaten as quickly and completely as the regular ones. Thus, McDonald's "supersize" serving of fries, which contains 540 calories, represents a 20 percent increase in calories over their "regular" serving. A "king size" candy bar may be as much as 80 percent larger than the regular size bar, and a large popcorn in a movie theater is 50 percent bigger than a medium size. In the United States, a mean of 3,700 kilocalories are available each day for every man, woman, and child, representing a third more than the recommended dietary allowance for men and twice that for adult women.

The explosion of "light" and "low fat" and "fat free" foods has led consumers to believe that these items are also calorie reduced or even calorie free, although their caloric content may be equal (or nearly so) to the nonspecialized product. (One venerable exception is the diet soft drink, and the new calorie-free fat substitutes now entering the market may constitute others.) Salad bars, also popular in the United States, can be equally deceptive. Consumers put high-calorie salad dressings on low-calorie salads to the extent that the caloric content of the salad exceeds that of a meal containing animal protein and fat. American women 19 to 50 years of age get more fat from salad dressings than from any other food (Hurley and Collins 1997).

Obesity is promoted not only by the consumption of fat but also by the overconsumption of carbohydrates and protein. Americans, in particular, are consuming too many of these macronutrients while maintaining or insufficiently reducing their intake of fats. Data from NHANES I (1970s) and NHANES II (1976–80) indicated that Americans only reduced their fat intake from 42 percent to 38 percent of calories – still far above the recommended fat intake of 30 percent of total daily calories (Bray 1993b).

Smoking

Smokers weigh consistently less than nonsmokers, and when individuals stop smoking they generally gain weight. Ex-smokers reach body weights similar to those of age- and sex-matched nonsmokers, although gross obesity appears to be more frequent in ex-smokers than in those who have never smoked. The increases in body weight of ex-smokers stem from a number of causes, including increased food consumption and decreased metabolic rate. In one study, it was found that young adults who smoked 24 cigarettes per day had a 200 kilocalorie greater daily expenditure of energy than when not smoking, and this increased energy expenditure was independent of energy intake and physical activity (Hofstetter et al. 1986). Another study revealed that middle-age and older male smokers had higher waist-to-hip ratios than nonsmokers, after controlling for BMI, dietary and alcohol intake, and activity levels (Troisi et al. 1991).

Socioeconomic Factors

Many studies have demonstrated a striking inverse relationship between socioeconomic status and the prevalence of obesity, particularly among women in developed countries. This relationship is true regardless of whether socioeconomic status (SES) is based on family income, educational level, or occupation. Fully 30 percent of women of lower SES in the United States are obese compared with less than 5 percent of those of the upper status groups. Some investigations have demonstrated that upwardly mobile women are less obese than women who remain in a low SES. The prevalence of obesity for men in lower SES is 32 percent compared with 16 percent among upper-class men.

Obesity is a socioeconomic disability in Western cultures. In general, the theory is that socioeconomic status influences obesity by education, income, and occupation, causing variations in behavior that change energy consumption and expenditure. However, obesity influences socioeconomic status by the stigmatization and discrimination it elicits, which, in turn, limits access to higher SES roles. There are ample data showing discrimination against obese individuals in terms of access to education, hiring for a variety of occupations, salary, and advancement (Allon 1982; Cassell 1995).

In a pioneering study, J. Sobal and A. J. Stunkard (1989) looked at the relationship between socioeconomic status and obesity in both developed and developing societies. They found that there was an inverse relationship between SES and obesity in industrialized societies, even stronger for women than for men, but a direct relationship in developing societies. The data pertaining to children are less clear. For boys in industrialized societies, the relationship between SES and obesity was either inverse or absent, but in developing countries it was clearly direct. For girls in industrialized countries, the relationship was inverse, as it was for women, whereas no relationship was found in developing countries.

Income is related to obesity mostly through access to resources. Individuals and families with higher incomes have more options in terms of access to food and food choices, although actual caloric intake may not vary by income. Occupation is related to obesity primarily through lifestyle factors in terms of energy expenditure on the job and during leisure activities. And finally, educational levels have been related to the prevalence of obesity, as lower educational levels are associated with lower income.

History of Obesity

Anthropological constructions have indicated a hunter–gatherer lifestyle during most of human history that was marked by much physical activity to secure adequate food, interspersed seasonally with decreased food intake. This variation selected genetically for individuals who were able to store energy as fat to carry them through lean times. Both contemporary foraging populations and those engaged in the incipient domestication of plants and animals show seasonal changes in weight that reflect variations in the availability of foods.

Studies of traditional hunting and gathering populations report no obesity. In contrast, many examinations of traditional societies undergoing processes of modernization that include production of generally high-carbohydrate food crops demonstrate a rapid increase in the prevalence of obesity. In fact, H. C. Trowell and D. P. Burkitt (1981) have noted that obesity in modernizing societies is the first "disease of civilization" to appear. The rapidity with which obesity becomes a health problem in the modernization process highlights the critical role of behavioral factors in its causation, as well as the evolutionary genetic propensities that were adaptive for traditional, calorically expensive lifeways.

Given the rarity of obesity in preindustrial societies, it is not surprising that there is a lack of ethnomedical terms for the obese state (Brown 1991). In fact, thinness has often been seen as a symptom of starvation or as a sign of disease, whereas plumpness has been viewed as a marker of health. For example, the Tiv of Nigeria distinguish between the very positive category of "too big" and the unpleasant condition of "to grow too fat." In some societies, for women in particular, fatness has been and remains a symbol of maternity and nurturing. The concepts that fat babies and children are healthy and that food is a symbol of love and nurture are nearly universal (Brown and Konner 1987). Moreover, from an evolutionary perspective, there are many biological advantages to the maintenance of energy stores as fat. These include an ability to survive longer during a fast, a greater ability to fight infectious diseases, fewer gastrointestinal tract problems, less anemia, healthier and higher birth-weight babies, and earlier age of menarche (Cassidy 1991).

The ethnographic data concerning body preferences in males is relatively weak, although it does suggest a preference for a more muscular physique, moderately tall stature, and general largeness. Traditionally, big, but not necessarily obese, men have been seen as successful. However, historical trends show variations in positive and negative associations with obesity.

Historical Medical Concepts

George Bray (1992) has outlined the scientific and medical history of ideas concerning obesity. In the Hippocratic texts, obesity was associated with infertility in women, a laxity of muscle, a red complexion, and sudden death. To lose weight meant strenuous physical activity before consuming meals prepared with sesame seasoning and fat because these satiated appetite. Dieters were to eat just once a day, take no baths, sleep on a hard bed, and walk naked as long as possible. Galen (130–215), who followed in the Hippocratic tradition, identified types of obesity and prescribed bulky foods with low nutrient content, baths before eating, and vigorous exercise.

The first monographs in which obesity was the primary subject were published in the seventeenth century. A mechanistic model of the body was popularly invoked, although there were other theories about fatness based on fermentation and putrefaction as the basis for an iatrochemical model.

The medical history of the eighteenth century was dominated by Hermann Boerhaave (1688–1738), who has been called the "most successful clinician and medical teacher of the century" (Ackerknecht 1982: 130), although his influence was exercised mostly through the students he trained. During the first part of the century, the earliest English language monograph on obesity and 34 doctoral dissertations dealing with the subject were published. A common theme was the imbalance of various systems resulting in disease. For example, the essay by Thomas Short (1690–1772) – a pioneer in vital statistics – on the origin of corpulence attributed it to blood stored in the oily parts of the body and not sufficiently discharged by perspiration. Short thought that fat was stored in little bags. He noted that corpulence was more common in countries with "wet air," which he believed decreased perspiration. Foods that were soft, smooth, sweet, and oily, as well as slothfulness, led to obesity. Thus, exercise was viewed as important, as were diets light in foods of a "detergent kind." Less nutritious kinds of food, such as fish, were to be consumed sparingly. Also recommended was less sleep, a reduction in passions, gentle evacuations, and tobacco smoking to stimulate the nerves of the mouth (Bray 1992).

During the second half of the eighteenth century, Boerhaave's students dispersed from Leyden to found new centers of clinical medicine at Edinburgh and Vienna, and during these years obesity, corpulence, and polysarcia became "species" following a Linnaean system of classification.

In the aftermath of the French Revolution, a new vitality emerged in clinical medicine, stimulated by the Paris Clinical School, as well as in basic sciences. The concept of energy balance developed, following the work of Antoine L. Lavoisier (1743–94) and the elaboration of the law of thermodynamics by Hermann L. F. von Helmholtz (1821–94). T. K. Chambers wrote extensively on obesity using theoretical models derived from thermodynamics.

English clinical medicine in the nineteenth century is notable for a work by W. Wardd entitled *Comments on Corpulency, Liniments and Leanness* (1829), which describes a number of clinical cases of massively obese individuals. In 1863 William Banting (1779–1878) penned the first popular diet pamphlet. Banting, a London undertaker, who had personally lost considerable weight to regain his health, advocated a diet of lean meat, dry toast, soft-boiled eggs, green vegetables, and liquids (Bray 1992).

The adipocyte (fat cell) was identified in German laboratories, and advances in neurology led to the description of several hypothalamic-pituitary causes of obesity, such as the Fröhlich syndrome (1901) and the Prader-Willi hyperphagia syndrome (1956); the Pickwickian hypoventilation syndrome (1956) is a nonneurologic type of obesity-associated ailment (Burwell et al. 1956; Butler 1990).

In the twentieth century we have seen an ever-growing understanding of the psychological, social, and neurophysiological mechanisms that control food intake. We have also just begun to develop important pharmaceutical interventions targeted at pathologies within these mechanisms.

Obesity in America

Hillel Schwartz (1986) and Jo Anne Cassell (1995) have both reviewed the history of obesity in the United States. Although many Americans currently associate body weight and size with moral weakness, such negative perspectives do not have a long history, and in fact, attitudes toward overweight people have changed many times throughout history. In general, when food was scarce, such individuals were viewed as prosperous and envied by their neighbors. By contrast, in times and societies with ample food, fashion usually favored slim and lean figures. In many instances, however, no moral judgments were attached to either overweight or lean status.

Beginning in the medieval period and continuing in America throughout the eighteenth century, morality plays were popular entertainment. Gluttony, one of the cardinal sins, frequently appeared as a theme involving excess or greed – and certainly a lack of self-restraint with regard to food and drink. The sin, however, was in consuming more than one needed and leaving others with less than their share. Body size or shape were not factors in gluttony, and being overweight carried no implication of sin.

In the early part of the nineteenth century, medicine focused on appetite and not thinness, and most physicians believed that fat represented a reserve that could be called upon in the event of disease, trauma, or emergency. Beginning at about mid-century, however, attitudes began to change under the influence of such individuals as Sylvester Graham (1794–1851) and the Kellogg brothers, who advocated a vegetarian regimen, coarsely milled flour, the consumption of cereal grains, and moderation in diet. They declared gluttony an evil, and obesity became a moral issue. During the Victorian period, however, in a countermovement, fashion again began favoring a rounded body shape and seven-course family dinners. Diamond Jim Brady and his companion, Lillian Russell, were widely admired for their insatiable appetites and came to symbolize the exuberant excesses of the era (Cassell 1995).

By the turn of the twentieth century, scientists had come to believe that body fat had its origin in the fat of foods consumed and that dietary fat passed unchanged through the digestive tract to be absorbed and deposited. Fat was again out of fashion. Cartoons and jokes about overweight persons began to appear in newspapers and magazines. Stout, once a perfectly good word, became uncomplimentary, and a person who was fat was considered ugly. William Howard Taft, at 6 feet 2 inches tall, weighed 355 pounds when he was President of the United States (1909–13). Newspaper cartoons showed his rotund size, and when he got stuck in the White House bathtub, the event was well publicized. A variety of products to help in weight loss suddenly became available, including appetite suppressants, diuretics, stimulants, and purgatives. Special teas, bath salts, and mechanical devices were also employed (Schwartz 1986).

A 1912 study by actuaries of insurance policy holders provided height, weight, and mortality figures that became the data base for actuarial tables used to determine, for the first time, that there was a relationship between body weight, health, and mortality. According to these statistics, moderate weight gain was appropriate before age 35 but became increasingly harmful in later life. Excess body fat had become a serious health liability, and during World War I, the entire nation went on a diet. Rationing and conservation efforts designed to ensure adequate rations for the soldiers also conveyed the notion that it was patriotic to be thin; to carry excess weight was un-American.

Obesity researchers in the 1920s and 1930s were divided as to whether obesity was due to exogenous or endogenous causes. "Exogenous" people overate but had firm muscles and were basically in good health. They were cheerful and happy. "Endogenous" people had a deficient metabolism, flaccid muscles, and poor health and were sad or sour in nature. Not surprisingly, men were generally placed in the former group and women in the latter. For some researchers, weight was a genetic matter, with fatness a dominant trait and slenderness a recessive trait.

As early as 1911, thyroid supplements had become available and were regularly prescribed for "glandular" disorders. Indeed, for a brief period in the postwar years, American physicians thought that many obese patients were suffering from inadequate amounts of thyroid hormones. So long as it seemed that there were endocrinologic and genetic causes for obesity, there was once again an abatement of moral judgment. But in the 1930s, medicine concluded that few people had true thyroid deficiencies after all, and nutritional scientists had reached the position that people were overweight simply because they ate too much. Moral judgments returned, and obesity was recast as the outcome of psychological problems leading to overeating.

The introduction of motion pictures with their frequently svelte movie stars led, among other things, to the popularity of weight-loss diets, particularly those originating in California. Perhaps the most famous was the "Hollywood 18-Day Diet." Another was the "banana diet" – the product of bananas and skim milk in a blender – and a forerunner of today's liquid diets.

Research emphasis changed once again in the 1940s as scientists defined obesity as "over-fatness." People learned that they might be overweight, but not overfat, and dieticians began to measure body fat with skinfold calipers. Psychological theories focused on such issues as depression, lack of self-esteem, boredom, and inner emptiness as precursors to overeating, which also acted as popular explanations. Fatness as a signal of psychological distress continues to be influential in many weight-loss programs that employ support groups.

In the 1950s, changes in American society brought more attitudinal changes about dieting and weight control. Supermarkets began to offer a number of low-calorie and diet products. Among these were 900-kilocalorie-per-day liquid-diet formulas that were an instant success and continue to be widely available in the United States. Surveys reported that 40 percent of all families were regularly using low-calorie or diet products by 1962 and 70 percent by 1970 (Cassell 1995).

In today's marketplace, novel fat substitutes are occupying shelves along with earlier sugar substitutes. New products from cookies to ice cream are both fat and sugar free. Books on dieting have also been popular, and in the 1960s, those on weight loss were best-sellers, especially if the authors promised that loss without the need to give up one's favorite foods. Five million copies of *The Doctor's Quick Weight Loss Diet* (Stillman and Baker 1967) were sold in 1967 alone, and books on dieting continued to lead book sales in the 1990s. In addition, in 1972 psychological therapy started to employ behavioral therapy, which has continued as a popular approach both for diet groups and commercial weight-loss centers. How, why, and where persons ate became as important as what they ate.

In the 1980s, Americans began to focus on physical fitness and exercise as a way to promote good health. A plethora of articles on dieting appeared in newspapers and popular magazines, along with information on increased activity levels. The message was to lose weight with exercise and diet, so as to be happier, healthier, and more attractive. A diet industry mushroomed to assist Americans in losing weight. The number trying to do so was estimated to be one-fourth of men and one-half of women, and annual sales of diet products had exceeded 30 billion dollars by the end of the 1980s.

Nonetheless, the incidence of obesity in America continued to increase and, predictably, there has been something of a backlash. In today's environment some overweight individuals have used the courts to press cases of discrimination based on body size, and there is a growing antidiet movement, with fashion houses, magazines, and psychological and educational support groups that champion the obese. These groups, such as the National Association to Advance Fat Acceptance (California), Ample Opportunity (Oregon), and the Diet/Weight Liberation Project (New York), promote positive images of obese individuals, arrange for social gatherings with singles groups, and work toward equity at places of employment and other venues where there is discrimination against obese individuals.

Many groups have newsletters; there are a number of national magazines, such as *Radiance: The Magazine for Large Women* (Oakland, Calif.), and some presses specialize in publications about obesity, food, eating disorders, and related psychosocial, political, and medical issues, as, for example, Fat Liberation Publications (Cambridge, Mass.). Other inroads are being made in the media and on educational and economic fronts to reduce the stigma of obesity in the United States. Given the high percentage of overweight Americans, the tide may once again be turning.

Nonetheless, Cassell (1995) suggests that weight watching and concern for body image have become an integral part of American culture as we enter the twenty-first century, and there is still great pressure to be thin. The health risks of excessive body fat are well documented scientifically, and articles on the subject appear daily in the popular literature. At the same time, a person's overweight status does not automatically imply ill health, and more effort on the part of health professionals is being directed toward evaluating an individual's overall health status before a recommendation for weight loss is made.

Causes of Obesity

Obesity has a multifactorial etiology, which includes genetic factors, metabolic and behavioral phenotypes, and environmental agents. Because it is a condition of excessive storage of energy, an understanding of energy balance is fundamental to understanding obesity. Energy balance is equal to energy intake minus energy expenditure, and, consequently, obesity becomes the result of a positive energy balance. Yet, energy balance is exquisitely sensitive. The average nonobese American male consumes approximately 1 million kilocalories per year, but his body fat stores remain unchanged if he expends an equal number of calories. However, a change of only 10 percent either in intake or output can lead to a 30-pound weight change in a single year (Bray 1987). More subtly, a gain of 11 kilograms (24 pounds) of weight during a 40-year time span can come about with a mean daily discrepancy between intake and expenditure of only 5 kilocalories.

Energy Intake

Individual differences in metabolic mechanisms are not well understood. Cross-sectional studies reporting energy intake for individuals with different body compositions have found that obese individuals may have high, normal, or even low energy intakes relative to normal-weight subjects (Lachance 1994) and that there is a poor correlation between daily energy intakes and expenditures (Edholm 1973). For most adults, the sensitivity of the energy balance system for change is less than 1 percent per year. The "normal" adult contains 140,000 kilocalories of energy in body fat, 24,000 kilocalories in protein, and only about 800 kilocalories in carbohydrate. Consequently, although an individual consuming 2,000 kilocalories per day of which 40 percent is carbohydrate will ingest an amount of carbohydrate comparable to body stores, protein intake will average only about 1 percent of total stores and fat intake considerably less than 1 percent (Bray 1987, 1993a, 1993b).

Energy balance with regard to the macronutrients has been illuminated in recent years by the discovery of specific enzymes and neurotransmitters with receptors in the central nervous system. The brain is sensitive to changes in circulating glucose levels, and a glucostatic mechanism may regulate the intake of fat and carbohydrates – the primary energy substrates. Carbohydrate stores have a high turnover rate and can be depleted quickly and frequently so that signals exist to monitor and correct for carbohydrate imbalances. Fat stores, on the other hand, are nearly limitless, and turnover is slow and infrequent. Thus, as a rule, increased energy intake results in increased fatness (Bray 1993a; Horton et al. 1995).

Energy Expenditure

Energy expenditure has a number of components, the most important of which is basal metabolic rate (BMR). The total energy cost of any given activity is equal to the BMR plus the work done and the heat produced. For sedentary populations, the BMR may comprise 50 percent to 70 percent of the daily energy expenditure. Wide variations in BMR are not accounted for by food intake, meaning that those people with the highest calculated BMRs are not those who eat the most food. However, BMR is depressed in starvation, in individuals with a restricted caloric intake, and in many obese individuals (Bouchard 1994).

Consistent with these findings are studies of energy expenditure involving both involuntary (for example, fidgeting) and voluntary movement that indicate that physical activity is reduced in obese individuals. However, even though physical activity is reduced, there is a higher cost for activity in overweight individuals, resulting in a tendency toward normal or even high levels of energy expenditure for a particular physical activity. In these instances much of the energy is lost as heat, rather than in muscular work. One problem of cross-sectional data is that finding an average level of energy intake for an individual who is already obese tells us little about previous levels of energy intake and energy expenditure that may have contributed to the development of obesity in the first place.

It is likely that genetic predisposition to obesity lies not only in a lower BMR but also in the reduction of heat production that occurs following a meal, that is, in lower diet-induced thermogenesis. A subnormal thermogenic response to food has been reported in clinical experiments among obese individuals and those who have been obese in the past (the post-obese), as well as among subjects maintaining a desirable weight on relatively low food intake. In sum, obese individuals are metabolically more efficient than lean individuals.

Taste Preference and Obesity

Taste preferences represent a major determinant of food intake and have been linked to obesity and weight gain. Genetic differences in taste preferences are heritable (Perusse and Bouchard 1994). For example, sensitivity to phenylthiocarbamide (PTC) is controlled by a major single gene. Individuals who can taste PTC, a bitter synthetic compound, avoid or reduce intake of foods containing chemically similar, but naturally occurring, compounds, such as cabbage, broccoli, and Brussels sprouts. Research indicates that some obese individuals may have an elevated preference for foods high in carbohydrates and fats, such as ice cream, chocolate, or pastries (Drewnowski 1988). In contrast, anorectic subjects show a preference for sweet but not for fatty foods. Food preferences may be regulated, in part, by peptides that stimulate the central nervous system, increasing neurotransmitters, such as beta endorphins, and, consequently, feelings of well-being. Finally, simply tasting (not swallowing) fat, either in cream cheese or peanut butter, increases insulin production and serum triglycerides. Such findings suggest that sensory receptors in the mouth initiate digestive responses not triggered directly by the nutrient and that the sensory qualities of fat may promote preference for fatty foods (Radloff 1996).

Psychological Factors

In recent years there has been a major change in discussions concerning the psychological aspects of obesity. In earlier psychogenic theories, obese persons were assumed to suffer from emotional disturbances and failures of impulse control. However, systematic assessment of the nature and extent of psychological problems of obese individuals have changed the psychogenic views of obesity to a somatogenic one. The psychosocial problems in question arise primarily from the stigma attached to obesity in contemporary societies.

Genetic Factors

Investigations of the genetic factors in human obesity have developed rapidly. Traditional family studies of parent, offspring, and sibling data identify the extent to which obesity is familial, but they pose the problem of separating the shared environment of families from genetic factors. Adoption studies overcome some of the difficulties encountered in family studies because individuals have a shared environment but not a biological relationship. Moreover, identical and fraternal twin studies can shed light on genetic as well as environmental contributions (Bouchard et al. 1988, 1990; Bouchard 1994).

Inheritable features include metabolic rates, hormone andenzyme levels, and the amount and patterning of subcutaneous fat. Data from a number of studies indicate that Body Mass Index has a heritability (range 0 to 1) from 0.4 to 0.6, suggesting that genes may be responsible for approximately one-half of the total phenotypic variation in obesity. Adoption studies found that BMIs correlated more strongly with biological than adoptive parents. Investigations in Denmark and Iowa of adult twins showed a high heritability of 0.8. Additive and nonadditive genetic components point to many obesity-promoting genes (Bouchard 1994).

A number of important genes that control eating and weight gain have been discovered in mice. These have human analogs, but obesity-promoting mutations of these genes have not been located in humans. Recently, mutations in the leptin receptor gene have been found among the Pimas of Arizona, the Finns, and the French (Bouchard and Bray 1996; Gibbs 1996). The obese gene encodes for leptin, a hormone produced by fat cells. Mice with a mutation in this gene produce either no leptin or a malformed version and are obese with weights up to three times those of normal mice. The diabetes gene codes for a receptor protein that responds to leptin by reducing appetite and increasing metabolism. Mice with a mutation of this gene do not receive the leptin signal and get very fat from infancy. Other genes are "fat" and "tubby." Mice with mutations in either gene put on weight gradually, more like the human pattern. Recent work on leptin and leptin receptors has focused on developing appropriate pharmacological interventions. Leptin causes obese and normal mice to lose weight by signaling the brain that the body has enough fat, which in turn suppresses appetite.

The search for genes and their products that control appetite led to the discovery in 1996 of the hormone urocortin, which is a powerful appetite suppressant in rats. Other promising research has concentrated on a neuropeptide that stimulates appetite and on lipoprotein lipase, an enzyme involved in fat deposition (Gibbs 1996).

Consequences of Obesity

Mortality

A number of studies have focused on mortality and morbidity associated with overweight and obesity. Those done in Norway, Canada, and the United States indicate that BMIs associated with lowest mortality lie in the range of 15 percent below to 5 percent above ideal weight, although recently, some physicians have argued that failure to control for the effects of smoking produces an artificially high mortality in leaner subjects. All studies with more than 20,000 participants have shown a positive relationship between overweight and mortality. But the Build Study of 1979 indicated that above-average weights are associated with optimal life expectancy. Moreover, 40 percent of all smaller employee, community, and random population studies have failed to demonstrate a relationship between body weight and mortality (Sjostrom 1993).

Similarly, the First National Health and Nutrition Examination Survey 9-year follow-up found that there was no additional risk associated with overweight among women and a statistically significant but moderate additional risk (relative risk 1.1 to 1.2) for men ages 55 to 74 years. Low body weight, however, was associated with increased mortality (relative risk 1.3 to 1.6), except for women age 55 to 64 years. These results suggest a need for clinically specific definitions of obesity and overweight, especially among the elderly (Tayback, Kumanyika, and Chee 1990).

A change in weight has also been associated with mortality in adulthood. The Nurses' Study, using age 18 as the standard, showed that increases in weight up to 9.9 kg either reduced or left unchanged the relative risk of mortality. However, weight increases of 10 to 19.9 kg and 20 to 34.9 kg resulted in relative risks of 1.7 and 2.5, respectively. In the Framingham Study, an estimated 10 percent loss in body weight corresponded with a 20 percent reduction in the risk of developing coronary artery disease (Committee on Diet and Health 1989). Independent of weight or BMI, a high waist-to-hip ratio or large deposits of fat in the center of the body (related to internal stores of visceral fat) are associated with increases in mortality and morbidity.

Data also suggest that obesity as assessed by BMI or other measures may mean different mortality and morbidity risks for different populations. For example, overall mortality was not associated with obesity among the Pima except for the most obese men (Knowler et al. 1991). Among Japanese-American men in the Honolulu Heart Program, the BMI, subscapular skinfold thickness and central obesity predicted coronary artery disease, but only subscapular skinfold thickness predicted stroke (Curb and Marcus 1991b).

Morbidity

A wide variety of disorders and problems are caused or exacerbated by obesity (National Institutes of Health 1985; Bouchard and Johnston 1988), and T. Van Itallie (1985) has listed these by organ system. For the cardiovascular system they are premature coronary artery disease, ventricular arrhythmia and congestive heart failure, hypertension, stroke, and varicose veins. Obesity can affect the respiratory system in terms of alveolar hypoventilation or the Pickwickian syndrome, obstructive sleep apnea, and ventricular hypertrophy. Under the digestive system rubric there may be an increase in gall bladder and liver diseases. For the hormonal and metabolic systems, diabetes mellitus, gout, and hyperlipidemia are the most common results of obesity. Kidneys may be affected, resulting in proteinuria and renal vein thrombosis. The skin may develop striae and plantar callus, and osteoarthritis of the knee and spine are exacerbated by obesity. Obesity increases the risk of endometriosis and breast cancer in women and can impair reproductive and sexual functions. Obesity also enhances the risk of surgical and anesthetic procedures and reduces physical agility, which can lead to accident proneness. Finally, obesity may interfere with the diagnosis of other disorders by physically obscuring their presence.

Social Stigma of Obesity

Obese individuals in the United States suffer from social and psychological prejudice. Even children hold these prejudices. When a group of 6-year-olds were shown a fat person's silhouette and asked to describe the person's characteristics, they said "lazy, cheating and lying" (Czajka-Narins and Parham 1990). In another study where children were shown drawings of an obese child, a child in a wheelchair, a child on crutches, a facially disfigured child, and a child amputee, they disliked only the latter more than the overweight child. Furthermore, children prefer to play with thin rather than fat rag dolls, and parents prefer to have thin rather than obese children photographed.

Obese adolescent females have reported fewer dates and less participation in school organizations than nonobese adolescents. College students, when asked whom they were least likely to marry, ranked obese individuals fifth lowest in desirability, following an embezzler, a cocaine user, an ex-mental patient, and a shoplifter. Adults rate nonobese figures as happier, having more friends, smarter, more attractive, less lonely, and less mean than obese persons. College students in another study stated that obese individuals were warm and friendly but also unhappy, without self-confidence, self-indulgent, undisciplined, lazy, and unattractive. It is interesting, however, that psychological profiles of obese individuals show personality characteristics and achievement levels that belie these prejudicial views (Probart and Lieberman 1992).

Health professionals in the United States also hold negative views of obese individuals. They consider obese individuals to be hypochondriacal, possessing impaired judgment, having inadequate hygiene, and indulging in inappropriate and self-injurious behavior. Additionally, they find obesity to be aesthetically displeasing. As mentioned, there is an active segment of the U.S. population working to counter such widespread prejudices (Price et al. 1987).

Treatment for Obesity

Dieting

Dieting is a routine aspect of life for many Americans, even among some who are not obese. Studies indicate that in the United States, 33 to 44 percent of adult women and 22 to 34 percent of adult men are actively dieting at any given time and that Americans spend an estimated 30 to 50 billion dollars a year on weight-loss programs. The incidence of dieting varies little by ethnicity for women, but among men, Hispanic Americans have the highest proportion of dieting and African-Americans the lowest. Dieting is most common among well-educated and higher socioeconomic classes (Kopelman et al. 1994; Elmer-Dewitt 1995).

Reports of dieting by high-school-age students are common. The National Adolescent Student Health Survey of eighth and tenth graders revealed that 61 percent of girls and 28 percent of boys reported dieting to lose weight. However, a longitudinal study of Arizona adolescents by the Nichters (1991) found extensive discourse about dieting but little modification of food behaviors or weight loss. Very few girls in this study reported using vomiting, diet pills, laxatives, or diuretics as weight-control methods. Many girls responded that they did not "diet to lose weight" but rather "watched what they ate continually" and avoided "fattening foods." Eighty-five percent rarely or never counted calories, nor did they know how many calories they consumed.

Although caloric restriction (usually 1,200 to 1,000 kcal/day) should be the only method of treatment for obesity, long-term analyses of results show that 95 percent of those who are successful at weight loss regain it within one to two years. Very low calorie diets (400 to 800 kcal/day) lead to rapid weight loss, but there is little evidence that long-term weight maintenance is improved. Repeated weight gain and loss cycles are called weight cycling or yo-yo dieting. Although there are questions about altered metabolism with weight cycling, lean tissue mass does not appear to be lost at an increased rate with each cycle (Garner and Wooley 1991).

Many weight-loss programs provide special foods low in calories and high in fiber as part of a comprehensive program. Weight-reduction clinics and lay support groups use a combination of diet with behavioral and exercise intervention. These approaches have costs associated with them, ranging from expensive diet clinics that provide specialized care with a multidisciplinary team of psychologists, dieticians, physicians, and exercise specialists to inexpensive lay support groups, such as Weight Watchers, Take Off Pounds Sensibly (TOPS), and Overeaters Anonymous. Recently, work-site and school weight-control groups have also been formed, emphasizing both weight loss and relapse prevention.

Behavioral therapy as an adjunct to dietary treatment improves compliance and may improve long-term results. Elements of behavioral therapy include self-monitoring of dietary intake; control of external eating stimuli; analyses and changes in eating behavior, including speed, time of day, and locus of activity; rewards for weight loss and weight maintenance; nutritional education; physical activity to improve both weight loss and overall well-being; and cognitive restructuring, concentrating on positive goals to counter negative, self-defeating thoughts (Kanarek et al. 1984).

Exercise

A number of mechanisms have been proposed to explain the association between exercise and weight control. The most frequently advanced benefits are an increase in lean body mass, resulting in a higher basal metabolic rate; increases in metabolic rate produced by the exercise and enduring beyond specific bouts of exercise; the energy expenditure of the activity itself; and the psychological benefits, including self-esteem, modulation of mood, and improved body image. The current recommendation is for regular low-level exercises (a heart rate below 60 or 70 percent of the maximum) that are beneficial and easy to maintain over a long duration.

A number of techniques can be employed to improve adherence to an exercise plan. These include setting goals, a program of relapse prevention, and behavior changes involving stimulus control and reinforcement in a social environment, perhaps including one's spouse. When they begin to exercise, many overweight individuals face a combination of physical and psychosocial burdens related to negative feelings associated with past experience. Some studies indicate that exercise alone can produce a modest gain in lean body mass and a loss in fat in weight-stable individuals. However, both animal and human experiments show that exercise does not conserve lean weight in the face of significant energy deficit (Stunkard and Wadden 1992; Bouchard and Bray 1996).

Drugs

In cases of extreme obesity or when there is fear of comorbidities associated with a central distribution of fat, drug therapy may be warranted. These drugs include agents that act on the noradrenergic and serotonergic systems, opioid receptors, and peptide agonists or antagonists. The most popular drugs – fenfluramine, fluoxetine, or dexfenfluramine and phentermine – increase serotonin levels. Other classes of drugs include thermogenic drugs, growth hormone agonists, and drugs that act directly on the gastrointestinal system, including enzyme inhibitors and inhibitors of absorption. These drugs are not without risk (heart valve abnormalities and pulmonary hypertension, for example, have been linked to a phentermine–fenfluramine pill) and, in fact, have not been used with substantially large populations long enough to assess long-term benefits or risks. This is partly because there was a hiatus of about 20 years in the United States when drugs were not developed specifically to treat obesity. Now, however, there are a number of pharmaceutical companies in the process of developing such new drugs (Gibbs 1996).

Surgery

A surgical procedure may be warranted for morbidly obese individuals. This may be in the form of liposuction or surgical reduction of fat deposits, usually from the abdominal apron. But food ingestion can be restricted by temporarily wiring the jaws, or its absorption can be reduced either through the reduction of stomach capacity by stapling or by creating a small intestinal bypass. Surgical intervention, however, is not without risk and sequelae, such as severe diarrhea.

Summary

Overweight and overfatness (that is, obesity) are conditions of epidemic proportions related to food consumption and activity patterns. The human ability to store fat and selectively mobilize it evolved as a defense against food shortages, cold climates, demanding physical labor, disease, and the physiological requirements of pregnancy and lactation. Our understanding of the physiological and genetic basis for obesity has increased considerably in the last decade.

Obesity has been linked to increased mortality and morbidity in nearly all organ systems. Moreover, psychosocial stigmatizing of the obese, at least in affluent countries, has an adverse impact on their education, occupation, social interaction, and self-esteem.

In the United States, a multibillion-dollar "diet industry" has developed that includes new diet products, medications, clinics, health clubs, support groups, and obesity specialists. With all of these efforts, including the increasing availability of fat- and sugar-free foods, we continue to get fatter – in the United States and around the world.

IV.F

Diet and Chronic Disease

IV.F.1 Diabetes

Diabetes mellitus (DM) is a heterogeneous group of endocrine disorders characterized by hyperglycemia (high blood sugar levels) during fasting or following a meal. Other characteristic symptoms of diabetes include excessive urination, urine containing sugar, hunger, thirst, fatigue, and weight loss. The disorder is caused by a resistance to the action of insulin, or a lack or insufficient production of insulin to transport glucose from the blood into cells where it is used as the primary energy source for cellular metabolism. Although diabetes has been a recognized disease for at least two millennia, only since the mid–1970s has there been a consensus on the classification and diagnosis of DM.

Insulin-dependent diabetes mellitus, also called juvenile diabetes or Type I diabetes, is an autoimmune disease that generally affects individuals under the age of 20 and has an acute onset. Noninsulin-dependent diabetes mellitus, Type II, or maturity onset diabetes mellitus, has a complex etiology often associated with obesity and most frequently occurs among individuals over 40 years of age. Ninety to 95 percent of diabetes worldwide is of the latter type. Gestational diabetes appears to be a subset of Type II diabetes, and there are rare genetic syndromes, such as hemochromatosis, drugs, and infections, associated with pancreatic diseases that can cause diabetes. The underlying pathophysiology of Type II diabetes involves the increasing resistance of cells, particularly muscle and adipose (fat) cells, to the transport of glucose across the cell membrane. This resistance or impaired glucose tolerance leads to the classic diagnostic criterion of abnormally high blood sugar concentrations. Glucose also appears in other bodily fluids, particularly urine. The presence of sugar in urine is called glycosuria. This was one of the first signs used in the diagnosis of diabetes. The urine of diabetics tastes sweet and, hence, may attract insects. Such observations were made by early Greek physicians.

This chapter focuses on the relationship of diet and diabetes in historical and cross-cultural perspectives. Three areas are addressed: (1) diet and etiology or causation of diabetes; (2) diet and the pathogenesis of diabetes; and (3) diabetes and diet therapy.

Ancient History through the Middle Ages

Physicians in ancient China, Egypt, Greece, and India wrote accurate clinical descriptions of diabetes. As early as the sixth century B.C., Hindu physicians recognized the clinical symptoms of diabetes and attributed them to dietary indiscretion. The Indian physician Susruta, for example, described the disease as the result of overindulgence in rice, flour, and sugar, which caused the urine to be like an elephant's in quantity. To counter excessive intake, Indian physicians in the *Caraka-Samttita* (c. 123) recommended moderate diets high in carbohydrates and fiber.

Diabetes in Indian Ayurvedic medicine has a complex etiology and pathogenesis. In Ayurveda, the human body is composed of three fundamental elements – *doshas, dhatus,* and *malas.* Health is maintained by a balance of these elements, and, consequently, a disturbance of equilibrium causes disease. There are three *doshas* that control various aspects of physiology. Each *dosha* has five divisions, and a disturbance in any one of these can cause diabetes. In addition, the body contains 13 categories of *srotas* (channels of circulation through which pass basic tissue elements), *doshas,* and waste products. Lack of exercise, sleeping during the day (thereby suppressing digestive functions), and excessive fatty food and alcohol consumption can disturb the *srota* involved in carrying the vital substances that comprise fat tissue resulting in diabetes.

More specifically, the etiology of diabetes can be attributed to the excessive consumption of yoghurt, the flesh of animals living in water and marshes, and rice or wheat and starch, especially in refined foods. Excessive worry also plays a role in consumption, sleep, and activity patterns. The treatment for diabetes in traditional Ayurvedic medicine involves reducing the body fat and inadvertently but effectively regulating the function of the pancreas with the use of *kerela* (bitter gourd). It is recommended in a dose of 30 milliliters twice a day, preferably on an empty stomach. Other botanicals are also used, including the long pepper *(Piper longum),* amalaki *(Emblica officinalis),* turmeric *(Curcuma longa),* Indian pennywort *(Hydrocotyle asiatica),* aconite, "Monk's Hood," "Blue Rocket," "Friar's Cap" (genus *Aconitum*), caltrops, ground burra-nut, puncture vine *(Tribulus terrestris),* and pure honey with hot water. Most vegetables are recommended for individuals with diabetes, but any forms of sugar, rice, potato, banana, cereals, and fruit are to be avoided. Fat is to be ingested in limited quantity.

In Chinese medicine, diabetes is a disease characterized by excessive, sweet urine and described in terms of *chi. Chi* is an energy force, or power, existing as a balance between "yin" and "yang." Yin is the force that is feminine, negative, cold, and dark, whereas yang is the force that is masculine, positive, warm, and bright. All substances of heaven and earth are divided into five elements: metal, wood, water, fire, and the earth. The body is a microcosm of these elements with a balance of yin and yang. Balance results in the maintenance of health, whereas a disturbance in this equilibrium produces ill health or disease. The excessive intake of sweets can cause obesity that, in turn, leads to excessive *chi* pushing up in the body and trapping yang in the stomach and large intestine, causing diabetes mellitus.

Although these organs are specifically involved, DM is seen as a whole-body malfunction. Diabetes is divided into three kinds of "thirst" based on location. Upper thirst involves the lung and heart, middle thirst the stomach and spleen, and lower thirst the liver and kidneys. People with a greater yin (female) body composition are the most susceptible to these three types of thirst. Traditional treatment modalities include diets low in carbohydrates and fat, light exercise, herbal medicinals, relaxation, and acupuncture.

Because diabetes mellitus had been relatively rare in Asian countries until the 1990s, current recommendations and treatment modalities often follow the Western biomedical models of etiology, pathogenesis, and therapy. G-Hyon Gang, investigating polytherapeutic approaches to diabetes in contemporary Korea, found that a majority of diabetics employ biomedical treatment plans with insulin or oral hypoglycemic agents and diet regulation. Salts and herbal preparations are used as adjuvants.

The Ebers Papyrus (c. 1550 B.C.) contains a prescription for an antidiabetic diet of wheat germ and okra. Both have been shown to lower blood glucose in animals. Early Arabic physicians described abnormal appetites and the loss of sexual function, but they did not note the sweetness of diabetic urine.

Aretaeus the Cappadocian (A.D. 81–138?) is credited with coining the word "diabetes." In Greek this means "to run through" or "to siphon." Having observed patients with extreme thirst and frequent and copious urination, he reasoned that their bodies acted like siphons sucking in water at one end and discharging it at the other. In his medical textbook, *The Causes and Signs of Acute and Chronic Disease,* he described diabetic patients as tormented by a burning thirst and thought diabetes was the sequela of an acute disease that attacks the bladder and kidneys. Aretaeus did not note that the urine of diabetics is sweet. He prescribed purgation; a mild diet consisting of sweet wine, cereals, and fruit; and steam baths. He advised a diet high in complex carbohydrates, including cereals, groats, and gruels, but one that also included simple sugars, such as those in fruit juices, dates, and raw quinces. The Greek physician Galen (A.D. 130–210?) also considered DM to be a disease of the kidneys and bladder. For Galen, treatment consisted of overcoming the acidity of the humors, slowing the movement of blood, and cooling overheated kidneys.

From the Renaissance to the 1920s

Diabetes was accorded little attention during the Middle Ages, but starting in the fifteenth century, urine became the focus for experimentation, and the amount and sweetness of urine was used to judge the efficacy of various therapies. Paracelsus (A.D. 1493–1541) evaporated the urine of diabetics and referred to the crystalline residue as "salt." He deduced that this "salt" causes the thirst and the production of excessive urine. He believed this was an imbalance of the humors resulting from a combination of "sulfur" and "salts" in the blood that overflowed into the kidneys, causing inflammation and excessive urinary excretion. He recommended steam baths and "julsip."

In the seventeenth century, Thomas Willis (1621–1675) noted the sweet taste of urine and may have been the first European to describe this classic symptom of DM. He prescribed tincture of antimony, as well as water of quicklime with shavings of sassafras. He also recommended anise, licorice, and raisins. Like others before him, Willis considered diabetes a disease of the blood. He thought the etiology related to particles of flesh that were dissolved in the blood, releasing the sweetness, and, therefore, recommended thickening the blood with starch and salt. A contemporary, Thomas Sydenham, proposed that diabetes was caused by the incomplete digestion of what he referred to as chyle of the blood. Other contemporaries proposed the treatment of sugar sickness with the use of bleeding, undernutrition, milk diets, opium therapy, and drinking lime water to neutralize acids.

In 1776, Matthew Dobson of Manchester was able to demonstrate and assay the amount of sugar in urine by evaporating it and weighing the dried residue. Dobson remarked that this residue looked and tasted like "ground sugar," and, hence, glycosuria became an important diagnostic tool that continues in use today. In fact, measuring the amount of sugar in the urine permits an assessment of the effectiveness of therapeutic interventions. In 1815, Michel E. Chevreul identified sugar (that is, glucose) in blood and, since the 1980s, blood glucose monitoring has been considered preferable to testing the urine for glucose.

Dobson had proposed a therapeutically rational diet high in meat and fat and low in grains and breads for diabetics. John Rollo, working in the late 1790s, prescribed rancid meat (preferably pork) and milk with the objective of restricting sugar intake and reducing glycosuria. He believed that diabetes was the result of a stomach disorder, which, by causing the improper digestion of food, prevented the proper assimilation of sugar. He noted that the amount of urine depended on the type of food that was eaten: Urinary production increased after the ingestion of vegetables and decreased when diets were high in animal fats and proteins. He advised his patients to consume breakfast and bedtime snacks of 24 ounces of milk, 8 ounces of lime water, and bread and butter. A noontime meal featured pudding made from blood and suet, and the evening meal included old, as opposed to fresh, meat from game. John Rollo's work was based on extensive metabolic studies of obese diabetic patients in the Greenwich Naval Hospital. His findings shifted the focus from the kidneys to the gastrointestinal tract and provided a scientific basis for therapeutic diets high in fat and protein and low in carbohydrates.

Gross autopsies performed in the 1850s and 1860s revealed no pancreatic abnormalities of diabetics. In 1855, the French physiologist Claude Bernard discovered that the liver secretes glucose from the animal starch or glycogen stored in it, whereas Bernard and Moritz Schiff found that the "destruction" of the pancreas in experimental animals did not result in the onset of diabetes. These findings supported the belief that a liver disease was the source of diabetes, but attention was redirected to the pancreas in 1889, when Joseph von Mering and Oscar Minkowski demonstrated that the complete removal of the pancreas did cause diabetes in dogs.

In the second half of the nineteenth century, work proceeded on two fronts: the anatomical and physiological elucidation of the pancreas and dietary interventions to control diabetes. In 1869, Paul Langerhans, in his M.D. thesis, described previously unrecognized cells in the rabbit pancreas, without suggesting any function for them. In 1893, Gustave Laguesse named these cells the "islets of Langerhans." Meanwhile, Minkowski, Laguesse, Eugene Opie, and others demonstrated that these cells produced an internal secretion that controlled glycosuria.

Observations by Apollinaire Bouchardat, culminating in a book on glycosuria in 1875, distinguished between insulin-dependent and noninsulin-dependent diabetics. Bouchardat imposed a very low carbohydrate diet to control glycosuria. Since then, recommendations for the inclusion of carbohydrates in the diet have varied enormously, depending on the prevailing ideas concerning pathophysiology and observations of patients' success (Table IV.F.1.1). Based on the earlier work of Rollo, meat-based diets were very popular in the middle and late 1800s. Some diets included nonsucrose sugars, such as the sugar alcohols (for example, sorbitol), and milk sugar or lactose. Low-starch vegetables, such as celery and Jerusalem artichokes, were also included.

Von Mering proposed a meal plan of 250 grams (g) of meat, 80 to 120 g of rice, semolina, or buckwheat grits, and an unlimited amount of stale bread. When carbohydrates were advocated as part of dietary control, they were generally high fiber, complex, starchy carbohydrates, such as oats. The starvation regimen often found in the late 1800s and prior to the discovery of insulin in 1921 was, in part, based on Bouchardat's observation that during the siege of Paris in 1871, the imposed starvation regimens or undernutrition led to better control of diabetic symptoms. This and later observations served as the basis for the "star-

Table IV.F.1.1. *A historical perspective on dietary recommendations for people with diabetes*

Years	Comments	Carbohydrate	Protein	Fat
Pre–1921	Starvation diets before insulin therapy	Very low	Very low	Very low
1920–1940	Advent of insulin therapy; diets based on food weights, high fat	20%*	10%	70%
1940–1970	First American Diabetes Association (ADA)/American Dietetic Association (ADA) exchange lists (1950)	40%	20%	40%
1971	Revised ADA/ADA dietary recommendations	45%	20%	35%
1986	New ADA/ADA dietary recommendations and exchange lists	≤60%	12–20%	<30%
1994	Individualized diets, less restriction, emphasis on low-fat and high-carbohydrate diet	Variable – but high ≤60%	10–20%	Variable – but <30% with <10% from saturated fat

*Percentage of daily calories.

vation diet." It is interesting to note that investigators at the Institute for Diabetes, Endocrinology and Metabolic Research in Zagreb recently observed an improvement in glucose control, primarily through weight loss, in populations in the war-torn former Yugoslavia.

Diets in the Age of Insulin Therapy

In 1921, Charles Best and Frederick Banting isolated pancreatic secretions and named them "insulin." They realized that insulin was responsible for the control of blood glucose levels and the appearance of the clinical symptoms of diabetes. During the 1920s, other endocrinologists characterized the hormones of the pituitary and adrenal glands and indicated that these were also involved in metabolism. However, insulin alone constitutes the antidiabetic hormone therapy in use today for all Type I diabetics and for some Type II diabetics who do not respond to oral hypoglycemic tablets (developed in the 1950s) or diet or exercise. Although it was first used therapeutically in 1922, it was not until the 1950s that appropriate bioassays of insulin were developed.

During the 1920s, Carl Petren advocated a diet high in fat because he was dissatisfied with the starvation and high-protein and high-carbohydrate diets. He deduced that an increase in nitrogen from protein metabolism aggravated acidosis, although we now know that ketoacidosis results from excessive use of fatty acids for energy. He also noted that a high fat intake had a protein-sparing effect that promoted increased carbohydrate use without increases in hyperglycemia and glycosuria. In addition, high-fat diets helped patients maintain their body weight. In the high-fat diet, 70 to 80 percent of the calories were consumed as fat, 10 to 20 percent were consumed as carbohydrates, and 10 percent, or less, as protein.

In the 1930s, H. P. Himsworth exonerated carbohydrates as a cause of worsening metabolic control, which led to a wider acceptance of increased carbohydrate use in diabetic diets. Diets in contemporary times have become increasingly liberal, with a current emphasis on those that are high in carbohydrates and fiber, but contain only moderate amounts of protein, and are low in fats, especially saturated fats (Table IV.F.1.1).

In the 1940s, the American Dietetic Association (ADA), the American Diabetes Association (ADA), and the U.S. Public Health Service sponsored a committee to develop a meal plan or diet that could be easily employed by diabetics. During this time period and well into the 1950s, meal plans were calculated on a daily basis with calories from macronutrients divided into percentages of carbohydrate (40 percent), protein (20 percent), and fat (40 percent).

In the 1950s, the exchange system was developed with its six categories of starches and bread, meat and meat substitutes, vegetables, fruits, milk, and fat. The exchange lists included foods by weight or volume that contained a specific quantity of calories, carbohydrate, protein, and fat. For example, one exchange from the starch–bread group equaled 80 kilocalories, 15 g of carbohydrate, 3 g of protein, and a trace of fat, whereas one exchange in the meat and meat substitute group for the lean meat category would be the equivalent of 55 kilocalories, 7 g of protein, and 3 g of fat.

Diabetics were taught to adhere rigidly to these exchanges, which were computed on the basis of the total number of calories appropriate for the individual to maintain, lose, or gain weight. Therefore, the number of exchanges in each group would be predicated on the total number of calories prescribed for the patient (for example, a 1,200 or 1,800 calorie diet). Table IV.F.1.1 illustrates the changes in the ADA/ADA recommendations for these proportions. In general, over the years, there has been a decline in the recommended proportion of fats, particularly saturated fats, an increase in carbohydrates, and a moderate decrease in protein. The exchange system did offer flexibility in devising diets that had both variety and palatability. A patient could have, for example, 8 ounces of milk or 8 ounces of yoghurt or 8 ounces of buttermilk, all the equivalent of one milk exchange with approximately the same amount of carbohydrate, protein, and fat content in all three. For a bread-starch exchange, one could have a slice of bread, six saltine crackers, or half a cup of rice, potato, oatmeal, or peas.

Diabetics using insulin therapy are required to eat at regular intervals during the day and to take one or more injections corresponding to food ingestion. The use of both regular and lente, or delayed-action, insulin helps maintain insulin levels to utilize the glucose from food. Various schemes have been proposed for the division of calorie intake throughout the day to correspond to periods of exercise and rest. In general, individuals using insulin therapy often have a snack before retiring. Children are frequently given snacks during late morning and late afternoon, as well as at bedtime. For insulin-dependent diabetics, snacking is especially important before exercise because exercise has an insulinlike effect that can lead to hypoglycemia – a potentially dangerous, even fatal, condition. Nutritionally preferred snacks normally have included a combination of protein, fat, and carbohydrate and explicitly excluded refined sugar. Until very recently, nonnutritive sugar substitutes provided the main sweeteners for "treats" for both children and adults with diabetes.

Dietary recommendations for diabetics in the 1980s, and continuing into the 1990s, have emphasized a decrease in fat intake, primarily because coronary heart disease is more frequent among diabetics, especially those who are obese when compared to age- and sex-matched peers without DM. A few studies that controlled for dietary components have demonstrated that increases in fat in the diet may be responsible for the movement of people from impaired glucose tolerance to frank diabetes. Recommendations are for diets low in saturated fat, cholesterol, and, more recently, polyunsaturated fats in favor of monounsaturated fats, such as those found in olive oil. There continues to be a renewed "heart-healthy" focus in diabetic diets. Limiting dietary fat decreases the frequently observed hyperlipidemias and enhances weight control in noninsulin-dependent diabetic adults. The World Health Organization (WHO) and various European professional societies recommend a total fat intake equal to or less than 30 percent of total energy intake, saturated fat equal to or less than 10 percent, and the maintenance of serum cholesterol equal to or less than 200 milligrams per deciliter. Because hypertension and vascular diseases, including strokes, are more frequent among diabetics, the recommended salt intake has also been decreased.

Over the last decade, careful attention has been paid to the types of dietary fats, although lowering plasma cholesterol levels has been the primary concern of "heart-healthy" diets. Lipid levels are only partially a reflection of dietary cholesterol and, in fact, are much more responsive to saturated fat intake and to the polyunsaturated–saturated fat ratio. Dairy products (milk, cheese, and yoghurt) contain both cholesterol and saturated fat, which has led to recommendations for lowfat dairy products and fat substitutes in bakery products. Fat substitutes, particularly for weight control, are now common in prepared foods in the United States. Like sugar substitutes, they will most likely become widely distributed and available for home food preparation. Among the different types of dietary fats, stearic acid appears to be a saturated fat that does not raise plasma cholesterol levels. It is common in beef and chocolate.

Polyunsaturated fats play an important role in lipid-lowering diets, particularly the omega-3 fatty acid series in fish oil. Monounsaturated fatty acids, like those in olive oil, have been associated with diets in the Mediterranean region where rates of coronary artery disease are low, yet fat intake is often relatively high. Olive oil is rich in one of the monounsaturated fatty acids, oleic acid, which can lower plasma cholesterol levels. Dietary recommendations may continue to become more specific as we understand the different roles of fats in the body and their contribution to diabetes, coronary heart disease, and obesity. At the moment, the ADA/ADA are recommending 30 percent or less of the total calories from fat and, of this, 10 percent or less from saturated fat, 10 to 15 percent from monounsaturated fat, and the rest from polyunsaturated fatty acids. This may be difficult to achieve for most among the general public, but with proper dietary education for diabetics, such recommendations, it is hoped, will help diminish both the morbidity and mortality associated with heart and vascular diseases.

Diet and Diabetes: Issues in the 1990s

Two nutrition policy and nutrition education initiatives for the U.S. population have had an impact on dietary recommendations for diabetics. These are the Food Guide Pyramid and the new food nutrition labels. For many decades in the twentieth century, the United States focused on the four food groups: bread and starches, meat and meat substitutes, dairy products, and fruits and vegetables. But in 1992, the U.S. Department of Agriculture (USDA) adopted a Food Guide Pyramid, putting foods into five groups plus a high-fat, high-sugar group. In the bread, cereal, rice, and pasta group, individuals are to eat 6 to 11 servings a day. Translated into the exchange system, this is approximately 80 calories per exchange with 15 g of carbohydrate, 3 g of protein, and a trace of fat. From the fruit and vegetable group, individuals are to eat daily 3 to 5 servings of vegetables (at approximately 25 calories a serving with 5 g of carbohydrate and 2 g of protein) and 2 to 4 servings of fruit (at 60 calories a serving with 50 g of carbohydrate). For the milk group, including milk, yoghurt, and cheese, 2 to 3 servings are recommended with an exchange value of 90 calories per serving, 12 g of carbohydrate, 8 g of protein, and 1 g of fat. For the meat, beans, eggs, and nut group, 2 to 3 servings a day are recommended at 55 to 100 calories per serving, 7 g of protein, and 3 to 8 g of fat. At the top of the pyramid, foods from the fats and sweets group are to be used sparingly with approximately 45 calories and 5 grams of fat for each fat exchange. The base of the pyramid is comprised of foods high in carbohydrates and has become the focus of nutrition recommendations for the U.S. population as a whole. The emphasis in the 1990s is to normalize the diet of individuals with diabetes by emphasizing wise choices from the same range of foods recommended to the general population. Thus, the ADA/ADA Exchange lists have been translated into the new Food Guide Pyramid scheme.

Recognizing the need to address ethnic food diversity and in keeping with the goal of individualizing diets, the ADA/ADA has produced a series of ethnic and regional food guides that feature specialty food items, for example, matzo, potato pancakes, and gefilte fish, among traditional and festive Jewish food items, and the tortillas, frijoles, and menudo of Mexican-American diets. Such foods are listed by exchange group and portion size, with a complete accounting of the calories and macronutrients for a portion. In addition, they include amounts of sodium, potassium, and fiber and a division of the fatty acids into saturated, monounsaturated, and polyunsaturated. These food guides are available for both professionals and patients.

After years of debate and deliberation by many interested parties, Americans, beginning in 1993, finally started to see the fruits of that controversy in the form of new food labels on most products carried by American supermarkets. The new food labels entitled "Nutrition Facts" provide serving size, the number of servings per container, the percent of calories in a serving, and the percent of calories from fat, as well as the total amount of fat and saturated fat, cholesterol, sodium, carbohydrate, dietary fiber, sugar, and protein. These nutrients are also presented as the percent of daily calories for 2,000 and 2,500 kilocalorie diets. In addition, listings on the labels include the percent of the daily requirement for vitamins A and C, along with calcium and iron contained in one serving of the food. The new food labels have been touted as an important point-of-purchase tool for diabetics, enhancing appropriate food choices with a balance of macronutrients, micronutrients, and calories.

Nancy Cooper (1988) summarized the important diet and nutrition goals for individuals with diabetes in the 1990s. These goals were as follows:

1. To restore normal blood glucose and lipid levels, thereby preventing hyperglycemia and/or hypoglycemia and delay the development of long-term cardiovascular, renal, retinal, and neurological complications.
2. To insure normal growth rates for children and adolescents with diabetes and to attain and/or maintain a reasonable body weight for adults.
3. To promote weight loss in obese individuals with changes in food intake and eating behaviors and an increase in physical activity.
4. To develop an individualized meal plan based on diet history, medication protocols, and activity levels that will benefit overall health and control diabetes.

New approaches to reach these goals are based on research that defines the physiological roles of food and the behaviors that involve food consumption. Work beginning in the 1970s by Phyllis Crapo and colleagues and D. J. A. Jenkins and colleagues radically changed ideas about carbohydrates based on the glycemic index of foods. The glycemic index is the area under a blood glucose response curve for a test food, divided by the area under the blood glucose response curve for a standard glucose load × 100. The response curve is developed from blood glucose measurements made both before food ingestion and at 30-minute intervals after, for a duration of 180 minutes. In testing a number of foods, these researchers discovered that the glycemic index for "refined carbohydrates" or sugars was very similar to those of many complex carbohydrates. For example, potatoes and sucrose both have very high glycemic indices, whereas pasta has a much lower glycemic index than either potatoes or bread. Numerous factors affect the glycemic response, such as the fiber and fat in food, cooking and processing of food, and the rate of food ingestion. There are many low glycemic foods such as peanuts, lentils, legumes, pasta, and dairy products. High glycemic foods include refined cereals, breads, and many root vegetables. Fat in a food will decrease the glycemic index. In the 1980s, researchers began to test meals rather than individual food items and discovered that there was a balance of glycemic indices among foods. Therefore, a food with a high glycemic index can be balanced by foods that have low glycemic indices in meal planning. The other consequence of glycemic index research has been the realization and scientific rationale that it is appropriate to include refined carbohydrates (that is, sugars) in meals because glycemic response studies have shown that equal grams of carbohydrate from sucrose and different types of starches produce similar glucose responses. Sugar, in moderation, is no longer prohibited.

The decade of the 1990s also saw a resurgence of interest in non-Western medical treatments and dietary prescriptions for diabetes. Although American physicians and dietitians have been particularly wary of claims made for dietary supplements, a 1992 issue of the *Journal of the American Diabetes Association,* Florida Affiliate, noted the finding of Richard Anderson that cinnamon increases by ninefold the ability of insulin to metabolize blood glucose. British researchers, particularly S. Swanston-Flatt, P. Flatt, C. Day, and C. Bailey have produced a number of publications evaluating traditional medicines prepared from herbs, spices, and plants. They now have a compendium of more than 700 different species of plants that have been advocated for diabetes treatment.

The efforts of these researchers are particularly noteworthy because they have completed a number of animal experiments, testing individual plants. One notable effect has been the reduction of intestinal glucose absorption because of the high fiber content of many of the plants advocated for diabetes control. Their article in *Proceedings of the Nutrition Society* (1991) is a particularly good summary of their experiments. Some of the herbs and spices they have tested include goat's rue, Java plum, nettle, and sumac. For vegetables they have looked at members of the brassica or cabbage family, lettuce, onion, and potato. They found, for example, that an extract of onion bulb improved glucose tolerance without altering plasma insulin response in normal mice. They also discovered that it exerted a hypoglycemic effect on noninsulin-dependent diabetics. They have tested a number of mushrooms and have found that, in diabetic mice, some of these stimulate insulin release and reduce the severity of hyperphagia, polydipsia, and weight loss.

Many teas made from extracts or infusions of fruits have been tested as well. The fruits have included apple, lime, lemon, raspberry, and blackberry, although most of these have failed to show a significant effect in diabetic animals. Yeast has also been viewed as an important source of chromium and B vitamins that may be deficient among some diabetics. Brewer's yeast has long been held to contain a factor that improves glucose tolerance, but no effect on glycemic control was evident in their testing of diabetic mice. The British researchers also found that the use of bitter melon or kerela *(Momordica charantia),* which is consumed as a vegetable in Asian diets, improves oral glucose tolerance without altering insulin response. West Indian cerasee and mistletoe both show some glucose-lowering effect. Infusions of alfalfa or lucerne *(Medicago sativa),* used to treat diabetes in South Africa, and eucalyptus leaves have proven somewhat effective in reducing hyperglycemia in mice. The British investigators advocate the use of these hypoglycemic agents as an adjunct to traditional therapy.

Starting with the oat bran craze of the late 1980s in the United States, an increased focus on fiber in the diet of diabetics has also occurred. But prior to that time, J. W. Anderson's research in the 1970s indicated an important hypoglycemic and hypolipidemic effect of fiber in the diet of diabetics. Recent work has focused on elucidating the different types of fiber, particularly digestible and nondigestible fiber, and their impact on glycemic control, cholesterol levels, weight reduction, and gastrointestinal disorders. Contemporary researchers advocate a diet yielding approximately 40 grams of fiber per day, which is about twice the usual intake of the U.S. population. Although the efficacy of such as a regimen has been shown in clinical studies, it may be difficult for individuals to modify their food intake sufficiently to obtain this amount of fiber and still eat a palatable meal.

Most research has not found a causal link between the onset of diabetes and diet (for example, sugar intake). However, several recent studies have indicated a link between cow's milk ingestion, the production of antibodies against casein (cow's milk protein), and the onset of Type I diabetes. Investigators suggest that this immune response can trigger an autoimmune response against the insulin-producing cells of the pancreas, destroying them and causing insulin-dependent diabetes mellitus. Although other researchers have not found such a link, cow's milk allergy is common among children.

Research on the role of breast feeding in the etiology of Type I diabetes has produced evidence both confirming and refuting the relationship. The arguments focus on the immunity conferred upon the infant by mother's milk, as well as the protection from immunological responses that could be catalyzed by cow's milk or cow's milk–based infant-feeding formulas, especially in very young infants.

Finally, we should note that Gerald Reaven (1992) has proposed that prenatal and early postnatal undernutrition, followed by overnutrition later in life, can also pose a risk for the onset of diabetes. He suggests that this disruption of normal embryogenesis produces an underlying mechanism of insulin insufficiency and/or glucose intolerance that can have a contributory effect on micro- and macrovascular disease and hypertension, as well as diabetes. He calls this Syndrome X.

Obesity has been a focus for the 1990s. Approximately 70 to 90 percent of adults are obese at the time diabetes is diagnosed. Weight reduction and/or weight control have been a primary goal of nutritional intervention. Unfortunately, the success rates of such nonpharmacological therapies have been very low. Most of the interventions have focused on behavior modification to reduce caloric intake and increase caloric expenditure. Special prescription diets are recommended for individuals who are showing the sequela or complications of diabetes, particularly low-sodium diets for those with hypertension and lower-protein diets for those with renal disease. The fourth population for which there are extensive dietary prescriptions are Type I diabetics and gestational diabetics who need special dietary control during pregnancy to insure healthy outcomes for their infants and themselves. During the 1990s, a greater emphasis has been placed on prophylactic diets to prevent obesity and the complications of diabetes.

In summary, the 1994 ADA/ADA recommendations set dietary goals for people with diabetes that are, generally, the same as those for the general population. The aim is to maintain a normal weight, reduce fat, increase fiber, reduce salt, and limit alcohol intake. The use of nonnutritive sweeteners and fats has been recommended. The new emphasis on the liberalization of diets, the availability of new foods, nonnutritive sweeteners, and fats will help to change the therapeutic diet from one that is only moderately palatable to one that is both desirable and efficacious in achieving the dietary goals for people with diabetes.

IV.F.2 Nutrition and Cancer

As early as the 1930s, experiments on laboratory animals revealed that diet can considerably influence the process of cancer causation and development (carcinogenesis) (Tannenbaum 1942a, 1942b; Tannenbaum and Silverstone 1953). It was several decades later, however, that the first epidemiological studies appeared to indicate that diet could play a role in human cancer. A key conference held in 1975, entitled "Nutrition in the Causation of Cancer," summarized the existing knowledge and hypotheses (Wynder, Peters, and Vivona 1975). From that moment, research in experimental systems, including animal models and epidemiological studies, increased rapidly, providing extensive information on the impact of nutritional traditions and specific macro- and micronutrients on several types of cancer. Considerable progress had already been made in several underlying sciences. For example, advances had been achieved in understanding the mechanisms of action of nutrients, the process of carcinogenesis, and the classification of carcinogens according to their mode of action (Kroes 1979; Weisburger and Williams 1991).

In particular, epidemiological studies on the international variations in incidence rates for certain cancers pointed to the existence of one or more exogenous factors that could be controlled. Observational studies had been conducted with migrants from countries with lower incidence rates to countries with higher incidence rates. A rapid increase from the lower to the higher incidence in those migrants supported the suggestion that environmental causes, and especially prevailing dietary habits, may influence the development of a number of neoplasms.

For example, in the Western world, high incidences of cancers in the lung, colon and rectum, breast, prostate, pancreas, endometrium, and ovary were observed. But these diseases were, until recently, quite rare in Japan and other Asian countries, where cancers of the stomach, esophagus, and liver were the major diseases. Yet, in migrant populations the risk of cancer shifted from the risk prevalent in their native country to that seen in the new host country, sometimes within the same generation (colon), sometimes in the next generation (breast) (Parkin 1993).

The results of experimental and epidemiological studies have led to hypotheses concerning factors involved in cancer causation. In fact, E. L. Wynder and G. B. Gori (1977) and R. Doll and R. Peto (1981) estimated that 35 percent of cancer mortality may be attributable to diet, thereby placing diet at the same "risk factor" level as smoking, which was calculated to cause about 30 percent of cancer mortality. In fact, current views suggest that dietary habits may account for 55 to 60 percent of cancer mortality. The interpretation of such multidisciplinary investigations has shed light on underlying mechanisms of cancer causation and has provided an understanding of the role of specific dietary risk factors.

In this chapter, the focus is the role of diet in cancer causation. First, attention is drawn to aspects of mechanisms in carcinogenesis. The major strengths and weaknesses of experiments in animal models and epidemiological studies are discussed, and then the major diet-related causes are examined and their suggested mechanisms and possible preventive measures described. The safest (but in the public's perception the most dangerous) intentional additives in food are evaluated for their cancer risk, as are nonintentional contaminants, along with substances that occur naturally in food. Finally, the key role that diet may play in an integrated approach to (chronic) disease prevention is presented. Health promotion through research-based nutrition not only is important for the individual but, on a global level, may also appreciably lower the cost of medical care. A research-based healthy lifestyle is designed to allow people to "die young, as late in life as possible," as Dr. Ernst L. Wynder, president of the American Health Foundation, has said.

Tumor Models: Strengths and Weaknesses

Animal tumor models are often used in experimental designs to study the mechanisms of cancer causation, to examine the effects of modulating factors on the genesis and development of cancer, to assess therapeutic modalities, and to explore possible adverse effects.

Tumor models are specifically used to investigate etiologic and physiopathological properties or processes, especially those which, for obvious practical and ethical reasons, cannot be studied in humans. The ideal animal tumor is histologically similar to the human neoplasm of concern, and latency period, growth, and tendency to metastasize should both be predictable and resemble those of the human neoplasm. The animals should be cost effective, be easily available, and have a genetic uniformity. Variables should be controllable, thereby making it possible to investigate the influence of isolated factors (Davidson, Davis, and Lindsey 1987; Galloway 1989; Weisburger and Kroes 1994).

For research into matters of nutrition and cancer, chemically induced tumors in animals, predominantly those in rats and mice, are the most important models because they usually best mimic existing types of human cancer (Kroes et al. 1986). For most, if not all, nutrition-related human cancers, tumor model systems are available. They provide an ideal research tool for investigating the influence of individual factors, either in the initiation phase or in the promotion–progression phase of tumor development, or in the overall process.

Possible leads from epidemiological studies can be further investigated in models, thus providing more detailed information, especially regarding risk factors and mechanisms that can be the basis for new epidemiological studies to test a presumed hypothesis. However, animal tumors are only approximations that are rarely identical to human disease. For example, relatively high dosages of genotoxic carcinogens are used to induce the tumor, which tends to distort circumstances when modulating factors are investigated.

Tumor metabolism, growth, potential for and pattern of metastasis, and clinical features can also differ from the human disease. Multiple tumors often occur in models, but seldom in humans. Moreover, the nutrition patterns of experimental animals can be quite distinct from those of humans. Nonetheless, diets can be designed in terms of macro- and micronutrient intake that mimic specific human nutritional traditions.

Animal studies are best understood as providing support for epidemiological studies. It is the integration of results from epidemiological and animal studies that provides the best insight into the etiology and growth of cancer, as well as its treatment, and brings us nearer to the ultimate goal of such research, cancer prevention.

Epidemiological Studies Concerning Nutrition and Cancer

Epidemiological research on cancer and diet seeks to associate exposure to certain dietary factors with the occurrence of cancer in selected population groups. Studies can be descriptive, reporting the occurrence of cancers in populations, in subgroups of a given population, or in a certain population over time. Observed patterns may be related to particular variables, such as diet, but although the results of such investigations are suggestive, they are certainly not definitive. Their use is especially valuable, however, in identifying populations at risk.

Correlation studies investigate the possible relationships between more-or-less crude exposure data and cancer incidence data in different populations or nations in order to generate new hypotheses. But they are generally of limited value, because national per-capita food intake and cancer incidence data are only approximations and differ from place to place in terminological definition and accuracy. Results should be used mainly as an indication of trends or relationships.

Another type of investigation is the case control study, in which the investigator is able to collect data from individuals instead of groups, and confounding variables can be controlled to a certain extent. In studies of a specific type of cancer, food intake data are collected and are compared to data similarly obtained in matched controls. When known biases and chance can be excluded, associations can be made between exposure and disease. Case control studies are relatively cheap and are of short duration but never prove causal relationships.

Much more expensive, time consuming, and elaborate are prospective cohort studies that focus on individuals in a given (large) population and establish exposure or nutrition data before the occurrence of the disease. Thus, at the time of disease occurrence, exposure data of the patients are compared to data from people not having the disease, thereby providing evidence for a possible causal relationship. Drawbacks in such studies are that the exposure assessment at any given time may not be representative of the individual's whole life, and this is especially likely in the case of diet.

Finally, intervention studies provide the investigator with the possibility of a random assignment of subjects of a given (often high-risk) population into groups that are treated or fed differently under controlled conditions. In this type of trial, causal relationships can be established.

In investigations focused on the relationship between nutritional factors and cancer, the methods used for determining dietary intake are crucial and difficult. All dietary intake measures share certain limitations, because people vary in their abilities to estimate the amount of something they have eaten. Indeed, sometimes they may even fail to notice or report consumption of certain foods, and they usually possess insufficient knowledge about the ingredients in the foods they consume. A further handicap is that accuracy in dietary recall deteriorates over time. Finally, in the case of cancer, it is very difficult to relate varying diets to the disease because the latter has a long course of development before becoming clinically manifest (10 to 40 years).

The major strength of epidemiological studies, however, is their focus on human populations, thus avoiding the need to extrapolate from other species. They tend to afford an opportunity to examine different effects at different exposure levels, and they are always realistic, in contrast to the high exposure levels usually employed with animals (National Research Council 1982; International Agency for Research on Cancer 1990; Weisburger and Kroes 1994). In this connection, however, it should be noted that in specific investigations into the role of nutrients such as fat, the experimental design in laboratory animals usually faithfully mimics the situation of human populations at high or low risk, thus providing relatively reliable comparative data. But at the same time, as noted, it should also be recognized that the normal food patterns of laboratory animals differ from those of humans.

Mechanisms of Carcinogenesis

The concept that chemicals can induce cancer through a variety of modes of action is derived from a greater understanding of the complex processes of carcinogenesis (Williams and Weisburger 1991). Cancer causation and development involves a series of essential steps (Figure IV.F.7.1). In the first step, a reactive form of carcinogen (often produced metabolically from a procarcinogen) binds to DNA, or DNA is altered by the effective generation of hydroxy radicals. This reaction, in turn, leads to translocation and amplification of specific genes, proto-oncogenes, or a mutation in tumor suppressor genes, that translate to a distinct expression of the properties of the cells bearing such altered genes (Williams and Weisburger 1991; Ronai 1992; Miller 1994).

The property to bind to DNA is the basis for the development of specific rapid, efficient, and economical in vitro bioassays, such as a mutation assay in prokaryotic or eukaryotic cell systems. Advantage can also be taken of the presence of enzyme systems performing DNA repair; these can provide effective complementary test systems to outline the possible DNA-reactivity of chemicals (Weisburger and Williams 1991; Weisburger 1994). Moreover, the ^{32}P-postlabeling procedure of K. Randerath and colleagues (1989) yields information about the presence of reactive carcinogen–DNA adducts.

When a chemical displays properties of reacting with DNA and inducing mutations and DNA repair in a number of cell systems, it can be considered DNA-reactive or genotoxic. Most human carcinogens are genotoxic. Other agents, such as the hormonoïd diethylstilbestrol (DES) or the hormone estradiol, may give rise to genotoxic products (Liehr 1990). The fact that a given product is genotoxic may signal that, with sufficient dosage and chronicity of exposure, it poses a cancer risk to humans.

Reactive oxygen, hydroxy radicals, or hydrogen peroxide can be generated in metabolic processes. On the other hand, there are endogenous defense mechanisms, such as catalase-destroying hydrogen peroxide or superoxide dismutase or glutathione peroxidase (in turn, involving glutathione [GSH] or sulfhydryl amino acids), that neutralize reactive oxygen. Exogenous antioxidants (such as those in vegetables, tomatoes, and tea), carotene, vitamins C and E, selenium, and sources of GSH aid in the disposition of reactive species (Harris 1991; Olson and Kobayashi 1992; Packer 1992; Sai et al. 1992).

The consequences of DNA–carcinogen interactions are beginning to be explored in terms of proto-oncogene – oncogene codon translation and amplification that can be measured by highly specific and sensitive polymerase chain reaction techniques

(Brugge et al. 1991). Errors may be introduced into DNA during biosynthesis (Echols and Goodman 1991). Mutational events in tumor-suppressor genes also yield abnormal DNA, which is of growing interest (Brugge et al. 1991). The rate of cell duplication is important in generating abnormal DNA. A rapid rate decreases the chances of successful repair and is a reason that growing organisms or proliferating tissues are often more sensitive to carcinogens (Cohen and Ellwein 1992). For example, radiation exposure during the Hiroshima atom-bomb explosion caused a fourfold higher breast-cancer incidence in the 10- to 15-year-old age group (with mammary gland cells in rapid DNA synthesis and mitosis) than in younger or older groups (Land et al. 1980).

Reactive carcinogens modify not only DNA but also proteins. Both types of interactions can serve as sensitive markers for qualitative and quantitative analysis, especially the readily measured hemoglobin adducts (Brugge et al. 1991).

Nongenotoxic carcinogens and promoters cannot cause cancer without an antecedent mutational event and cell change. For example, mice with mammary tumor virus (MTV) develop mammary tumors proportional to the level of estrogen administered, but those without MTV do not, no matter what dose of estrogen is used (Highman, Norvell, and Shellenberg 1977). The action of promoters requires their presence at relatively high levels for a long time, and that action is often tissue specific. For example, bile acids are promoters of colon cancer, and very high dosages of sodium saccharin act as a promoter for cancer of the urinary bladder. The interruption of gap junctions and intercellular communication plays a key role in promotion, and promoters can be detected through this characteristic (Yamasaki 1990; Trosko and Goodman 1994).

As promoters are nongenotoxic substances, linear extrapolation for health-risk assessment seems unrealistic and, actually, scientifically improper (Kroes 1987; Williams and Weisburger 1991; Weisburger 1994). In order to better assess risk using appropriate epidemiological and biostatistical approaches, new procedures to define the mode of action of epigenetic (nongenotoxic) agents are being developed. Most likely, dose-response studies will yield a typical pharmacological S-shape response, with a definite no-effect level. This is especially important when fundamental insights into the properties of carcinogens and promoters are applied to the area of nutritional mechanisms in cancer causation.

Thus, chemical carcinogens can be classified into two main groups: (1) DNA-reactive substances that are genotoxic in appropriate test systems and (2) epigenetic (nongenotoxic) agents operating by producing some other specific biological effect as the basis for their carcinogenicity. Genotoxic carcinogens alter DNA, are mutagenic, and lead to transformed cells with neoplastic attributes. Nongenotoxic carcinogens involve other mechanisms, such as cytotoxicity, chronic tissue injury, hormonal imbalances, immunologic effects, or promotional activity.

Diet-Related Cancers

Several extensive reviews addressing diet-related neoplasms have been published in the past decades. In the Western world, cancers associated with nutrition account for a substantial percentage – about 35 to 45 percent – of premature deaths. In this section, characteristics of the different types of cancer, their established or suggested relationships with dietary factors, and their presumed mechanisms of action are described. In addition, possible measures to prevent or decrease the risk of developing the disease are discussed.[1]

Oral Cavity, Pharynx, and Esophagus

Cancers of the oral cavity and pharynx account for approximately 400,000 new cancer cases each year in the world. High incidences are noted in France, Switzerland, northern Italy, Central and South America, parts of Pakistan, and India. These cancers occur much more frequently in males than females, and differences between high- and low-incidence areas may be as much as 20-fold.

High-incidence rates of cancer of the esophagus are found in the so-called Asian esophageal cancer belt, which extends from eastern Iran, along the Caspian Sea, through Turkmenistan, Tajikistan, Uzbekistan, and Kyrgyzstan, and into parts of China. Except for the high-incidence areas, where the sex ratio almost equals 1:1, males show predominantly higher incidences. World incidence rates differ more than 100-fold, and globally more than 300,000 new cases occur each year.

Cancer of the esophagus is especially common among individuals who chew or smoke tobacco and drink alcoholic beverages. Consumption of alcohol alone – especially hard liquor – seems to be a risk factor as well (Seitz and Simanowski 1991; Castelleto et al. 1994). Smoking and alcohol consumption have a synergistic effect on carcinogenesis in the upper alimentary tract. In Asian and African populations, dietary deficiencies of zinc, riboflavin, vitamins A and C, manganese, and molybdenum may play a role, as well as mycotoxins, bracken fern, opium pyrolysates, and betel quids. The consumption of salted fish is an established risk factor in southern Chinese populations, probably because of the formation of specific nitrosamines (Craddock 1992; Zeng et al. 1993). Consumption of very hot beverages, along with the use of substances that irritate the oral cavity, pharynx, and esophagus, all of which lead to increased cell proliferation, may enhance the incidence of neoplasia.

However, substantial differences in incidence between high- and low-risk areas indicate that there exists considerable potential for prevention. Frequent consumption of fresh fruits and vegetables, as well as tea, appears to be associated with a lower risk for these types of cancer. The potential reduction has been estimated to be around 75 percent (Negri et al. 1993). Preventive measures involve the avoidance of tobacco and very hot beverages, along with moderate alcohol use and a well-balanced diet that includes a sizable increase in the regular consumption of vegetables and fruits (Block, Patterson, and Subar 1992).

Stomach

In the 1980s, gastric cancer was still considered to be the most common cancer in the world. Indeed, with almost 700,000 new cases per year, it represented approximately 10 percent of all cancers. Differences between high- and low-incidence areas vary by 40-fold. However, a large decrease in rates has occurred in most populations during the last four to five decades, indicating a reduction in exposure to tissue-specific carcinogens and/or the introduction of a protective agent.

Males suffer approximately twice the incidence and mortality of females, although the sex ratio is not constant by age group. The sex ratio equals 1:1 in people under the age of 30, but the disease is rare in this group. High-risk populations usually consume considerable quantities of pickled vegetables, dried salted fish, smoked fish, and other smoked, salted, and dried foods. Consumption of certain salted and pickled fish has yielded high levels of mutagenicity and evidence of carcinogenicity. One of the mutagens present has been identified as 2-chloro-4-methylthiobutanoic acid. This finding was totally unexpected, because in the past, nitroso compounds were associated with stomach cancer (Chen et al. 1995).

By contrast, a negative association has been established between mutagenicity and the regular intake of green leafy vegetables and citrus fruits. Laboratory experiments show that vitamins C and E block the formation of mutagens when fish is treated with nitrite, mimicking pickling (Weisburger 1991).

Infection with *Helicobacter pylori* and associated conditions, such as atrophic gastritis, ulceration, partial gastrectomy, bile acid reflux, and pernicious anemia, are additional risk factors. Several of these increase cell-duplication rates, rendering the gastric cells more sensitive to genotoxic carcinogens.

A high level of consumption of salted, pickled, or smoked food was once customary in the Western world. However, better access to home refrigeration, improved and cheaper transport - and, therefore, increased availability - of fresh fruit and vegetables seems to correlate well with the decline of this type of cancer (Howson, Hiyama, and Wynder 1986; Weisburger 1991). The relevant mechanism begins with the development of atrophic gastritis due to the cytotoxic activity of salt and vitamin deficiencies. The consequent decrease in gastric acidity permits uninhibited bacterial growth. Bacterial growth then converts dietary nitrates to nitrites, which are further metabolized into carcinogenic nitroso derivatives or reactive carcinogens (Correa 1992; Chen et al. 1995). Because vitamins C and E are known to be effective inhibitors of nitrosation, it is plausible that an increased intake of these vitamins, or foods containing them, should reduce the risk of gastric cancer by inhibiting nitrosation.

Preventive measures are the introduction of food refrigeration, the reduction of salt and pickled food intake, and an increased consumption of fruits and vegetables. Especially in areas with high prevailing environmental nitrate levels, vitamin C and vitamin E supplementation may be useful for preventing formation of nitrite-derived reactive carcinogens and reducing nitrite produced by conversion of nitrate in the mouth. The preventive potential has been estimated to be about 50 percent but may well be much higher.

Colon and Rectum

Approximately 600,000 new cases of colorectal cancer are diagnosed worldwide each year. It is particularly a disease of the developed countries, which to some extent reflects increasing life expectancy. Differences in incidence may be 60-fold. The lowest incidence rates are found in Africa and Asia, although incidences are rising, especially in areas where the risk was formerly low, as in Japan. Colon cancer affects the sexes equally. The distribution for rectal cancer is similar to that for colon cancer. Incidences are usually lower, and there is a male–female ratio of 1.5:2.0, especially in high-incidence areas.

Epidemiological evidence suggests that (Western) lifestyle is an important determinant of risk for colorectal cancer: Migrants to Western countries acquire a higher risk for the disease in the first generation, and Mormons and Seventh Day Adventists enjoy a low risk. Familial polyposis, ulcerative colitis, and Crohn's disease are identified risk factors for colon cancer, but these are uncommon conditions.

Diets high in fats and low in fiber and vegetables are associated with increased risk for colon cancer. A fat–fiber interaction has been suggested, and the type of fiber is important as well (Kroes, Beems, and Bosland 1986; Weisburger 1992). It is interesting to note that some polyunsaturated fats found in fish and some vegetable seeds inhibit colon cancer formation. Moreover, olive oil intake, as in the Mediterranean countries, does not increase the risk of the nutritionally linked cancers or heart disease, a fact also documented in animal models (Reddy 1992). An inverse relationship has also been found for the consumption of fruits and vegetables, as well as for calcium intake and regular exercise; the same is true of coffee and tea for colon and rectal cancer, respectively (Baron, Gerhardson de Verdier, and Ekbom 1994).

Experimental and epidemiological research has revealed that bile acids promote cancer formation (Reddy 1992). The case is similar with alcohol, especially for rectal cancer, perhaps accounting for the higher male-to-female ratio (Seitz and Simanowski

1991). Recent surveys also indicate that intake of heavily fried or grilled meat and gravies is positively related to colorectal cancer, suggesting that chemicals produced during the frying or grilling of meats (heterocyclic aromatic amines) may be the initiating carcinogens, particularly for breast, colon, and, perhaps, prostate and pancreatic cancer (Adamson et al. 1995).

Suggested mechanisms in colon cancer development are the increased bile acid concentrations in individuals consuming high levels of many types of dietary fat. The higher concentrations of bile acids may lead to increased turnover of the epithelial cells of the intestines, reflecting increased risk of carcinogen–DNA adducts to cause translocation and amplification of abnormal genes or mutated tumor-suppressor genes. This phenomenon is inhibited by increased dietary calcium. The toxicity of bile acids is also reduced at a lower luminal pH. Alcohol may act as a promoter at the level of the rectum, and its metabolite acetaldehyde, which occurs at higher concentration in the rectum, may induce cytotoxicity, thus leading to increased cell proliferation and turnover.

Dietary fibers at adequate concentrations are thought to dilute and particularly bind the genotoxic agents present in the gut, decreasing fecal mutagenic activity. Fibers also modify the metabolic activity of the gut flora and lower luminal pH. Wheat bran increases the bulk of the gut contents, thus diluting bile acids and decreasing their adverse effect on the mucosal lining of the bowel (Reddy 1992). Regular physical exercise also lowers transit time of the luminal contents and appears to decrease risk of colorectal cancer. Fruits and vegetables generally reduce cancer risk through several mechanisms (Block et al. 1992). They provide fibers and antioxidants that can detoxify active genotoxins and also contain a number of chemopreventive agents, such as indole derivatives, that are anticarcinogenic. Tea antagonizes the effect of heterocyclic amines present in fried or broiled meats, which are thought to be carcinogens for the colon.

Potential reduction of colorectal cancers through prevention has been estimated at 35 percent, mainly of distal colon cancer and rectal cancer. The risk factors for proximal colon cancer are not well known, although general recommendations for lower risk may apply to colorectal cancer overall. This would involve a low fat intake (20 to 25 percent of calories), use of monounsaturated fats such as olive oil, an adequate fiber intake (25 to 30 g/day), moderate alcohol consumption (an average of 2 drinks/day), fish 2 to 3 times a week, an increased calcium (lowfat milk or yoghurt) intake (1,200 to 1,500 mg), increased consumption of vegetables and fruits (ideally 5 to 9 servings/day), tea (4 to 5 cups per day), and regular exercise.

Breast

Breast cancer is the third most common cancer in the world; every year about 600,000 new cases are detected, which is about 9 percent of the global cancer burden. It is important to distinguish between premenopausal breast cancer, in which diet plays a minor role (except for some protection afforded by consumption of vegetables and fruits, including soy products), and peri- and postmenopausal disease, in which diet may exert important controlling effects. Breast cancer occurs almost exclusively in women, and in high-risk areas (North America and western Europe), the incidence is about 4 to 30 times higher than in low-risk areas like China, Japan, and Sri Lanka, although there has been an appreciable increase in Japan during the last decade – the result of a westernization of dietary customs.

Important risk factors for breast cancer are a family history of the disease, a low number of offspring, avoidance of breast feeding of infants, a late age at first pregnancy, an early menarche, a late age at menopause, and high consumption of fats (about 30 to 40 percent of calories) and, possibly, alcohol. During the last decade, increasing evidence has been adduced indicating that there is an inverse relationship between breast cancer and increased intake of vegetables and fruits. Food antioxidants (such as selenium, retinoids, and polyphenols), as well as bran cereal fibers, have been suggested as inhibiting factors. Obviously, endocrine factors are important in breast cancer development. Fat may increase breast cancer risk by its control of hormonal regulation. In addition, high fat and high energy intakes, coupled with lack of exercise, lead to obesity, a possible contributory factor in breast cancer in postmenopausal women.

Obesity, however, seems inversely related to the risk of breast cancer in premenopausal women. F. De Waard has developed a unifying concept on the etiology of breast cancer, which focuses on the events that occur during adolescence and early reproductive ages (see Weisburger and Kroes 1994). He has suggested that preneoplastic lesions develop at early ages, from 15 years onward. Several factors, such as nutritional status, high fat intake, low consumption of protective vegetables, fruit, and fibers, along with reproductive life, interact in inducing a long period of cell proliferation without sufficient differentiation in the breast.

On the other hand, early pregnancy and long-term lactation will raise the differentiation of cells, thus limiting the proliferation of less differentiated cells, the latter being more vulnerable to genotoxic attack. Fat may also influence the immune system, increase prostaglandin synthesis, and increase membrane fluidity, all phenomena bearing on the promotion and growth of neoplastic cells. Therefore, the appropriate dietary preventive measures are avoidance of heavily fried or broiled meats, a limited fat intake (possibly as low as 20 to 25 percent of total calories), preference for monounsaturated fats such as olive oil, an increased intake of vegetables, fruits, tea, and insoluble bran cereal fiber, and an energy intake that balances energy need with the avoidance of obesity. In this latter connection, an increase of exercise has been shown to lower risk and assist in weight control.

Endometrium and Ovary

Endometrial cancer strikes approximately 150,000 women in the world each year, with tenfold differences in incidence, depending on location. High incidences are found in Argentina, the United States, Canada, and western Europe, whereas a low incidence has been noted in Asian populations. Identified risk factors are, in particular, endogenous estrogen and higher amounts of exogenous hormones employed for the management of menopausal and postmenopausal symptoms. Obesity and fat consumption are also associated with increased risk. Estrogen therapy, as practiced for postmenopausal symptoms between 1960 and 1975, has been documented as a causal element for endometrial cancer, most probably because it was given in relatively large dosages and was not balanced by progesterone. If the action of limited amounts of estrogens is balanced by progesterone, cancer risk is decreased.

The role of obesity or high fat consumption in endometrial cancer may be explained by the fact that fat cells produce estrogen, which itself is a key effector in neoplastic development through its specific effect on endometrial tissue and on overall endocrine balances. As dietary factors may be responsible for an appreciable percentage of cases, limited fat intake and avoidance of excessive energy intake are suggested preventive measures. Regular exercise, likewise, constitutes a protective element.

Ovarian cancer is common in western Europe and North America, whereas it has a low frequency in Indian, Japanese, and other Asian populations. Unlike that of many other types of cancer, the incidence of ovarian cancer in the Western world has remained rather constant over time. The risk factors for ovarian cancer are the same as those for breast and uterine cancer, meaning a positive association with endocrine factors and dietary fat intake and a negative association with parity and elements that suppress ovulation. Thus, oral contraceptives may substantially reduce the risk of ovarian cancer. Limited fat intake (perhaps 20 to 25 percent of calories or less) and consumption of vegetables and fruits are suggested as preventive measures.

Pancreas

Pancreatic cancer occurs more frequently in developed countries, comprising approximately 3 percent of the worldwide cancer burden. The disease, however, is increasing in incidence over time and has a very high mortality rate because of late diagnosis and, thus, has low success in therapy. Every year, approximately 140,000 new cases are diagnosed. In the last 40 years, pancreatic cancer incidence has doubled in western Europe and quadrupled in Japan (Hirayama 1989).

Tobacco smoking has been implicated as a major risk factor, which can explain the increasing incidence, especially in those countries where the pancreatic cancer incidence is still relatively low. Convincing evidence also exists from experimental animal research that carcinogens from tobacco and a high fat intake are positively related, whereas caloric restriction, selenium, and retinoids are inversely related. Of interest is the role shown by trypsin inhibitors in pancreatic carcinogenesis in experimental animals. These trypsin inhibitors do reduce trypsin levels in the gut, stimulating the secretion of cholecystokinin (CCK) as a feedback phenomenon. CCK stimulates pancreatic growth, thus promoting pancreatic carcinogenesis. Trypsin inhibitors, present in soy proteins, are heat labile. Soy proteins are high-quality foods, but they should be incorporated in foods and cooked (Watanapa and Williamson 1993).

Epidemiological research reveals a positive relationship for dietary fat, fried or grilled meats, and, possibly, alcohol or cholesterol, whereas an inverse relationship has been observed for caloric restriction, omega-3 fatty acids (fish and some seeds like flax seed), and fresh fruits and vegetables (Bueno de Mesquita 1992). Preventive potential has been estimated to be 70 percent. Cessation of tobacco smoking, moderate alcohol use, low fat consumption, and increased intake of vegetables and fruits are the main measures for prevention. This is particularly important because of its grim prognosis. Thus, control is optimal through prevention by lifestyle adjustment.

Prostate

Prostate cancer is the fifth most common cancer among males, and especially predominant in older males. Approximately 240,000 new cases of clinical invasive prostate cancer occur each year, and high-incidence areas are northwestern Europe and North America; in the latter, African-Americans have a particularly high incidence. Low rates are found in India, China, and Japan. There exists a 50-fold difference between populations with the highest rates of prostate cancer (blacks in Detroit, Michigan) and populations with the lowest incidence (Asians in Shanghai, China) (Nomura and Kolonel 1991). Endocrine factors may play a role in prostate carcinogenesis, but geographic pathology indicates that dietary factors are probably also important. Populations with a tradition of high fat and high protein intake have a high risk. The diet controls the endocrine balance.

Negative associations have been suggested for vitamin A, beta-carotene, vegetables, fruits, selenium, fish, and fiber. Sugar and egg consumption are weakly positive (Bosland 1986). Genetic, sexual, and dietary factors seem to play a role in prostate carcinogenesis, indicating a multifactorial process. As is true for other endocrine-controlled neoplasms, a dietary regime low in fat and rich in vegetables and fruits, coupled with regular exercise, may contribute to lower risk irrespective of sexual and genetic elements (Wynder, Rose, and Cohen 1994).

Lung

It is surprising to note that more and more data have become available to indicate that lung cancer is influenced by dietary factors. Clearly, the disease is associated with cigarette smoking, but since E. Bjelke (1975) and G. Kvale, Bjelke, and J. J. Gart (1983) found in metabolic epidemiological studies that smokers with a higher level of vitamin A in plasma had a lower risk of lung cancer, more attention has been given to dietary factors (Ziegler et al. 1992; Le Marchand et al. 1993). Also, for humans, an inverse relationship between lung cancer development and fruit and vegetable intake has been observed, whereas other data suggest a positive relationship between dietary fat intake and lung cancer (Wynder, Taioli, and Fujita 1992). In addition, the antioxidants in tea may provide a protective effect. Currently, there are more smokers in Japan than in the United States or the United Kingdom, but the incidence of lung cancer is lower in Japan. It has been suggested that the Japanese have a lower risk because of a lower total fat intake and more frequent intake of fish, soy foods, and tea.

Therefore, although the first recommendation should be to quit smoking – or, in fact, never to start – an increased intake of fruits and vegetables (especially those containing retinoids) and also of fish, soy-derived foods, and tea, coupled with a lowered fat consumption, may serve as preventive measures and could be particularly appropriate for ex-smokers.

Food Additives, Contaminants, and Natural Toxins

For decades, the possibility of cancer risks from food additives and contaminants has been widely publicized, especially in the developed countries, where there has been an increase in the addition of various substances to food for preservative and commercial purposes. Thus, food additives and contaminants are viewed by many as a major threat to human health – and one that may cause cancer. Scientific information, however, shows exactly the opposite: Food additives are safer than everyday traditional nutrients, and the same is true for most contaminants (Miller 1992; Weisburger 1994; Weisburger and Kroes 1994).

Such opposite perceptions may be explained by the misinterpretation of epidemiological reports in the late sixties, when the term "environmental" (as in "environmental factors") was used to account for major causes of cancer. In fact, what was meant was as lifestyle factors, but the general public (and especially the news media) misinterpreted this to mean synthetic chemicals, including food additives and contaminants.

In addition, several episodes have enhanced this misconception, as, for example, when certain food additives (that is, some food dyes in Western countries and the preservative AF-2 in Japan) were first permitted and later correctly withdrawn because of their demonstrated carcinogenicity in animals (Sugimura 1992). Regulatory action, especially in the United States, aimed at such chemicals as sodium saccharin and cyclamate, further deepened public suspicion. Yet the latter substances are now considered safe, at least at the normal intake levels that humans experience. In fact, certain substances with antioxidant properties, which are used as food additives, are even believed to reduce cancer risk. Thus, Wynder and Gori (1977), as well as Doll and Peto (1981), have estimated that cancer mortality from food additives ranges from –5 to +2 percent, the negative score specifically addressing the beneficial aspects of antioxidants used in foods.

Additives are used to improve the stability and storability of foods, as well as their flavor, consistency, appearance, texture, and nutritional quality. In certain cases, they are a necessity, such as in the case of preservatives that prevent food-borne microbial infections. And in any event, the risk of disease from food additives today is minimal, because efficient and effective control practices are available and applied to ensure safety.

Contaminants of human-made origin are, like food additives, extensively tested in animals before use, and the levels permissible in crops are well controlled internationally. Thus, the margin of safety for pesticide residues in food runs usually between 1,000 and several millions, whereas for several macro- and micronutrients, the margin of safety is as small as 2 to 10 (Kroes in press). In fact, B. N. Ames and colleagues (1990, 1992) have listed a number of naturally occurring substances in food that, because of uncontrolled exposure, provide much more concern for cancer risk than synthetic chemicals. About half of such natural chemicals that have undergone standard high-dose animal cancer tests proved to be animal carcinogens, such as the mold-generated hepatic carcinogen, aflatoxin (International Agency for Research on Cancer 1993b). In addition, as noted, powerful carcinogens are formed during the cooking of meats and during the salting and pickling of some fish and meats.

The natural defenses of humans, however, may make them capable of detoxifying low doses of most toxins, whether synthetic or natural. For example, despite a continuing low-level presence of aflatoxin B_1 in some foods, the incidence of primary liver cancer in the United States and Europe is not significant. Yet it is quite high in parts of Africa and China, where the dietary contamination is appreciable and where more people carry the hepatitis B antigen, potentiating the action.

Certainly, in light of the foregoing, it seems relevant to invest more research capacity in the identification of possible risks and benefits of naturally occurring substances. This is especially true because many are also known to possess anticarcinogenic properties – properties that are believed to be the reason for the inverse relationship between several cancers (and heart diseases) and the regular intake of vegetables, fruits, and tea.

Food preparation has entailed cancer risk in the past and will continue to do so in the future. Preservation methods, for example, such as the use of salt or pickling solutions, are associated with a high risk of stomach cancer and in some areas, such as China, with cancer of the esophagus. Salted fish causes nasopharyngeal cancer, and salt and high nitrate (saltpeter) concentrations in several meat products can lead to the formation of carcinogenic nitroso compounds, or of the chloro analog of methionine, either in the food itself or in the stomach. Salt is cytotoxic to the gastric mucosa, translated by increased cell duplication rates and, in turn, to more efficient carcinogenesis. Some salted, pickled foods contain direct-acting mutagens thought to be gastric carcinogens (Weisburger 1992; Chen et al. 1995). Salt, not balanced by potassium from vegetables, and calcium from dairy products is also a cause of hypertension and stroke. In Japan (Sugimura 1992) and in Belgium (Joossens, Hill, and Geboers 1985), formal plans were introduced to lower salt intake by people.

Charcoal-broiled meats or fish have at their surface polycyclic aromatic hydrocarbons that are established animal carcinogens. But it is important to note that the ordinary cooking (broiling, frying) of meats or fish can produce powerful mutagens, consisting of about 19 heterocyclic amines (also established animal carcinogens) for specific target organs. They are believed to be the key carcinogens causing increased incidence of several human cancers, such as those in the breast, prostate, colon, and pancreas. Certainly it has been shown that those who generally eat well-done meat increase their risk of colon cancer. The formation of heterocyclic amines during the heating of meats can be reduced by preliminary brief microwave cooking (removing essential creatinine) or by the addition of antioxidants, soy protein, or the indole amino acids tryptophan and proline, which all compete with creatinine in the so-called Maillard reaction, forming heterocyclic amines (Weisburger and Kroes 1994).

Prevention: An Integrated Approach

A substantial amount of solid epidemiological and experimental evidence indicates that the majority of human cancers, and indeed many other chronic diseases, such as heart disease, hypertension, and adult-onset diabetes, are largely preventable. Complex causes have been, or are being, identified, and the underlying mechanisms elucidated. Control of many major diseases of humankind in the past, such as scurvy, pellagra, rickets, polio, smallpox, rabies, and tuberculosis, has been achieved by prevention strategies. Therefore, a clear and balanced prevention approach to the effective control of human cancers (and other chronic illnesses, such as cardiovascular diseases) is likely to be successful as well.

Experience in the past two decades with other chronic ailments, such as cardiovascular diseases, indicates that the application of sometimes even simple measures can have a considerable impact on their outcome (Meyskens 1992). In fact, cancer prevention runs a decade behind the scientific understanding of the disease, as a number of lifestyle-associated factors contributing significantly to cancer risk are well known. Tobacco and nutritional traditions, in particular, and – to a lesser extent – radiation, some chemicals, and certain viruses, are documented, avoidable risk factors.

Wynder and Gori (1977), Doll and Peto (1981), and J. H. Weisburger (1992) have contributed substantially to the evidence of preventive potential for many types of cancer through their listing and documentation of avoidable risks of cancer. Unfortunately, not only are such concrete factors as tobacco, diet, lifestyle, and radiation contributing to the cancer burden, but poverty does as well, because the need for essential lifestyle changes has been difficult to communicate effectively to the lower socioeconomic groups (Tomatis 1992).

Cancer prevention programs should be based on reliable epidemiological and laboratory evidence, and on ethical and moral responsibility, and ought to specify clearly achievable outcomes in mortality and morbidity reduction. Moreover, they should be integrated with other chronic-disease-prevention programs. The multifactorial elements, such as nutritional traditions, sedentary habits, and tobacco use, which represent a risk for diseases like coronary heart disease, hypertension, stroke, obesity, and many neoplastic diseases, have to do with lifestyle. In fact, these factors are the *major causes and modulators of these diseases.*

Table IV.F.2.1 depicts several realistic actions to take in order to lower the risk for certain common diseases. In the Western world, nutritional traditions with a relatively high fat intake (38 to 46 percent of energy intake), low cereal fiber, and low vegetable and fruit consumption, along with a lack of regular physical exercise, are associated with high incidence and high cost of the management of chronic diseases, such as cardiovascular diseases, diabetes, obesity, and specific types of cancer. In the Far East and in Central and South America, prevailing illnesses seem to stem from other nutritional traditions, such as the use of highly salted and pickled foods and a limited variety in diet. Currently, the changing nutritional habits in Japan to a Western style parallel an increase in heart disease and the kind of cancers common in the Western world. This provides strong additional support for the thesis that dietary customs and specific chronic diseases are related.

Today's knowledge enables us to recommend a healthy dietary regime in which fats should be

Table IV.F.2.1. *Chronic disease prevention and health promotion*

Action	Lower risk
1. Quit smoking or use a low-tar and nicotine cigarette.	Coronary heart disease; cancers of the lung, oropharynx, kidney, bladder, pancreas, cervix
2. Quit chewing tobacco or snuff dipping.	Cancer of oral cavity, esophagus
3. Lower the fat intake to at least 20–30% of energy (calorie) intake, preferably lower (15–20%).	Coronary heart disease; cancers of the distal colon, postmenopausal breast, prostate, pancreas, ovary, endometrium
4. Limit protein intake to 10–15% of calories; include vegetable proteins.	Colon cancer, kidney diseases, aging
5. Increase vegetables and fruits considerably (ideally 5–9 servings); provide sufficient essential micronutrients.	Most chronic diseases, aging
6. Increase fiber, soluble as well as insoluble (1:1), to 25–35 grams.	Cancer of colon, breast; constipation, diverticulosis, appendicitis
7. Increase Ca^{2+} intake (skim milk, yoghurt, some vegetables, sardines).	Cancer of colon, osteoporosis
8. Reduce intake of heavily fried or grilled foods, especially meats and gravies.	Cancers of colon, breast, pancreas; heart disease
9. Avoid pickled, smoked, and salted foods.	Cancer of stomach, esophagus, nasopharynx, liver; hypertension, stroke
10. Lower salt Na^+ intake; balance $K^+ + Ca^{++}/Na^+$ ratio.	Hypertension, stroke, cardiovascular disease
11. Have regular moderate exercise.	Coronary heart disease; cancer of the colon, breast; aging
12. Maintain proper weight; avoid obesity.	Coronary heart disease; cancer of the endometrium and kidneys; postmenopausal breast cancer; diabetes
13. Moderate use of alcoholic beverages.	Liver cirrhosis, liver cancer, cardiomyopathy, male impotence, oropharyngeal and esophageal cancer
14. Practice sexual hygiene.	Cancer of the cervix, penis; AIDS
15. Moderate sun exposure.	Skin cancer, melanoma, skin aging

replaced by complex carbohydrates (starches) that should provide around 70 to 75 percent of the calories needed for energy. Furthermore, a protein intake of between 10 to 15 percent from animal and vegetable sources (more in growing young children, less in older individuals) is recommended. Fats should consist of a fair proportion of monounsaturated oils, such as olive oil or canola oil, and omega-3 fatty acids as found in fish and some seeds, like flaxseed.

Excessive salting, pickling, and smoking of food as a mode of preservation should, ideally, be abandoned, and foods should be preserved by refrigeration or freezing, or eaten fresh. Caloric intake should be equal to energy need as an effective means to avoid obesity. The intake of fruits and vegetables should be increased considerably – ideally to more than 5 servings per day. Bran cereal fibers, or breads baked with high-fiber flour, increase stool bulk, avoid constipation, and lower the risk of colon and breast cancer and perhaps other diseases. A low intake of total salt, 3g/day or less, and adequate calcium (1,000 to 1,500 mg) and magnesium (300 mg) are beneficial; less is needed on a low-protein diet. Moderate, but regular, physical exercise is also part of a healthy lifestyle. Alcohol consumption ought to be moderate, but adequate fluid intake (2 to 2.5 liters daily for adults) is essential for maintenance of physiologic functions. Tea, an extract of the plant *Camellia sinensis,* is, after water, the second-most-used beverage in the world. Because it is made with boiling water, it is sterile even if the water source is not pure. Tea is rich in fluoride, potassium, and especially in antioxidants that lower the risk of coronary heart disease and many types of cancer (Weisburger 1996; Weisburger and Comer this volume).

These recommendations will contribute to better health by lowering the risk for major chronic diseases. In education and in medical practice, emphasis must be placed on the importance and the efficacy of available methods for chronic disease prevention. One task of practicing nutritionists and home economists ought to be that of devising practical recipes for cooks to incorporate the essence of a new, health-promoting lifestyle that the public will find attractive. Indeed, it is essential to devise appealing dishes and drinks for the public that are also designed for chronic disease prevention, and when such preventive approaches are successful, health-care costs should decrease. Good health into old age is not only a desirable goal for the individual but may have major economic savings for the population at large. To repeat our earlier quotation, the ultimate goal, as expressed by Ernst Wynder, should be "to die young, as late in life as possible" (Wynder et al. 1994).

Over the course of the twentieth century, cardiovascular disease (CVD) has become the leading cause of death in the United States. CVD is also a significant cause of morbidity and mortality in many other industrialized countries and regions, such as Scandinavia, the United Kingdom, Australia, and Canada. Most CVD is manifested as coronary artery disease (CAD), usually based on atherosclerosis. This "epidemic" of CVD has been attributed to the poor lifestyle habits of members of late-twentieth-century industrialized, urban society, who smoke tobacco, exercise rarely, and indulge in fat-laden diets (Kannel 1987).

A striking similarity of these factors leading to disease is that each – in most cases – can be modified by an individual at risk for coronary disease, even without professional guidance and in the absence of public health initiatives. But risk factors are not always easily eliminated. Addiction to tobacco is difficult to overcome. Exercise may be problematic for some people, given constraints on time posed by other obligations. Everyone, however, must eat, and perhaps for this reason, of all the possible causes of heart-related diseases, diet has received the most attention.

This chapter explores the relationship between nutrition and heart-related diseases by describing selected nutrients that have been implicated in the pathogenesis, prevention, or treatment of CAD. Most of the available data come from population studies. It appears unlikely that any single nutrient will soon be identified as the specific dietary agent that causes atherosclerotic diseases. Moreover, any individual nutrient is but a small part of a larger group of chemicals that make up any particular "food." As of this writing, the overall relationship between diet and heart disease remains obscure. It will require many years of medical, nutritional, and food science research before we can hope to weave into a meaningful tapestry all of the puzzling threads of nutritional biochemistry and CAD pathophysiology.

Pathogenesis of Atherosclerosis

In the middle of the nineteenth century, it was discovered that lipids constituted a major component of atherosclerotic plaque (Vogel 1847). This observation led investigators to wonder how this lipid collection was formed and how it might be related to disease. They noted that when people with CAD died, examination of the vessels that supply blood to the heart (the coronary arterial endothelium) revealed greasy, yellow "plaques" adhering to the endothelial cells. These plaques varied in thickness and composition, reflecting both the age of the subjects and the severity of their disease. A few decades into the twentieth century it was widely recognized that CAD lesions were due to atherosclerosis, with cell death within the lesion (Leary 1935). Additional clues to disease severity – and the longevity of the disease process – were later found in the presence of blood substances, such as lipids and macrophages, and in structural damage to the surrounding endothelium.

Noting precisely which endothelium is diseased may provide clues to the disease process. Although CAD is often conceptualized as a systemic disease, the location of atherosclerotic lesions is not random, nor are they necessarily "systemic." Some areas of the blood vessels are more "lesion-prone" than others, and these sections differ structurally and functionally from "non-lesion-prone" sites (Schwartz, Valente, and Sprague 1993). Lesion-prone sites are more permeable to substances that lead to the development of CAD. Any adequate explanation of the disease process must explain these morphological and topographical features.

Although autopsy findings may serve to document an underlying disease process, they represent only one moment in the lifetime of the affected individual and cannot alone explain the natural history of the disease. One approach to understanding the disease process is to conduct experiments using an animal that exhibits a similar set of lesions. In 1943, D. V. Dawber and L. N. Katz studied chickens that developed atheromata and suggested that their findings might be relevant to spontaneous disease (Dawber and Katz 1943).

Pigs also provide a useful model for studying human atherosclerotic CAD – a model used to good effect by investigators in the 1960s and early 1970s. When pigs were fed a low-fat, cholesterol-free diet, researchers initially noted a degeneration of smooth muscle cells. As the pigs aged, the degenerated smooth muscle cells accumulated and caused intimal thickening. If there was no injury to the blood vessel during this thickening stage, the pigs experienced no disruption of the endothelium of the artery. However, if the investigators mechanically injured the endothelium, intimal thickening progressed to form a more substantial plaque – one that could impede blood flow within the artery.

This early plaque contained not only degenerated smooth muscle cells but also collagen, a fibrous tissue that made the plaque less compliant. Plaque thickening could be further accelerated (in concert with mechanical injury) with dietary factors, including oxidized sterols, such as vitamin D_3 and 25-hydroxy cholesterol (a derivative of pure cholesterol). In advanced stages of atherosclerosis, lipid infiltrated the plaque. Other factors were found to influence development of the lesion. As the vessel lumen narrowed during plaque development, reduced blood flow through the area reduced oxygen delivery to the structures supplied by that blood vessel, and the hypoxemia thus produced sped up lipid accumulation in the plaque. As the plaque continued to thicken, the endothelium was stretched thin, sometimes thin enough to rupture.

The gap left by this process was then vulnerable to infiltration by lipoproteins. In animals that did not have the intimal injury, there was no progression past the intimal thickening. When investigators used electron microscopy to compare the experimentally induced atherosclerotic vessels of the mature pig with those obtained from a human who had undergone open heart surgery for CAD, they could detect no histological differences.

These animal studies were vital to our present understanding of the atherosclerotic process in humans. Recent research supports the concept that the arterial endothelium must sustain a mechanical injury to begin the process of pathologically significant plaque formation. Other blood components now known to be involved in this process are monocytes, platelets, and lipid–protein complexes, such as low-density lipoprotein (LDL) and lipoprotein(a). Also part of the process of plaque formation are chemical mediators, such as adhesive cytokines, chemoattractants, free radicals, and proteolytic enzymes.

Currently, most investigators believe that in early atherogenesis, monocytes (a type of white blood cell) are recruited to a "lesion-prone" area of the artery's innermost wall, or intima. Before the plaque can be formed, the monocyte has to attach to the endothelium, a process orchestrated by various chemoattractant substances (for example, oxidatively modified LDL cholesterol) and adhesive cytokines (for example, interleukin 1-beta). Once attached, the monocytes migrate through the endothelium and attach to its underside, away from the portion of the endothelium that is in contact with the bloodstream.

In this new space, the monocytes are transformed into a different type of cell, known as macrophages. As long ago as the early 1900s, pathologists observed macrophages associated with mature atherosclerotic plaques, but their presence was believed to be incidental. In the late twentieth century, however, macrophages have been assigned a pivotal role in atherogenesis. The macrophage synthesizes a variety of substances that activate the inflammatory response in the affected area, such as oxygen free radicals, proteases, and lipases. These cause the macrophage to take up oxidatively modified LDL and change its appearance so that the cell has a foamy appearance when viewed with a microscope. The cells are thus called "foam cells."

The next step in the process of atherosclerosis is necrosis of the foam cell, likely due to cytotoxicity from the oxidatively modified LDL. Smooth muscle migration and proliferation are mediated by a platelet-derived growth factor, a potent chemoattractant. Fibroblastic growth factors probably regulate smooth muscle cell proliferation. In the area of the plaque where there is the greatest density of macrophages, rupture may occur due to the high local concentration of macrophage-derived metalloproteases. This process ultimately results in blood clots that can obstruct blood flow – mural or occlusive thrombosis. Occlusion, whether temporary or not, creates a locally hypoxemic environment, which further enhances plaque growth. Oxidized LDL may initiate an autoimmune process that also adds to the inflammatory reaction occurring in the lesion-prone area.

The intricate atherosclerotic process provides investigators with many avenues of exploration for prevention and intervention. From a nutritional standpoint, the most obvious factors are cholesterol, dietary fat, and the biochemical precursors for the substances that may enhance or intervene in plaque formation: omega-3 fatty acids, protein, "antioxidant" nutrients (for example, vitamin E, beta-carotene, vitamin C), and other dietary substances. As an alternative approach to dietary prevention, one might consider dietary changes that would decrease the activities of the substances that enhance arteriosclerosis.

Cholesterol

Early Epidemiological Studies

In the mid–1940s, Ancel Keys (1963) and William Kannel (1971) and their colleagues designed two large-scale studies to examine longitudinally what caused people to develop coronary artery disease. These investigators believed that by recording the essential characteristics of a large group of at-risk people and by comparing those who went on to develop CAD with those who did not, they could identify particular risk factors for the disease. These two sets of studies have had a profound influence on the development of the field.

Keys and his associates studied 281 Minnesota business and professional men who were 45 to 55 years of age and clinically healthy at the start of a 15-year study period. Each year, the men were given a detailed physical examination, with particular attention to the cardiovascular system. Examiners noted each man's weight, relative body fatness, blood pressure, and serum cholesterol concentration. They measured two different pools of cholesterol in addition to total cholesterol: high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol. During the 15 study years, 32 deaths occurred, 17 of which were directly attributable to CAD. Body weight and fatness were not predictive of disease, but the men in the upper part of the blood pressure distribution had a greater risk of CAD. Most compelling were the findings with regard to cholesterol. They indicated a direct relationship between blood cholesterol and risk of CAD, extending over all levels. The men who remained healthy had significantly higher HDL cholesterol than did subjects who developed CAD (mean 45.29 milligrams [mg] per deciliter as compared with 39.45). Detailed statistical analysis, however, failed to support the hypothesis that HDL cholesterol level was an independent predictor of CAD risk. Rather, high LDL and total cholesterol were more important predictors of CVD.

The Framingham Study (Kannel et al. 1971) followed 2,282 men and 2,845 women in Framingham, Massachusetts, for 14 years, starting in 1948. As in the Keys study, investigators were attempting to identify factors related to the onset of clinical coronary disease. Subjects were free of known coronary disease at the time of enrollment and were subdivided into groups based on their serum lipid content. After 14 years, 14 percent of the men and 6 percent of the women had developed some clinical manifestation of CAD. The incidence of CAD increased with age, and the baseline serum lipids and lipoproteins were higher in the CAD group than in the other subjects. Furthermore, the lipid profiles in the CAD subjects were high when compared to profiles in other parts of the world, such as France and Japan, where low CAD rates have been reported.

Investigators were unable to demonstrate that a particular lipid played a greater role than others. However, they did observe differences between men and women. In men and younger women (<55 years), the differences between those with CAD and those without the disease were more related to the total cholesterol. In older women (>55 years), prebeta lipoprotein (very low density lipoprotein or VLDL) discriminated better than total cholesterol between women with and without CAD. These two studies, coupled with what was known about atherosclerotic plaque composition, further supported the idea that one key to solving the mystery of atherosclerosis was to determine the relationship between blood lipids and plaque formation. Moreover, of all blood lipids, cholesterol appeared to be the most important.

Sources of Cholesterol

Cholesterol occurs naturally in eukaryotic cells (cells with a membrane-bound nucleus). In humans, cholesterol serves many vital functions. It acts as an integral part of the cellular membrane, serves as a chemical backbone for essential substances (for example, steroid hormones, vitamin D), and assists in digestion through its role in the formation of bile salts. Given the central role of cholesterol in biochemical and physiological functions, it is not surprising that the substance became a central focus for biochemical researchers. Although all human cholesterol was once thought to be ingested (Leary 1935), we now know that humans are able to manufacture cholesterol de novo, primarily in the liver and, to a lesser extent, in intestinal and other cells. Thus, even if one consumed a very low-cholesterol diet, the adult liver and intestine would still manufacture approximately 800 milligrams of cholesterol per day, which is enough for normal human functions. But cholesterol also reaches the body through dietary means for most humans, except those who are strict vegetarians and consume neither flesh nor dairy or egg products. Thus, cholesterol in atherosclerotic plaque formation could come from either de novo synthesis or dietary sources. The interaction between de novo cholesterol synthesis and dietary cholesterol, and the subsequent metabolism of cholesterol, is an intricate and fascinating phenomenon.

Serum cholesterol is transported bound to protein, such as apoprotein, along with phospholipids and other circulating fat-soluble compounds. These lipoproteins (or lipid:apoprotein molecules) are classified according to increasing density: From lower to higher density they are called chylomicrons, very low density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). LDL typically contains 60 to 70 percent of the total serum cholesterol and HDL about 15 to 20 percent. The remaining cholesterol is carried in VLDL and chylomicrons.

The apoprotein portions contain biochemical signals that regulate the entry and exit of particular lipids at specific targets. For instance, chylomicrons transport dietary cholesterol, triglycerides, and other lipids from the intestine to the liver and adipose tissue. VLDL transports de novo synthesized cholesterol and triglycerides from the liver to adipose tissue. The residue is transformed into LDL, which is very rich in cholesterol. LDL moves cholesterol to peripheral tissues and regulates de novo cholesterol synthesis. Nonhepatic target cells possess specific LDL receptors that allow the cell to take up LDL cholesterol. The receptor number can be increased and decreased depending on the needs of the target cell. HDL presumably carries cholesterol from peripheral tissues back to the liver.

LDL regulates cholesterol metabolism through feedback inhibition. First, the cholesterol that is released from the LDL after it is inside the cell suppresses the key synthetic enzyme, HMG-CoA reductase, slowing de novo cholesterol formation. Second, when cholesterol concentration within a cell is adequate for its needs, the cell shuts down the manufacture of additional LDL receptors, thus preventing it from taking up more cholesterol.

Relationship of Cholesterol to CAD

Perhaps the clearest link between cholesterol, LDL, and arteriosclerosis comes from people with homozygous or heterozygous familial hypercholesterolemia. People who inherit both genes of this autosomal recessive disorder (homozygotes) have extraordinarily high levels of total and LDL cholesterol in circulation. Depending on the type of inheritance, they suffer from premature CAD either as a child or as a young adult. The defect in most cases is an absence or deficiency of functional LDL receptors, impeding the movement of LDL-cholesterol into target cells. Because LDL cannot satisfactorily get cholesterol inside a cell, there is no mechanism to turn off HMG-CoA reductase, and cholesterol biosynthesis continues unchecked. The excess cholesterol, primarily found with LDL, is deposited in various tissues, including arterial endothelium. These cause myocardial infarctions at a very young age. Because dietary cholesterol restriction does not affect de novo synthesis, it is of very limited value alone in the management of these individuals.

Heterozygous familial hypercholesterolemia is relatively common (1:500 births), but is certainly far less common than CAD. Nonetheless, the association between cholesterol and CAD at extreme levels supports the idea that cholesterol is a factor in the development of CAD, particularly as it is consistent with numerous epidemiological studies that demonstrate a relationship between total and LDL cholesterol and CVD. Some of these are within-population studies, such as the Framingham and Minnesota studies discussed in the section "Early Epidemiological Studies." Others compare different populations or people who move from one population to another. These studies often consider the importance of culture – particularly as manifested in what people eat – and, thus, bring us closer to the overall topic of this chapter and this work, which is diet.

The observation that different communities have different rates of CAD provides an important counterbalance to overly deterministic theories of disease causation, as well as engendering a series of ideas leading toward an understanding of the possible impact of diet on cholesterol and on CAD. C. D. De Langen, a Dutch public health physician, noted in the 1910s and 1920s that the incidence of CAD was extraordinarily low among residents of the island of Java (Snapper 1963). He explained part of this difference as being the result of differences in diet; Javanese stewards who worked on Dutch steamships soon developed a pattern of coronary health similar to that of the native-born Dutchmen who worked on the ships.

In 1941, I. Snapper made a similar series of observations about people native to northern China. He said that the difference could, perhaps, be attributed to the "equanimity of the Chinese," but suggested that diet was probably a more important explanation. These observations led the American scientist Ancel Keys to wonder about the geographical variation in the incidence of CAD (Keys 1983). He initiated a massive study, published as *Seven Countries: A Multivariate Analysis of Death and Coronary Heart Disease.* This detailed work was begun in 1947 and eventually resulted in the study of a total of 12,763 men over 10 years in Yugoslavia, Finland, Italy, the Netherlands, Greece, the United States, and Japan. Conclusions are complex (on a scale with the study itself), but they show a clear relationship between the dietary intake of saturated fat and cholesterol and the incidence of coronary heart disease. Other between-population studies have shown that in countries where CVD rates are low, the serum LDL levels also tend to be low (for example, rural Japan and China compared to the United States and Finland).

Other investigations (following the lead of De Langen) have examined changes in CAD incidence with migration. Most have shown that when people move from a region with a low incidence of CAD to a region with a high incidence of CAD, and adopt the lifestyle of their new country, their likelihood of having CAD approaches that of the region to which they have moved. For instance, Japanese people living in their native Japan, in Hawaii, and in San Francisco, have an increasingly higher incidence of CVD: Age-adjusted rates among Japanese people were 1.6 per 1,000 person-years in Japan, 3.0 in Hawaii, and 3.7 in San Francisco (Kato et al. 1973). Saturated fat intake as a percentage of calories in the three populations was 7, 23, and 26 percent, respectively. The dietary trends among these populations emphasize the importance of the type of fat intake: Foods high in saturated fat also tend to be high in cholesterol. What happened to Japanese people moving from Japan to Hawaii to San Francisco seems clear enough. As they adopted a progressively more Western diet with a higher intake of saturated fats, their incidence of heart disease increased.

Cholesterol-Lowering Intervention

If the changing of diet results in a changing rate of heart disease, then public education efforts to heighten personal awareness of cholesterol levels may be serving as a broad and effective means of intervention. There are some encouraging signs. From 1980 to 1987, in the Minneapolis–St. Paul area, there was a significant decrease in total serum cholesterol and in the numbers of individuals with significant hypercholesterolemia (greater than 5.04 micromoles [mmol] per liter or 195 mg per deciliter) (Burke et al. 1991). However, despite the downward trend of cholesterol in the study population as a whole, many individuals (67 percent) with cholesterol levels high enough to require dietary and/or medical therapy remained unaware of their condition.

On a national level, the National Health and Nutrition Examination Survey (NHANES), undertaken between 1976 and 1980 (NHANES II) and from 1988 to 1991 (NHANES III), found an increase in the number of people with total cholesterol values less than 5.17 mmol per liter (200 mg per deciliter) and a decrease in those with total cholesterol values greater than 6.21 mmol per liter (240 mg per deciliter).

Although these population-based observations may reflect national public-health efforts to reduce total and saturated fat and cholesterol, such hopeful trends probably do not completely explain the decline in mortality from CVD. During the 1980s in the United States, there was also a decline in the use of tobacco, a major risk factor for CAD. In addition, there were changes in the diagnosis and management of CAD, including more widely available cardiac catheterization, angioplasty, functional cardiac studies (for example, dipyridamole and thallium stress echocardiograms), and development and utilization of new medications (for instance, thrombolytics, cardiospecific beta-blockers, and angiotensin converting enzyme inhibitors). Thus, at present, the relative importance of population-based cholesterol lowering in bringing about a declining CVD death rate remains unknown.

Nonetheless, although many factors could alter mortality from CAD, the lowering of cholesterol would intuitively seem both important and appropriate. Prevention of CAD among a community of individuals can be viewed from two perspectives: primary prevention and secondary prevention.

Primary prevention. Efforts to prevent persons from developing a particular disease fall under the rubric of primary prevention. In the case of CAD, primary prevention implies reducing the disease incidence for people with risk factors but who have not yet developed it. The Lipid Research Clinics Program (1984) and the Helsinki Heart Study (Frick et al. 1987) were large, randomized, controlled clinical trials that indicated that reducing serum cholesterol in persons without known CAD reduces the incidence of CAD onset. However, these trials were short (less than 10 years) and did not (or could not) demonstrate that primary prevention lengthens the life span by delaying or preventing the onset of CAD. Individuals who have hypercholesterolemia as their only risk factor for CAD likely do not add many years to their life by reducing their cholesterol level (Browner, Westenhouse, and Tice 1991). Indeed, some studies have even suggested a rise in the incidence of violent deaths among individuals with the lowest cholesterol levels, although the relevance of such observations remains controversial.

Secondary prevention. On average, however, 3 to 4 years of life can be gained by individuals who have CAD and reduce their serum cholesterol by dietary and/or by medical means. This approach – intervention in the presence of known disease – defines secondary prevention.

The idea that diet has some relationship with heart disease, and that changing the diet can help people with heart disease, has been around for some time. What entered and left the body were long held as being critically important to its general functioning. Thus, it should come as no surprise to see comments about treating heart disease with diet from, essentially, the very first speculations about heart diseases in general (Fothergill 1776, cited in Leibowitz 1970). We should not attempt, however, to read these comments as having the same sort of specificity we now associate with statements about disease causation and diet.

For the early twentieth century, some insight into generally accepted notions of diet and heart disease may be derived by consulting a series of articles published in 1913 by the American Medical Association (AMA), the "cordial reception" of which led to their presentation in book form. The opinions expressed in these articles may be regarded as reflecting a general consensus, at least among allopathic physicians. Some of what was advised for the patient with heart disease seems logical (if not necessarily appropriate) to the late-twentieth-century reader, such as the suggestion that coffee should be avoided or that obese patients should lose weight in order to help the functions of their hearts.

Other approaches, such as administering hydrochloric acid to aid in digestion, now seem clearly out of place. But what is most striking is the emphasis on the idea that diet should be individualized, at least in part because it is limited by "what the patient will do." Rather than being dogmatic about what constitutes a "correct" diet, advisers would do better to tailor their recommendations to the specific social and cultural setting of the person under treatment.

Across the Atlantic, the noted British physician Sir Clifford Allbutt, Regius Professor at Cambridge University in England, was also concerned about individual variation in dietary suggestions (Allbutt 1915, particularly 238–54 of Vol. 1). He considered the question of overfeeding to be a relative one: What was a good diet for one person might be gluttony for another. He noted that cholesterol was associated with atherosclerosis, but he saw also the wide variation in the diets of people who developed atherosclerosis.

More recently, many trials have examined the value of cholesterol reduction in the management of CAD. These studies usually randomized patients with known CAD to receive some type of treatment (diet, drug, lifestyle change) versus "usual care" or placebo. The outcomes of interest in these studies tended to be occurrence of angina, myocardial infarction, death, and regression of atherosclerosis. Most subjects had total serum cholesterol concentrations greater than 5.00 mmol per liter. To determine regression or progression of atherosclerosis, baseline coronary angiograms were compared with those at the end of the study period. The angiograms were assessed with quantitative angiography and/or global score assessment. Both methods asked the same question: Are the areas of stenosis the same, less, or greater than at baseline, and is there a relationship between the extent of plaque regression and the amount of cholesterol lowering?

The Cholesterol-Lowering Atherosclerosis Study (CLAS) (Blankenhorn et al. 1987) investigated the effects of drug therapy in a randomized, placebo-controlled trial using men ages 40 to 59 years who had undergone coronary artery bypass graft surgery. After two years of treatment, patients who had been given the cholesterol-lowering drugs colestipol and niacin instead of placebos exhibited a reduction in total cholesterol, a reduction in LDL-cholesterol, and a significant amount of atherosclerotic plaque regression and preservation of native coronary arteries. However, the incidence of coronary events was no different between the two groups.

A fairly recent study by D. Ornish and colleagues (1990) explored the influence of lifestyle changes on reversal of CAD in a randomized controlled trial that followed men and women for one year. The treatment group experienced aggressive lifestyle interventions, including the imposition of a very low cholesterol, strict vegetarian diet. Their overall dietary fat was reduced to 10 percent of calories, far lower than in the usual American diet, which contains 35 to 40 percent of calories from fat. The treatment group demonstrated regression of atherosclerotic lesions and reduction of serum cholesterol and LDL-cholesterol.

The investigation has been criticized for flaws in randomization. Morever, the practicality of implementing such a drastic dietary intervention for the general population with CAD has also been questioned. However, the findings are provocative and suggest that a radical reduction in dietary fat can greatly influence serum cholesterol and plaque regression. The study subjects also received psychological and behavioral interventions and increased their exercise. Whether such changes can alter morbidity and mortality from CAD over one's lifetime to a greater extent than more conservative, yet aggressive, approaches to cholesterol lowering remains to be elucidated.

The St. Thomas Atherosclerosis Regression Study (STARS) (Watts et al. 1992) focused on 90 men with CAD and mild hypercholesterolemia for approximately three years. It investigated the effects of usual care versus two interventions: a low-cholesterol diet and a low-cholesterol diet with the cholesterol-lowering drug, cholestyramine. Both interventions reduced the frequency of cardiovascular events and the progression of coronary artery narrowing.

The Monitored Atherosclerosis Regression Study (MARS) (Blankenhorn et al. 1993) was a randomized, double-blind, placebo-controlled study of 270 men and women with CAD that evaluated the effect of a low-cholesterol, reduced-fat diet with and without the HMG-CoA reductase inhibitor lovastatin. This trial demonstrated regression of atherosclerotic plaques; however, there was no difference in cardiac events between the treatment and placebo groups. At first glance, these results may seem to contradict the STARS trial, but the diet in the control group of the STARS study was not one designed to lower plasma lipids. In the STARS trial, both the lipid-lowering diet and the diet plus cholestyramine resin reduced coronary events to the same degree. They were significantly different from the usual care group, but not from each other.

The data on the role of cholesterol, particularly LDL-cholesterol, in the pathogenesis of CAD is compelling. Epidemiological population studies strongly suggest a positive relationship between elevated serum cholesterol and mortality rates from CAD. Primary and secondary prevention trials support the contention that reducing LDL-cholesterol, through a lipid-lowering diet with or without adjuvant medication, alters disease progression in middle-aged men. It is less clear if therapy will significantly reduce the incidence of subsequent cardiac events. The trials have not demonstrated an impact on longevity. However, it is certainly possible that future studies will do so. Studies in the Scandinavian Simvastatin Survival Study (known as 4S) seem to show an overall decrease in the death rate for people who already had heart disease when treated with potent cholesterol-lowering drugs (Scandinavian Simvastatin Survival Study Group 1994).

Dietary Fat

The influence of diet on CAD may reflect the amount of fat a person ingests. But the type of fat consumed may be just as important as the amount. Cholesterol is a type of fat found only in animal cells, not in plant cells. Low-cholesterol diets stress not only a reduction in dietary cholesterol but also a reduction in overall dietary fat, especially saturated fat. This approach is necessary because animal fat is laden with cholesterol. Animal fat is also primarily a saturated fat. Thus, the current recommendations by several national advisory panels are to decrease the consumption of saturated, cholesterol-rich animal fat, and to increase the amount of monounsaturated and polyunsaturated, or plant-derived, fat. Because poultry and fish contain more polyunsaturated fat than beef or pork, the recommendations also suggest consuming more poultry and fish as protein sources.

In dietary recommendations made in 1970 in the "Report of the Inter-Society Commission for Heart Disease Resources" (which were incorporated into "Dietary Goals for the United States by the United States Senate Select Committee on Nutrition and Human Needs"), the consumption of fat was expected to decrease from 42 to 30 percent of calories. Since 1909, Americans had consumed an average of 600 mg of cholesterol per day, but with these recommendations, cholesterol consumption was projected to decrease to 300 mg per capita per day. Such recommendations were considered radical at the time, and those who proposed diets based on them were concerned about the ability of patients to consume such a diet while maintaining normal protein nutrition.

More recently, however, the National Research Council's 1992 recommendations have emphasized that in order to better meet the national goal of reducing total cholesterol concentrations to less than 5.04 mmol per liter, daily calories from fat should not exceed 30 percent of total calories, and two-thirds of that fat should be monounsaturated and polyunsaturated.

Saturated versus Unsaturated Fats

Can the rise in CVD mortality seen in countries like the United States and Scandinavia be attributed to the type of dietary fat, as well as to dietary cholesterol? The answer to the question seems to be yes. In the first half of this century, although U.S. CVD mortality rates rose dramatically, the increase in consumption of total and saturated fat was much more modest. However, during the same period, consumption of polyunsaturated fat rose two to three times (Friend 1967; Page and Marston 1979). In Europe during World War II, as wartime deprivation curtailed animal fat and, in fact, total fat consumption, the number of deaths due to CAD fell dramatically. In the 1970s, rural Romanians consumed 900 mg of cholesterol per day – 50 percent more than Americans at the time – but Romanian CVD mortality rates were approximately 20 percent lower, perhaps because their dietary fat intake was 30 percent less than the average in the United States (WHO 1976).

Such observations implicate dietary fat, not just dietary cholesterol, in atherogenesis. Further, the nature of the fat (that is, saturated or unsaturated) may be important. Whether a fat is saturated or not has to do with how many hydrogen atoms are bound to carbon. Carbon atoms form the "backbone" of a fat molecule and can maximally bind to 4 other atoms. If 4 binding sites are used, the carbon atom is said to be "saturated." If only 2 binding sites are used, the carbon atom forms a double bond with another carbon atom and is said to be "unsaturated." Saturated fatty acids have no carbon double bonds, monounsaturated fatty acids have one carbon double bond, and polyunsaturated fatty acids have two or more carbon double bonds.

Epidemiological studies have observed that mortality from CVD is lower in southern European countries. There, total fat consumption is not remarkably low compared to other industrialized nations, but there is a greater consumption of monounsaturated fats, such as olive oil.

In 1928, two Chinese biochemists suggested that the low rate of CAD in China might be explained by the polyunsaturated fat linoleic acid (Snapper 1963). Others have later shown that this substance can lower serum cholesterol (Ahrens et al. 1959). In the United States, increased consumption of linoleic acid, primarily through greater consumption of corn oil products, parallels the decline in population serum cholesterol concentrations.

Marine Oils

Fish oils appear to lower serum lipids in animals and humans (Bronte-Stewart et al. 1956; Nelson 1972). In the 1970s, epidemiologists attempted to explain a striking difference in the incidence of CAD between Eskimos, who rarely suffer from CVD, and Danes. They found a major dietary difference, not in total fat consumption but in the amount of fish oil consumption. Eskimos who have diets high in omega-3 fatty acids (found in fish oil) have prolonged bleeding times, as well as a decreased number and aggregation of platelets – all features associated with a reduced incidence of coronary thrombosis. Several hypotheses have been presented to explain the antiatherogenic effects of marine oils. They include altered plasma cholesterol and triglyceride concentrations, altered metabolism of prostaglandins and leukotrienes, and a variety of other physiological responses (Zhu and Parmley 1990).

Laboratory experiments have suggested possible mechanisms for the effects of marine oils. Animals fed a diet high in omega-3 long-chain polyunsaturated fatty acids and dietary cholesterol had a reduction in the number and size of atherosclerotic lesions. This may have resulted from chemical changes that affect how blood cells adhere to lesion-prone areas. Associated with these physiological changes were alterations in the prostaglandin synthetic pathway reflected by decreased thromboxane A2, increased prostacyclin, decreased leukotriene B4, and increased leukotriene B5. Most of these studies have also demonstrated significant lowering of plasma total cholesterol, LDL-cholesterol, and triglyceride levels. HDL-cholesterol has generally been unchanged.

Clinical investigations have shown that the consumption of fish oil in normal volunteers and in patients with hyperlipidemia can remarkably decrease plasma triglyceride levels, with inconsistent effects on plasma cholesterol and HDL-cholesterol. Perhaps as a result, fish oil supplements were widely marketed in the 1980s. But although epidemiological studies of Eskimos suggest a chemoprotective effect of fish oil, it is unclear that increasing fish oil in an American or northern European diet will impact CVD mortality rates. In addition, problems with fish oil supplements, including a bad flavor and unpalatable belching, pose compliance problems for patients with CVD risk.

Other Dietary Components

Dietary Protein

Sources of dietary protein include meat (for example, beef, pork, lamb, and wild game), poultry (such as chicken, turkey, and quail), fish, seafood, dairy products, eggs, grains, legumes (for example, peanuts, soy, and dried beans), nuts, and seeds. Depending on one's culture, religion, ethnicity, and other socioeconomic variables, the primary daily protein source will vary. Different protein sources contain varying amounts and types of fat. The discussion in the section "Dietary Fat" has pointed out that saturated animal fat is most relevant to hyperlipidemia, unlike plant lipids, which are unsaturated.

Milk protein has been implicated as an important nutrient in atherogenesis for more than 20 years, most notably in S. Seely's epidemiological analyses (1981, 1988). By reviewing the CVD mortality rates in men from 24 countries along with food consumption data, he found a significant correlation between CVD and the consumption of unfermented milk proteins, the only exception being cheese (1981). In 1988, Seely studied food consumption patterns of men and women in 21 countries that might be associated with

CVD mortality. He observed significant positive correlations between CVD mortality and milk, milk products, sugar, and oats. There were negative correlations with fish proteins, vegetable proteins, and fish fat.

Proteins are made of amino acids, and one of those amino acids – arginine – has become the subject of intense scrutiny. The discovery in the 1980s and 1990s that mammals endogenously synthesize nitric oxide, a toxic substance, has led to an enormous body of literature describing the physiology, immunology, and biochemistry of this substance. It is produced by the enzymatic conversion of L-arginine to nitric oxide by nitric oxide synthetase. This reaction occurs in several tissue types, including endothelium, macrophages, and the brain. Nitric oxide produced in endothelium causes relaxation of the vessel and, hence, vasodilation.

L. Castillo and colleagues (1995) demonstrated that up to 16 percent of dietary arginine may be converted to nitric oxide in healthy volunteers. Several investigators have reported abnormal coronary arterial vasodilation, probably related to nitric oxide production in patients with increased cholesterol (Creager et al. 1990), hypertension (Linder et al. 1990), and CAD (Zeiher et al. 1991; Egashira et al. 1993). M. Jeserich and colleagues (1992) found significantly lower plasma L-arginine concentrations in patients with hypercholesterolemia (greater than 270 mg per deciliter), as compared to patients with normal cholesterol levels (less than 220 mg per deciliter). The relationship of these findings to CVD pathogenesis remains to be elucidated. It is unclear whether this difference in arginine levels is because of diet or because of the process of atherogenesis.

Dietary Carbohydrates and Fiber

Carbohydrate foods provide the bulk of daily energy needs. Animal studies have found that if the ratio of energy to protein is low, serum cholesterol tends to be lower. In humans, decreased energy intake may be associated with less obesity, a lower incidence of diabetes, and reduced cholesterol (total and LDL) (Kannel 1987).

Thus, modification of these atherogenic risk factors by modifying energy intake may be beneficial. The other main dietary energy source is fat, which provides about twice the number of calories per gram as carbohydrate does. Thus, to reduce overall energy intake and reduce atherosclerotic risk, it is desirable to obtain energy calories primarily from carbohydrate sources.

The association of fiber with hyperlipidemia has also received attention. Soluble fiber consumption is associated with reduced serum cholesterol. D. J. A. Jenkins and colleagues (1993) studied soluble fiber supplementation in conjunction with a lipid-lowering diet in 43 healthy men and women of normal weight. They observed a significant reduction in total cholesterol in both groups compared to baseline, but the soluble fiber group attained an even greater reduction.

Vitamins

"Antioxidant" nutrients have recently gotten a great deal of media and scientific coverage. These compounds include beta-carotene, vitamin E, and vitamin C. There are several reasons for this interest. LDL-cholesterol is oxidatively modified through chemical mediators released from the macrophage during atherosclerotic pathogenesis. Nonnutrient antioxidant substances (for example, probucol, butylated hydroxytoluene) inhibit the progression of atherogenesis in rabbits, presumably due to an alteration in oxidatively modified LDL-cholesterol (Bjorkhem et al. 1991; Mao et al. 1991). Antioxidants such as vitamin E work by "grabbing" a hydrogen atom. Having done so, they are now the oxidized molecule, and they have thus prevented another moiety, such as LDL, from becoming oxidized. Epidemiological studies suggest that people with high plasma levels of vitamin E have a lower risk of CVD. Similar results have been obtained when examining beta-carotene intake and CVD incidence. In the Nurses' Health Study, CVD risk was reduced 30 to 40 percent in those individuals with high calculated intakes of vitamin E or beta-carotene. The data on vitamin C were unconvincing (Stampfer et al. 1987; Stampfer et al. 1993).

M. Abbey, P. J. Nestel, and P. A. Baghurst (1993) investigated LDL oxidation in nonsmoking men and women who were randomized to receive either a placebo or an "antioxidant" vitamin supplement (18 mg beta-carotene, 250 mg d-alpha-tocopheryl succinate, and 12 mg zinc) for 6 months. During the 6-month study period, the supplemented group's LDL was less able to oxidize than the control group. I. Jialal and S. M. Grundy (1993) also demonstrated a decrease in LDL oxidation rate in men supplemented with vitamin E.

There are, however, several problems with recommending supplements of vitamin E or any other of the "antioxidants." First, many of these vitamins have biochemically important interactions. For instance, vitamin C may reduce vitamin E needs by reducing oxidized vitamin E. The chemically reduced vitamin E can then be "recycled" and used again as an antioxidant. Second, no well-controlled randomized clinical trials have determined what dose of antioxidant may be needed to accomplish atherosclerosis prevention without adverse side effects. We do not even know which nutrient (or mixture of nutrients) should be tested. Further, it is not known if in vitro LDL oxidation is the best marker for what these nutrients may do in atherogenesis.

Thus, while it is probable that some of these nutrients play important roles in lipid metabolism (which may affect CVD), we simply do not know enough about them to make sweeping recommendations. If individuals would reduce their dietary fat to 30 percent of calories and increase their consumption of complex carbohydrates to 55 percent of calories (including fruits and vegetables), they would likely increase their ingestion of these "antioxidants," with numerous overall health benefits and without risk.

Alcohol

Several studies suggest a possible benefit of alcohol ingestion. LDL-cholesterol levels appear to be lower in individuals who consume moderate amounts of alcohol: 1 to 3 bottles of beer, glasses of wine, or shots of liquor per day. At higher levels of alcohol ingestion, LDL is further reduced, probably due to the replacement of alcohol for energy calories at the expense of ingesting foods containing cholesterol and fat. Alcohol is the only substance humans ingest (nonpharmacologically) that can raise HDL-cholesterol, a finding that probably explains the beneficial effect of alcohol ingestion in reducing CVD mortality. However, in addition to its beneficial effects on blood lipids, alcohol is a drug with significant potential for abuse. Thus, most public health officials, physicians, and scientists are concerned about advising alcohol as a therapeutic modality for hyperlipidemia and CVD prevention.

Miscellaneous Dietary Components

S. Warshafsky, R. S. Kamer, and S. L. Sivak (1993) examined five placebo-controlled randomized trials on the effects of garlic supplementation on serum cholesterol. About one-half to one clove of garlic per day decreases serum cholesterol by about 9 percent. Proposed mechanisms of garlic's effects on blood lipids include increased bile acid excretion and reduced HMG-CoA reductase activity in the liver. However, carefully controlled studies of garlic remain to be done.

In concert with the antioxidant hypothesis, certain minerals have been implicated in atherogenesis. Selenium is able to act as a free-radical scavenger through its role as a cofactor in the enzyme glutathione peroxidase. However, the epidemiological studies on selenium consumption and CVD mortality do not bear out a probable relationship.

Conclusion

We have reviewed several dietary components that have been implicated in the pathogenesis of cardiovascular disease. The contribution of most nutrients appears to revolve around their ability to influence the serum lipid profile – total cholesterol, LDL-cholesterol, HDL-cholesterol, triglycerides, and the various apoproteins.

There is a need to look beyond serum lipids, however. Besides influencing a specific set of measurable laboratory parameters, nutrients must impact the pathogenesis of disease through biochemical and molecular alterations at the cellular level. This milieu of biochemical reactions and interactions is ultimately the most consequential to the dietary pathogenesis, prevention, and therapy of cardiovascular disease. We will doubtless continue to receive information about the important benefits of "nutrient A" on "function B," and physicians, scientists, patients, and the public will try to make sense of these assertions.

Yet one must remember that nutrients are but small components of the whole chemical "package" that makes up a particular food or group of foods. Other properties of additional components in food may work synergistically or antagonistically, or act as innocent bystanders in cardiovascular disease chemoprotection and pathogenesis. It is unlikely that in years to come a single nutrient – will be uncovered as "the cause" of CAD. More likely, further investigation will describe the subtle interactions of various dietary components with an individual's genome, in concert with other cardiovascular risk factors, such as tobacco use, diabetes mellitus, hypertension, hypoestrogenemia, stress, and obesity. Researchers probably will demonstrate that it is not just one or two nutrients or dietary factors that are critical, but the diet as a whole.

Consider an 88-year-old, generally healthy man who had a verified consumption of 20 to 30 whole eggs per day (Kern 1991). Despite this incredibly high daily cholesterol intake (12,953 micromoles), his total cholesterol was only 5.18 mmol per liter (200 mg per deciliter), and his LDL-cholesterol was 3.68 mmol per liter (142 mg per deciliter). It appears that he had compensated for his dietary excess by excreting excess cholesterol bound in bile acids in his stool. Thus, how an individual utilizes the diet biochemically may be as important as the diet itself.

We are not yet in a position to predict which people will do well with high cholesterol intake and which will not. In the meantime, it is prudent to follow the recent dietary guidelines of the National Research Council, which stress a diet containing 15 to 20 percent of calories from protein, 25 to 30 percent of calories from dietary fat, and the remaining calories from complex carbohydrates, such as whole grains, vegetables, and fruits.

These guidelines were put forward as death rates from CAD were falling, and there is no shortage of advocacy groups ready and willing to take credit for this reduction. But it is most probably the result of many lifestyle changes, among them declining use of tobacco (at least in the United States, when considered for all members of the population combined); better emergency medical services; improved in-hospital treatments; and, of course, dietary modifications. As noted, change in diet has a particular appeal as an explanation because it is the only one of these factors that daily affects each and every member of society. And, as the new millennium dawns, it would seem that dietary intervention to prevent CAD has proved to be a successful means of secondary prevention for those people who have already incurred a cardiac event, even if the utility of such intervention as a means of primary prevention, applied to entire populations, remains controversial.

We should also bear in mind that the debate over diet and heart disease is being conducted in a very public arena, and an arena in which diet and heart disease are only one aspect of a more general tension over questions focusing on personal risk and responsibility. In the case of heart disease, these questions have stirred a broad-based popular reaction. No longer are discussions of diet and the heart confined to the pages of medical journals, but they can now be found in practically every issue of widely circulating newspapers and magazines. One good example is an extensive and detailed analysis questioning the overall importance of cholesterol in heart disease – indeed, dismissing "The Cholesterol Myth" – in the *Atlantic Magazine* (Moore 1989a). In the same year that this essay appeared, it was also published in expanded form as a book (Moore 1989b).

Public skepticism about the importance of diet in heart disease is also apparent in cartoons. One, in the *New Yorker* magazine (January 16, 1989: 39), shows a man starting to eat a huge oatmeal muffin. The caption reads: "Wellness update: Thirty-year-old man starting on the twenty-five-thousand-pound oat-bran muffin he must consume over forty years in order to reduce significantly his risk of death from high cholesterol."

This and countless other less-than-reverent cartoons constitute widespread cultural markers that express a number of popular reactions to the diet–heart hypothesis. First, they ventilate frustration at the gospel of eating for one's heart (or for health in general). And given a culture in which the average person is daily bombarded with images of food, with much of the easiest food to acquire and consume that which is likely to be least beneficial for preventing heart disease, this frustration is understandable. Such cartoons also reflect a general lack of conviction that altered diets will "work" against heart disease – a skepticism that primary prevention trials have thus far failed to address convincingly. At a lay level, most people know (or have heard of) someone who has lived to a ripe old age while engaging in near-constant dietary indiscretions, whereas someone who ate "right" and stayed fit may have suffered an early death. Epidemiologists might discount the relevance of such anecdotes, but they can have a major impact on popular perceptions of risk and disease, especially when the behavior that is being advocated may be neither easy nor (seemingly) pleasurable.

The popular reaction against dietary constraints also raises fundamental questions of personal versus public responsibility. If someone has CAD, whose fault is it? The choices people make about what to eat are limited by the cultural world in which they live, so to what extent is the larger society to be held responsible? And, if one is personally accountable for what foods are consumed, then should a "healthy lifestyle" make a difference in terms of how much one pays for health or life insurance?

Finally, what is the disease here? Is it CAD, or is it high cholesterol? We should not lose sight of the fact that blood lipids are merely surrogates for what is most important – the disability and death that come from CAD and CVD. Keeping track of these differences is important. First, it can help to maintain focus on the ultimate goals of therapy and not allow us to become sidetracked by that which is easier to effect. Second, it will prevent the labeling of a large percentage of the population as "diseased" simply because of a high lipid profile. The answers to the questions raised in this chapter are unlikely to come purely from the accumulation of more and more data, because the prevention controversies are also fueled by "hidden ideological, structural, and professional factors" (Aronowitz 1994).

IV.F.4 The Cardiovascular System, Coronary Artery Disease, and Calcium: A Hypothesis

The Circulation

The central organ of the human circulatory system, the heart, must be among the most remarkable creations of nature. In the longest-living individuals, it works continuously for a hundred or more years, executing something like 4,000 million working strokes and moving 350,000 cubic meters of blood, enough to make a small lake. In individuals who die of heart disease, it is not, as a rule, the heart itself that fails but some auxiliary mechanism, like one of its arteries, or the pacemaker. If an artery, supplying a small part of the heart, is blocked, the tissues receiving oxygen and nutrients from that vessel die. If the area involved is not so large as to endanger the entire heart, the damage is gradually repaired by the immune system. The dead cells are removed but cannot be replaced; the gap they leave is filled with scar tissue. While the repair is carried out, the heart continues to work.

Among other remarkable properties of the heart is a virtual immunity from cancer and a good resistance to inflammatory diseases. When the body is at rest, the heart contracts approximately once every second. Its contraction – the systole – lasts about one-third of a second; its relaxation period – the diastole – two-thirds of a second. During hard physical exercise, the heart rate increases about three times.

The arterial system is like a many-branched tree. Its trunk, the aorta, is about three centimeters in diameter at its origin. The branches become progressively smaller and end in a network of capillaries of microscopic size. On the return side, blood is collected by small venules, which join to form veins and end in two large venous trunks. The entire length of the system is more than enough to encircle the earth.

The function of the circulatory system is to deliver nutrients to the cell population of the body and to collect their waste products. The system is waterborne, but a very small quantity of water carries a comparatively enormous cargo. The volume of water in the blood, and that of the substances dissolved or floating in it, are approximately equal.

A water-based transport system can readily transport water-soluble substances, but those are only a small part of the nutrients carried in blood. The most difficult technical problem is the transport of gases, notably oxygen and carbon dioxide. These are soluble, but only sparsely so in water. If they were carried only in aqueous solution, a very large quantity would be required for their transport. The problem is solved by the use of iron porphyrin, a substance that can readily take up oxygen and equally readily release it. The porphyrins are incorporated in large hemoglobin molecules, with molecular weight of 64,000, and these, in turn, are incorporated into red blood cells. It is interesting to note that the mammalian type of hemoglobin is the end product of a long process of development in evolutionary history. Invertebrate blood contains a large variety of hemoglobin-like substances (erythrocruorins), with molecular weights ranging from 17,000 to 1,250,000, in some cases copper-based compounds being used instead of iron. Red blood cells constitute about 40 percent of the blood by volume. Allowing an equal quantity of water for their flotation, 80 percent of the total capacity of the circulatory system is engaged in the task of oxygen transport.

Similar difficulties are presented by the transport of lipids and other hydrophobic substances. If they were simply released in water, they would stick to each other and to vessel walls. There are two solutions to the problem. One is the conjugation of a water-insoluble molecule with one or more other molecules to form a water-soluble complex. The other expedient is the use of carrier proteins. These are large molecules in comparison with the lipids they carry, serving, in effect, as packing cases for them. The protein molecule turns a hydrophilic outer surface to the watery medium in which it floats, and can pack a large quantity of hydrophobic molecules inside, shielded from contact with water.

The protein carrier with its lipid cargo constitutes a lipoprotein. As the carrier protein is heavier than water, the lipid it carries is lighter; the specific weight (or density) of their combination depends on the proportion of the two constituents. When the cargo of transport proteins is mainly cholesterol, they constitute low-density lipoproteins (LDL). Some lipoproteins carry cholesterol and other lipids from dead cells to the liver for reuse or excretion. They transport a small quantity of lipids; hence, they constitute high-density (HDL) lipoproteins.

The aqueous portion of the blood, the plasma, carries a variety of organic and inorganic substances, such as blood sugar (glucose) and salts. Among them are three kinds of proteins, albumin, globulin, and fibrinogen, serving various functions. The chemical messengers, hormones, which have to be transported from organs that produce them to receptors in other parts of the body, are always in transit in the blood, and so are enzymes, vitamins, and the like.

Moreover, the circulatory system is the highway that invading microorganisms try to use for spreading in the body, and cancers also spread by blood-borne fragments. To cope with these hazards, the system is defended by the immune mechanism, notably by several types of white blood cells (polymorphonuclear leukocytes, lymphocytes, and monocytes). The function of these cells is to seek out, ingest, and kill invading microorganisms, penetrate areas of infection, and phagocytose foreign matter and dead cells. The circulatory system is also the target organ of several plant toxins, some of which can act as vasodilators or constrictors, blood coagulants, or anticoagulants. The rye fungus ergot, for example, is such a powerful constrictor of peripheral blood vessels that, in the past, it created numerous epidemics in countries where rye was an important food item. The toxin ergotamine, mixed with rye flour, was capable of cutting off the circulation of the limbs, causing death by gangrene.

Apart from the effect of poisons upon them, arteries are subject to several other disorders (see the section "Specific Hazards of the Circulatory System). Larger arteries are more vulnerable than small arteries. Veins are not entirely trouble free but, in comparison with arteries, are notable for their smooth functioning and resistance to disease. They do, of course, work under less onerous conditions than arteries.

Not surprisingly, arterial disorders are among the leading causes of mortality in advanced countries with older populations. In a few countries, they are responsible for more mortality than all other causes combined. The current worldwide yearly toll of coronary artery disease is about two million deaths, to which cerebrovascular disease (strokes) add half a million. Disorders of the peripheral circulation can cause deaths, but since the elimination of ergotism, the numbers are small.

Specific Hazards of the Circulatory System

The foregoing review attempts to show the complexity and potential vulnerability of the circulation system. However, the exact causes of the most important arterial disorders are still not known, and the intent in this essay is to highlight a few specific hazards that could be relevant to their pathogenesis.

When the heart contracts, it compresses its own blood vessels, the coronary arteries, so that although it supplies all other organs in the body with blood, it cannot supply itself. The perfusion of the heart is effected by an auxiliary mechanism, working on the same principle as a flywheel in a mechanical system by drawing energy from a prime mover in one part of a power cycle and returning it in another part. The corresponding mechanism in the circulation is an elastic reservoir, consisting of the aorta and parts of its large-branch arteries. During systole the walls of the reservoir are distended, storing energy in their stretched elastic tissues; during diastole they contract, generating sufficient pressure to maintain blood flow in the circulation, including the by-then-relaxed coronary arteries. This arrangement, however, makes the nutrition of the heart dependent on the elasticity of the aorta and the other arteries that constitute the elastic reservoir. Several aspects of the aging process can bring about the deterioration of the elastic properties of tissues, representing a special hazard for the heart.

A similar problem arises in connection with the blood supply of the artery wall. The walls of arteries have a cell population that must be supplied with oxygen and nutrients like any other tissue. The difficulty in supplying them arises from the fact that the artery wall is compressed by the blood flowing through it, with a radial pressure gradient across it, the inside being more compressed than the outside. Large arteries have their own blood vessels, the *vasa vasorum,* which enter them on the outside and perfuse the outer half of the artery wall. They cannot perfuse the inner half, because the pressure available to force blood through these small arteries is insufficient to overcome the compression of that part of the artery. Consequently, the inner half of the artery wall must obtain oxygen and nutrients from blood flowing through the artery. The technical problems associated with this process are probably the basic causes of arterial disorders.

Oxygen and water-soluble nutrients can apparently diffuse through the layer of cells – the endothelium – that constitute the inner lining of the artery wall, and there are no known disorders caused by deficiencies of such nutrients. The main difficulty is the transfer of lipids from arterial blood to tissues in the inner half of the artery wall. As mentioned, lipids in the blood are carried by large protein molecules, which do not diffuse into tissues. Cells in need of them have to capture them by means of surface receptors that bind lipoproteins on contact (Goldstein and Brown 1977). The receptors are located in a special area of each cell's surface, the coated pit. When receptors have captured a sufficient quantity of lipoproteins, the coated pit sinks into the cell and unites with a lysosome, the digestive organ of the cell (Simonescu, Simonescu, and Palade 1976; Anderson, Brown, and Goldstein 1977).

A brief description of the construction of the artery wall is needed at this point. The artery wall is a three-layered structure. Its inside, the intima, consists of a single layer of flat endothelial cells and a thin, liquid-filled subendothelial space. The second layer, the media, forms the bulk of the artery wall. It consists of elastic laminae and smooth muscle in varying proportions. The largest arteries, such as the aorta, are mainly elastic; those next in size, mainly muscular. The muscles of the media form peripheral bands, the contraction of which can reduce the lumen of the artery, regulating blood flow through it. Thus they reduce blood flow to organs at rest and increase it to organs in a state of high activity. However, individual smooth muscle cells also exist in the artery wall and perform the same duties as fibroblasts in other tissues. They can secrete various types of elastic and nonelastic fibers that are used mainly in the repair of injuries. Lastly, the outer layer of the wall is a tough connective-tissue covering.

The exact causes of the most important artery disease, atherosclerosis, are not known with certainty. A plausible explanation of the pathogenesis of the disorder is the following: The endothelial cells of the intima, in direct contact with blood inside the artery, capture lipoproteins in the plasma, as do other cells, by means of surface receptors. They do this not only for their own use but also for the supply of other cells in the inner half of the artery wall. Receptors in coated pits sink, as usual, into the interior of the endothelial cell, but in this case, they travel through the cell to emerge on its other side, where they discharge their load of lipoproteins into the subendothelium (Schwartz et al. 1977).

The hazard of the process, at least in prosperous countries, is not that they cannot transfer enough lipids into the subendothelium, but that they transfer too much. Presumably, if a cell captures lipoproteins from blood for its own use, it ceases to produce surface receptors when its needs are satisfied, but if it does so for other cells, it does not receive clear signals when to stop. The quantity actually transferred may depend on the availability of lipoproteins in the plasma.

In developing countries where the population lives on a barely adequate, or less than adequate, diet, the lipoprotein concentration in the plasma is correspondingly low, and the risk of endothelial cells oversupplying the cell population of the median layer of the artery wall is small. In prosperous countries, hyperlipidemia is common, presumably resulting in the almost universal occurrence of fatty suffusions in the intima of some arteries.

Such accumulations of lipoproteins, beginning in infancy or early childhood, could be the initiating event in atherosclerosis, even if the given description is only a simplified – possibly oversimplified – account of the earliest stage of atherosclerosis. Fatty streaks make a patchy appearance in the aorta and some other large arteries. The coronary circulation is usually more heavily involved than others, so that the concentration of lipoproteins in the plasma cannot be the only factor involved in pathogenesis.

Another hazard arises from the fact that arteries must be self-sealing in case of injuries; otherwise, small injuries may cause fatal hemorrhages. Injuries are sealed in the first instance by platelets – small discs 2 to 4 micrometers (μm) in diameter – circulating in immense numbers in the bloodstream. When the wall of a blood vessel is injured, collagen – a tough connective tissue inside it – is exposed. Collagen apparently attracts platelets, which immediately adhere to it. The platelets then release a substance that attracts more platelets and that makes them sticky, causing them to aggregate and form a temporary plug. This is subsequently converted into a more stable clot, after a complicated set of reactions, by fibrin. The latter is produced by the conversion of the soluble plasma protein, fibrinogen, into an insoluble substance. The fibrin originally forms a loose mesh, but ultimately it becomes a dense, tight aggregate.

This essential defense mechanism can become a life-threatening hazard, because advanced atherosclerosis can result in the ulceration of the artery wall, which, in turn, may invoke the clotting reaction. The ultimate result can be a thrombus, occluding the artery.

Atherosclerosis

Atherosclerosis begins with the already mentioned lipid suffusions – the fatty streaks – in the subendothelium of some arteries. The space immediately beneath the single layer of endothelial cells inside the artery is originally small, but it is gradually extended by lipid deposits. The accumulating lipids are mainly cholesterol esters (cholesterol with an attached fatty acid molecule). Cholesterol can act as a weak base and, combined with a weak fatty acid, constitutes the equivalent of an inorganic salt. As there are many types of fatty acids that can combine with cholesterol, there are many types of cholesterol esters. The most important esters are oleates and linoleates, which are cholesterol combined with oleic and linoleic acid, respectively.

Cholesterol is a highly stable waxy substance, an essential constituent of every single cell in the body. The flexibility of the animal body, in comparison with the more rigid structure of plants, is due to the fact that the outer shell of plant cells is cellulose, a comparatively rigid substance, whereas that of animal cells is a complex, three-layered construction, containing proteins and lipids, including cholesterol. These cell membranes combine toughness with flexibility. In addition to the cell itself, its organelles have similar membranes.

The usefulness of cholesterol does not alter the fact that its accumulations in the artery wall can become harmful. Not known with certainty is why deposits of cholesterol esters accumulate inside artery walls. The possibility that if the density of lipoproteins in the plasma is high, endothelial cells transfer more than the required quantity from the blood to the subendothelium has been mentioned. The arising fatty streaks are visible without magnification as yellowish lines or small patches on the luminal surface of the artery. These streaks are flat, or only slightly raised, so that they do not obstruct blood flow and are not known to cause any clinical symptoms; hence, they appear to be harmless.

Fatty streaks appear in large arteries, particularly the aorta, at a very early age, probably in infancy. They are universal in children of all races in all parts of the world, but in developing countries they disappear in early childhood, whereas in prosperous countries they persist and spread. They occupy about 10 percent of the aorta in children; in adult life the affected area may increase to 30 to 50 percent.

In spite of their apparent innocuousness, fatty streaks may not be entirely harmless. They may, for instance, impede the diffusion of oxygen and water-soluble nutrients from blood flowing through the artery to tissues of the artery wall covered by them. But whatever the reason, the immune mechanism of the body treats them as foreign matter. The lipid accumulations are immediately invaded by phagocytes (monocytes), making their way into the lesions from arterial blood. They are apparently capable of separating adjacent endothelial cells slightly and slipping through the gap. Inside the fatty streak they engulf cholesterol esters until they are swollen with them. The lipid-laden phagocytes presumably attempt to leave the site of the lesion, but unlike other tissues, arteries are not drained by lymphatics, making it difficult for phagocytes to find their way out. Occasionally they can be found in the blood, and so some can escape, but many of them die in the attempt, so that ultimately dead foam cells, as lipid-laden monocytes are called, become the main constituents of fatty streaks.

Subsequently, fatty streaks are invaded by another type of cell: individual, motile smooth muscle cells, migrating into the lesion from the media. These perform the same function as fibroblasts in other tissues. They are cells capable of secreting various elastic and nonelastic fibers, used mainly in the repair of injuries. The fibers bridge over gaps in tissues separated by the injury. As far as possible, they attempt to restore the status quo ante, but when this is not possible, they do a serviceable repair. The ends of a broken bone, for instance, would initially be held together by inelastic fibers until new bone is formed to fill the gap. Under natural conditions, the bone would heal crookedly because the repair mechanism does not have the power to reset it in its original form.

Another function of fibroblasts is to encapsulate foreign matter in the body. If the immune mechanism is powerless to deal with some invading microorganism, an attempt might be made to encapsulate its colonies, as, for instance, in tuberculosis. This is essentially the function that fibroblasts of smooth muscle origin appear to fulfill in fatty streaks. Probably they attempt to break up a continuous layer of lipids, dead phagocytes, and other cell debris into a number of separated accumulations, which are then encapsulated by layers of fibrous tissue. This is how the archetypal lesion of atherosclerosis, the fibrolipid plaque, is thought to arise. The two basic components of the fibrolipid plaque are a white cap of connective tissue and an underlying pool of necrotic debris. The proportion of the two components can vary considerably, and so can the extent of the lesion and the number of fibrous caps in it. In the advanced stage of the lesion, the fibrous caps can be so numerous that they give the luminal surface of the artery wall the porridge-like appearance from which the disorder takes its name.

The fibrolipid plaques are elevated above the surface of the intima and thus represent an obstruction to smooth blood flow. It must be remembered, however, that the lesions are virtually universal in the population of advanced countries. They begin in early childhood and last throughout life, causing no discomfort or inconvenience of any kind for decades. Indeed, in the majority of the population they remain silent until death from some other cause. They can be best conceptualized as a potentially lethal disorder, but one that is generally under the firm control of the defense mechanism of the body.

In the last, uncontrolled stage of atherosclerosis, arteries densely covered by fibrolipid plaques may ulcerate, possibly leading to the adhesion of platelets to the lesions and ultimate thrombus formation. Ulcerated arteries may calcify. The much-thickened intima of the artery wall can fissure, become partly detached, and cause the condition known as an aneurysm. If the lumen of the artery, already narrowed by fibrolipid plaques, is further obstructed by a thrombus or aneurysm, it may become completely occluded, cutting off the blood supply of tissues served by the given artery.

To repeat, the basic cause of atherosclerosis in prosperous countries is thought to be excess lipid intake, and preventive efforts throughout the century have been directed at the reduction of fats in the diet. The main difficulty has been that an effective reduction of lipids seems to require such a Spartan diet that the population of advanced countries has not been persuaded to adopt it. Much evidence, however, is available to suggest that even if this assumption is correct, it can be only a part of the story. There must be other contributory factors that determine why arterial disorders become a lethal disease in some individuals and remain in their harmless, controlled stage in others.

For example, there are considerable differences between the geographical distribution of coronary artery disease and cerebrovascular disease (strokes). The latter appears at a lower level of prosperity, the highest mortality rates occurring in moderately prosperous countries, such as Bulgaria and Portugal, where the consumption of animal fats is comparatively low. With increasing prosperity and increasing fat consumption, mortality from strokes tends to drop. Thus 40 years ago, the world leader in stroke mortality was Japan. The dramatic rise of prosperity in that country was accompanied by considerable changes in diet, the consumption of animal fats increasing by about 50 percent. At the same time, there was a sharp decrease in the incidence of strokes, and stroke mortality is now approximately half that of 40 years ago. The lipid theory of atherogenesis does not differentiate between atherosclerosis in coronary arteries and atherosclerosis in cerebrovascular arteries, and so the fall of cerebrovascular mortality in Japan (as well as a similar sharp fall in the United States in the first half of the twentieth century) provides directly contradictory evidence.

If possible, preventive measures should eliminate atherosclerosis completely, but if that is not a practical possibility, preventing the transition from the controlled to the uncontrollable stage would be nearly as useful. Therefore, an understanding of the basic process of atherogenesis is not enough. It is also necessary to investigate contributory causes and other factors that promote or retard its development. Well-known factors of this nature are cigarette smoking, diabetes, and hypothyroidism, all of which may promote atherogenesis and hasten the onset of its terminal stage, but which fall far short of providing a complete explanation. The low prevalence of coronary artery disease in Japan, for instance, has not been changed by heavy smoking habits. The effect of smoking, diabetes, and hypothyroidism is probably not specific to arterial disease, but is rather a general weakening of the immune mechanism.

Progress toward a better understanding of the causes of artery diseases can proceed along two lines. One is the study of the pathogenetic process itself. If that were completely understood, the causes might be self-evident. Until then, important pointers may be provided by epidemiological studies. Knowledge of the parts of the earth in which artery diseases are highly prevalent and of those in which they are not should throw light on the conditions that promote or retard the disorders and to help in an underdstanding of their causative agents.

Epidemiological Studies

Arterial disorders have a distinct geographical distribution. They are generally very low or nonexistent in poor countries but are the leading cause of mortality in some of the most prosperous countries. Such a pattern creates the impression that the circulatory system, in spite of its complexity and potential vulnerability, is well able to cope with its natural hazards. Prosperity may have introduced some new condition – perhaps a surfeit of food in place of scarcity – that has changed a trouble-free mechanism into one susceptible to trouble.

An alternative possibility is that the difference is the result of the prolongation of life in prosperous countries. Arterial disorders appear in old age; therefore, the longer duration of life increases their share among causes of mortality. Yet another possibility is that the difference is the result of racial characteristics, Europeans being more vulnerable than Asians or Africans. Climatic conditions could be another factor, with arterial disease being more prevalent in temperate than in warm climates.

Epidemiological studies have eliminated a number of these possibilities. For instance, immigrant studies have disposed of the racial hypothesis. Black people may be free of arterial disease in Africa, but in the United States they are as vulnerable as American whites. Nor is the prolongation of life a satisfactory explanation. When mortality rates are compared in the same age groups in developing and advanced countries, it is still only the population of prosperous countries that is highly vulnerable to arterial disease. The critical factor appears to be diet. Thus, when population groups migrate from poor to prosperous countries, they, or their descendants, gradually become subject to the mortality patterns of their hosts. Migrants going from prosperous to poor countries take their diseases with them. This is, presumably, because migrants from poor to prosperous countries are willing enough to adopt the food of their hosts, but those moving in the other direction are not willing to embrace the poorer diet of their hosts.

Yet although such epidemiological studies have produced useful results on general points, they have brought little progress in matters of detail, such as the identification of food items connected with specific disorders, or finding the reason for the epidemiological peculiarities of some disorders. Why, for example, is worldwide mortality from coronary disease highest in Finland and that from strokes in Bulgaria?

One reason for the apparently limited usefulness of epidemiology is the intrinsic difficulty of the task. The diet of prosperous countries consists of something like a thousand food items, containing a million chemical substances, all potential suspects. None, however, is strongly poisonous, suggesting that perhaps the pathogenic agent may not be present in just one food item but in several, in different proportions, so that the correlation between the disease they collectively cause and one of the food items may only be weakly positive.

Possibly an equally important factor retarding progress might be regarded as a self-inflicted injury. Although the identification of the true causes of artery diseases is difficult, nothing is easier than the presentation of suspects on the basis of superficial arguments. Some of the favorite concepts of popular medicine, such as the particularly harmful effect of saturated fats or the assumed protective effect of dietary fiber, garlic, onions, and the like, are not the results of epidemiological studies but of superficial observations, or they are simply guesses.

An early comparison was that between the "low-protein, lowfat, high-fiber" diet of this or that African tribe and the "high-protein, high-fat, low-fiber" diet of prosperous countries, giving rise to the fiber industry. In fact, the differences between the diets of African tribesmen and the population of rich countries are innumerable. The tribesmen eat fewer apples, chocolates, and cabbages than do people in the West and do not take a sleeping pill at night and a tranquilizer in the morning. The main virtue of fiber is probably the fact that it is a nonfood that may help to prevent overnutrition.

When it was pointed out that Eskimos – whose diet was not a lowfat, low protein, high fiber one – did not suffer from arterial diseases, the objection was sidestepped with the suggestion that they consumed the unsaturated fat of marine animals, not the hard fat of land animals. When it was pointed out that the French consumed as much animal fat and proteins as the British, yet the mortality from coronary disease in France was about a third of that in Britain, the "protective" effect of garlic, onions, and red wine was suggested as a possible explanation. Not even a guess is available as to how garlic, onions, and the like might protect the circulatory system. Yet such ideas, for some reason, are immediately taken up by the media and popular medicine, often impeding serious research. It may also be well to remember that the first task of research is to discover the causes of arterial disease. When those are known, attention can be turned to protective effects, but before they are known with certainty, protective effects are usually invoked to cover discrepancies between facts and theory.

A new line of approach emerged in the 1940s with the Framingham study. The basic idea was to recruit a large number of participants and keep a record of their food consumption until they all died. Then the diet of those who died of coronary disease could be compared with that of the participants who died of other diseases, providing valuable information about the dietary causes of coronary disease. In some of the later trials, the protocol was slightly changed. Some participants were persuaded to change their habits (for example, to reduce fat intake, or to give up smoking), whereas others were allowed to continue with their customary diets and other practices. Thus, prospective studies became intervention trials. A large number of these were conducted in many countries, among others by M. R. Garcia-Palmieri and colleagues (1980), the Multiple Risk Factor Intervention Research Group (1982), and G. Rose, H. D. Turnstall-Pedoe, and R. F. Heller (1983).

Neither the Framingham trial nor its many successors, however, have produced clear evidence identifying the causes of coronary disease, and some of the results have been contradictory. At least one of the reasons for the poor performance of prospective studies is likely to be the gross inaccuracy of the food consumption data they collect. The data are obtained by means of periodic samplings by the method of "24-hour recall," and are subject to several errors. A one-day sampling in, let us say, a month is unlikely to be truly representative of food consumption for the whole period. The data, as collected, are nonquantitative, and the quantities must be estimated by the conductors of the trial. There have to be errors of recall. These are in addition to several confounding factors, such as individual sensitivities to food toxin. If an individual dies of a food-related disorder, it is not necessarily because his consumption of the food was too high. Another possibility is that his resistance to its toxic effect was too low. Also to be remembered is that atherosclerosis is a virtually universal disorder in prosperous countries. Thus, those participants in a trial who die of other diseases may also be in an advanced stage of atherosclerosis. Finally in the case of intervention trials, the persuasion aimed at one group of participants to change habits (such as quitting smoking) is often little different from that directed at the other group by doctors and the media.

This writer suggests that food consumption statistics of advanced countries provide more reliable information regarding the type and quantity of food consumed in a community than do data collected individually in periodic samplings. Statistics are not free of errors, but they are unlikely to be of such magnitude that two studies can produce directly contradictory results. Comparing population groups rather than individuals has, at least, the advantage of eliminating individual susceptibilities. The results of a statistical study conducted by this writer (Seely 1988) is recapitulated in the following section.

A Statistical Study

When searching for the correlation between one or more food items and mortality from a given disease, statistics are likely to present a blurred image. This is partly on account of chance correlations and indirect correlations, and partly on account of statistical errors. Food consumption statistics of prosperous countries, for example, include a large amount of waste, whereas death certificates may give erroneous causes of death. Prosperity-related diseases can be positively correlated with virtually any aspect of that prosperity, such as the number of two-car families in a community, as well as with the consumption of the food item that is the presumed actual cause of disease. The consumption of a number of luxury foods increases together with prosperity. All such errors tend to mask the connection between real causes and effects. In an attempt to sharpen the image, the following expedient was tried.

Let us consider a statistical study in a group of prosperous countries, such as the 21 countries of the Organization of Economic Cooperation and Development (OECD), for which both mortality and food consumption statistics are available (Seely 1988). The object is to see if a consistent association can be found between mortality from coronary artery disease and the consumption of one or more food items. It may be advantageous to restrict the initial search to the four countries with the highest, and the four countries with the lowest, mortality from coronary disease because the contrast between the two groups may bring the critical differences between them into sharper focus. The range of mortality between the two groups is wide. Male coronary mortality in the leading country, Finland, is about eight times as high as in the country with the lowest mortality, Japan. The average male coronary mortality in the four leading countries – Finland, Ireland, United Kingdom, and Sweden – is four times as high as in the low-mortality group – Spain, France, Portugal, and Japan. Thus it seems unlikely that a food item, the consumption of which in the low-mortality group *exceeds* that in the high-mortality group, can play a significant part in the causation of coronary disease, and thus it can be excluded from the list of suspects with a reasonable degree of confidence.

In our statistical study, the source of mortality data are mortality statistics of the World Health Organization (1983–6) and that of food consumption are statistics of the Organisation for Economic Co-operation and Development (1981). Mortality statistics are for 1983, or the nearest available year; food consumption statistics are for 1973. The reason for the time interval between them is that foods containing some mildly noxious substance result in a disorder only after a long delay. The exact interval cannot be estimated, but empirical observations suggest that 10 years is reasonable.

In order to ensure that no food item for which consumption statistics are available is overlooked, it is necessary to consider *all* food appearing in them. As noted, the diet of prosperous countries includes about a thousand food items, yet the statistics give consumption figures for about 50 items. There is obviously no guarantee that foods not appearing in statistics cannot be causative agents for a disorder, but at least it can be said that all *major* food items are included in the statistics. The possible connection between a food item and a disease can be verified by the calculation of correlation coefficients. The simplest case of perfect correlation is exact proportionality between the consumption of a food item and mortality from a given disease. In other words, if in a country the consumption of x coexists with a number of deaths from a disease, y, then in other countries, where the consumption of that food is 2, 3, or 4 times higher than in the first country, mortality is also 2, 3, or 4 times higher. In a more realistic case the relationship is $y = ax + b$, where a and b are constants, and correlation is perfect if mortality in every country corresponds exactly to the value obtained from the equation. Perfect positive correlation is expressed by the correlation coefficient 1, entire lack of correlation by the coefficient 0, and perfect negative correlation by –1.

The results of the study are reproduced in Table IV.F.4.1. This shows the correlation coefficients calculated for each item appearing in the cited food consumption statistics for eight countries. Table IV.F.4.2 shows male age-compensated mortality rates in these countries and gives some of the more important food consumption figures from which the correlation coefficients in Table IV.F.4.1 were calculated. The highest positive correlations in Table IV.F.4.1 are as follows: oats 0.95, whole milk 0.91, milk proteins (excluding cheese) 0.91, milk fats (excluding butter and cheese) 0.91, sugar 0.90, total milk protein 0.86, beer 0.86, total milk fats 0.84, total animal fats 0.77, total animal proteins 0.74.

When correlations were checked for all 21 OECD countries, the high correlation with beer was found to be spurious. The countries with the highest beer consumption, notable Germany, Austria, the Netherlands, and Denmark, have only moderately high mortality from coronary disease. The other correlations, including that of oats, were confirmed.

The most surprising finding of the study is the near-perfect correlation between coronary mortality and the consumption of oats. At the time of the investigation, we could offer no explanation or even a suggestion as to what constituent of oats could have a connection with arterial disorders, but an attempt at an explanation follows shortly.

The connection between milk consumption and coronary disease has been suspected for a long time, based mainly on the geographical correspondence

Table IV.F.4.1. *Correlation coefficients between age-compensated male mortality rates from ischaemic heart disease and the consumption of various foods in 8 member countries of the Organization of Economic Cooperation and Development. The 8 countries comprise the 4 with the highest coronary mortality (Finland, Ireland, U.K., Sweden) and the 4 with the lowest mortality (Spain, Portugal, France, Japan). Source of mortality data: World Health Organization statistics for the year 1983 (or nearest); source of food consumption data: statistics of the Organisation of Economic Cooperation and Development for the year 1973*

between them. Figure IV.F.4.1 shows this graphically for member countries of the Organisation for Economic Co-operation and Development. Many papers have been published on the subject, notably by J. C. Annand (1961), K. A. Oster (1971), J. J. Segall (1980), and S. Seely (1981), although the authors could not agree on the mechanism of interaction between milk and the arteries. It is interesting to note from Table IV.F.4.1 that whatever the noxious constituent of milk may be, some process in cheese manufacture appears to destroy it.

Sugar is also a long-standing suspect. However, the main objection to the suspicion is that no reasonable proposal has ever been put forward to explain why and how sugar might have an adverse effect on arteries (Yudkin and Roddy 1964).

Table IV.F.4.2. *Sample data on which Table IV.F.4.1 is based. Mortality rates below denote age-compensated male mortality rates (European standard) from ischaemic heart disease. Food consumption in grams/day*

	High-mortality group				Low-mortality group

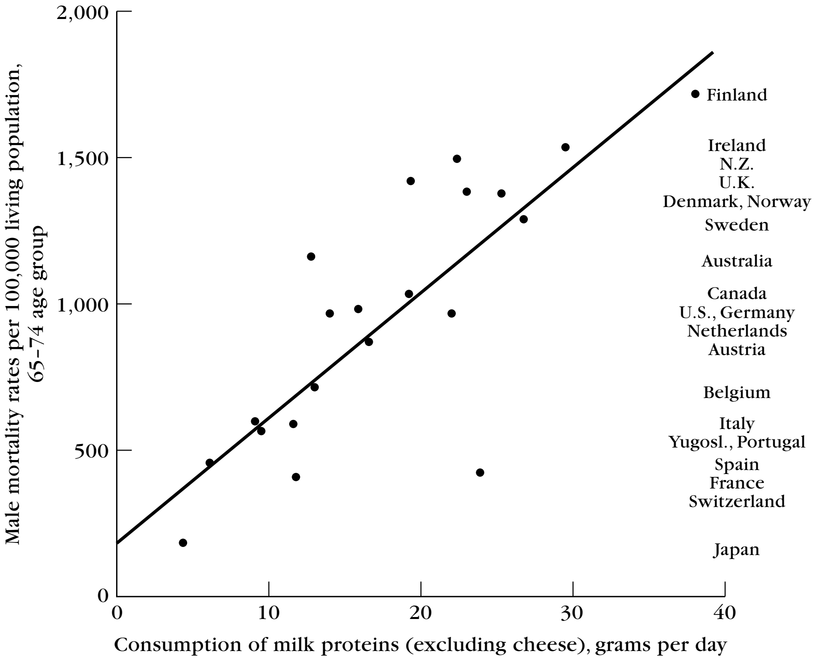
Figure IV.F.4.1. Male coronary mortality in the 65–74 age group in OECD countries and the consumption of milk proteins (excluding cheese). Reproduced from *International Journal of Cardiology*, with the permission of the publishers, Elsevier Science Publishers, Amsterdam. *Note*. Mortality statistics are for 1987 (or the nearest year for which statistics were available); food consumption data precede mortality statistics by ten years.



The food items, for the possible atherogenic effect of which reasonable explanations *are* available, are animal fats and proteins. Yet, as shown by Table IV.F.4.1, the correlation coefficients between them and coronary mortality are considerably weaker than those found for oats, milk, and sugar. Clearly, this helps to demonstrate the complexity of the problem.

Perhaps a clue to the resolution of some of these difficulties can be found by considering one distinguishing feature that cow's milk and oats have in common: They both have a high calcium content. That of cow's milk is 120 milligrams (mg) per 100 grams (g) (as compared with 31 mg per 100 g of human milk); the calcium content of oats is 80 mg per 100 g (McCance and Widdowson 1980). Hence, we arrive at the possibility that the missing link in the pathogenesis of coronary disease is the excessively high calcium content of the Western diet.

Calcium in the Western Diet

What might be called the "natural human diet" is low in calcium, as are present-day diets in most developing countries, where the daily intake amounts to about 200 to 500 mg. The calcium content of the European diet was probably the same in past centuries, giving rise to the frequent occurrence of calcium deficiency disease – rickets – in children.

The large increase in the calcium content of the Western diet came with the increasing use of cow's milk as a staple food for all age groups. The calcium content of milk is high, and it serves the needs of infants whose rapidly growing skeletons need a comparatively large amount. Calves grow at 4 times the rate of human infants; hence, cow's milk contains 4 times as much calcium as human milk. The average intake of milk and dairy products in prosperous countries is usually between ¼ and ½ liter a day, containing 300 to 600 mg calcium. Three hundred mg is sufficient to convert the intake from other foods into an abundant 600 to 700 mg, and half a liter of milk into an excessive 900 to 1,000 mg. In many Western countries, the calcium intake from cow's milk is more than that from all other foods combined.

Calcium is an essential nutrient, but in the ideal case, the dietary intake should not exceed requirements because the excretion of the surplus is a difficult task. The requirement of the human body can be estimated from the following data: The adult body contains about 1,100 grams of calcium, 99 percent of which is in the skeleton. The remaining 1 percent is needed for various essential functions, such as the generation of nerve impulses, muscular contraction, blood coagulation, and so forth. The skeleton reaches its maximum size and weight at the age of 35 years. While the skeleton is growing, it takes up a daily average of 80 mg calcium. After the age of 50 years, the skeleton begins to shrink, releasing calcium.

All body fluids contain calcium. About 100 mg is lost daily in urine and about 15 mg in sweat, though with hard physical exercise, sweating can excrete 80 mg calcium in a day. In addition, digestive fluids, such as saliva and pancreatic juice, discharge calcium into the digestive tract, and this amount is not completely reabsorbed. Allowing 150 mg calcium daily for this loss, the calcium requirement of a young adult, depending on physical exercise, amounts to 330 to 390 mg/day, and that of an old person about 240 mg/day. The dietary intake should exceed the needs of the body by about 20 percent to allow for calcium passing unabsorbed through the intestines, making the daily requirement for a hard-working young adult 470 mg, that of old people 290 mg. When the risk of coronary heart disease is considered, we are mainly interested in the older age groups. In their case, a possible dietary calcium intake of the order of 1,000 mg is *several times* the quantity they need, and that from milk alone can be twice that amount.

The uptake of calcium from the small intestine is a controlled process, so that an excessive dietary intake does not necessarily mean that calcium finding its way into body fluids must also be excessive. Control is exercised by a vitamin D metabolite, cholecalciferol, synthesized in two steps in the liver and kidney. This metabolite is the signal for the synthesis of a carrier protein in the intestine, which is the actual transfer agent for calcium through the intestinal wall. If the calcium content of the plasma is already adequate, the synthesis of cholecalciferol is discontinued, and the excess calcium passes unabsorbed through the alimentary canal. However, newly born infants do not yet possess this control mechanism. In their case, milk sugar, lactose, facilitates the absorption of calcium from the small intestine by a simple diffusion process. Under natural conditions, this facility does not involve a health hazard because when infants are weaned, lactose disappears from their diet. In a prosperous society, however, infants are never weaned, in the sense that lactose remains in their diet from birth to death. Not only is milk, therefore, high in calcium but its lactose content also enables it to bypass the control mechanism of the body (Bronner 1987).

It might be mentioned that when milk is fermented, lactose is converted into lactic acid, a biologically inactive substance. Fermented milk and its products, such as cheese, are very high in calcium but do not provide the facility for evading the intestinal control for its absorption. This is the probable reason that the correlation between mortality from coronary disease and cheese consumption is much weaker than it is with the consumption of whole milk.

If the quantity of calcium absorbed from the intestine exceeds requirements, a good excretory mechanism exists for disposing of the excess. The kidneys normally excrete about 100 mg/day. Concentration of calcium in the urine (hypercalciuria) involves the risk of stone formation in the kidneys, but a second excretory mechanism is available to support them. The surplus calcium becomes protein bound and is excreted by the liver, not the kidneys. In individuals in prosperous countries, the concentration of protein-bound calcium in the plasma, 1.16 millimoles (mmol) per liter (l), is nearly as high as that of diffusible calcium, 1.34 mmol/l (Ganong 1987), demonstrating that calcium intake in Western countries, indeed, tends to be excessive.

The effective excretory mechanism ensures that most of the surplus calcium is eliminated, but a small fraction escapes and is ultimately precipitated in soft tissues. Under normal conditions, this process is so slow that a large dietary calcium excess can be tolerated for decades, the calcification of soft tissues becoming a health hazard only in old age. Misuse, however, can overwhelm the excretory mechanism. In the 1950s, for example, it was customary to treat gastric ulcer patients with large quantities of milk, amounting to about 2 liters per day, until a disproportionately high mortality from coronary disease was observed among them (Briggs et al. 1960). Two liters of cow's milk contains 2.4 grams of calcium, together with lactose facilitating its absorption from the intestine. The calcium absorbed from this source by the body may amount to a daily intake of 1.8 grams, perhaps 6 times the amount needed by elderly individuals. The excretory mechanism may well be incapable of dealing with such a gross excess.

As noted, excess calcium that cannot be excreted ultimately finds its way into soft tissues. Large arteries, notably the aorta, are particularly vulnerable to calcification. The heavy calcification of the aorta in individuals who died of heart disease was already observed by the pioneers of medicine in the nineteenth century, who correspondingly called the disorder "the hardening of the arteries."

Calcium deposits in arteries have two important pathological effects. One is the calcification of atherosclerotic plaques. A recent autopsy study by A. Fleckenstein and his group (1990) has found that atherosclerotic lesions appear to attract calcium from their earliest stage onward. Fatty streaks already contain, at an average, 10 times as much calcium as the surrounding normal arterial tissue. Normal atherosclerotic plaques contain 25 times as much, advanced plaques in individuals who died of coronary disease, 80 times as much. Such advanced plaques are, in effect, calcium plaques. Calcium compounds, mainly apatite, constitute about half of their dry weight, cholesterol and its compounds about 3 percent. It is calcium that gives advanced plaques bulk and rigidity and makes them potential obstacles to blood flow.

Secondly, mural deposits of calcium in the aorta and other large elastic arteries encroach on their elasticity. As pointed out, these arteries constitute an elastic reservoir that is distended when the heart injects a volume of blood into it during systole, storing energy in its stretched elastic tissues. The contraction of the reservoir generates diastolic pressure and maintains blood flow in the circulatory system when the heart is at rest. As the heart compresses its own arteries when it contracts, its perfusion is entirely dependent on an adequate diastolic pressure.

If the elasticity of the reservoir deteriorates, an increasing systolic pressure is needed to maintain diastolic pressure at a given value. Perfusion failure in a part of the heart occurs when the aging, partly calcified elastic reservoir cannot generate sufficient pressure to force an adequate quantity of blood through narrowed and obstructed coronary arteries. Calcification is involved both in the reduction of diastolic pressure generated by the reservoir and in the obstructions presented by advanced atherosclerotic plaques. Thus, calcium excess in Western diets may well be the most important factor in the pathogenesis of coronary artery disease (Seely 1989, 1991). If the populations of Western countries were alerted to this possibility and advised to reduce their consumption, a large reduction in mortality could well be the result.

In a recent trial (Woods et al. 1992), coronary patients were treated with magnesium sulphate with beneficial results. A possible explanation is that the excretion of the four main electrolytes – sodium, potassium, calcium, and magnesium – is an interlinked process. The most difficult task of excretion for the kidneys arises when the intake of these minerals is unbalanced, high in some, low in others. Thus in the 1960s, rats on a high-cholesterol diet also had their food unbalanced in electrolytes, with an excessive sodium–potassium and calcium–magnesium ratio (Sos 1965). The rats died of repeated, humanlike heart attacks, but their lives could be prolonged if the imbalances were moderated. Thus, if human diet has an excessive calcium content, the best remedy would be its reduction, but failing that, an increase in magnesium intake can be beneficial.

As mentioned in the section "A Statistical Study," epidemiological studies show a positive correlation between mortality from coronary artery disease and the consumption of oats, as well as of milk. The calcium content of oats, 80 mg/100 g, is high, but the strong correlation with coronary disease would probably arise only if they also contained some substance promoting the absorption of their calcium from the intestines. An oat grass, *Trisetum flavescens,* is known to contain vitamin D_3, capable of causing calcinosis in grazing animals, but no data are available to show that this also applies to cultivated oats.

The apparent connection between mortality from coronary disease and climate has been noted. The countries with very high mortality, such as Finland, Latvia, Lithuania, and Russia, have cold climates. In warmer climates, mortality is generally lower and, in tropical countries, very low or nonexistent. This may be explained by corresponding differences in calcium excretion. In a cold climate, the amount of calcium excreted by sweating is usually small, whereas a person doing hard physical work in the tropics can lose more fluid, and possibly more calcium, in sweat than in urine.

If arterial calcification is one of the main causes of death from coronary disease – the "skeleton in the atherosclerosis closet," as a recent article called it (Demer 1995) – this could be a blessing in disguise. The most important source of dietary calcium is one easily identifiable food item, cow's milk – hence, arterial calcification is *preventable.* The best way of achieving such prevention would be the reduction of milk consumption, particularly by elderly people. An alternative course might be the elimination of lactose from fresh milk. As mentioned, the worldwide toll of coronary disease is about two million deaths per year. The possibility deserves careful consideration.

VOLUME ONE

List of Tables, Figures, and Maps — *page* xix
List of Contributors — xxix
Preface — xxxvii
Acknowledgments — xxxix
*Introduct*ion — 1

Part I Determining What Our Ancestors Ate — **11**

I.1. Dietary Reconstruction and Nutritional Assessment of Past Peoples: The Bioanthropological Record — 13
Clark Spencer Larsen

I.2. Paleopathological Evidence of Malnutrition — 34
Donald J. Ortner and Gretchen Theobald

I.3. Dietary Reconstruction As Seen in Coprolites — 44
Kristin D. Sobolik

I.4. Animals Used for Food in the Past: As Seen by Their Remains Excavated from Archaeological Sites — 51
Elizabeth S. Wing

I.5. Chemical Approaches to Dietary Representation — 58
Ted A. Rathbun

I.6. History, Diet, and Hunter-Gatherers — 63
Mark Nathan Cohen

Part II Staple Foods: Domesticated Plants and Animals

II.A. Grains **75**

II.A.1. Amaranth 75
Mary Karasch

II.A.2. Barley 81
Joy McCorriston

II.A.3. Buckwheat 90
G. Mazza

II.A.4. Maize 97
Ellen Messer

II.A.5. Millets 112
J. M. J. de Wet

II.A.6. Oat 121
David M. Peterson and J. Paul Murphy

II.A.7. Rice 132
Te-Tzu Chang

II.A.8. Rye 149
Hansjörg Küster

II.A.9. Sorghum 152
J. M. J. de Wet

II.A.10. Wheat 158
Joy McCorriston

II.B. Roots, Tubers, and Other Starchy Staples

II.B.1. Bananas and Plantains 175
Will C. McClatchey

II.B.2. Manioc 181
Mary Karasch

II.B.3. Potatoes (White) 187
Ellen Messer

II.B.4. Sago 201
H. Micheal Tarver and Allan W. Austin

II.B.5. Sweet Potatoes and Yams 207
Patricia J. O'Brien

II.B.6. Taro 218
Nancy J. Pollock

II.C. Important Vegetable Supplements

II.C.1. Algae 231
Sheldon Aaronson

II.C.2. The *Allium* Species (Onions, Garlic, Leeks, Chives, and Shallots) 249
Julia Peterson

II.C.3. Beans, Peas, and Lentils 271
Lawrence Kaplan

II.C.4. Chilli Peppers 281
Jean Andrews

II.C.5. Cruciferous and Green Leafy Vegetables 288
Robert C. Field

II.C.6. Cucumbers, Melons, and Watermelons 298
David Maynard and Donald N. Maynard

II.C.7. Fungi 313
Sheldon Aaronson

II.C.8. Squash 335
Deena S. Decker-Walters and Terrence W. Walters

II.C.9. Tomatoes 351
Janet Long

II.D. Staple Nuts

II.D.1. Chestnuts 359
Antoinette Fauve-Chamoux

II.D.2. Peanuts 364
Johanna T. Dwyer and Ritu Sandhu

II.E. Animal, Marine, and Vegetable Oils

II.E.1. An Overview of Oils and Fats, with a Special Emphasis on Olive Oil 375
Sean Francis O'Keefe

II.E.2. Coconut 388
Hugh C. Harries

II.E.3. Palm Oil 397
K. G. Berger and S. M. Martin

II.E.4. Sesame 411
Dorothea Bedigian

II.E.5. Soybean 442
Thomas Sorosiak

II.E.6. Sunflower 427
Charles B. Heiser, Jr.

II.F. Trading in Tastes

II.F.1. Spices and Flavorings 431
Hansjörg Küster

II.F.2. Sugar 437
J. H. Galloway

II.G. Important Foods from Animal Sources

II.G.1. American Bison 450
J. Allen Barksdale

II.G.2. Aquatic Animals 456
Colin E. Nash

II.G.3. Camels 467
Elizabeth A. Stephens

II.G.4. Caribou and Reindeer 480
David R. Yesner

II.G.5. Cattle 489
Daniel W. Gade

II.G.6. Chickens 496
Roger Blench and Kevin C. MacDonald

II.G.7. Chicken Eggs 499
William J. Stadelman

II.G.8. Dogs 508
Stanley J. Olsen

II.G.9. Ducks 517
Rosemary Luff

II.G.10. Game 524
Stephen Beckerman

II.G.11. Geese 529
Kevin C. MacDonald and Roger Blench

II.G.12. Goats 531
Daniel W. Gade

II.G.13. Hogs (Pigs) 536
Daniel W. Gade

II.G.14. Horses 542
Daniel W. Gade

II.G.15. Insects 546
Darna L. Dufour and Joy B. Sander

II.G.16. Llamas and Alpacas 555
Daniel W. Gade

II.G.17. Muscovy Ducks 559
Daniel W. Gade

II.G.18. Pigeons 561
Richard F. Johnston

II.G.19. Rabbits 565
Peter R. Cheeke

II.G.20. Sea Turtles and Their Eggs 567
James J. Parsons

II.G.21. Sheep 574
Daniel W. Gade

II.G.22. Turkeys 578
Stanley J. Olsen

II.G.23. Water Buffalo 583
Robert Hoffpauir

II.G.24. Yak 607
Richard P. Palmieri

Part III Dietary Liquids

III.1. Beer and Ale 619
Phillip A. Cantrell II

III.2. Breast Milk and Artificial Infant Feeding 626
Antoinette Fauve-Chamoux

PART V

Food and Drink around the World

Part V comprises a history of food and drink around the world, from the beginnings of agriculture in the Near East to recent excitement generated by the "Mediterranean diet." It is divided chronologically as well as geographically, which invariably creates anomalies and overlap that invite explanation. Illustrative is the treatment together of South Asia and the Middle East in view of the culinary impact of Islam on both regions. Or again, because of an abundance of available authorities on food and drink in the various European countries (and their many regions), that section could easily have mushroomed to the point of giving lie to a title that promised "world history." Thus, we have dealt with Greece, Italy, and the Iberian countries under the rubrics of "The Mediterranean" and "Southern Europe."

For the Americas, we have two Caribbean entries, which might seem somewhat disproportionate. But it should be noted that the chapter that provides a pre-Columbian historical background for the Caribbean region does so for South America and lowland Central America as well, whereas the chapter treating the period since 1492 reveals the mélange of cultures and cuisines of the region, in which those of Africa blended with others of Europe and Asia, even though the dishes often centered on plants originally cultivated by the region's indigenous peoples.

In Part V, alarm about the danger of the demise of national and regional cuisines is sometimes expressed – triggered, at least in part, by fast-food chains, born in the United States but now reproducing wildly across the globe from Mexico City to Moscow, Bridgetown to Brussels, and Phnom Penh to Paris. It is interesting to note how the standardized nature of fast foods contrasts so starkly with the usage of foods in an earlier period of globalization, which took place during the centuries following the Columbian voyages. Then, burgeoning nationalism ensured that although various cultures adopted most of the same foods, they prepared them differently, just as regional cuisines arose in similar fashion to proclaim a distinctiveness from the metropolis.

Yet, even though nationalism has faded in the West, the ongoing globalization of everything from economics to politics seems once again, in the case of foods, to be provoking a like reaction, doubtless because the homogenization process appears paradoxically to spur a need for cultural autonomy. Thus, although fast food has its place in a world in a hurry, it is almost certainly not the harbinger of planetary food uniformity it stands accused of being. Indeed, it is probably best to conceive of food globalization as a process of expanding the availability of more and more foods, reaching the point at which the ingredients of the national dishes of the world are increasingly available to anyone anywhere. Another comforting indication that national cuisines are not on the verge of extinction is the vital and rapidly expanding field of culinary history, discussed in the last chapter of Part V.

V.A

The Beginnings of Agriculture: The Ancient Near East and North Africa

The Sumerians may have said it best: "Food: That's the thing! Drink: That's the thing!" (Gordon 1959: 142). From bread and beer to wine and cheese, the people of the ancient Near East and North Africa developed a rich cuisine based on a set of crops and livestock domesticated in Southwest Asia, and a sophisticated technology of food preparation and preservation. This chapter traces the history of diet and foods of hunter-gatherers who lived at the end of the Stone Age in the Near East and North Africa, the impact of the development and spread of agriculture, and the social context of food and drink in early Mesopotamian and Egyptian civilization.

Geographical Background

Patterns of subsistence in any society reflect geography and cultural development. The civilizations of the ancient Near East and North Africa developed in a complex environmental mosaic that encompassed coasts and inland plateaus, high mountains and lands below sea level, barren deserts, fertile plains, and dense woodlands. The boundaries of the environmental zones have shifted over the years because the region has known both dry periods and moister phases.

People, too, have wrought changes on the land as they assisted the movement of plants and animals from their original homelands. Over the millennia, humans have turned deserts into gardens with irrigation, and have transformed naturally productive lands into deserts by overgrazing and fuel cutting. Specifying the environmental picture at any particular place and time is not an easy task.

Elevation has also had a profound influence on vegetation and climate in the Near East and, ultimately, the productive capacity of the land. Levantine mountains form the western border of the Fertile Crescent, and the Taurus-Zagros chain lies to the north and east, from Mediterranean Anatolia to southwestern Iran. The winter months bring the snow and rain that support forests and grasslands. The three main vegetational zones are forests in the mountains and hill zones surrounding the Fertile Crescent, steppe at slightly lower elevations, and desert in the lowlands.

The natural forest and steppe forest formations are dominated by oaks. Conifers of various types occur throughout. Pistachio is common in both the Mediterranean forests and the southern Zagros (Zohary 1973). This band of hilly country borders undulating grasslands and shrubby steppe to the south. Lying south of the steppe are the hot deserts of Arabia. The Tigris and Euphrates river systems originate in the mountains in the north, run through Mesopotamia, and drain into the Persian Gulf, providing a distinct riparian habitat, as well as an important source of water for irrigation. During the last 15,000 years, the margins of these environmental zones have shifted back and forth with drier and moister climatic phases (Zeist and Bottema 1991).

North Africa has a less hospitable environment than the Near East. The Sahara desert spans the continent; on its southern margins are the dry Sahel grasslands, and along its northern periphery are more semiarid lands. The immense Sahara has a varied terrain with scattered oases, depressions, high ground, rugged hills along the Red Sea coast, and mountains in the central region. Higher mountains lie to the northwest in the Maghreb. Along the North African coast, light winter rains sustain a narrow band of green. The Nile Valley is the lushest region in North Africa because of the river water derived from Equatorial Africa, but the desert lies just beyond the river valley.

The Near East
