Palm Oil

Although there are many different palms that can provide oil, palm oil of commercial importance is obtained from the African oil palm, *Elaeis guineensis.* The name *Elaeis* is derived from the Greek word for oil. Palm oil is obtained from the fruit, whereas palm kernel oil comes from the seed kernel. Their fatty acid compositions are different, with palm kernel oil having a high content of lauric acid (palm kernel oil is similar to coconut oil in fatty acid composition). Palm oil is currently one of the most common oils worldwide, and oil amounts have increased dramatically since the 1980s.

Palm oil use in human diets can be dated back as far as 3000 B.C. Crude palm oil has a long history of use in western Africa, and in the eighteenth century, trade in the oil began between Africa and Europe. Wild palms are still a significant source of oil in West Africa, but recent increases in oil-palm cultivation have occurred in Latin America and Southeast Asia, with about 70 percent of present-day world palm oil production centered in the latter region.

Palm is the highest yielding of the oil-bearing plants, with an average of between 4 and 10 tons of oil per hectare per annum. Three types of palm have been characterized: *Dura,* with a thin flesh and thick, hard shell; *pisifera,* with thick flesh and little or no shell; and *tenera,* with a thick flesh and intermediate shell. The *tenera* variety is a cross between a *dura* female and pollen-bearing *pisifera.* Because the progeny of *tenera* are not uniform, cloning (asexual reproduction) of this palm has been practiced to improve yield and quality.

Traditional processing of palm to obtain palm oil, as practiced by the local populations, includes separation of the fruit, softening of the fruit, maceration, pressing, and oil purification. The softening process usually takes place by allowing the fruit to ferment in a pile for several days. The fruit may be further softened by boiling and then maceration in a mortar. After placement in a large oil-impermeable container, the oil is separated by kneading the material. Oil is skimmed from the top and may be filtered and then heated to remove the water.

The quantity of recovered oil in older traditional processing was low (less than 40 to 50 percent of total oil), and the quality of this crude oil was poor, compared to oil extracted and refined with more modern methods. If the fruits are not quickly heat treated, the free fatty acid level increases rapidly because of fungal lipases, and indeed, free fatty acid contents as high as 50 percent have been measured in traditionally processed oils. The flavor of oil with a high free fatty acid content is preferred in some areas of West Africa, where palm oils have traditionally been unrefined and have always had a high free fatty acid content. However, for most people, very high free fatty acid levels usually make the oil unsuitable for food use and more amenable to industrial applications, such as soap making. Oils obtained from wild trees by traditional processes are classified as soft (less than 12 percent),

Table II.E.1.7. *Nontriacylglycerol materials in crude palm oil*

Component	Concentration (ppm)
Carotenoids	500–700
Vitamin E compounds	699–1,000
Sterols and sterol esters	360–600
Squalane and aliphatic hydrocarbons	250–550

semisoft (less than 35 percent), or hard (greater than 45 percent), depending on the free fatty acid levels.

Crude palm oil contains a number of nontriacylglycerol components, including carotenoids, tocopherols and tocotrienols, sterols and sterol esters, phospholipids, and hydrocarbons (including squalane). The levels of these compounds in crude palm oil are shown in Table II.E.1.7. Palm oil contains very high levels of tocopherols and alpha tocotrienal (Table II.E.1.5). The carotenoids include lycopene and alpha and beta-carotene and are the cause of the deep red color of the oil. The main carotenoids are alpha- and beta-carotene, which make up over 90 percent of the total. Although there is experimental evidence linking dietary intake of carotene with protection against some types of cancer, the current practice is to remove the carotenes by bleaching to produce light-colored oil. Moreover, removing the carotenoids substantially improves the oxidative stability.

Recently, there has been a campaign virtually condemning the so-called tropical oils (palm, palm kernel, and coconut oils) as bad for human health. The argument has been that because they are high in saturated fats, these oils raise cholesterol levels in the body. Food products have been labeled "we use no tropical oils," their manufacturers and processors employing partially hydrogenated oils instead. Yet the notion that the addition of tropical oils to food products could lead to an increase in cardiovascular deaths ignores the fact that at least in Western diets (and especially in the United States), animal products and soybean oil are the main sources of saturated fats in the diet. It also ignores the cloud of suspicion now enveloping the use of partially hydrogenated oils.

The fatty acid composition of palm oil is quite different from that of coconut or palm kernel oil. The latter are lauric oils with about 80 to 90 percent saturated fat, predominantly lauric acid (41 to 55 percent), myristic acid (13 to 23 percent), and palmitic acid (4 to 12 percent). Palm oil is rich in oleic acid and low in saturates (less than 50 percent), relative to coconut and palm kernel oils. Experimental evidence so far indicates that there is no nutritional danger posed by the inclusion of palm oil in a Western diet, nor, for that matter, is such a danger posed by diets that derive a high percentage of total fat from palm oil (Berger 1994; Ong, Choo, and Ooi 1994). In fact, when palm oil is added to a Western diet, the level of plasma HDL cholesterol typically rises, leading to a better LDL:HDL ratio, and this ratio – rather than the amount of total plasma cholesterol – appears to be the better indicator of the risk of coronary artery disease.

Palm oil can be fractionated to produce olein and stearin fractions; when heated to about 28° C, some 25 percent of the total remains solid (palm stearin). The liquid fraction (palm olein) has a greater unsaturated fatty acid content and can be further fractionated at 20–22° C (facilitated by the addition of a solvent) to yield a more liquid fraction, as well as an intermediate one. The fatty acid compositions of palm olein and palm stearin are shown in Table II.E.1.8. These fractions can be used for particular applications; for example, palm olein is commonly added to infant formulas because of its high oleic acid content. Plastic fats containing zero trans fatty acids are developed by interesterifying palm stearin and a more saturated fat, such as palm kernel oil. Palm olein has been used as a frying medium and has excellent stability because of its low linoleic and linolenic acid content and high levels of tocopherols. Cocoa butter equivalents can also be developed by using intermediate palm oil fractions.

Sunflower Oil

The sunflower *(Helianthus annuus)* is a wildflower that originated in the Americas. It was taken to Spain in 1569 for ornamental use, but later was grown for its oilseeds, especially in Russia. Newer, high-oil strains of sunflower have been developed, with oil contents upwards of 40 percent, as compared with 20 to 32 percent for traditional varieties.

Sunflower oil has a naturally high level of linoleic acid and is low in linolenic acid. The fatty acid composition of sunflower oil is highly variable and depends on climate, temperature, genetic composition, stage of maturity, and even the positions of individual seeds on the head of the flower. As the temperature of a region of sunflower cultivation increases, the oleic acid content increases and that of linoleic acid decreases, although together they always comprise about 90 percent of the fatty acids in sunflower oil.

Table II.E.1.8. *Fatty acid compositions (weight percentage) in palm olein and stearin*

Fatty acid	Olein	Stearin
12:0	0.1–1.1	0.1–0.6
14:0	0.9–1.4	1.1–1.9
16:0	37.9–41.7	7.2–73.8
16:1ω7	0.1–0.4	0.05–0.2
18:0	4.0–4.8	4.4–5.6
18:1ω9	40.7–43.9	15.9–37.0
18:2ω6	10.4–13.4	3.2–9.8
18:3ω3	0.1–0.6	0.1–0.6
20:0	0.2–0.5	0.1–0.6

A typical fatty acid composition in cold environments includes 14 percent oleic acid and 75 percent linoleic acid, whereas in warm environments, it is 50 percent oleic and 43 percent linoleic acid. Because most sunflowers are grown in moderate climates, however, the actual variation in sunflower oil composition is, as a rule, not as marked as it might be.

New varieties of sunflower oil have been developed with modified fatty acid compositions. The fatty acid composition of a sunflower oil high in oleic acid is shown in Table II.E.1.4. High-oleic sunflower oils originated in Russia in the mid–1970s as a result of selective breeding and mutagenesis. The original Russian high-oleic line, "Prevenets," has been developed into sunflower lines that have a stable high–oleic acid composition minimally affected by growing temperature (Morrison, Hamilton, and Kalu 1994). The high-oleic acid and low-linoleic acid composition makes the oil very suitable for frying, and the oxidative stability of products fried in high-oleic sunflower oil is excellent. However, flavor quality has been reported to suffer if the linoleic acid level is too low.

Crude sunflower oil contains a number of non-triglyceride components, including waxes, sterols, hydrocarbons, and tocopherols. Waxes, which create problems because they produce clouding of the oil, are removed in a process whereby the oil is cooled and the solids that develop are filtered off. The tocopherols in sunflower oil consist primarily of alpha-tocopherol, which is good from the viewpoint of human nutrition because this tocopherol is the most biopotent form of vitamin E. However, tocopherols stabilize oils from oxidation, and the gamma and delta forms are much more active antioxidants in vitro than the alpha. In sunflower oil, the low levels of these tocopherols produce a lower-than-expected oxidative stability when compared to other vegetable oils with a higher degree of unsaturation.

Rapeseed (Canola) Oil

Rapeseeds include a number of closely related species in the genus *Brassica.* The three main species *(Brassica nigra, B. oleracea,* and *B. campestris)* have been manipulated by hybridization and chromosome doubling to produce *B. napus, B. carinata,* and *B. juncea.* The different Brassica species have different seed sizes, colors, oil contents, and proximate compositions. The term "rapeseed" is used for any oil-bearing Brassica seed, including that of mustard. Common names for some rapeseed species are shown in Table II.E.1.9.

Table II.E.1.9. *Common names for rapeseed species*

B. napus	Rape, rapeseed, oil rape, oilseed rape, swede rape
B. campestris	Turnip rape, rapeseed, oil turnip, polish rape
B. juncea	Leaf mustard, Oriental mustard, Indian mustard, rapeseed
B. nigra	Black mustard
B. oleracea	Kale, cabbage

The use of rapeseed oil for food and illumination originated in Asia (later spreading to the Mediterranean and Europe), and today, it is the most widely used cooking oil in Canada, Japan, and some other countries. Cultivated in India at least 3,000 years ago, rapeseed was introduced into China and Japan by the time of Christ. By the thirteenth century, rapeseed was cultivated for oil in Europe – especially eastern Europe – and recently, it has been grown in Canada and the United States. Its first use was probably as an oil for lamps and lubrication; in addition, the nourishing oil cake residue of rapeseed makes a good feed for cattle.

Research in the 1960s showed that the erucic acid found in rapeseed oil caused fatty infiltration of the heart and changes in the cardiac muscle in experimental animals. The oil was therefore banned in many places, and although subsequent work showed that rapeseed oil presented no threat to human health, there were intensive efforts to develop low–erucic acid cultivars of the plant. In 1985, the U.S. Food and Drug Administration (FDA) conferred a GRAS ("Generally Recognized As Safe") status on rapeseed products; not only was the oil deemed safe, but because of its very low content of saturated fat, it suddenly became viewed as the most healthy of cooking oils. Following the GRAS designation, U.S. production increased greatly, from 27 million pounds in 1987 to almost 420 million by 1994 (Trager 1995). In addition to its own production, the United States imports huge amounts of the oilseeds from Canada, although the end product's name was changed, understandably, from rapeseed to Canola oil.

Recent developments in rapeseed breeding have resulted in seeds that are modified in fatty acid composition, and low–erucic acid rapeseed (LEAR) oils have been produced by Canadian breeding work with *B. napus* and *B. campestris* (Table II.E.1.4). Double-low oils also are low in glucosinolates and include Canola (formerly Canbra) oil. To be considered a Canola or LEAR oil, the erucic acid content must be lower than 3.5 percent, although typically the level is less than 1 percent.

Canola oils are similar to soybean oils in that they contain appreciable levels of linolenic acid. Although some other vegetable oils have higher levels (for example, oils from flax seed or linseed contain about 55 percent linolenic acid), these are not common in the diet and are subject to very rapid rates of oxidation. In no small part because it has the lowest saturated fat content of any major cooking oil, Canola has been called an ideal mixture for health, nutrition, and food use (Ackman 1990). The oil has high amounts of oleic acid, reasonably low linoleic acid, and a moderate omega-6 to omega-3 ratio. The high-oleic level is beneficial nutritionally, as oleic acid tends to lower LDL cholesterol, with no drop – and even a slight increase – in HDL cholesterol, resulting in a net positive change in the HDL:LDL ratio.

Peanut Oil

The peanut or groundnut *(Arachis hypogea),* like the bean, is a member of the family Leguminosae. It is native to South America, probably originating in or around lowland Bolivia, but as early as 3100 to 2500 B.C., peanuts were common on the coast of Peru, and by the time of the Columbian voyages, they had spread throughout much of the New World (Coe 1994). In the sixteenth century, the peanut was carried to West Africa from Brazil by Portuguese traders, and because it was first brought to the United States from West Africa in slave ships, the misconception arose that the plant was of African origin.

While the Portuguese moved the peanut eastward, the Spaniards carried it west. It was introduced into the Philippines by Ferdinand Magellan and spread thereafter to other parts of Asia. Peanuts can be grouped into four different types: Runner, Spanish, Virginia, and Valencia. Runner peanuts are small and high yielding, Spanish are small seeded, and Virginia are large seeded. Valencia are large seeded and are often found with 3 to 5 seeds per pod.

Normal peanut oil has almost no linolenic acid and about 25 percent linoleic acid. As a rule, it contains about 50 percent oleic acid and is considered a premium oil for food use because of its excellent stability and its pleasant, nutty flavor. As with some other oilseeds, temperature affects the fatty acid composition, with cool climates resulting in greater linoleic and lower oleic acid levels. High-oleic peanuts were developed at the University of Florida during the 1980s and have subsequently become commercially available. A typical fatty acid composition of a high-oleic peanut oil is shown in Table II.E.1.4. Peanut oil, including the high-oleic variety, is characterized by relatively high levels of long-chain saturated fatty acids (up to 6 percent), up to and including 26:0. High-oleic peanut oil is between 7 and 10 times more stable in the face of oxidation than normal peanut oil (O'Keefe, Wright, and Knauft 1993), and roasted high-oleic peanuts have about twice the shelf life of normal peanuts (Mugendi, Braddock, and O'Keefe 1997; Mugendi et al. 1998).

P. J. White (1992) has pointed out that in the past, peanut oil was wrongly reported to contain significant levels of linolenic acid because of the mistaken identification of 20:0 or 20:1ω9 as linolenic acid. Depending on analytical conditions, it is possible to have coelution of linolenic and 20:0 or 20:1ω9. Similarly, reports exist in which arachidonic acid (20:4ω6) has been mistakenly identified in vegetable oils, but, in fact, arachidonic acid has never been found in vegetable oils.

Cottonseed Oil

Cotton (any of the various plants of the genus *Gossypium*) has been grown for its fiber – used in the manufacture of rope and textiles – for close to 5,000 years. Doubtless, in the distant past, the oil-rich cotton seeds were also utilized for illumination, as a lubricant, and probably for medicinal purposes. Indeed, most of the vegetable oils seem to have been first utilized for such nonfood applications.

The widespread use of cottonseed oil, however, is a relatively recent phenomenon that began in the United States. Some of the oil is derived from the extra-long staple *G. barbadense,* but the overwhelming bulk of the world's production (90 to 98 percent) comes from the short staple *G. hirsutum,* and short-staple cotton had to await the invention of the cotton gin by Eli Whitney in 1793 to become commercially viable. Thereafter, short-staple cotton spread across the southern United States, and surplus seed was converted into oil. Initial attempts at commercialization, however, were unsuccessful: Unlike long-staple cotton, the short-staple species had a tough seed coat that retained lint.

This problem was resolved in the middle 1850s with the invention of a machine to crack the hulls. High oil prices encouraged cottonseed oil extraction, and in the late 1880s, the Southern Cotton Oil Company was founded in Philadelphia. Its many seed-crushing mills, located throughout the South from the Carolinas to Texas, made it the largest producer of cottonseed oil, as well as the first U.S. manufacturer to make vegetable shortening.

One problem that remained was the odor of cottonseed oil, but this was eliminated at about the turn of the twentieth century with a deodorizing process invented by the company's chemist David Wesson. The procedure involved vacuum and high-temperature processing and led to the production of Wesson Oil, which revolutionized the cooking-oil industry (Trager 1995). Thereafter, cottonseed oil became the first vegetable oil to be used in the United States and then the dominant oil in the world's vegetable oil market until the 1940s.

Cottonseeds contain gossypol, which is produced in the seed glands and must be removed or destroyed in both oil and meal. Gossypol is heavily pigmented and can produce a dark color in the oil, and it is also toxic. Fortunately, it can be almost completely removed during the refining process, and in addition, glandless seeds devoid of gossypol have been developed.

Crude cottonseed oil contains as much as 1 percent of cyclic fatty acids. The main fatty acids are malvalic and sterculic, which are present in the form of glycerides. Cottonseed oil is characterized by a high saturated fat level, which is much higher than that of corn, canola, soybean, sunflower, peanut, and safflower oils.

Coconut Oil

The coconut palm *(Cocos nucifera)* has been enthusiastically described as the "tree of life" or the "tree of heaven" because it provides leaves and fiber for the construction of dwellings and shells for utensils, as well as food, milk, and oil. Although the coconut palm has been exploited by humans for millennia, its origin is subject to debate, with some scholars claiming it to be native to South America and others supporting a Southeast Asian origin. The question is a difficult one because coconuts can still germinate after floating on the ocean for months, a capability which has facilitated their spread throughout the tropical world. Compared with other oilseed crops, coconuts have a high per-acre yield of oil, about half of which is used in nonfood applications (such as soaps and cosmetics), whereas the other half goes into foods.

Coconut oil is extracted from the dried meat of the nuts (copra). Copra has one of the highest fat contents of all the materials used for oil (Table II.E.1.1), making it easy to obtain oil by pressing. Coconut oil contains high levels of the medium chain saturated fatty acids (10:0, 12:0, and 14:0) and is solid at room temperature.

The saturation of coconut oil confers a high degree of stability toward oxidation, but hydrolysis of coconut oil to yield free fatty acids causes soapy off-flavors because of the free lauric acid present. Fatty acids longer than lauric acid, however, produce little or no off-flavor.

Animal Fats and Oils

Milkfat (Butter)

Milkfats are derived from any number of different animals, but most by far is provided by the bovine; consequently, in this chapter, milkfat means that from cows. A lactating cow can produce as much as 30 kg of milk per day with a milkfat level of 2.6 to 6 percent, and thus for many years, butterfat was produced in greater quantity than any other fat or oil.

Milkfat, which has a much more complex composition than any of the other common fats, contains about 97 to 98 percent triglycerides, 0.1 to 0.44 percent free fatty acids, 0.22 to 0.41 percent cholesterol, and 0.2 to 1.0 percent phospholipids. More than 500 different fatty acids have been identified in milk lipids. The fatty acid patterns in milkfat are complicated by mammary synthesis of short-chain fatty acids and extensive involvement of rumen bacteria in lipid synthesis and modification (Jensen 1994). As a rule, butterfat is predominantly composed of palmitic acid, followed by oleic and myristic acids (Table II.E.1.10). About 66 percent of the fatty acids in a typical milkfat are saturated. The trans fatty acid levels in milkfat have reportedly ranged between 4 and 8 percent.

Table II.E.1.10. *Fatty acid composition of butterfat (weight percentage)*

Fatty acid	Range
4:0	2.8–4.0
6:0	1.4–3.0
8:0	0.5–1.7
10:0	1.7–3.2
12:0	2.2–4.5
14:0	5.4–14.6
16:0	26–41
18:0	6.1–11.2
10:1	0.1–0.3
12:1	0.1–0.6
14:1ω5	0.6–1.6
16:1ω7	2.8–5.7
18:1ω9	18.7–33.4
18:2ω6	0.8–3.0

There has been a great deal of interest over the past 30 years in modifying the fatty acid composition of butterfat to decrease the saturated fat content (Sonntag 1979b). Because cows have a rumen, fats that are directly provided in the diet are extensively degraded and hydrogenated. The fat also can have negative effects on the rumen bacteria, causing a lowering of milk and milkfat production. This problem has been solved by providing "protected" fats to the animal.

Methods of protecting fats from rumen metabolism include the polymerizing of protein around fat with formaldehyde and the preparation of calcium soaps, which are mostly insoluble at rumen pH. Dairy fats with high linoleic acid contents have been developed, but they suffer from severe quality problems and are unmarketable (McDonald and Scott 1977).

Recently, dairy fats have been prepared with high oleic and low saturate composition by feeding a calcium salt of high-oleic sunflower oil (Lin et al. 1996a, 1996b). This has provided lower saturated fatty acid composition and higher monoene while maintaining product quality. Oleic acid oxidizes about 10 times more slowly than linoleic acid and provides a better health benefit.

Marine Fats

Marine fats and oils, which are among the oldest exploited by humans for food and other uses, are divided into those from fish (cod, herring, menhaden, sardine, and so forth), from fish livers (cod, shark, halibut), and from marine mammals (whales). Marine oils are characterized by a very complex composition compared to vegetable oils and many animal fats, which poses challenges in the accurate identification and quantification of their fatty acids. Moreover, data derived from old technology may not be accurate.

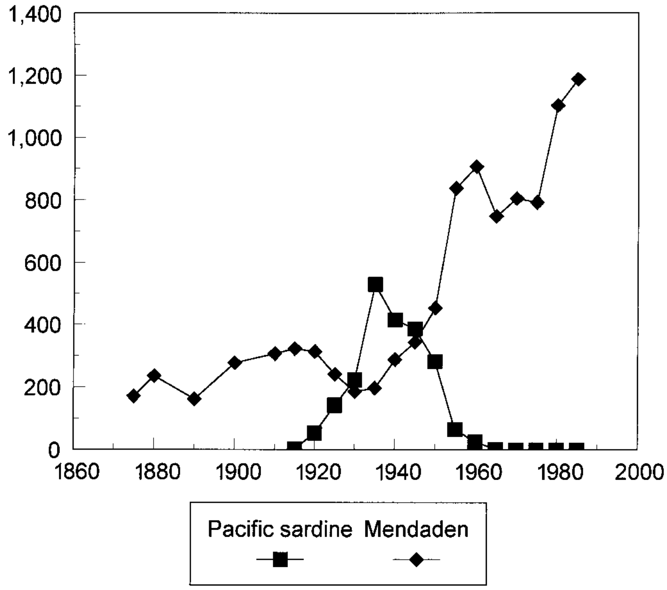

Figure II.E.1.5. Effects of overfishing in Pacific sardine fishery, 1918–60.

Fish oils. Fish oils are obtained from tissues that contain a high fat content, including those of herring, pilchard, menhaden, and anchovy. The production of the various fish oils is dependent on both fishing efforts and overfishing. In Figure II.E.1.5, it can be seen that the Pacific sardine fishery was extremely successful for about 20 years, after which the fish stocks were depleted so that a fishery could no longer be supported. It is sad to note that this is the rule rather than the exception in many fisheries worldwide.

Early production methods consisted of boiling the fish in water, followed by pressing, and then removing the oil by skimming. Improved oil quality and recovery was obtained as steam cooking and screw presses were introduced. Much of the fish oil produced in earlier days went into nonfood uses, such as linoleum, paints, and soaps.

Currently, oils from marine sources constitute some 2 to 4 percent of the world's consumption of fats, and about one-third of the world's fish catch consists of small and bony but high-fat fish that are converted into fish meal and oil. Fish oils for food use are often partially hydrogenated because they oxidize rapidly in comparison with vegetable or animal fats and oils. Partial hydrogenation results in a loss of polyunsaturated fatty acids, monoenes, dienes, and trienes, which obviously has negative effects on the nutritional value of hydrogenated oils. Because of the interest in omega-3 fatty acids found in fish oils, recent work has focused on the incorporation of processed, but not hydrogenated, fish oils in food products.

Fish liver oils. The livers of some fish have a high fat content and are rich in vitamins A and D. Although many different species of fish (for example, pollock, haddock, shark, halibut) have been exploited for their liver oils, the cod has provided more than 90 percent of the total volume. Cod livers contain from 20 to 70 percent fat; the range is so great because codfish deposit fat prior to spawning and deplete it during spawning. Thus, there is a cyclical fat content in their livers, and this has a dilution effect on the levels of the fat-soluble vitamins.

Cod liver oil was reportedly used for medicinal purposes in the eighteenth century, long before the discovery of vitamins or an understanding of most nutritional diseases. Medical uses included treatment of bone afflictions, rheumatism, tuberculosis, and, later, rickets. There was an intensive search for the active ingredient in cod liver oil that caused such positive therapeutic effects. The hunt was described by F. P. Moller (1895: 69):

> The oldest of these active principles, iodine, was detected as one of the oil's constituents as far back as 1836. . . . When the iodine active principle was exploded another, trimethylamine, took its place, and as a result herring brine, from being a rather neglected commodity, became for a short time the desideratum of the day. After a quick succession of other active principles, too evanescent to be worthy of even an obituary notice, the turn came for the free fatty acids. No theory and no fact then supported the idea that these acids were the active principle. . . . Still, the belief entered some active mind that they were the essential constituents.

Moller concluded incorrectly that there was no specific active principle in cod liver oil. Yet, liver oils provide fat-soluble vitamins. However, when consumed at the levels required to derive significant health benefit from the fatty acids present in fish liver oils, there is a risk of hypervitaminosis A or D.

The levels of fat-soluble vitamins in various fish liver oils are shown in Table II.E.1.11. Excessive levels of both vitamins A and D_3 can be toxic. Although the actual value is not clear, as little as 50 micrograms of vitamin D_3 per day over extended periods appears to produce toxicity symptoms in humans (Groff, Gropper, and Hunt 1995). Daily levels of 250 micrograms for several months have resulted in soft-tissue calcification, hypertension, renal failure, and even death. The recommended daily intake of vitamin D is 5 to 10 micrograms. The vitamin D level in fish oils ranges up to 750 micrograms per gram. Obviously, extended daily use of a high-potency fish oil should be avoided. Cod liver oil, which constitutes the majority of all liver oils sold today, has modest but nutritionally significant levels ranging up to 7.5 micrograms per gram.

The recommended daily intake of vitamin A is 1,000 retinol equivalents. One retinol equivalent is equal to 1 microgram of all-trans retinol. Toxicity is seen at levels around 10 times greater than the RDA, so that a daily intake of 10 mg of all-trans retinol would result in toxic symptoms. Symptoms of toxicity include itchy skin, headache, anorexia, and alopecia. The extremely high vitamin A levels in some liver oils would make it fairly easy to consume toxic amounts of vitamin A.

Whale oils. Whale oils are derived from marine mammals. The worldwide production of whale oils has decreased as populations of whales have been depleted. Oils from the baleen whales (sei, right, blue, humpback, and minke), as well as toothed and sperm whales, have been employed in industrial applications and human food use. Sperm whales *(Physeter macrocephalus),* in particular, were prized in the past for their "spermaceti" oil, which was used in smokeless lamps, as a fine lubricant, in cosmetics, and in automatic transmission oils. One sperm whale could yield 3 to 4 tons of spermaceti.

Table II.E.1.11. *Fat-soluble vitamin levels in fish liver oils*

Fish liver oil	Vitamin A, retinol equivalents/g	Vitamin D_3 µg/g
Cod	165–3,000	0.5–7.5
Haddock	45–900	1.3–1.9
Dogfish	60–45,000	0.1–0.7
Halibut	1,200–49,500	13.8–500
Mackerel	900–49,000	19–25
Tuna	15,000–300,000	400–750
Hake	480–960	0.25–3.3
Swordfish	6,000–120,000	50–625

Whale oils saw food use in some, but not all, countries when whale harvests were high. Europe, Canada, and Japan, for example, utilized hydrogenated whale oil in margarines for almost 50 years. During that time, the production of fish oils was much lower, increasing only as the production of whale oil decreased. Whale oils were also employed in the manufacture of shortenings after hydrogenation, a process which results in the production of many trans fatty acid monoene isomers.

Conclusion

The types and amounts of fats and oils that have been consumed vary greatly worldwide among people and have changed significantly over the past century. Fatty acid intakes will undoubtedly change in the future as oilseeds with altered fatty acid compositions reach new markets.

II.E.2 Coconut

Milk Bottle on the Doorstep of Mankind

In prehistoric times, the water content of the immature coconut fruit was more important as a drink than was any part of the mature nut as a food. In recent history, the emphasis has also been on a nonfood use of coconuts as oil. The oil extracted from the kernel of the ripe coconut is an industrial raw material for products ranging from soap to explosives. From prehistory to the present, coconut has served many human communities around the tropics in a variety of ways. In 1501, King Manuel of Portugal itemized some of its uses at a time when the coconut was first becoming known in Europe: "[F]rom these trees and their fruit are made the following things: sugar, honey, oil, wine, vinegar, charcoal and cordage . . . and matting and it serves them for everything they need. And the aforesaid fruit, in addition to what is thus made of it, is their chief food, particularly at sea" (Harries 1978: 277).

Unfortunately, it is not possible to provide as much information as one might want on the coconut in prehistory. This is because heat and humidity work against the preservation of fossils, and thus there is a dearth of archaeological materials, coprolites, and biological remains on tropical seashores where the coconut palm is native. Coconut residues do not accumulate because the palm grows and fruits the year round. This makes crop storage unnecessary and, in fact, because of their high water content, coconut seednuts cannot be stored; they either grow or rot. And the tender, or jelly, coconut is even less likely to survive in storage.

The sweet liquid in the immature fruit, however, is safe to drink where ground water may be saline or contaminated. It is a very pleasant drink, and coconuts are readily transported by land or sea.

In short, coconut is potable, palatable, and portable! Unlike drinks that are bottled, canned, or otherwise packaged, coconuts are sustainable and recyclable. It has been suggested that as the "milk bottle on the door step of mankind" (Harries 1981), the coconut could have played a significant role in the diets of our human ancestors in the time before agriculture.

Leafy Vegetables, Fruits, and Nuts

Millionaire's Salad

Although not strictly a green leafy vegetable, coconut heart of palm can be compared with blanched leafy vegetables, such as endive, or celery, or globe artichoke. It has been called "millionaire's salad" on the assumption that only the very rich can afford to fell an entire palm and have the leaf stalks cut away to expose the large bud, which is the part that is eaten. Palm hearts are best eaten fresh, but they can be cooked, canned, or pickled (Harries 1993).

Other palms can also be employed in this manner; indeed, with some palm species, harvesting heart of palm is a commercial operation. Certainly palm heart production could easily be commercialized for the coconut palm, especially in tropical coastal areas where tourism has replaced indigenous agriculture. One coconut heart may account for 40 side salads, and over-aged palms, overgrown seedlings from coconut nurseries, and those sprouting like weeds in neglected groves could be used for this purpose. It would even be practical to plant them at high density for sequential harvesting.

Farmers, however, are reluctant to cut down coconut palms, even when these are over-aged. They do not thin out palm stands that are too dense to be productive, and they usually ignore overgrown seedlings. All this may be attributable to a past in which the coconut palm was potentially the sole surviving food plant after a tidal wave or hurricane. Thus, the notion persists among some that to cut down a coconut palm threatens future life support. Moreover, in some communities, coconuts are planted to celebrate a birth, and if the palm dies or is felled, the human life it was planted to commemorate may be jeopardized. A recent example of the extreme reluctance to cut down the trees occurred during Liberia's civil war, when coconut palm hearts were eaten by the starving population only as a last resort.

Apple for the Teacher

Botanically, the coconut fruit is a drupe. Plums, peaches, and cherries, which are also drupes, have edible outer parts to encourage dissemination by animals. Other palms as well, particularly the date, have soft, sweet, and edible fruit, but the coconut is different because the outer covering, the husk, is generally bitter and stringy when young and dry and fibrous when mature. However, some rare individual coconut palms have an edible husk that is less fibrous, spongier, easily cut, and sweet to chew like sugar cane (Harries 1993).

The coconut "apple" is, botanically, the haustorium of the germinating seed. The haustorium begins to develop at the earliest stage of germination, even before the shoot or roots emerge through the husk. Coconuts harvested in this condition are suitable for domestic purposes or for second-grade copra, but generally not for desiccated coconut. Often the apple is put aside to eat. It is slightly sweet, and slightly oily, with a cottony texture. As the endosperm lasts up to 15 months during germination, a large apple is found in well-developed seedlings. In places where coconuts grow, children walking to school may grasp the leaves of a sprouted seednut and uproot it. Still holding it by the leaves, they swing it against the trunk of the nearest mature palm to split the husk and crack open the shell. Then they pick out and eat the apple (Harries 1993).

An unusual form of the mature coconut has a jelly-like endosperm. This can be eaten fresh, scooped with a spoon from the shell of the freshly cracked coconut. It is called *makapuno* in the Philippines, where it is highly esteemed, and *dikiri-pol* or similar names in India and Sri Lanka. It is known in other coconut-growing countries, such as Indonesia, and has been reported in the Solomon Islands. The most interesting fact about it is that the embryo is normal but can only be germinated under the artificial conditions of a tissue culture laboratory.

A coconut with aromatic endosperm, favored in Thailand for drinking and preparing a cooked dessert, is also known in Malaysia and Indonesia.

Lovely Bunch of Coconuts

The coconut has at times been treated as something of a joke by Europeans, and it was popularized in the music hall song, "I've got a luverly bunch of coconuts." Historically, it was first introduced to Europe as *Nux indica,* or the nut from the Indies. This was possibly a generic name applied to the shells of all other palms that survived the long overland journey; and it may have referred to nutmegs as well (Ridley 1912). Such nuts and shells were kept as novelties, and even ornamented (Fritz 1983).

Friar John of Montecorvino (around 1292) described *Nux indica* as "big as melons, and in colour green, like gourds. Their leaves and branches are like those of the date palm" (quoted in Desmond 1992: 9). But it was not until after the Portuguese sailed to the Indian Ocean in 1499, and brought back fresh samples, that the coconut was distinguished from other palm fruits and from the nutmeg (although people in the countries where these plants grow cannot imagine that such a confusion could exist).

After the fibrous husk is removed, the brown, hard-shelled nut can be split to expose the kernel. Unlike an almond, for example, which also has a fibrous outer covering, a shell, and a kernel, the coconut is generally not used as a nut because of its large size, although health food and vegetarian shops often include slices of coconut kernel in packets of mixed nuts. In England, coconuts sold in greengrocers' shops (without husks) are usually split open and hung outside for birds to feed on, especially in winter.

Oils, Fats, and Food

Fish and Chips

Coconut oil is most certainly a part of the diet in the countries where it grows. But equally importantly in those countries, it may be an unguent for the hair, an emollient for the body, a rust inhibitor for iron, and a fuel for lamps. Its first industrial use in Europe was as a lubricant in textile mills, although it subsequently became important to soap makers. Some of the latter are among today's industrial giants, and they still import coconut oil for the excellent lathering properties it imparts. It is interesting to note, however, that when soap manufacturers began using coconut oil, they unintentionally fostered the fish and chip shop.

This famous institution, the forerunner of all fast-food takeaways, became part of the social fabric in Britain (Harries 1988). Fish and chips date from the middle of the nineteenth century. Before then, local "soap-boilers" accumulated animal fat as the major ingredient of laundry soap. But animal fat was chiefly available in the winter months, when animals were slaughtered if they could not be fed, whereas coconut oil was available year-round from overseas colonial possessions that had an abundance both of the crop and of cheap labor.

Whether for soap or for cooking, coconut oil was particularly acceptable because it was convenient to handle. In a cool climate it does not even look like oil; below 20° to 26° C it becomes a greasy, somewhat crystalline, white or yellowish solid fat. In other words, outside the tropics, coconut oil becomes solid and resembles animal fat. It was also a good substitute for animal fat because there was no risk from infectious disease in its production.

The virtues of coconut oil were extolled at the beginning of the twentieth century in an advertisement for "Nut Lard" as:

> an absolutely pure vegetable fat, extracted from the coco-nut. It is sweeter than ordinary lard or butter, and cheaper than either. It is white, odourless, does not turn rancid and is infinitely superior to ordinary lard for all culinary purposes. It can be used with the most delicate dishes without altering the natural flavour of the dish.

This advertisement went on to state that "'Nut Lard' contains neither salt nor water . . . [and] [i]n cold weather, 'Nut Lard' may become hard – it should then be shredded before using. . . ." The most telling part of the advertisement was that "'Nut Lard' is unequalled for frying fish, it does not splutter, there is no smell, and it can afterwards be strained and kept for future use" (Anon. 1912: 41–2).

It was in the nineteenth century that such flamboyant advertising became a significant factor in marketing. In particular, industrial soap makers started large-scale advertising of their products, with the prepackaged brand names that still survive today. Such competition put the small, local soap boilers out of business, and when they could no longer sell soap, they looked for something else to do with their existing equipment – deep copper pans over open fires. The coconut oil they had previously used for soap was now put to work frying fish and chips.

Coconut Oil

In coconut-growing countries, coconut oil is prepared in the home by heating coconut milk until a clear oil separates. Commercially, the extraction of oil from copra (dried or smoked coconut meat) is one of the oldest seed-crushing industries in the world. Extraction methods range from simple techniques employed in villages to modern high-pressure expellers and prepress or solvent extraction plants that can process more than 500 tons of copra a day. In Indonesia, some processors cook chopped fresh kernel in previously extracted coconut oil before pressing. Various methods have been developed for "wet" processing of edible grade oil and flour from fresh meat, but none are yet commercially viable (Harries 1993).

Coconut oil is the most important of the small group of commercial fats that contain a high proportion of glycerides of lower fatty acids. The chief fatty acids are lauric (45 percent), myristic (18 percent), palmitic (9 percent), oleic (8 percent), caprylic (7 percent), capric (7 percent), and stearic (5 percent). There is also a minute amount of tocopherol (vitamin E). The natural volatile flavor components of fresh meat and oil are mostly delta-lactones. Lauric oils are characterized by high saponification value and have the lowest iodine value of vegetable oils in common industrial use. Coconut oil, as it is ordinarily prepared in tropical countries, ranges from colorless to pale brownish yellow in hue. In temperate climates, or air conditioning, it appears as a greasy, somewhat white or yellowish, solid fat that has a melting point between 20° and 26° C. Until refined, it has a pronounced odor of coconut. Coconut oil is refined, bleached, and deodorized using standard vegetable oil–processing technology. If coconut oil is cooled until crystallization, part of the oil produces a semi-solid mass, which is then separated under hydraulic pressure.

The solid fraction, coconut stearine, is a harder fat with a higher melting point. It is used as a valuable confectionery fat and as a substitute for cocoa butter because of its brittleness and "snap" fracture. The liquid fraction, coconut oleine, has a correspondingly lower melting point and is used in margarine manufacture. Hydrogenation converts its unsaturated glycerides into stearic glycerides. The resulting product has a melting point higher than coconut stearine and is used as a brittle confectionery fat, which resembles cocoa butter. When refined and deodorized, coconut oil mixed with nonfat milk is often used as a replacement for whole milk. Other uses include the making of imitation dairy products, coffee whiteners, soft-serve desserts, frozen desserts, whipped toppings, milk shake mixes, and chocolate-filled milk.

Coconut oil is used because of its bland flavor, resistance to oxidation, and stability in storage, as well as a unique liquefying property that contributes to the "mouth-feel" of the food of which it is a component. The main nonedible uses are in soaps, detergent foam boosters, lubricating oil additives, mineral flotation agents, shampoo products, and corrosion inhibitors. Lauric oils enhance the lathering quality of soaps, and this quality makes coconut oil particularly useful for hard water or marine soaps. A feature of soapmaking with coconut oil is the higher yield of glycerol (14 percent compared with 10 percent for most oils). Other nonedible uses include illuminating or fuel oil in rural areas and in ceremonial lamps. Coconut stearine is also used to advantage in candle manufacture. Coconut oil will directly fuel unmodified diesel engines.

Copra

When the industrial demand for coconut oil developed in the nineteenth century, sailing schooners, and later tramp steamers, visited Pacific islands where the palm was plentiful. Fresh coconuts are a bulky and perishable cargo because of the husk and high water content. The fruit is made up of about 50 percent husk, 12 percent shell, 10 percent water, and only about 28 percent meat (kernel). The fresh coconut meat itself contains about 47 percent moisture. Thus, it was more convenient to ship copra, which the islanders could prepare in advance by drying the kernels, either in the sun or, if needed quickly, over a fire.

Commercial copra plantations today still use sun drying, direct firing over a barbecue, or indirect hot air in various sorts of kiln. The moisture content is reduced from between 45 and 50 percent to between 6 and 8 percent, and the oil content increases from 35 percent to between 60 and 65 percent. For safe storage, the moisture content of copra should be 6 percent, yet at the first point of sale it often has a much higher level. It dries further during storage, but molds may attack under such conditions. One of these is *Aspergillus flavus,* which produces aflatoxin. The possible presence of this carcinogen should serve as a stimulus for industry to improve copra quality or to bypass making it and process the fresh fruit instead (Harries 1993).

Edible (Ball) Copra

Copra may also form naturally inside the whole ripe nut. As early as the middle of the sixth century, Cosmas Indicopleutes said of the coconut: "If the fruit is gathered ripe and kept, then the water gradually turns solid on the shell, while the water left in the middle remains fluid, until of it also there is nothing left over" (Desmond 1992: 7). Copra formation occurs when nuts are kept in dry environments, and with those varieties that do not germinate quickly. The endosperm (kernel) eventually comes away from the shell and forms a ball of copra that rattles loosely inside the nut. The husk can remain intact so that the shell will not crack, and the whole copra-formation process requires some 8 to 12 months. Fires may be lit to help the drying. The heat and smoke do not contaminate the endosperm, which retains a very high quality (Harries 1993).

Copra Cake and Copra Meal

After the oil is extracted from copra, a good-quality residual cake will contain 6 to 8 percent oil, with a protein content of around 20 percent. Copra meal, the solvent-extracted residue, is 1 to 3 percent oil, depending on the efficiency of the plant. Cattle and poultry feeds incorporate both cake and meal; this combination results in firmer butter and harder body fat in cattle than that induced by other oil cakes. Cake with a high oil content is generally fed to pigs, but a deficiency in certain amino acids, notably tryptophan, lysine, methionine, and histidine, limits the amounts used in animal feeds. If aflatoxin is present in poorly prepared copra, it can pass into the cake or meal (Harries 1993).

Coconut Flour

Coconut flour suitable for human consumption is produced when oil is extracted from fresh coconut kernels rather than from copra. The flour is used in making bread and other foods. But, as just noted, it is not superior to other protein sources in the proportions of the various amino acids (Harries 1993).

Coconut–Confectionery

Sugar and Honey

The coconut palm is also a fine source of nectar. It begins to flower 3 to 5 years after planting, depending on growing conditions, and once started, it opens a new inflorescence regularly at 25- to 30-day intervals throughout the year. The palm goes on flowering for the remainder of its 80-year or longer life span. Every inflorescence includes hundreds of male flowers that open sequentially over a 3-week period, and each contains a drop of nectar when first open, which attracts honey bees and bumblebees in the early morning. Each inflorescence also carries female flowers, sometimes more than a hundred. For about a week each month, female flowers are receptive to pollination for a day or two and produce an almost continuous flow of nectar droplets from three exposed and easily accessible nectaries. The flowers are also visited by birds (honeyeaters), and even by lizards.

The activity of insects draws attention to the nectar, whose sweetness is readily sampled by touching with a finger (easily reached in young palms). These may have been the clues that encouraged early domesticators and cultivators to find a way of increasing the flow of nectar. This method is known as tapping, and it produces toddy, as described in detail in the section "Water into Wine."

Sweet toddy, boiled in shallow pans to its crystallization point, gives a 12 to 15 percent yield of jaggery. This rough sugar is hard, semicrystalline, and golden brown in color. A lesser degree of concentration gives treacle (or syrup) (Harries 1993). Beehives are often kept in coconut groves to enhance fruit set. The year-round flowering in a coconut plantation assures a perpetual supply of nectar, and the hives can also serve as sources of pollen.

Desiccated Coconut

The characteristic taste of coconuts (when mature) and, to a certain extent, their texture (when grated and dried, or desiccated), are among their most important features for spicing and flavoring. In the United Kingdom, television advertisements for a chocolate-covered, coconut-filled confection give an entertaining, but faulty, impression that the coconut falls from the palm already peeled and neatly split in half. In reality, the manual labor involved in making desiccated coconut, including harvesting, peeling, cracking, deshelling, and shredding, is far from amusing and not necessarily rewarding. Australians like their favorite cake covered with desiccated coconut, which makes Australia a large importer of this product. Yet, farmers on neighboring Pacific islands, who cannot grow much else than coconuts, neglect the crop because of low world market prices for their product.

Desiccated coconut was first manufactured in the early 1880s. It is an important product, sensitive to changes in production costs, and easily susceptible to overproduction. Nuts are stored for three or four weeks before being dehusked in the field and carried to the factory. When the shell is chipped off, the kernel comes away easily. Damaged or germinated nuts are rejected to make low-grade copra. The brown testa is removed, usually by hand, though machines are available. The kernels are then washed and sterilized to avoid the risk of salmonella. After sterilization, disintegrators reduce them to a wet meal, or cutters produce fancy cuts, such as threads or chips. Drying is by indirect drier at 75–80° C, or by direct firing at 120° C. The dried product is cooled and graded before being packed. Parings, oil, and drain oil are byproducts.

Desiccated coconut should be pure white, crisp, and have a fresh taste. It should have less than 2.5 percent moisture, 68 to 72 percent oil (on dry weight), less than 0.1 percent free fatty acid (as lauric), and about 6 percent protein. If there is more than 6 to 7 percent sucrose, then sugar has been added. Unavailable carbohydrate is about 18 percent and crude fiber about 4 percent, and there is some mineral content. Desiccated coconut is widely used in sweets, biscuits, cakes, and cake fillings (Harries 1993).

Coconut – Milk, Water, and Wine

The "Cocoa's Milky Bowl"

Dr. Samuel Johnson's *Dictionary* of 1755 contained run-together articles on coco (the nut) and cocoa (the source of chocolate). As a result, spelling became confused, and for some time the word coconut was misspelled as "cocoa-nut." Thus, the poetic allusion to the "cocoa's milky bowl" refers to the "coconut," *Cocos nucifera,* and not to cocoa, *Theobroma cacao* (Child 1974). Yet even explaining this commits a further solecism, because coconut "milk" is a manufactured product. Unfortunately the distinction between coconut milk and coconut water is not always kept clear, even in research publications by coconut scientists. Coconut milk is prepared by squeezing freshly grated endosperm, usually with a little added water, through cloth. On storing, coconut cream forms an upper layer, and when either emulsion is heated, a clear oil separates. This is the basis of the time-honored village method of oil extraction. But coconut cream is also produced industrially in both liquid and spray-dried forms, and the national cuisines of coconut-growing countries use it extensively (Harries 1993).

Water into Wine

Both alcoholic and nonalcoholic beverages that are products of the coconut palm depend on the technique known as toddy tapping. As with other fruit juices, the watery sap that is the toddy can be converted to wine and other products by fermentation and distillation (the sugar content of coconut water from the immature nut also allows it to be fermented, but this is not common). Many types of palms are tapped in Southeast Asia, and the practice dates from at least the seventh century (Burkill 1935).

Unlike maple or rubber trees, which are dicotyledons where the layer of cambium below the bark is tapped, palms are monocotyledons, and the vascular strands are scattered through the tissue. Casual observers sometimes think that it is the coconut leaf stalks that are tapped. In reality, tapping uses the unopened flowering inflorescence. This is a large structure which, when cut in the tapping process and seen from ground level, could, indeed, be mistaken for the cut leaf stalk. There are many flowering stalks within an inflorescence, each able to exude sap. They are packed tightly into an enveloping spathe that would normally split to allow pollination. Binding the spathe tightly prevents it from splitting naturally. It may also be lightly beaten and flexed to stimulate sap flow. Once ready, the end is cut off to allow the sap to drip into a receptacle. The toddy tapper visits the palm, morning and evening, to decant the accumulated sap from the container before fermentation gets too active. Sap flow continues for many days, and each day a sliver is removed to reopen blocked vascular elements and increase flow. This continues until only a stump remains, and the next inflorescence in sequence is prepared.

Obviously, tapped bunches do not flower normally, and the palm ceases to set fruit. If the sap flow decreases, the palm is allowed to rest. The palm may respond with particularly high yields of fruit on the next normal bunches. Excessive tapping followed by high fruit set could shorten the life of the palm. However, the financial return to the farmer would more than compensate for this shorter life (Harries 1993).

Toddy is initially sweet and watery, and the containers used to collect it are rinsed but not sterilized between uses. Because the weather is warm where coconuts grow, and collection is slow because the palms have to be climbed, fermentation to alcohol is practically unavoidable.

Toddy produced overnight and collected first thing in the morning contains about 3 percent alcohol and 10 percent fermentable sugar. Certain additives may slow or stop fermentation. Otherwise, fermentation continuing for 33 hours produces palm wine with an 8 percent alcohol content. Sweet, unfermented toddy contains 16 to 30 milligrams of ascorbic acid per 100 grams, and the content changes little during fermentation. The yeast in fermented toddy adds vitamin B (Harries 1993).

Arrack is the product of the distilling of fermented toddy. Doubly distilled arrack is the basis of local gins, rums, and so forth, with the addition of appropriate flavors.

As with other wine-making substances, coconut toddy can also become vinegar. Fermenting toddy with free access to air produces 45 percent acetic acid in 10 to 14 weeks. This is matured in closed casks for up to 6 months and, perhaps, flavored with spices and colored with caramel.

Coconut Water

The entertainer Harry Belafonte may not have been completely accurate when he sang that coconut water was "good for your daughter" and "full of iron," or that it could "make you strong like a lion." But he was praising the one thing about coconut that makes it different from all other plants – the large amount of water in the immature fruit.

Modern texts on coconut underrate the value of coconut water or overlook the part it played in the domestication of the coconut. Earlier writers had no such reservations. In 1510, Ludovici de Varthema wrote that "[w]hen the nut begins to grow, water begins to be produced within; and when the nut has arrived at perfection, it is full of water, so that there are some nuts which will contain four and five goblets of water, which water is a most excellent thing to drink . . ." (cited in Harries 1978). As mentioned, coconut water is often wrongly called milk. As early as 1583, by which time the coconut had become well known, Father Thomas Stevens praised the ubiquitous coconut and its refreshing milk [sic], saying "this is so abundant that after drinking the contents of one nut, you scarcely feel the need of another" (Desmond 1992: 29).

The immature fruit, used for drinking, will not fall naturally but must be cut from the palm. Bunches are selected just as they reach maximum size, when a jellylike endosperm begins to line the cavity of the still thin and soft shell. At this stage each nut is full size, full of water with no airspace (it does not splash when shaken), and very heavy. Usually, the harvester cuts one or two entire bunches of nuts and lowers them to the ground on a rope. If they fall, the weight of water cracks or even bursts the soft shell inside the soft husk, whereupon the water drains away and the fruit rots (Harries 1993).

The coconut that is freshly harvested from a bunch that has been in the sun has a natural effervescence and will hiss with released gas when opened. Nevertheless, nature's "packaging" of this "product" leaves it at a disadvantage against internationally trademarked colas and mineral waters, because young coconuts deteriorate over a few days unless kept cool. Cutting away some of the husk reduces their size so they can be more efficiently kept in refrigerated storage, which extends "shelf life" considerably. There are instances when coconuts meant for drinking are transported hundreds of kilometers in refrigerated trucks, but this occurs only when such a vehicle would otherwise travel empty, where the roads are good, and where an affluent urban market has no other access to coconut. Moreover, the use of the coconut as a drink is marginalized by most conventional agricultural treatments. It is seen as reducing the crop of copra from which oil is extracted.

At the proper stage, coconut water contains about 5 percent sugar, and a large nut may have as much as 25 grams of sugar. The water also contains minerals, amino acids, and vitamin C. In addition to fermenting easily, yielding alcohol and vinegar, coconut water has auxinic and growth-promoting properties when used in plant tissue culture. Historically, various medicinal values were attributed to it. There is no doubt that it is a fine oral rehydration fluid for the severe diarrhea of cholera and other diseases. Because coconut water is naturally sterile, it may be injected intravenously to substitute for blood plasma in emergency surgery, and in combination with egg yolk, it finds use as a diluent in artificial insemination.

Coconut – The Tree of Life

Depending on variety, coconut fruit takes from 11 to 15 months to reach maturity, and the palm produces a new inflorescence every 3 to 4 weeks. This means that all the stages of fruit development, from youngest to oldest, are present on any palm at any given time of the year. In the fourteenth century, Jordanus of Séveras, who thought that the coconut was a "marvel," wrote that "both flowers and fruit are produced at the same time, beginning with the first month and going up gradually to the twelfth," so that there are flowers and fruit in eleven stages of growth to be seen together (quoted in Desmond 1992: 9). In this respect it meets the specifications of the biblical Tree of Life, "which bare twelve manner of fruits, and yieldeth her fruit every month" (Revelations 22:2).

According to Peter Martyr (d'Anghiera), writing about 1552, "[s]ome people believe that the germs of these trees were brought by the waves from unknown regions" (Harries 1978: 270). Four hundred years or so later it is now speculated that coconut may have originated on the coasts and islands of Gondwanaland, after which a wild form floated into the Indian and Pacific Oceans, but not the Atlantic. Domestication subsequently occurred in the Malaysian region (Southeast Asia and the western Pacific). The wild and domestic forms were both taken into cultivation, and introgressive hybridization between them produced the wide range of varieties recognized today (Harries 1990).

The original importance of the coconut palm was to coastal communities. With fish and shellfish to eat, coconut provided refreshing, sweet, and uncontaminated drinking water in an otherwise saline environment. No tools were needed to get it, and daily consumption of the water contained in one or two coconuts was enough to ensure good kidney function. The wild type of coconut spread without human interference, but domestication enhanced its drinking qualities in particular. The domestic type depends on human activity for survival and dissemination (Harries 1979).

The coconut preceded the Polynesians in those parts of the Pacific region to which it could float, and the Polynesians took domesticated forms to the islands that they settled (Lepofsky, Harries, and Kellum 1992). Before the development of the copra industry, coconut was a multipurpose plant on small Pacific islands, and its food potential was neither more nor less important than any other use. But another use was in interisland transportation. The islanders in the Indian and Pacific Oceans discovered that coconut husk fibers could be important in building and rigging sailing ships. Moreover, they took young fruit on board, at the start of a voyage, as self-contained, individual servings of uncontaminated drinking water.

The coconut palm was first grown as a plantation crop in the 1840s, because the industrial process for making soap, patented in 1841, required a cheap source of oil, which coconut oil from copra (the dried endosperm of the nut) could provide. And then, between 1846 and 1867, the development of dynamite from nitroglycerine had the remarkable effect of turning glycerine, a once discarded by-product of soap manufacture, into a more profitable item (Harries 1978).

Thus, for industrial and political empire builders, the coconut was a cheap source of raw material and also of war material. The "coconut cult" and "coconut boom" were features of the stock market in the early years of the twentieth century, and coconut plantations were established throughout the tropics.

The strategic importance of the coconut following World War I was clearly demonstrated when the German territories in Africa and the Pacific, with their extensive plantations, were taken away as reparation. As a result, the Japanese administered the Caroline, Mariana, and Marshall islands and, in 1942, they added other important coconut-growing countries to their collection. At the time, Indonesia and the Philippines by themselves accounted for more than 50 percent of the world supply of copra; Indochina, Malaya, Borneo, New Guinea, the Solomons, and the Gilbert Islands provided a further 25 percent.

With the end of the World War II, as nuclear weapons displaced high explosives, the military importance of the coconut gave way to other oil crops. Thus, because of their high palmitic acid content, palm oil and cottonseed oil were preferred over coconut oil for making the new "conventional" weapon, napalm. Similarly, in industry, coconut oil soap, excellent for lathering in hard or saline water, and coconut fiber (coir), valued for resilient, water-resistant rope, were ousted by petroleum-based detergents and synthetic fibers (Harries 1978).

Other animal life forms besides humans have also been associated with the coconut. Two are of cultural interest in relation to coconuts, as well as being foods in their own right: the coconut crab and the palm weevil. The coconut crab, or "robber crab" *(Birgus latro),* is a massive land-living crab that can climb coconut palm stems and is reputed to cut off nuts before returning to the ground to eat them. Its association with the coconut is not purely fortuitous. The coconut travels long distances over the Indian and Pacific Oceans by interisland floating and can easily carry the small postlarval stages of the crab. This would account for the equally widespread distribution of an otherwise terrestrial crab, which only spends about 30 days of its larval life in coastal waters. Charles Darwin observed that the coconut crab "grows to a monstrous size," and "is very good to eat" (Harries 1983). Unfortunately, on many islands where it was once found, the crab has been eaten to extinction.

Palm weevils *(Rhynchophorus spp.)* are a serious pest in coconut groves, killing palms directly by burrowing in the stem, and indirectly as a vector of the red ring nematode. The palm weevil grubs grow as large as a man's thumb, and subsistence cultivators can collect hundreds of them from fallen or felled palm stems. When fried in their own fat and eaten, the larvae provide a protein- as well as an energy-rich diet.

Another insect activity related to the coconut is the gathering of pollen by honeybees, and today health-food shops sell coconut pollen. As with other pollens, it is collected by incorporating a trap in the hive entrance that removes the pollen pellets as the bees return from foraging. But it could also be collected directly from male flowers. Coconut breeders routinely harvest and process male flowers for kilogram quantities of pollen used in artificial pollination for F_1 hybrid seed production (Harries 1973). Here again, the year-round flowering of the coconut means that regular supplies of pollen are easy to maintain.

When coconut oil was first available in Europe, it was advertised as healthy, whereas animal fats or dairy products were associated with communicable diseases. Now noncommunicable diseases, such as heart diseases and cancer, are of more concern. But the routine use of coconut oil for frying fish or for making margarine had been discontinued in Western societies (mainly as a matter of economic supply and demand) long before the diet conscious became wary of coconut oil, and it continues to be used directly in tropical diets and for vegetable ghee in India.

Coconut oil is easily digested and is absorbed into the system almost as rapidly as butterfat. This is attributed to the low molecular weight of the fatty acids. In common with other vegetable oils, coconut oil contains virtually no cholesterol, but there are objections to its food use because of the high saturation of its fatty acids. In the United States, "tropical oils" have come under attack from pressure groups, whose criticisms overlook the fact that most coconut oil is used for nonedible purposes, and that many of its food uses are to improve the quality of factory-prepared products. Only in coconut-growing countries, where it makes lower quality protein and carbohydrates more acceptable and more digestible, is the coconut still used extensively for cooking. In fact, it may turn out that naturally saturated medium-chain coconut oil is healthier than artificially hydrogenated short-chain vegetable oils.

Finally, what more can be said about the coconut than was said in the "Account of Priest Joseph," circa 1505: "In conclusion, it is the most perfect tree that is found, to our knowledge" (cited in Harries 1978).

II.E.3 ~ Palm Oil

The oil palm *(Elaeis guineensis)* is a native of West Africa. It flourishes in the humid tropics in groves of varying density, mainly in the coastal belt between 10 degrees north latitude and 10 degrees south latitude. It is also found up to 20 degrees south latitude in Central and East Africa and Madagascar in isolated localities with a suitable rainfall. It grows on relatively open ground and, therefore, originally spread along the banks of rivers and later on land cleared by humans for long-fallow cultivation (Hartley 1988: 5–7).

The palm fruit develops in dense bunches weighing 10 kilograms (kg) or more and containing more than a thousand individual fruits similar in size to a small plum. Palm oil is obtained from the flesh of the fruit and probably formed part of the food supply of the indigenous populations long before recorded history. It may also have been traded overland, since archaeological evidence indicates that palm oil was most likely available in ancient Egypt. The excavation of an early tomb at Abydos, dated to 3000 B.C., yielded "a mass of several Kilograms still in the shape of the vessel which contained it" (Friedel 1897).

A sample of the tomb material was submitted to careful chemical analysis and found to consist mainly of palmitic acid, glycerol in the combined and free state, and a mixture of azelaic and pimelic acids. The latter compounds are normal oxidation products of fatty acids, and the analyst concluded that the original material was probably palm oil, partly hydrolyzed and oxidized during its long storage. In view of the rather large quantity found, the oil was probably intended for dietary purposes rather than as an unguent.

A few written records of the local food use of a palm oil (presumably from *Elaeis guineensis*) are available in accounts of European travelers to West Africa from the middle of the fifteenth century. Red palm oil later became an important item in the provisioning trade supplying the caravans and ships of the Atlantic slave trade, and it still remains a popular foodstuff among people of African descent in the Bahia region of Brazil (Northrup 1978: 178–86; Hartley 1988: 1–3; R. Lago, personal communication, 1993).

The British Industrial Revolution created a demand for palm oil for candle making and as a lubricant for machinery. In the early nineteenth century, West African farmers began to supply a modest export trade, as well as producing palm oil for their own food needs. After 1900, European-run plantations were established in Central Africa and Southeast Asia, and the world trade in palm oil continued to grow slowly, reaching a level of 250,000 tonnes (metric tons) per annum by 1930 (Empire Marketing Board 1932: 117–23; Hartley 1988: 8–23; Lynn 1989: 227–31).

Meanwhile, the invention of the hydrogenation process for oils and fats in 1902 created the possibility of Western employment of palm products as, for example, in the making of margarine. Yet hydrogenation was more useful for liquid oils like groundnut, palm kernel, and coconut oils than for palm oil. After World War II, further improvements in palm oil refining technology and transport methods made it possible to use largely unhydrogenated palm oil in Western food products (Lim 1967: 130–2; Martin 1988: 45–8).

A rapid expansion of the palm oil export trade followed, accompanied by a marked growth in the plantation sector of production. Between 1962 and 1982, world exports of palm oil rose from about 500,000 to 2,400,000 million tonnes per annum, and Malaysia emerged as the world's largest producer, accounting for 56 percent of world production and 85 percent of world exports of palm oil in 1982. Expanded production in Malaysia was achieved mainly by the privately owned estate sector, which increased its oil palm holdings more than tenfold in the 1960s and 1970s; and by the Federal Land Development Authority (FELDA), whose large-scale schemes organized oil production along plantation lines, although ownership was vested in the workforce of "smallholders" (Khera 1976: 183–5; Moll 1987: 140–62).

By 1990, world production had reached nearly 11,000,000 tonnes per annum, with a worldwide trade of 8,500,000 tonnes (Mielke 1991: 110). Although red palm oil is still used in soups and baked dishes in West Africa, elsewhere in the world, palm oil is eaten mainly in a highly refined form. Its food uses vary from the vanaspati and ghee of India to the margarine, cooking oils, and biscuits of Europe and the United States.

The Oil Palm: Wild and Planted

West Africa

West Africa is the classic region of smallholder production, both of food and export crops. The oil palm, which has been both, flourishes in natural association with yam and cassava cultivation throughout the wetter parts of the region. In eastern Nigeria, which

C. W. S. Hartley (1988: 7, 16) called "the greatest grove area of Africa," densities of 200 palms per hectare (ha) were common in the late 1940s, and densities of more than 300 palms per hectare were not unknown.

These palms were typically self-seeded and tended (to varying degrees) by local farmers. Farther west, in the kingdom of Dahomey and in settlements established by the Krobo people near Accra, some deliberate plantings may have been made as the palm oil export trade developed from the 1830s (Manning 1982; Wilson 1991). However, as J. Reid (1986: 211) has noted, the word *plantation* was often used by contemporary European observers to mean a food farm on which oil palms happened to be growing. Moreover, although in Dahomey descriptions exist of seedlings being transplanted from the bush onto areas cleared for farming by slaves, this does not mean that the practice was universal. In any event, palm oil exports from Dahomey were much smaller than from the Niger Delta, where oil palms were planted deliberately in swampy regions outside their natural habitat, but where the bulk of production was carried out using natural groves. In the 1840s, Dahomey and the Niger Delta exported approximately 1,000 and 13,000 tonnes per annum respectively; by the 1880s these totals had risen to 5,000 and 20,000 (Manning 1982: 352; Reid 1986: 158; Martin 1988: 28–9; Lynn 1989: 241).

Beginning in the late nineteenth century, a number of experimental oil palm plantations were created by Europeans in West and west-central Africa. One of the earliest was founded in Gabon in 1870 by Roman Catholic missionaries (E. J. Mulder, personal communication, 1968). But like many of the other nineteenth-century plantations in West Africa, these ventures were unsuccessful. By comparison with African smallholders, European planters were highly specialized and vulnerable to the marked trading fluctuations of the late nineteenth century. Many also lacked capital but committed themselves to long-term investments of a type that African farmers sensibly rejected.

In the case of palm oil, money was spent paying laborers to produce, plant, and tend seedlings, often on marginal land, in regions where natural groves already contained more palms than local farmers could spare the time to harvest (Hopkins 1973: 212–14; Martin 1988: 46).

Thus, when in 1907 William Lever sought large-scale land concessions in the British West African colonies in order to produce palm oil for his Lancashire soap mills, the Colonial Office was reluctant to help him. In a region characterized by small, fragmented, and often communally owned farms, it was felt that Lever's scheme would be hard to administer, politically risky, and commercially unsound. Lever was left to pursue his dreams in the Belgian Congo, where the existing levels of both trade and population were far lower and where the colonial administration welcomed European enterprise (Hancock 1942: 188–200; Wilson 1954: 159–67).

Following the Lever debate, the West African palm oil industry remained in the smallholders' hands. Few other entrepreneurs came forward to press the case for plantations, although a number of state-run estates were established under French influence in the Ivory Coast after 1960. By 1981 these estates covered a total of 52,000 ha, with a further 33,000 ha planted with oil palms in the surrounding villages (Hartley 1988: 31).

Yet even this development was relatively modest in scale, as shown in unpublished data from Nigeria, West Africa's largest producer of palm oil. The area of wild palm groves, only partly harvested, was estimated at 2,400,000 ha, whereas there were 72,000 ha of estate plantations and another 97,000 ha of smallholder plantations. Estate plantations, which require large consolidated areas, are still difficult to create in Nigeria because the oil palm–growing regions are densely populated and the complex traditional land holding system has been carefully preserved. Elsewhere in West Africa, population densities are lower, but the problems of obtaining labor to sustain plantation developments are correspondingly greater.

Central Africa

In the late nineteenth century, both the German colonizers of Kamerun and the Belgian rulers of the Congo were keenly interested in applying European farming and processing techniques to the palm oil industry (Laurent 1912–13; Rudin 1938; Jewsiewicki 1983). But German botanical and mechanical trials were cut short by World War I, following which the German territories in Africa were divided between the French and the British.

In the Congo, however, Lever's initial land- and produce-buying concessions (granted in 1911) proved to be the foundation for a long process of experimentation, which eventually revolutionized the palm oil industry worldwide. New planting materials led to dramatic increases in yields, thus cutting the cost of production; and improved machinery led to high oil quality at a competitive price. Alongside developments in European and American food-processing techniques, the Congo innovations paved the way for the entry of palm oil into Western diets.

Lever was originally more interested in setting up mills than plantations in the Congo, but his initial investments brought heavy losses (Fieldhouse 1978: 507–9). The fruit supply from wild trees proved hard to control, both in the amount brought to the mill and in its quality upon arrival. Overripe or bruised palm fruit made for highly acidic, low-quality oil, whereas unripe bunches gave low yields. Yet Lever Brothers (and its successor Unilever after 1929) was unwilling to incur the heavy initial costs of planting trees unless planting materials were improved to reduce the running costs. The Germans in Kamerun had identified an exceptionally thin-shelled palm fruit with a high oil content as early as 1902 (Hartley 1988: 50). But their "lisombe" palm, later to become known as the Tenera type, was found only rarely in the wild and failed to breed true.

In a renewed drive to encourage European investment in their colony and, in particular, in oil palm plantations, the Belgians began in 1922 to investigate this German discovery. An experimental plantation of Tenera palms was created at the Yangambi research station in the Congo, and in the 1930s these palms were subjected to a three-year testing program by M. Beirnaert. Meanwhile, private Tenera plantings had been made by Unilever and its subsidiary, the United Africa Company, in the British Cameroons and in the Belgian Congo itself (Courade 1977; Fieldhouse 1978).

Tenera seed also found its way to Sumatra and Malaya in the 1920s, although there, as in Central Africa, it failed to breed true. Beirnaert's painstaking experiments finally showed why: The Tenera palm was actually a hybrid of two other types, the thick-shelled Dura and shell-less Pisifera, and when self-pollinated would produce 50 percent Tenera, 25 percent Dura and 25 percent Pisifera (Beirnaert and Vanderweyen 1941).

Beirnaert's discovery was published at the height of World War II, and it was not until after 1945 that it could be turned to practical use with the establishment of large-scale and long-term Tenera breeding programs. It is ironic that the Congo was not the state that gained the most. Its oil palm plantations did expand from 52,000 ha in 1938 to 93,000 in 1945 and 147,000 in 1958, with a further 98,000 ha under smallholder cultivation by the end of that period (Mulder, personal communication, 1968; Hartley 1988: 30). But political unrest following independence in 1960 led to stagnation and decline in the industry.

Unilever, however, the most important single investor in 1960 with 47,000 ha under oil palms, remained loyal to the newly independent country of Zaire through two decades of intermittent losses and political uncertainty. Thus, Unilever managers remained in place following nationalization in 1975, and the company was allowed to take back full control of the estates two years later (Fieldhouse 1978: 530–45). But at a national level, the research effort was decimated, and new planting was very limited after 1960, in marked contrast to developments at the same time in Southeast Asia.

Southeast Asia

The oil palm was first introduced to Southeast Asia in 1848, when four seedlings, originating from West Africa, were planted in the botanical gardens at Buitenzorg (now Bogor) in Java (Hartley 1988, 21). But this introduction did not lead to a plantation industry for some time, although offspring of the palms were used as ornamentals by tobacco planters.

In 1905 a Belgian agricultural engineer, Adrien Hallet, arrived in Sumatra and noticed that its palms grew more quickly and bore a richer fruit than counterparts in the Congo, where he had previously worked. Just as the oil palms in southeastern Nigeria bore a fruit with more oily pulp and a smaller kernel than their counterparts farther west, so did the Deli Dura palms, descended from the four Buitenzorg seedlings, hold a distinct advantage over the ordinary Duras of West and Central Africa (Leplae 1939: 25–7; Martin 1988: 47).

This superiority probably reflected the optimal soils, rainfall, and sunshine conditions of Southeast Asia, rather than any special genetic quirks of the Buitenzorg palms. However, the fact that all the Deli Duras were descended from so few parents meant that the early planters could expect fairly uniform results (Rosenquist 1986). This lowered the risks associated with plantation cultivation, an effect reinforced by the absence of the palm's usual pests and diseases in its new geographic setting.

The relatively high yields and low risks from planting oil palms in Southeast Asia helped the industry to grow quickly, following the pioneering plantings of Hallet in Sumatra and of his friend Henri Fauconnier in Malaya in the 1910s. By 1919 more than 6,000 ha had been planted in Sumatra, rising to 32,000 in 1925, by which time 3,400 ha had come under cultivation in Malaya. Over the next five years, a further 17,000 ha were planted in Malaya, while the Sumatran area doubled.

This rapid expansion came not only because of growing confidence in the oil palm but also because of the grave postwar problems of the rubber industry. The oil palm was seen as a useful means of diversification to avoid a dangerous dependence on rubber. The pace of new planting slowed during the worldwide slump of the 1930s, but by 1938 Malaya had nearly 30,000 and Sumatra more than 90,000 ha under cultivation (Lim 1967: Appendix 5.2; Creutzberg 1975: Table 11; Hartley 1988: 21).

Developments in Sumatra hung fire for some time after 1945, as shown in Table II.E.3.1. Meanwhile, developments in Malaysia were more rapid, especially after 1960, when the replanting of old rubber estates with oil palms was stimulated by FELDA's smallholder schemes.

At the same time, the Malaysian government and the estate sector launched several systematic Tenera-breeding efforts, in which high-yielding parents were selected and through which increasingly productive planting materials were generated. The new trees not only yielded more fruit but also produced a type of fruit that was ideally suited to the new screw presses which, having been tried out in the 1950s in the Belgian Congo, became widely used in Malaysia from the mid-1960s. These innovative developments have been described as "one of the world's outstanding agricultural achievements" (Anwar 1981). The land area involved is shown in Table II.E.3.2.

Latin America

A distinct species of the oil palm, *Elaeis oleifera* (also known as *Elaeis melanococca*), is indigenous to Latin America. Since the late 1960s, plant breeders have begun to take an interest in this variety because its oil has a high iodine value and unsaturated fatty acid content, making it especially suitable for food use. However, the fruit is often small, with a thin oil-yielding mesocarp surrounding a large, thick-shelled kernel. Harvested bunches often contain a low proportion of fruit of quite variable quality. Hence, the plant has not been cultivated commercially, although it is frequently found in riverside or swampy areas, and the oil is used locally for cooking, soap boiling, and lamp fuel (Hartley 1988: 85–9, 681–3).

Elaeis guineensis seeds were introduced to Central America by the United Fruit Company, which brought seeds from Sierra Leone to Guatemala in 1920, and from Malaysia to Panama in 1926 and Honduras in 1927. Other introductions from Java and the Belgian Congo followed, but the first commercial planting of 250 ha took place only in Guatemala in 1940. The United Fruit Company's main interest was, traditionally, the production of bananas for export, but large banana-producing areas were destroyed by Fusarium wilt, and in consequence, oil palm and other crops were being tested as replacements.

The oil palm, however, proved vulnerable to disease in its new setting, and difficulties were encountered in identifying suitable growing conditions. Nonetheless, a successful development was founded on the northern coastal plain of Honduras, and in addition to developing plantations on its own land, the United Fruit Company stimulated oil palm cultivation by neighboring smallholders, whose fruit could then be processed in the company mills. Seed was also supplied to other Latin American countries (Hartley 1988: 33–6; D. L. Richardson, personal communication, 1993).

The beginnings of commercial planting in Latin America are summarized in Table II.E.3.3. By 1992 the total area planted to *Elaeis guineensis* in Latin America had grown to 390,000 ha – still a small fraction of the area in Africa or Southeast Asia. The distribution of plantings by country and sector is shown in Table II.E.3.4.

Processing Technology

Until the early years of the twentieth century, palm oil was processed only by traditional village methods, by which loose fruits were collected from the ground or a few bunches were cut from the tree. Beginning in the 1920s, however, the United Africa Company and British colonial officials in Nigeria started experimenting with steam cookers and hand presses designed to make production at the village level more efficient in terms of labor use and oil yield. Yet a lack of cash prevented most farmers from trying the new machinery, with the exception of a few lucky recipients of free samples or government subsidies in the 1940s (Martin 1988: 64–6, 127–9).

A separate process of trial and error led to the development of the sophisticated factories required to deal with the volume of fruit produced on modern plantations and to produce oil of the high and standardized quality that would appeal to Western food processors. Such factories handle almost all the palm fruit of Southeast Asia, whereas in West Africa and Latin America, processing is carried out by a wide variety of methods, yielding oil for local consumption and for industrial as well as edible uses in the West.

Whatever the scale and sophistication of the process, the following main steps are required:

1. Separation of individual fruits from the bunch.
2. Softening of the fruit flesh.
3. Pressing out of the oily liquid.
4. Purification of the oil.

Traditional Village Process

Whole, ripe, fresh fruit bunches (FFB) are cut from the palm. With young trees this can be done from ground level. With older trees in West Africa, harvesting is still often accomplished by a man climbing the tree, secured to it by a loop of rope or other locally available materials, such as rattan and raffia fiber (Vanderyst 1920). But on plantations, a curved knife attached to a bamboo is used. After cutting, most of the fruits are still firmly attached to the bunches, which are divided into a few sections, heaped together, moistened, and covered with leaves. Natural fermentation during two to three days loosens the fruits so that they can be picked off the bunch sections by hand.

Following this step, two major variants in the process are used to produce two oils with different characteristics – those of soft oil and those of hard oil. The regions producing each type have changed since Julius Lewkowitsch (1895: 429) identified Saltpond in present-day Ghana as the cheapest source of hard oil, and Drewin on the Ivory Coast as the best place to buy soft oil. But the basic methods have changed little since they were first described by colonial officials in the 1910s and 1920s (Laurent 1912–13; Gray 1922; Faulkner and Lewis 1923; Martin 1988: 32–3).

For soft oil production, the fruits are separated as soon as they are loose enough and boiled with water for 4 hours to soften the flesh, which is very fibrous. The cooked fruit is emptied into a large container, which may be a pit lined with clay, an iron drum, or a large wooden mortar. It is then reduced to a pulp with pestles or by treading it under foot. The resulting mash may be diluted with water, and the oil is skimmed off or squeezed out of the fibrous mash by hand. In some instances, a sieve made of palm fronds is used to retain the fibers. At this stage the liquid product, which contains oil, water, and fruit fibers, is often boiled up with additional water and skimmed again, although this step is omitted in some cases. Finally, the oil is again heated to boil out the residual water.

Lewkowitsch (1922: 546) also reported on the preparation of small quantities of oil for kitchen use directly from freshly picked fruit, by boiling the fruit and skimming the oil. Such oil had good keeping properties and often a free fatty acid content below 2 percent; but yield was very low, and not available for export.

In the hard-oil process, the fruit is allowed to ferment for 3 or more days longer than in the soft-oil process, until the flesh is soft enough. It is then pulped by treading underfoot in an old canoe or pounding in a mortar. Oil is allowed to drain out for up to 3 days, then water is added, and the mix is trodden again. Further oil rises to the surface and is skimmed. The oil is boiled up with water in another container and finished as described for soft oil.

These two processes differ in some important respects. The prolonged fermentation in the hard-oil process results in a much greater enzymic breakdown of the neutral fat and, therefore, in a much higher free fatty acid content. The yield obtained by this process is also much lower. However, it has a substantial advantage in that the labor and firewood requirements are also much lower. Table II.E.3.5 summarizes these differences.

Table II.E.3.5. *Comparison of village palm oil processes*

	Soft oil	Hard oil
Proportion of oil recovered	40–50%	20–40%
Free fatty acid content	3–12%	20–40%
Elapsed time to produce clean oil (days)	5–7	10–14
Human days' work for one ton oil*	420	133

*Includes harvesting.

Sources: Nwanze (1965), and personal communication, J. H. Maycock of the Palm Oil Research Institute of Malaysia (1991).

The strong characteristic flavors developed during both of these processes, as well as the naturally strong red color of the oil, are appreciated by local cooks and visiting gourmets, but they present severe limitations in the export markets. The high free fatty acid content and solid consistency of hard oil limits its range of uses, making it well suited to soap boiling but not to food processing. The solid consistency of hard oil is not due directly to the free fatty acids formed during the fermentation step but rather to the diglycerides, the other fragments obtained when one fatty acid is split from the neutral triglyceride molecule. M. Loncin and B. Jacobsberg (1965) have demonstrated the formation of a eutectic between triglycerides and diglycerides, resulting in a minimum melting point and maximum softness at a diglyceride content of 7 percent.

Mechanization of the Small-Scale Process

With the rapid twentieth-century growth in West African exports came the introduction of simple machines to reduce labor requirements and increase oil yield from a given quantity of fruit. Early machines, before and after the 1914–18 war, as described by Hartley (1988: 694–703), included a cylinder fitted with manually operated beaters, which was fed with softened fruit and hot water. After "beating," an oil-water mixture was run off through a sieve. Another system used a special cooker and a press as adjuncts to the soft-oil process.

The first device to become widely adopted, however, was a modified wine and cider press: the Duchscher press. This consisted of a cylindrical cage of wooden slats, held in place by iron hoops, and a ram on a screw thread. The screw thread was turned manually by means of long bars (in the manner of a ship's capstan), forcing the ram onto the pulped fruit. The exuding liquid was collected in a trough surrounding the cage.

Similar presses, but using a perforated cylindrical metal cage, are still in use today, giving yields of 55 to 65 percent of the oil present. A recent analysis of the needs for mechanization in the village has concluded that this is still the most practical implement, because it can be made and maintained locally and is inexpensive by comparison with other presses (C. E. Williams, personal communication, 1981). However, farmers in Nigeria (which was once the world's largest exporter of palm oil) have, since the 1950s, been reluctant to invest in this or other improvements because of the low producer prices offered by the state-controlled marketing boards. It is to be hoped that recent reforms of marketing structures in Nigeria and elsewhere in Africa will encourage renewed innovation at the village level (Martin 1988: 126–36).

The next development in pressing was the introduction in 1959 of the hand-operated hydraulic press by Stork of Amsterdam. This was capable of processing 600 to 1,000 pounds of fruit per hour and could recover 80 percent of the oil present. The hydraulic mechanism was later motorized.

A different approach to mechanization brought forth the Colin expeller (first patented in 1904), which in essence is similar to a domestic mincer. It consists of a perforated cylindrical cage, fitted with a spiral screw or "worm," which is turned manually through a gear. Cooked fruit is fed to the worm through a hopper, and the pressure developed as the worm pushes the fruit forward forces oil out through the perforations. Spent fiber and kernels are discharged at the end of the cage. The machine has a capacity of 100 kg cooked fruit per hour, or 250 kg per hour if motorized. The Colin expeller became popular after 1930, mainly in Cameroon. Its limitations were a reduced efficiency with Dura fruit, which forms the bulk of the wild oil palm crop; rapid wear of the screw; and a relatively high cost. The principle of the expeller, however, has been further developed into the screw press found in all modern oil mills (Hartley 1988: 703–5).

The presses described here provided a relatively efficient process for the step of pressing out the oily liquid during oil production and led researchers to seek improvements in the other steps. Several innovations have resulted from a project begun by the Nigerian Institute for Oil Palm Research (NIFOR) during the 1950s in cooperation with the Food and Agriculture Organization of the United Nations (FAO) and the United Nations Development Program (UNDP).

The following unit operations and equipment are involved in palm oil production.

1. Fruit bunch cookers, which are wood-fired cylindrical tanks. They are loaded with cut-up fresh fruit bunches (FFB).
2. A bunch stripper operated by hand, which consists of a cylinder made up of slats and turns on a horizontal axis that tumbles the cooked bunch sections until the individual fruits separate from the bunch and fall between the slats.
3. A digester (to break up the softened fruit and release its oil from its cells), consisting of a horizontal cylinder in which beater arms rotate, driven by a small diesel motor.
4. A hydraulic press, which was introduced in 1959.
5. A clarification unit consisting of two linked tanks, whereby heating with water causes the oil layer in the first tank to overflow at the top into the second tank. There it is dried by the waste heat from the fire under the first tank.

Extraction efficiencies of 87 percent at a free fatty acid (FFA) level of below 4 percent are routinely attainable by this process. Between a quarter and a half ton of fresh fruit bunches per hour can be processed, depending on cooker capacity.

A number of variants of this process are in use:

1. Bunches are allowed to ferment so that only loose fruit is loaded into the cooker. This variant yields oil of higher FFA.
2. The hydraulic presses may be driven by a small diesel engine.
3. Clarification can take place in simple tanks with direct heating.
4. Cooking of bunches may be by steam, whereby whole bunches are loaded into a tank fitted with a perforated plate about 15 centimeters (cm) from the base. Water is boiled under the plate, and the steam penetrates through the bunches.
5. In Ghana, an interesting operating procedure has been developed, in which the mill owner provides mill facilities to the farmers, who are then responsible for the bunch stripping and cooking of the fruit. Mill operatives carry out digesting and pressing procedures, after which the farmers take away the oil from their own fruit for clarification (G. Blaak, personal communication, 1989).

The advantages for the farmers are numerous: They need no capital investment in mill equipment; there are no arguments regarding purchase price of FFB; if farmers produce high-quality Tenera fruit, they retain the full benefit; and farmers pay only a processing charge. Their net profits are higher than those obtained selling FFB, even if they employ labor to carry out their share of the processing.

Larger-Scale Processes

The small-scale processes just described are suitable for the processing of FFB from wild oil palm groves or from smallholdings. The main objective is to produce red palm oil for traditional food use.

The processing of the large quantities of fruit produced by plantations or by large smallholder cooperatives, however, requires a progressively greater degree of mechanization and mechanical handling as the quantity increases. Furthermore, since oil produced on a large scale is usually intended for export or for local refinery processes, the ultimate objective is a neutral oil of bland flavor and nearly white color. To attain this quality, the processes (including the handling of FFB) are designed to minimize the development of free fatty acids and oil oxidation.

A simple factory process of intermediate scale, in which the material is still handled manually between processing stages, is the Pioneer mill, which was developed by the United Africa Company around 1939. It is designed to process about three-quarters of a ton of fruit per hour, which is the equivalent of about 1 ton of fruit bunches, following the removal of the fruit from the bunch stalks. The process consists of the following steps:

1. Autoclaving – 200 kg of fruit is loaded into a vertical batch autoclave mounted on a gantry and cooked under steam pressure of 20 pounds per square inch for 15 minutes.
2. After cooking, the fruit is discharged by gravity into a digester fitted with a stirrer, which breaks it up and releases the oil from the cells.
3. The resulting mash is treated in a basket centrifuge, operating at 1,200 revolutions per minute.
4. The oil flowing from the centrifuge passes through a screen to remove the fiber, and then to a settling tank.
5. The settling tank contains a layer of hot water, and the oil is pumped in below water level. The water is boiled for 15 minutes and then allowed to settle. The oil layer is decanted through a hot-water layer in a second settling tank.
6. The tank is heated to boiling point for 15 minutes and allowed to settle. The clean oil is put into drums.
7. The sludge from the two settling tanks is further treated by boiling and settling, and the residual oil is recovered.

An oil mill of essentially the same design, with a capacity of 2 to 3 tons of fruit per hour, was featured in the Wembley Exhibition of 1924 by Nigerian Products Ltd., Liverpool, and was apparently demonstrated in operation there (Elsdon 1926: 316–22). In 1950 there were 13 Pioneer mills in operation in Nigeria. The numbers increased to 65 in 1953 and more than 200 in 1962, producing about 25,000 tons. But, subsequently, their use has declined (Mulder, personal communication, 1968).

The Pioneer mill cannot meet the needs of well-established plantations generating large volumes of fruit. To keep costs down and output up, it is vital to have a fully mechanized power-operated mill. The development of such mills began in Kamerun and in the Congo before World War I. Mills using centrifuges for oil extraction were in operation in the Congo in 1916, in Sumatra in 1921, and in Malaya in 1925 (Hartley 1988: 703–5). Centrifuges were largely replaced by hydraulic presses in the 1930s, although they were still being operated at Batang Berjuntai, Malaysia, in 1982. Batch-fed hydraulic presses were, in turn, replaced by continuous screw presses, which saved labor and handled much larger volumes of fruit. At this final stage of innovation, the development of agricultural and processing technology went hand in hand. The screw press tended to mangle the fruit of the Dura palm, with its relatively thin layer of oil-bearing mesocarp, but proved ideally suited to the Tenera variety (Maycock, personal communication, 1991).

The principal steps involved in the production of palm oil today are the following:

1. Harvest at optimum ripeness.
2. Transport FFB to an oil mill with minimum bruising.
3. Transfer FFB to sterilizing cages.
4. Sterilize FFB by steam under pressure.
5. Transfer cooked FFB to a bunch stripper.

6. Transfer fruit to a digester.
7. Press in single-screw or twin-screw press.
8. The oily discharge from the press, containing water and fruit debris, is passed through screens and settling tanks.
9. The oil phase from the settling tanks is passed to a clarifying centrifuge. The sludge, or heavy phase, from the settling tanks is centrifuged and the recovered oil returned to the settling tanks.

African Food Uses

In West Africa, palm oil has a wide range of applications. It is employed in soups and sauces, for frying, and as an ingredient in doughs made from the various customary starch foods, such as cassava, rice, plantains, yams, or beans. It is also a condiment or flavoring for bland dishes such as *fufu* (cassava). A basic dish, "palm soup," employs the whole fruit. The following dishes from Ghana are illustrative of the wide range of palm oil use (Wonkyi Appiah, personal communication, 1993).

In the case of palm soup, first wash and boil palm fruits. Next, pound the fruit and mix with water to a paste. Add meat or fish, vegetables, onions, spices, and salt. Boil for 25 minutes and simmer for a further 15. Serve the soup with cooked rice, yam, plantain, *fufu,* or *kpokpoi.* (The latter is a corn dough, steamed and cooked, with okra and palm oil stirred in.)

Palm oil is also used in baked dishes, and one popular dish has different names according to the local language. When *Ofam* in Twi, or *Bodongi* in Fanti, is prepared, ripe plantains are pounded and mixed with spices, some wheat or corn flour, beans, and perhaps eggs. Palm oil is stirred into the mixture and the whole is then baked in the oven. The dish is served with ground nuts. *Apiti* is a similar dish, baked in leaves, without beans or eggs.

The characteristic flavor of palm oil prepared by village methods is an important feature of these dishes. Indeed, it is one of their most "traditional" features. Several of the other key ingredients, such as salt, wheat, or (in popular eastern Nigerian dishes) stockfish, became widely available only in the nineteenth and early twentieth centuries, when they were imported from Europe in exchange for palm oil itself (Martin 1988: 28–9, 50).

Early Western Food Uses

The fully flavored red palm oil produced by West African village methods has not proved suitable for food use in the importing countries of the West, where the consumer requires a bland cooking fat, near white in color, or a margarine, similar in appearance to butter. Today's plantation-produced palm oil can be bleached and neutralized to meet Western requirements, but in the nineteenth and early twentieth centuries, the high FFA content even of "soft" West African palm oils made them too difficult and uneconomic to neutralize (Andersen 1954: 27). Even before loading aboard ship, they fell far short of the current quality standard of less than 5 percent FFA, 0.5 percent moisture, and 0.5 percent dirt; and a slow ocean voyage did little to improve matters, as the acidity tended to increase en route (Vanneck and Loncin 1951).

Throughout the nineteenth century, exported oil from West Africa was placed in wooden casks usually supplied from Europe in the "knocked down" state and put together before being filled. Sailing ships became much larger in size and were gradually displaced in the second half of the century by steam ships, which were able to call at a greater number of ports and make more regular voyages (Lynn 1989). This development probably improved the overall quality of oil arriving in Europe, but as the oil was still made on a small scale by different methods and carried in casks, there was plenty of variation.

This quality problem could have been resolved in the late 1920s, when bulk storage tanks were installed at some African loading ports, initially in Nigeria and the Belgian Congo. It was then possible for incoming oil to be washed and cleaned before bulking, with an improvement in quality (Iwuchukwu 1965; Mulder, personal communication, 1968). However, hardly any Nigerian palm oil was suitable for the European food industry until the 1940s.

When Sumatran and, later, Malayan plantations started to export oil in the 1920s, their fruit was harvested systematically from the beginning. It was transported with minimal bruising to the factories and processed in a standardized way. Bulk shipment was developed from the outset. The first shore tanks were installed at Belawan in North Sumatra in the 1920s, and oil from Malaya was taken there by steamer from 1931 onward. In 1932 the Malayan planters set up their own Palm Oil Bulking Company with an installation at Singapore (Shipment of palm oil in bulk 1931; United Plantations Berhad, unpublished documents; T. Fleming, personal communication, 1993).

It thus became possible to develop and maintain the quality standards that are now current worldwide. The planters aimed to produce oil of 3.5 percent FFA, which would then fall well within the limit of 5 percent FFA on arrival in Europe or America. Oil arriving at above 5 percent FFA was sold at a discount, depending on the excess acidity (Hartley 1988: 687).

European food manufacturers could now begin to introduce palm oil on a commercial basis, drawing on earlier experiments and fitting it into two long-standing patterns of fat use. In central and northern Europe, indeed in cool weather regions generally, the traditional fats are the products of the farm yard – butter, beef tallow, and lard. In southern Europe, with its dry hot climate, olive oil has been in general use for thousands of years. Thus, consumers have had available either a plastic product of solid appearance or a clear liquid oil, and the cooking and eating habits developed accordingly.

Respect for these traditions led to the invention in 1869 of margarine and its development as a replacement for butter, when the latter was in short supply. Margarine was originally made from beef fat, and the plastic nature of butter was attained by blending in a liquid fraction separated from beef fat by crystallization. Margarine proved so popular that European supplies of beef fat did not suffice. Imports from the New World were important in the nineteenth century, but various imported vegetable oils gradually took the place of beef fat margarine blends as refining techniques developed. The fact that even "soft" palm oil is a solid fat in temperate climates, with a consistency quite similar to butter, made it an obvious candidate for such experiments, and the first recorded trial took place in 1907 (Feron 1969).

The refining and bleaching process required to render suitable palm oil involved a great deal of research and empirical know-how. Illustrative is some unpublished correspondence (copies held by K. G. Berger) between Dr. Julius Lewkowitsch, a consultant chemist in oils and fats, and a Liverpool trading house, the African Association Limited. Dr. Lewkowitsch had invented a process for rendering palm oil into an edible product and had entered into an agreement, dated January 24, 1905, to share the costs of development of the process with the African Association.

Evidently the work proceeded rather slowly, because in September 1907, Lewkowitsch received a letter from the Vice-Chairman of the African Association, saying: "I have sent you under separate cover a sample of refined beef suet. . . . Would it be possible to have the samples of the palm oil products made up to appear like this sample? I am afraid I shall never satisfy my Co-Directors until I can show them a palm oil product they can eat." A successful prototype was probably produced eventually, because in 1910 a small manufacturing concern, V. B. Company, was incorporated and the African Association was paying Lewkowitsch a regular salary as managing director from 1910 to 1912.

The first decade of the twentieth century also saw the introduction of hydrogenation of oils, a process by which liquid oils could be turned into plastic or hard fats to a controlled degree. As a result, vegetable oil–based "shortenings" were produced to replace lard and beef tallow as ingredients for cakes, pastries, and biscuits and as frying fats. Once adequately refined, palm oil was easily introduced in blend formula for these types of products and had the advantage of not requiring hydrogenation. By the mid-1930s, the relatively clean and less acidic plantation-produced palm oil of Malaya and Sumatra was finding a ready market in the United States, where it was used not only in fine toilet soaps but also in the making of compound lard. Over 50,000 tonnes per annum were used in the American compound lard industry between 1935 and 1939 (Lim 1967: 130–2).

Wartime interruptions of supplies from Asia during the 1940s forced American manufacturers to find substitutes for palm oil, and the market was slow to revive afterwards. However, in Britain, wartime shortages of butter encouraged the use of palm oil in both margarine and compound lard, and this market continued to grow in the 1950s (Lim 1967: 131). British manufacturers, through the home Ministry of Food and the West African Produce Control Board, were able to corner the market in British West African palm oil (Meredith 1986). The Produce Control Board and, from 1949, its successor, the Nigerian Oil Palm Produce Marketing Board, played an important role in bringing the quality of this oil up to the standards set in Southeast Asia.

A grading system was set up as follows:

Grade I	under 9 percent FFA
Grade II	9 to 18 percent FFA
Grade III	18 to 27 percent FFA
Grade IV	27 to 36 percent FFA
Grade V	over 36 percent FFA

Higher prices were paid for the better grades, and there was an immediate response from the village producers, which enabled a Special Grade palm oil to be specified in 1950 with maximum 4.5 percent FFA at time of purchase. A significant premium was paid for this oil, with the result that Special Grade oil, which was only 0.2 percent of production in 1950, jumped to over 50 percent by 1954. In 1955, the specification was tightened to 3.5 percent FFA, and by 1965 Iwuchukwu (1965) reported that more than 80 percent of material for export had reached this quality.

Market Developments Since 1950

The development (mainly since the 1950s) of convenience foods and of snack food manufacture on an industrial scale opened up additional uses for palm oil, because of its good resistance to oxidative deterioration and its better ability to withstand the high temperatures used in frying than most alternative oils (Kheiri 1987; Berger 1992). The market developed especially rapidly after 1970, as the trees planted during the 1960s in Malaysia matured and as the Malaysian government and estate sector began to promote their product more actively in the West. Asian markets had also become important by 1980, as Western processing techniques were applied to meet local needs.

Figure II.E.3.1 shows that the world production of palm oil, together with its share in world supplies of oils and fats, increased dramatically from 1970 onward. Yet by this time, in many parts of Africa the industry had declined (Table II.E.3.6). Nigeria, for example, had no exportable surplus of oil after 1970 and, in fact, became a net importer of palm olein in the 1980s. Exports from Zaire became very limited in the 1980s, and the Ivory Coast, with exports of 60,000 to 100,000 tonnes per annum, was left as the only significant African supplier. Meanwhile, as shown in Table II.E.3.6, new Asian producers were emerging, in particular Papua New Guinea and Thailand. By 1990, exportable surpluses of 10,000 to 30,000 tonnes per annum were also reaching the world market from Honduras and Costa Rica (Mielke 1991: 111).

As Malaysian production grew, both the planters and the government realized that it was vital to improve processing methods and to encourage the growth in demand for palm oil. The estate sector took the lead during the 1960s, developing higher grades of crude palm oil to suit European needs. Later, the government joined in the development of refineries and new products to suit Asian, as well as Western, tastes.

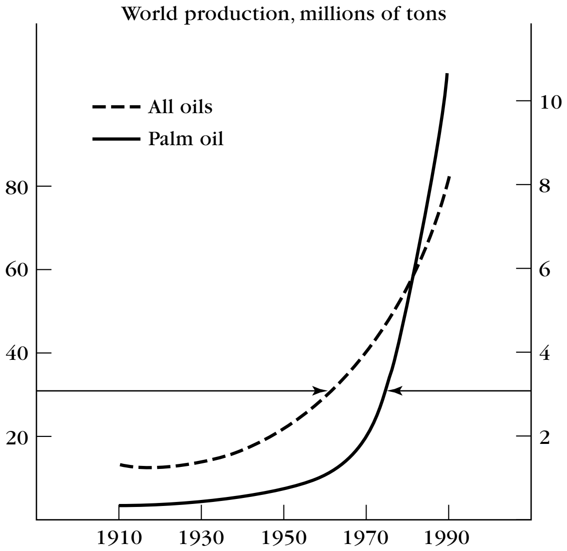

Figure II.E.3.1. World production of palm oil, 1910–90.

Table II.E.3.6. *Palm oil exports from selected countries (thousand tonnes per annum)*

Country	1950–3	1962–5	1970–3	1982–5	1990
Nigeria	180	130	8	–	–

Table II.E.3.7. *Specifications of special grades of crude palm oil*

	SPB	SQ	Lotox
FFA max %	2.0	2.0	2.5
Moisture max %	0.1	0.18	0.18
Impurities max %	0.002	0.02	0.02
Iron max ppm	10.0	4.0	3.0
Copper max ppm	0.5	0.2	0.2
Peroxide value mg/kg max	–	3.0	3.0
Anidine value max	–	–	4.0

Sources: Loncin and Jacobsberg (1965) and Johansson and Pehlergard (1977).

The old standard of 3.5 percent FFA on leaving the factory continued to apply to the bulk of crude Malaysian palm oil. However, in the last 30 years it has been recognized that the production of a stable refined palm oil of good color is also dependent on characteristics other than FFA content, as shown in Table II.E.3.7. In particular, the degrees of oxidation and contamination with catalytic traces of metals are important. But surveys indicate that the peroxide value (a measure of the state of oxidation) of standard palm oil arriving at Malaysian ports or refineries fell from 3.9 milligrams per kilogram to 2.3 milligrams per kilogram between 1974 and 1991 (Jacobsberg 1974; Wong 1981; V. K. Lal, personal communication, 1991).

Planters, both in the Belgian Congo (Zaire) and in Malaysia, also sought to develop a premium product with exceptionally low FFA, obtained through stricter harvesting routines and processing with minimum delay. "Special Prime Bleach" (SPB) grade was developed in the Belgian Congo (Loncin and Jacobsberg 1965), having a maximum of 2 percent FFA and reduced levels of iron and copper contamination, while in Malaysia two special grades became available, namely "SQ" and "Lotox." The SQ and Lotox specifications include limits for oxidation characteristics as well as trace metals and in practice satisfy the most stringent requirements of the European market (Johansson and Pehlergard 1977).

A separate development, which also improved the quality of palm oil arriving in Europe, was the introduction in the 1960s of "parcel tankers." These are specialized ships of up to 30,000 tons. The cargo space is subdivided into a number of separate tanks, generally with a capacity of between 100 and 1,000 tons. Tanks are fitted with separate pumps and pipelines so that different liquid cargoes can be carried without contamination. With the very large export trade from Southeast Asia, parcel tankers are capable of economically carrying palm oil and other oils of different grades to destinations all over the world. Appropriate shore installations have been developed since 1960 in the exporting ports of Southeast Asia and in most receiving ports in Europe, United States, and Japan, and are being developed in countries that have only recently become large importers. Like the development of bulk shipment from Malaya in the 1930s, this innovation was fostered by cooperation among the planters, who marketed their oil through a common Malayan Palm Oil Pool from 1953 to 1974 (Allott and Wong 1977).

By 1974 the volume of Malaysian oil exports and the diversity of markets had grown to the point at which a free marketing system was more appropriate. The range of palm oil products exported was also growing, following the application of the fractionation process first developed for beef tallow in the 1870s. This technique separated crude palm oil into olein and stearin. The olein remains a liquid oil in hot climates and, therefore, readily fitted into the large Indian demand for cooking oil.

From 1970 the Malaysian government encouraged and licensed private enterprises to set up refineries that could both fractionate palm oil and use it in a more traditional manner to produce shortenings for Asian markets. In India, for example, there is a large consumer demand for vanaspati, a shortening developed as a replacement for butterfat ghee. Similar shortening products are traditional in Pakistan, Egypt, and other Middle East countries. Often lacking their own refining facilities, such countries have tended to import palm oil products from Malaysia in fully processed, ready-to-eat form.

The Malaysian government encouraged this trend by offering tax concessions for refineries in their early years and by progressive remission of the export tax on crude palm oil, graded according to the degree of processing of the end product. This development received a mixed reaction in Western Europe, which had ample processing capacity and extensive technical know-how (Berger, personal observation). However, it proved successful in stimulating the growth of new Asian markets, as shown in Table II.E.3.8.

Table II.E.3.8. *Palm oil imports to selected regions (thousand tonnes per annum)*

Region	1960	1970	1980	1990

Although private enterprises had an excellent record in developing new processing techniques, they often felt hampered by their distance from major markets, which posed difficulties in designing and introducing new products. In 1979 the Malaysian government set up a specialized Palm Oil Research Institute (PORIM) as a statutory body, financed by a levy on palm oil production. A major part of its mission was the development of application technology for palm oil and the propagation of the information to end users anywhere in the world. By studying consumption patterns of oils and fats, the Institute's staff was able to identify potential new markets and provide the technical input needed for their development (PORIM 1981: 1–5). Their work proved useful to producers worldwide, especially from the late 1980s on when a debate arose over palm oil's nutritional value.

Nutritional Properties of Palm Oil

Briefly, the general nutritional functions of fat are to:

1. Provide energy efficiently.
2. Supply the essential linoleic and linolenic acids.
3. Carry the fat soluble vitamins A, D, and E.
4. Improve the palatability of foods.

The specific nutritional properties of palm oil may be considered in relation to its chemical composition. Typical values are given in Table II.E.3.9.

Table II.E.3.9. *Composition of pam oil*

1. The main fatty acids	Percentage
C14:0	1.0
C16:0	43.7
C18:0	4.4
C18:1	39.9
C18:2	10.3
C18:3	0.4
Others	0.3

2. The main glycerides	Percentage	Major components
Trisaturated	8.5	(PPP)
Mono unsaturated	37.7	(POP, PPO)
Di-unsaturated	11.7	(OOO, PLO)
More unsaturated	11.7	(OOO, PLO)

3. The nonglyceride components

Crude palm oil	Ppm	Main component
Carotenoids	640	beta-carotene, alpha-carotene
Tocopherols	850	gamma-tocotrienol, alpha-tocotrienol, alpha-tocopherol
Sterols	300	beta-sitosterol, campesterol
Triterpene alcohols	800

Table II.E.3.10. *Tocopherol content of typical refined palm oil*

alpha-tocopherol	180 ppm
alpha-tocotrienol	149 ppm
gamma-tocotrienol	239 ppm
delta-tocotrienol	62 ppm

Source: Gapor and Berger (1983).

The unsaturated acids present are mainly oleic, with a useful level of linoleic and a small amount of linolenic acid. In consequence, palm oil has a high stability to oxidation. Palm oil is readily absorbed and shows a digestibility of 97 percent or greater, similar to that of other common edible oils.

As in other vegetable oils, the middle 2-position is mainly occupied by unsaturated fatty acids. This is different from animal fats, where the 2-position is usually occupied by a saturated fatty acid.

Unrefined, or "virgin," palm oil is one of the richest natural sources of carotenoids. Regrettably, these are removed during the industrial refining process so that their nutritional benefits are lost, except to populations who traditionally use palm oil in the unrefined state.

The tocopherol content (see Table II.E.3.10) is one of the most interesting features in palm oil because it consists mainly of the tocotrienols, with an unsaturated side chain. These are not found in the other common vegetable oils.

Analytical work has shown that an average of 50 to 60 percent of the tocopherol content remains after refining, but the extent of removal depends on the refining conditions used. The tocopherols are important natural antioxidants, although their antioxidant activity is somewhat lower than the synthetic phenolic antioxidants permitted in foods. They are less volatile and, therefore, more persistent in high-temperature conditions, such as in deep-fat frying. The tocopherol content is a major factor in stabilizing palm oil against oxidation. The nutritional benefit of tocopherols in a number of disease conditions in which free radicals or oxidation are implicated has become a very active field of research, although to date little has been done on tocotrienols as such.

The three major component fatty acids of palm oil – palmitic, oleic, and linoleic acids – are also the most common fatty acids found in vegetable oils. Palm oil has been used as a traditional food in West Africa probably for thousands of years, which provides some evidence that it has good nutritional properties.

Research into coronary heart disease in relation to diet led to the general hypothesis of A. Keys, J. T. Anderson, and F. Grande (1957) that saturated fatty acids raised blood cholesterol levels, whereas linoleic acid reduced them. Subsequent refinements of the hypothesis (Hegstedt et al. 1965) indicated that saturated acids did not all have the same effect. In particular, D. M. Hegstedt and colleagues concluded that myristic acid was 3 to 4 times more effective than palmitic acid in raising blood cholesterol levels.

The early work leading to these hypotheses did not use palm oil in the experimental diets. However, between 1985 and 1987, concern was expressed in the media, principally in the United States, that the saturated fatty acid content of palm oil meant that it would raise blood cholesterol levels and was, therefore, an undesirable food component. This assertion was not based on any direct experimental evidence. Instead, a review of the few dietary experiments in which palm oil had been used (as a control, not as the subject of investigation) showed that, in general, a small reduction in blood cholesterol level was experienced (New findings on palm oil 1987).

Subsequently, a study in Nigeria, a principal traditional consumer of palm oil, was published (Kesteloot et al. 1989). Serum lipid levels were measured in 307 men and 235 women, whose ages were 15 to 64 (mean 38.8) for men and 15 to 44 (mean 31.4) for women. Mean values for total serum cholesterol were 156.3 and 170.9, respectively, and for HDL cholesterol 46.0 and 49.0. Subjects consumed their normal diet, with 84 percent of the fat intake from palm oil. These serum lipid levels compared very favorably with black and white populations in the United States, where total fat intake is much higher, and where palm oil comprises only 1 to 2 percent of total fat intake (Park and Yetley 1990).

A number of new dietary studies have addressed the nutritional properties of palm oil, particularly in its effect on blood lipids. T. K. W. Ng and colleagues (1991), for example, found that when palm olein formed 75 percent of fat intake in a normal Malaysian diet, total serum cholesterol was significantly reduced, by 9 percent from the level at entry, and that the reduction was almost entirely in the undesirable LDL cholesterol. The study was carried out on 20 men and 7 women of average age 24.

A. Marzuki and colleagues (1991) used 110 residential high school students of both sexes as subjects (ages 16 to 17). Although the normal menu was provided, palm olein was the sole cooking oil for 5 weeks. This was followed by a "washout" period of 6 weeks on regular cooking oil and a second experimental 5 weeks in which only soya bean oil was used. There was no difference in plasma total LDL or HDL cholesterol between the two trial periods.

K. Sundram and colleagues (1992) carried out a double blind crossover study on 38 men, in which 70 percent of the fat in a normal Dutch diet was replaced by palm oil. There was no effect on total serum cholesterol, but a significant increase of 11 percent in HDL 2 cholesterol, resulting in a beneficial decrease in the LDL/HDL 2+3 ratio. G. Hornstra and co-workers (1991) also measured plasma lipoprotein (a), which is strongly associated with an increased risk of ischemic cardiovascular disease. They found a highly significant 10 percent decrease in this component during the test diet period, and the decrease was greatest in subjects with an initial high level of lipoprotein (a), that is, those with an enhanced risk.

R. Wood and colleagues (1993) examined the effect of six different fats used as components of items of a normal American diet on 30 middle-aged men. When refined palm oil formed 60 percent of the dietary fat intake, there was no significant effect on total cholesterol, but HDL cholesterol was increased compared with the baseline diet.

Ng and colleagues (1992) studied 33 subjects consuming a Malaysian diet containing 34 percent of calories as fat. When palm olein was 23 percent of energy (that is, two-thirds of the fat intake), there was no significant difference in serum total – LDL or HDL cholesterol contents from the levels at entry. The use of olive oil in place of palm olein gave almost identical results, although the ratio of Thromboxane B_2 to Prostacyclin PGFI alpha was significantly lower during the palm olein dietary period.

D. Heber and colleagues (1992) found no increase in the plasma total cholesterol level of 9 subjects, but a small rise in plasma HDL cholesterol when one-half of the dietary fat was palm oil. The diet contained 35 percent energy as fat.

A. S. Truswell and co-workers (1992) conducted 2 trials (21 and 30 subjects, respectively) in which one-half of the dietary fat was palm olein. He found that a 10 percent increase in HDL cholesterol accounted for the 3 percent rise in total cholesterol observed.

The conclusion is that palm oil, used as a dietary fat at a high level – 10 to 20 times that usual in a Western diet – does not raise serum total cholesterol. However, the level of serum HDL cholesterol (popularly described as the "good" cholesterol, because in this form cholesterol is catabolized and removed) was significantly increased in several of the recent studies.

Mention might also be made of two additional studies, by R. C. Cottrell (1991) and C. E. Elson (1992). These authors reviewed 139 and 180 scientific publications, respectively, and both concluded that palm oil was a nutritionally satisfactory component of the diet. Cottrell wrote that "the decision to use palm oil in food products should be based on a rational appraisal of its technical performance value rather than on a misconceived view of the health implications of its use" (Cottrell 1991: 989S–1009S).

Nonetheless, the view still persists in some circles that palm oil is an unhealthy tropical grease, and it is difficult for palm oil producers to counter this perception because the product had little or no public image among Western and Asian consumers before the start of the recent media debate. Processed until it has become an anonymous ingredient, and used in a wide variety of compound fats and such other items as biscuits, its original flavor and feel have been lost to most consumers. But now that the wider nutritional benefits of palm oil's natural carotenoids are becoming more generally recognized, perhaps it is time to rediscover the fully flavored red oil and promote its use, not only in Africa and Latin America but also in Asia and the West.

II.E.4 Sesame

Botanical Description

Sesame (*Sesamum indicum* L.) belongs to the Pedaliaceae, a small family of about 15 genera and 60 species of annual and perennial herbs. These occur mainly in the Old World tropics and subtropics, with the greatest number in Africa (Purseglove 1968). Sesame is a crop of hot, dry climates, grown for its oil- and protein-rich seeds. The oil is valued for its stability, color, nutty flavor, and resistance to rancidity.

A large number of cultivars are known (Bedigian, Smyth, and Harlan 1986). These differ in their maturation time, degree of branching, leaf shape and color, and number of flowers per leaf axil, which may be 1 or 3. The locules in the capsule usually number 4 or 8. The known cultivars also vary in length of capsule, in intensity of flower color, and especially in seed color, which ranges from pure white to black, with intervening shades of ivory, beige, tan, yellow, brown, red, and gray. The seeds are about 3 millimeters long and have a flattened pear shape. The capsules open automatically when dry, causing the seed to scatter.

Production

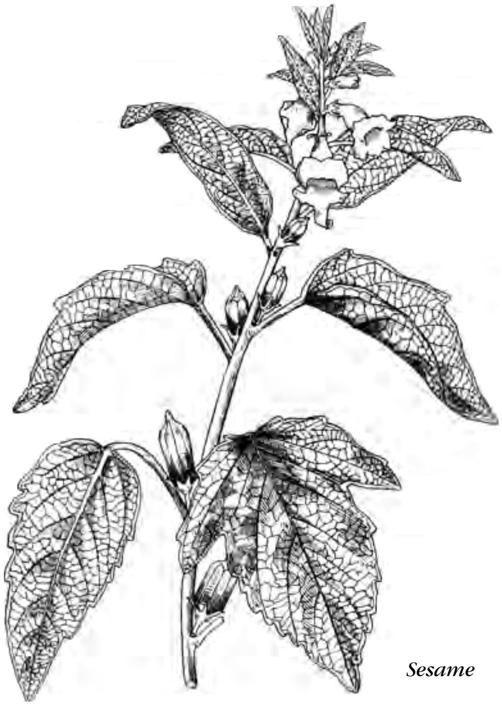
Sesame is usually grown as a rain-fed crop. It has many agricultural advantages: It sets seed and yields relatively well under high temperatures, it is tolerant of drought, and it does reasonably well on poor soils. It is very sensitive to day length and is intolerant of waterlogging. The major obstacle to the expansion of sesame is its habit of shattering: The absence of non-shattering cultivars, suitable for machine harvest, results in labor-intensive harvest seasons. Because of this obstacle, the crop is not suitable for large-scale commercial production (although breeding for non-shattering traits has been ongoing). Instead, sesame has typically been grown on a small scale for local consumption or in places where labor is cheap. The major sesame-producing countries, listed in order of decreasing tonnage, are India, China, Myanmar (formerly Burma), Sudan, Nigeria, and Uganda (FAO 1992).

Chemical Composition and Nutritional Value

Oil

The chief constituent of sesame seed is oil, which usually constitutes 40 to 60 percent of seed weight. This is a greater oil content than most other oil crops (Hussein and Noaman 1976; Tinay, Khattab, and Khidir 1976; Salunkhe et al. 1991). Sesame oil content is related to seed color, although this is specific to geographic location. For example, the white-seeded varieties in the Sudan have a lower oil content than the red-seeded varieties (Bedigian and Harlan 1983), but in Ethiopia white or light-colored seeds usually have more oil than dark-colored seeds (Seegeler 1989).

Seed color differences are also economically significant. In West Bengal, white-seeded sesame is sold at a price at least 30 percent higher than that of brown-seeded or black-seeded varieties because of its higher oil content and greater culinary utility (Chakraborty, Maiti, and Chatterjee 1984). But appreciation of sesame by seed color can also be cultural: The Japanese, for example, prefer black-seeded varieties (Y. Kakehashi, personal communication, 1995), whereas the Sudanese prefer white-seeded ones.



Sesame

In a collection of sesame plants from around the world, tested by D. M. Yermanos and colleagues (1972), the mean oil content in 721 samples was 53.1 percent; the oil was clear and colorless in 47.4 percent of the samples and light green in 37.2 percent, with the remaining samples dark green or brown. Short plants tended to have colorless oil, whereas tall plants had light green oil, and early plants had higher seed oil content. Earliness, yellow seed color, and large seed size were associated with a lower iodination value. However, Y. K. Sharma, A. D. Deodhar, and S. K. Gangrade (1975) reported no relationship between oil content and iodination values, free fatty acids, and carbohydrate content.

Fatty acids. Sesame oil contains about 80 percent unsaturated fatty acids, with oleic acid and linoleic acid predominating and present in approximately equal amounts (Lyon 1972). Sesame has more unsaturated fatty acids than many other vegetable oils, and its higher proportion of unsaturated to saturated fatty acids makes it a potentially important dietary source of essential fatty acids. Linoleic acid is required for cell membranes, for transportation of cholesterol in the bloodstream, and for blood clotting (reviewed in Salunkhe et al. 1991).

Antioxidants. Sesame oil is remarkably stable because of its natural antioxidants, sesamin and sesamolin, two compounds not found in any other oil (Bedigian, Seigler, and Harlan 1985). These are phenylpropanoid lignans and serve to protect against rancidity (Weiss 1971; Salih 1993), which may be one reason that sesame is nicknamed the "Queen of Oilseeds." Other unsaponifiable substances in sesame oil include sterols, triterpenes, pigments, and tocopherols.

Protein

The press cake remaining after the oil is expressed is approximately half the initial seed weight and high in protein. C. K. Lyon (1972) reported a protein content range of 17 to 32 percent. Although low in lysine, sesame proteins are especially rich in the essential amino acids methionine and tryptophan, and sesame meal flour is recommended as an excellent source of methionine-rich proteins (Villegas, González, and Calderón 1968). These can be a valuable supplement to pulse proteins, such as those in beans or chickpeas, which contain adequate amounts of lysine but are usually deficient in sulfur-containing amino acids (Fernández de Campoy 1981). S. A. Godfrey, B. J. Frances, and C. S. Kamara (1976) have suggested a combination of cowpea (deficient in methionine) and sesame to overcome the problem of limiting amino acids.

Carbohydrates

The carbohydrate content of sesame seeds (21 to 25 percent) is comparable to that of peanuts and higher than that of soybeans (Joshi 1961). D. J. Wankhede and R. N. Tharanathan (1976) have reported that sesame contains 5 percent sugars – d-glucose, d-galactose, d-fructose, sucrose, raffinose, stachyose, planteose, and sesamose – as well as higher homologues of the planteose series.

Minerals and Vitamins

Sesame seeds are a good source of calcium, phosphorus, and iron. Nearly one-half to two-thirds of the calcium in the seed is present as oxalate, and a major part of it is located in the outer husk of the seed. The seeds are often dehulled for food use; thus, the oxalate does not interfere with the absorption of calcium. Sesame seeds contain high levels of thiamine, riboflavin, and nicotinic acid (Tabekhia and Mohammed 1971). When made into sesame butter, they lose 52.5 percent of their thiamine and 50.2 percent of their nicotinic acid. The oil is rich in vitamin E.

Minor Constituents

Sesame contains among the highest levels of phytate found in nature (Boland, Garner, and O'Dell 1975). In foods, phytate can be detrimental to the absorption of trace elements such as zinc, presumably through formation of a stable insoluble complex that does not release zinc to the absorption sites in the intestinal mucosa. It is conceivable that the indigestible phytate-protein complexes could make zinc and other nutrients even less biologically available. In attempting to isolate and characterize the phytate, B. L. O'Dell and A. de Boland (1976) found that it was not readily extracted by neutral aqueous solvents because it exists as an insoluble magnesium complex.

While studying the natural occurrence of *Fusarium* toxins in feedstuffs, C. J. Mirocha and colleagues (1976) reported, for the first time, the natural occurrence of zearalenone in sesame seed. The presence of aflatoxin B_1 was sought in 292 samples of seeds other than peanuts, and sesame was among the 8 found to contain it, at 0.06 mg per kg (Monacelli et al. 1976).

In addition, unhulled sesame contains 1 to 2 percent oxalic acid (Lyon 1972), which can be removed by decortication.

Changes Effected by Processing

Roasting

Sesame seed is used as a nourishing food as well as a flavoring agent, and its characteristic flavor is developed by dry-roasting the dehulled material. S. N. Chaudhry (1988) investigated the chemical changes in protein quality induced by roasting at various temperatures. He determined that optimal roasting of sesame (with respect to flavor and oil quality) required a temperature of 200° C for a duration of one hour. G.-C. Yen and S.-L. Shyu (1989), however, concluded that sesame oil prepared under optimum processing conditions meant roasting at 200° C for 30 minutes.

Extraction

Sesame oil can be extracted from the whole seeds by several different processes (Johnson and Raymond 1964). Chaudhry (1988), who compared press-extracted to solvent-extracted oil (from roasted sesame seeds), reported that press extraction can release impurities (such as pigments and metal ions) that could react with the oil, resulting in complex formation. Solvent extraction, on the other hand, can cause the loss of desirable flavoring compounds during the evaporation of the solvent. A method of crushing sesame seeds for oil extraction is described in *Law's Grocer's Manual,* published about 1892:

> Sesame is also widely cultivated in Syria, where, in preparing the oil, the grain is soaked in water for 24 hrs, and then placed in an oblong pot, coated with cement, on which two men work a wooden hammer of 20 lb. weight. . . . Efforts are not made to mash the kernels. The skins are separated in a tub of water, salted to a degree sufficient to float an egg. The bran sinks, while the kernels remain on the surface. The sesame seeds are now broiled in an oven, and sent to the mill to be ground. From the millstone the oil drops into a jar, and is thick, of a dark yellow colour, and sweet (quoted in David 1970: 54).

Toxicity

Sesame seeds are extremely powerful allergens, and sensitized persons may suffer urticaria, Quinke's edema, asthma, and even anaphylaxis (Kägi and Wüthrich 1993). Although such reactions to sesame seeds are rare, the potential danger should be recognized, especially in view of an increasing demand for vegetarian foods.

Origin

Sesame was cultivated in ancient India, Sumer, Egypt, and Anatolia and throughout the Greco-Roman world for its edible seed and for its oil (Bedigian 1985; Bedigian and Harlan 1986). It is often described as the oldest oilseed plant used by humans (Joshi 1961; Weiss 1971). There has been some confusion about its origin, however, that has been discussed by N. M. Nayar and K. L. Mehra (1970), Nayar (1976), and Dorothea Bedigian (1984).

A group of wild and weedy forms native to India and described as *Sesamum orientale* L. var. *malabaricum* Nar. shows close morphological, genetic, and phytochemical affinities to the cultivar. Bedigian (1988) and colleagues (Bedigian, Seigler, and Harlan 1985; Bedigian, Smyth, and Harlan 1986) have provided evidence to support the theory that domesticated sesame arose from this progenitor on the Indian subcontinent. D. Zohary and M. Hopf (1994) concurred with Bedigian and J. R. Harlan (1986) that the botanical evidence supports a relatively late introduction of sesame into the Near East and the Mediterranean region. The genus is restricted to the Indian subcontinent, where there are only a few wild species, and to Africa south of the Sahara, where there are numerous wild species.

The Archaeological Record

The Indian Subcontinent: Harappa

The oldest known remains of sesame seeds were found at the Indus Valley civilization site of Harappa (Vats 1940), in Pakistan, where excavators uncovered "a quantity of lumped and burnt *Sesamum*" specimens. M. S. Vats (1940) dated the sesame to about 3500 to 3050 B.C. but this was before the advent of radiocarbon dating, and the dates are probably much too early (see Bedigian 1985 and Bedigian and Harlan 1986 for reviews of the evidence and its archaeological context). The Indus Valley, however, is probably the area where the plant was first cultivated.

The Preclassical Near East

Mesopotamia. To date, no sesame seeds have been recovered from excavations in Mesopotamia.

Egypt: King Tutankhamen's Tomb. The discovery of sesame seed remains associated with the burial of King Tutankhamen (around 1350 B.C.) pushes back the date of the earliest record for sesame seeds in the Near East (Vartavan 1990). Some 30 boxes of plant remains from his tomb were stored at the Royal Botanical Gardens, Kew, England, where botanist Leonard Boodle worked on cataloging these specimens until his death in the 1930s.

Recently, Christian L. T. de Vartavan, a graduate student, had the good fortune of being allowed to go through these boxes to examine the contents. A letter to Bedigian from Mr. Vartavan, dated July 20, 1988, stated that there were 60 milliliters (ml) of sesame seeds, which were the main ingredients of one of the many containers in the tomb filled with food, drinks, ointments, perfumes, and oils. Vartavan viewed these seeds as "the most striking find" among the remains from the room designated by Howard Carter (who discovered the tomb in 1927) as the "Annexe" to Tutankhamen's tomb. These seeds from the Annexe represent the only find of sesame ever recorded from investigations of ancient Egypt, as well as the earliest sesame from the Near East and from Africa.

Armenia: Karmir Blur. Remains of sesame seeds dated between 900 and 600 B.C. have been found at this early Iron Age Urartian site on the outskirts of Yerevan. Four large jars containing carbonized sesame seed were excavated. Elaborate devices for the extraction of sesame oil indicate that the Urartians processed the seeds for oil (Piotrovskii 1950, 1952;

Kassabian 1957; Bedigian 1985; Bedigian and Harlan 1986).

Jordan: Deir Alla. Some 200 sesame seeds dating from about 800 B.C. were uncovered in Iron Age beds at this site in Jordan, according to R. Neef (1989).

Turkey. Sesame seeds were recovered at the Gordion ruins in Anatolia during the 1989 excavation of the "Destruction Level" (around 700 B.C.). The seeds are from a pure sample (about 250 ml) from within a pot that was found on the floor (along with other pots containing pure wheat, barley, and lentil). Massive burning and the collapse of the roof seems to have effectively sealed the contents on the floor (N. Miller, personal communication, 1990).

Early Literary Records

The Indian Subcontinent

The fact that the Sanskrit words for oil and for sesame seed are the same suggests that sesame may be one of the earliest oil-bearing plants to have been brought under cultivation (Sampson 1936: 221). One of these words, *tîla,* has been employed in religious ceremonies from very early times. It was regarded as holy (Hopkins 1968), and an offering of *tîla* seeds was considered effective in removing sins (Gupta 1971). Offerings of water and sesame were said to free an individual of all debts to his ancestors.

The Near East

Mesopotamia. Early Old Babylonian (OB) documents contain numerous references to sesame oil (Simmons 1978). Texts list the expenditure of sesame oil "for the inner bolt," "for the fire offering," "for the prince," "for the royal purification rite," "for the inner bolt on the day of Akitu," "for the sizkur divine name," "for the Elunum divine name," "for the regular offering," and "for anointing the banner." These are all special cultic applications that employed the oil to lubricate, soap, or fuel someone or something, almost certainly at springtime festivals (W. Doyle, personal communication, 1984).

The article for *ellu* in the *Assyrian Dictionary of the Oriental Institute, Chicago* (better known as the *Chicago Assyrian Dictionary* [CAD], ed. Oppenheim et al. 1958) provides as one definition: "[C]lean, pure in connection with oil, etc. . . . fine oil . . . sweet oil . . . pure sesame oil, sesame oil of the first [pressing]," used for anointing and making perfume. Another definition is: "[H]oly, sacred."

The *šamaššammū* article prepared for the CAD's "Š" volume (Reiner ed. 1989: 301–7) mentions several texts that help to identify *šamaššammū* as sesame. The article itself contains many references to oil pressing, including one text (Keiser 1917) that specifies *šamaššammū pesûtu* (white *šamaššammū.*) The texts concerning white-seeded *šamaššammū* provide evidence of considerable importance in helping to distinguish flax from sesame because there are no flax cultivars with white seeds (J. Miller, personal communication, 1984).

Egypt. The earliest Egyptian textual reference to sesame seems to have been in the Tebtunis Papyri 3 (Part 2, No. 844) that dates from 256 B.C. (Lucas 1962: 336). H. Deines and H. Grapow (1959) indicated that sesame was used as a medicine. Pliny (1938: 15.7.31) wrote that a large amount of oil in Egypt was obtained from gingelly *(sesamum).*

The difficulty is to identify the ancient words for sesame. There is a striking linguistic resemblance of the Mesopotamian word *šamaššammū* to related Near Eastern terms, such as the Arabic word *simsim* and the name of a plant with edible seeds that is transcribed *smsmt* (Germer 1979). V. Loret (1892) regarded the Coptic name for sesame, *oke,* as Egyptian in origin. Another word from the hieroglyphs, *ake,* referred to a plant that produced oil and had seeds that were used medicinally. *Ake,* then, could be the Egyptian name for sesame (Loret 1892). But whether this later became the highest-quality oil, which was *nhh,* that one encounters from the nineteenth dynasty (1320 to 1200 B.C.) onward, remains a mystery. The assertion by some authors that *nhh* was *Ricinus* oil has been disputed on the grounds that castor oil is unpalatable (Keimer 1924) and also toxic.

Classical Greece

Sesame was cultivated extensively in the Greco-Roman world, but more for its edible seed than for its oil. The writings of Greek travelers and historians make it clear that sesame was well known in Mesopotamia by the time of the Iron Age, which began in about the eighteenth century B.C. About 300 years later, Herodotus (1928) observed that the only oil the Babylonians used was from sesame.

The cultivation of sesame in ancient Armenia was documented in the fifth century B.C. by Xenophon, who wrote: "In (western Armenia) . . . there was a scented unguent in abundance that they used instead of olive oil, made from pork fat, sesame seed, bitter almond and turpentine. There was a sweet oil also to be found, made of the same ingredients." Xenophon also placed sesame in two other parts of Anatolia. One was Cilicia – "[t]his plain produces sesame plentifully, also panic and millet and barley and wheat" (1901: I.ii.22) – and the other was "Calpe Haven in Asiatic Thrace," farther west. "Calpe lies exactly midway between Byzantium and Heracleia," has "good loamy soil . . . produces barley and wheat, pulses of all sorts, millet and sesame, figs in ample supply, numerous vines . . . indeed everything else except olives" (I.ii.22).

Imperial Rome

Cultivation requirements. Columella, in the first century A.D., reported accurately that "it [sesame] usually requires loamy soil, but it thrives no less well in rich sand or in mixed ground. . . . But I have seen this same seed sown in the months of June and July in districts of Cilicia and Syria, and harvested during autumn, when it was fully ripe" (1941: 2.10.18). He also wrote that "[i]n some districts [of Anatolia] such as Cilicia and Pamphylia, sesame is sown this month [late July to August]; but in the damp regions of Italy it can be done in the last part of the month of June" (11.2.56). This report would seem to indicate that, like the Babylonians, the Cilicians and Pamphylians grew sesame as a second crop after harvesting barley or another earlier crop.

Pliny, also writing in the first century A.D., said that gingelly [*Sesamum*] and Italian millets were summer grains and that gingelly came from India, where it was also used for making oil; and the color of the grain was white. He appears to have known sesame well. His advice for soaking the seeds prior to milling is reminiscent of the practice in Urartu: "Gingelly is to be steeped in warm water and spread out on a stone, and then rolled well and the stone then dipped in cold water so that the chaff may float to the top, and the chaff again spread out in the sun on a linen sheet, before being rolled again" (Pliny 1938: 18.22.98). In addition, E. L. Sturtevant (1972) stated that the Romans ground sesame seeds with cumin to make a pasty spread for bread.

Urartu (Armenia)

Based upon his participation in the excavation of an oil-extraction workshop at the Urartian site of Karmir Blur near Yerevan, Z. Kassabian (1957: 113) reconstructed Urartian techniques for sesame oil production as follows:

> Sesame reserves were brought to the oil press. They were washed in a basin-shaped stone container, 79 cm in diameter, carved from a block of tufa. The basin joined a cylindrical pipe made of the same stone, that allowed waste liquid to drain out beyond the citadel. Sesame seeds were soaked to ease the removal of the tegument. After maceration and thorough pressing, the sesame was moved in a semi-moist condition to the oil press (workroom #2). Here they pounded the sesame using mortars and pestles.

Details about the plant remains and tools uncovered at Karmir Blur have been summarized by Bedigian and Harlan (1986: 146–7). The workrooms were furnished with fireplaces for parching the seed. Other finds included clay storage jars 1.5 meters tall, cakes of pressed sesame (the solid residue that remains after seeds are crushed for oil), and stone mortars, pestles, and graters.

Arabia

Language. Gingelly, a name for sesame that is still often used today in India and Europe, is derived from the Arabic *juljulân* (Dymock et al. 1893; Gove 1967). Spaniards say *ajonjoli,* the French *jugleone,* and present-day Arabic medicinal and botanical works employ both *al-juljulân* and *simsim.* The word *juljulân* was in use by the eighth century, as evidenced in a poem (quoted in *Lisan al-'Arab* [1981]) by Waddâh el Kubani-al Yamani (died 709) (Faroukh 1965): "The people laughed and said: 'The poetry of Waddâh the Kinanite!' My poetry is only salt mixed with *juljulân.*"

Clearly, *juljulân* had the meaning of tiny seeds, and sesame was a plant proverbial for its heavy production of tiny seeds (Charles Perry, personal communication, 1995). But *juljulân* is usually defined as "sesame before the seeds are removed," that is, the capsule. Abu al Gauth said, "*Al-juljulân* is sesame in its hull [or peel], before it is harvested." Charles Perry (personal communication, 1995), a specialist in Near Eastern languages, has discussed the relationships among the various terms. He wrote: "The Hebrew *shumshom* (mentioned in the Mishna but not in the Bible), Aramaic *shushma,* Armenian *shusham,* Turkish *susam,* Arabic *simsim,* Greek *sesamon,* and the rest go back to the word recorded in Sumerian (though whether it's really of Sumerian origin or borrowed from Akkadian, the Semitic language spoken by the Sumerians' neighbors, is a moot question; there were borrowings in both directions). This is the usual Arabic word for sesame. For instance, in the *Arabian Nights,* when Ali Baba says 'open, sesame' he says *iftah, ya simsim.*"

Symbolism in legend. The Sudan Department of Agriculture and Forests and Department of Economics and Trade bulletin on sesame (1938) opens with a concise version of "Ali Baba and the Forty Thieves":

> When the robbers had departed Ali went to the door of the cave and pronounced the magic words he had heard them use, "OPEN SESAME." The door opened and he went inside and the door closed behind him. So astonished was he at the sight of the treasures in the cave and so absorbed in contemplation of them that when at last he desired to leave the cave he had quite forgotten the formula "OPEN SESAME." In vain he cried aloud Open wheat, Open barley, Open maize, Open lentils; none of these availed and the door remained shut.

The significance of sesame in Arab culture is suggested by the fact that it was chosen as "a magical means of commanding access" (Arulrajan 1964). Once, sesame was thought to have mystical powers, and for some it still retains a magical quality. In fact, "open sesame" has become a common cliché that is still used today. But the question "why sesame?" remains, and the answer might be that the high-quality sesame oil could have been thought to act magically to oil locks and open doors; in addition, sesame capsules do dehisce spontaneously (magically?) to release their seeds.

Persia

Symbolism in legend. Another example, this one of sesame employed as an omen, comparable to its usage in the magical incantation "Open Sesame," occurs in the *Iskandarnama* (Book of Alexander), one of the *Sharafnama,* the "Book of Kings," completed A.D. 1010. Accompanied by an illustration of a miniature of Alexander the Great feeding sesame seed to birds (Titley 1979: 8, 10–11), the story

> relates the parleying and battle between Alexander the Great and Darius. The Sultanate *Sharafnama* in the British Library has a rare illustration of an episode in which Darius insulted Alexander by sending him a polo stick and ball and a bowl of sesame seed. Darius was angry because Alexander had not sent him gifts in the traditional manner and despatched a messenger to tell him so. Alexander equally angry replied that Darius had treasure enough already whereupon Darius sent him the polo stick and ball and a bowl of sesame seed saying that as Alexander behaved like a child he should have the playthings of a child. The sesame seed represented the countless soldiers in the great army Darius proposed to send against him. Alexander chose to interpret the gifts in another way and saw them as omens of victory. To him the polo ball represented the world (i.e. Darius' possessions) which Alexander would draw towards himself with the stick (i.e. by means of his army) as in polo. He threw the seed to birds which pecked every grain from the ground and he told Darius that it would be thus that his soldiers would wipe out the army of Darius. He then sent the messenger back to Darius with a bowl of mustard seed as a symbol of his own soldiers. The miniature graphically portrays this incident with a flock of hoopoes, parrots, pigeons, starlings and crows pecking the grain watched by Alexander and his retinue while the polo sticks and bowl of remaining seed are in the background (Titley 1979: 10–11).

China

According to the *Pen Ts'ao Kang Mu* (1596) by Li Shih-Chen, a classic ancient Chinese herbal and medical treatise, sesame was brought from the West by General Chang Ch'ien during the Han dynasty (second century B.C.), probably via the Silk Route. The Chinese name *tzuh-ma* indicates introduction from overseas, and the Han dynasty was marked by expansion that opened China to things foreign, including foreign foods (Yü 1977: 80). Y. S. Yü has written that because sesame appears three times in the text, it seems to have been particularly important. Moreover, he suggests that the "barbarian grain food" *(hu-fan)* enjoyed by Emperor Ling (A.D. 168–88) was most likely grain food cooked with the flavorful sesame.

Yü (1977: 81) quotes another source (Ch'i 1949: 294–5): "Under the Later Han, a great variety of noodle foods were cooked, including boiled noodles, steamed buns (modern *man-t'ou*), and baked cakes with sesame seeds." In T'ang times these were extremely popular foreign cakes, and a steamed variety containing sesame seeds was particularly well liked. In the capital city, these cakes were sold by foreign vendors – seemingly Iranians for the most part – on street corners (Hsiang 1957: 45–6, cited in Schafer 1977: 98). F. W. Mote listed sesame-oil noodles among a group of sacrificial food offerings made to ancestors during the Ming dynasty and suggested: "[W]e can assume that they reveal the tastes and food ideals of the former poor peasant family which now found itself the imperial family, and that the foods offered were also those actually eaten in the imperial household" (Mote 1977: 217).

Record of Modern Usage

India

Sesame is employed extensively in India, especially in the states of Gujarat and Tamil Nadu. Among other things, the seeds, with rice and honey, are used to prepare funeral cakes *(pindas)* that are offered to the ancestors in the Sraddh ceremony by the Sapindas (Dymock et al. 1893). *Tilanna,* sesame-rice balls formed in the shape of cows, are offered to relatives and friends of the deceased after a funeral. This ritual is enacted to say a proper farewell to the departed, and, as mentioned, the offering of sesame seeds is considered effective in removing sins (Gupta 1971). Indeed, *tilanjali* is a derived word meaning "to bid a final good-bye/to leave" (Chaturvedi and Tiwari 1970).

There are also many other uses. According to Dymock et al. (1893: 26–7): "On certain festivals six acts are performed with sesame seeds, as an expiatory ceremony of great efficacy, by which the Hindus hope to obtain delivery from sin, poverty, and other evils, and secure a place in Indra's heaven." These acts are *tilodvarti* ("bathing in water containing the seeds"), *tilasuayi* ("anointing the body with the pounded seeds"), *tilahomi* ("making a burnt offering of the seeds"), *tilaprada* ("offering the seeds to the dead"), *tilabhuj* ("eating the seeds"), and *tilavapi* ("throwing out the seeds"). In proverbial language, a grain of sesame signifies the least quantity of anything. Examples of this usage are *til chor so bajjar chor* ("who steals a grain will steal a sack") and *til til ka hisab* ("to exact the uttermost farthing") (Dymock et al. 1893: 27).

S. M. Vaishampayan (personal communication, 1977) has noted that at the festival of "Makar Sankranti," which takes place on January 14 (when the sun enters the Zodiac sign "Makar," or Capricorn), the Hindus eat a composition of *gur* (brown sugar) and *til,* which they call *tilkut.* Among the Maharashrian Brahmins, elders offer sweetmeats made out of sesame seed and powdered sugar to youngsters, and bless them, saying: "*Tilghya, Gulghua* and *Gode bola,*" which means "have sesame sweets and be sweet with everybody."

Donald Lawrence, Professor Emeritus of Botany at the University of Minnesota, who corresponded with this author about the uses of sesame in India, sent some beads from Pune, India (courtesy of Makarand S. Jawadekar), that are made of sesame seeds encrusted with sugar. Jawadekar, in a letter to Lawrence, dated February 9, 1986, wrote: "Newly wed brides wear, on January 14th, the necklace made out of these sugar-sesame beads – believed to bring good luck."

The Middle East and North Africa

This region shares common foods and similar preparation methods as a result of a historically steady exchange of ideas as well as trade goods. The peoples of Arabia, of the emirates in the Persian Gulf, of Armenia, Egypt, Greece, Iraq, Iran, Israel, Jordan, Lebanon, Somalia, Sudan, and Syria all prepare versions of *hummus* and *baba gannouj,* combining the flavors of chickpea and smoky eggplant with sesame paste, *tahini,* as well as sesame candies and biscuits.

The word for sesame in the Armenian dictionary (Yeran n.d.) is *shushmah,* not unlike the Sumerian word *šamaššammū* (confirmed by Charles Perry, personal communication, 1995). There are two versions of an Armenian coffee cake prepared with sesame. One is *pagharch,* a leavened bread in which the dough is folded with sweetened sesame paste.

Another version is a specialty item prepared just before Armenian Easter. A soft dough is allowed to rise to double its size, and a sesame mixture is brushed upon it. Then the dough is rolled like a slender jelly roll, which is finally coiled into a flat round circle and allowed to rise again before baking. Bread rings topped with sesame seed are sold everywhere in Turkey and take their name, *simit,* from *simsim.* In Morocco, sesame is known as *jinjelan.* It is used in Moroccan bread and desserts and, when toasted, the seeds are a popular garnish for chicken and lamb *tagines.*

In Sudan, sesame used for oil and seed constitutes one of the country's food staples (Bedigian and Harlan 1983). An enormous genetic diversity of traditional sesame cultivars in Sudan seems to correspond with the region's cultural diversity (Bedigian 1991). People are extremely fond of sesame as both a food and a metaphor for something small and precious. Sesame is used in the form of a solid cake blended with sugar, called *tahneeya* in the Sudan; the name for the sesame paste alone is *taheena. Taheena* is employed as a sauce, with fresh tomatoes and cucumbers, or with *tamia,* a fried chickpea patty to which sesame seeds can be added.

Egypt takes 90 percent of Sudan's exported sesame to make *halvah.* Rural growers in Sudan deliver their sesame seeds to oil presses called *assara,* powered by camels or engines (Sudan Department of Agriculture and Forests and Department of Economics and Trade 1938; Bedigian and Harlan 1986).

East Africa

Sesame, *nyim,* is one of the traditional crops of the Luo of western Kenya, and it is very likely that the crop arrived there when the first Luo migrated from the Sudan (Ogot 1967). Yet today, there is substantially less cultivation of sesame than there was at the beginning of the twentieth century. Most of the sesame for sale in western Kenya comes from Uganda, and such a decline in sesame cultivation is not a singular event. Similarly, finger millet, *cal,* which has historical significance for the Luo and was probably brought to Kenya by them during the earliest migrations from the Sudan, is now being replaced by maize, despite the fact that millet is more nutritious. Much of this has to do with British colonialism, which replaced sesame with corn oil or even less healthy hydrogenated shortenings.

When sesame is used in Kenya, it is pounded into a paste to be served with sweet potatoes or with local leafy greens. The paste can be diluted and used as a dip called *dengo;* it may also be added when cooking fish. A *winja,* combining black sesame seeds, finger millet, and dry beef cooked in sesame oil, is a special dish for a new son-in-law before his wedding. The dish is also used to appease spirits and to prevent lightning strikes – in short, to ward off harm.

China and the Far East

The Chinese considered sesame to be the best of the oilseeds, and their name for sesame oil *(hsiang yu)* means "fragrant oil." According to Bray (1984: 524–5): "Not only does it have all the qualities mentioned in the *Thien Kung Khai Wu,* the expressed cake is a protein-rich livestock food (sometimes eaten, fermented, by humans in India and Java), and in China it was recognized as an excellent fertilizer." B. Cost (1989) called sesame seed oil "a contender for the world's most seductively flavored oil, a seasoning fundamental to the cuisines of China and Japan. Like the Chinese sesame paste, the oil is pressed from roasted seeds. Cooking with it is a waste, since it loses its flavor over high heat and is expensive."

Regarding sesame seed paste, Cost (1989) has written that (unlike the Middle Eastern *tahini*) the Chinese paste is made from roasted, rather than raw, sesame seeds. As a flavorful peanut butter–like sauce, it is used mostly in sauces and dressings for cold dishes and salads, but occasionally in marinades. It is also a constituent of *shichimi* ("seven spices"), consisting of the dried orange berry of an indigenous ash (related to the Sichuan peppercorn, and ground dried chillies), flakes of dried orange peel, white poppy seeds, sesame seeds, black hemp seeds, and bits of seaweed. This is a mixture that can be sprinkled over a variety of dishes.

Japanese sesame tools. Y. Kakehashi (personal communication, 1995) has indicated that, in Japan, fresh sesame seeds are toasted prior to adding them to a dish to enhance its flavor. The Japanese use a clay container, designed specifically for this purpose, called *goma iri* (*goma* is sesame). It is glazed inside and is approximately 10 centimeters in diameter and 20 centimeters in length, including the handle. The shape is hollow (like a rubber tire) except for its completely flat bottom; the sides fold inward toward the open center, preventing the seeds from escaping as they pop during the parching. The toasted seeds are collected by pouring them out of the conical funnel-shaped hollow handle. There is also a special ceramic mortar, *suribachi,* for grinding sesame seeds. It has corrugations inside that allow gentle crushing to take place.

Europe

Mary Tolford Wilson (1964) has noted the mercantilistic encouragement the British provided for cultivating sesame in their American colonies. The hope was that sesame oil might replace the olive oil they imported from European rivals, and thus sesame became one of those commodities whose colonial production the British encouraged. By contrast, the use of sesame was discouraged and even prohibited in nineteenth-century France in order to protect local rapeseed-growing interests, a policy that hints at the popularity of sesame at that time.

The United States

If the British contemplated the production of sesame oil in America, it may have been Africans who brought the seed to their attention. One name applied to sesame in the southern United States is *benne.* Lorenzo Turner (1969: 62) has compiled a comprehensive list of Africanisms in the Gullah dialect, in which *bene* is a feminine personal noun that means sesame in Bambara (French West Africa) and Wolof (Senegal and Gambia). Jessica Harris (personal communication, 1995), the culinary historian whose specialty is African-American foods, was astonished to learn this fact. She has not seen many examples of African-American words for foods in which the original language can be so specifically identified.

It is the case, however, that the contributions of African slaves to crop introductions in the Americas have rarely received sufficient recognition. In their free time, slaves tended their own gardens, where they grew vegetables, including greens and "presumably African favorites such as okra, sorghum, black-eye peas, eggplant and benne seed" (Hess 1992: 8). These crops were very likely brought from Africa during the slave trade, along with yams, watermelons, and indigo.

That sesame was in colonial America by 1730 may be seen in a document in the *Records in the British Public Record Office Pertaining to South Carolina.* A letter from one Thomas Lowndes, dated August 26, 1730, reads:

> My Lords, a planter in Carolina sent me some time ago a parcel of seed, desiring I would try it, and see of what use it would be, for if it turn'd to account South Carolina could with ease produce any quantity of it. By an experiment I found twenty one pounds weight of seed produced near nine pounds of good oyl, of which more than six pounds were cold drawn and the rest by fire. The name of the seed is Sesamum it grows in great abundance in Africa and Asia, and the inhabitants of those parts eat it, as well as use it for several other purposes. Pliny and many other good authors ancient and modern treat of this seed. It rejoyces in the Pine Barren Land (which is generally a light sandy soil). . . . This seed will make the Pine Barren Land of equal value with the rice land . . . and is for many purposes even prefereble to oyl olive.

Some decades later, on May 25, 1774, the *Georgia Gazette* printed an early shipping record of sesame (page 2, column 2) aboard the ship *Savannah,* which carried 500 pounds of "benny" along with 20,000 pounds of sago, 200 gallons of soy, 200 pounds of vermicelli, 1,000 pounds of groundnuts, and a 10-gallon keg of sassafras blossom.

The most famous figure of America's early years to be interested in sesame was Thomas Jefferson, who earnestly recommended sesame growing to his friends (Wilson 1964). Jefferson's "Garden Book," which is the richest single source on the crop and records plantings of sesame grown at Monticello as long as the book was kept (to 1824), was edited and published by E. M. Betts in 1944. In it is a letter from William Few of New York to Jefferson, dated January 11, 1808, that was not transcribed by Betts but cited this way: "Tells Jefferson how to extract oil from Beni seeds and the history of its introduction to America." A facsimile of the original manuscript was provided to this author by the Manuscript Division, Library of Congress. Here is the text of the unpublished document:

> When introduced into the southern states? We have no certain account of a tradition of its introduction. The Negroes are well acquainted with it and fond of cultivating it. It was probably introduced from the Slave Coast, but as we

> know that it was cultivated up the Mediterranean in very early time, it is possible that we may have received it from that quarter. If the correct orthography of the name could be ascertained it might determine the question. We know that we received our rice from both of these sources and it may have been the same case with the benne. When it was introduced it can be difficult to ascertain as it has never interested us as an object of agriculture or curiosity. We only know that the oldest of our inhabitants remember it from their earliest days.

The Caribbean

Trinidad. Bene (sesame) is included in the lexicon of Wolof contributions to the language in Trinidad (Warner-Lewis 1991). Africans in nineteenth-century Trinidad had a ceremony of thanksgiving and ancestor intercession called the *saraka,* during which animal sacrifice and offerings of unsalted food were made. Ritual plant ingredients for the ceremony included kola nut (sent as a token to guests with their invitations), rum, stout and wine, bene (called *ziziwi*), black-eyed peas and rice, corn cooked with olive oil, and bread. Similarly, a Yoruba wedding in central Trinidad was characterized by a feast that included *bene* made into balls and sugar cake (Warner-Lewis 1991). Rice, black-eyed peas, potato, and grated, dried cassava also formed part of the menu.

Jamaica. That Africa was the source of sesame reaching Jamaica is reflected in a local name, acknowledged in a publication by J. Lunan as early as 1814. Sesame was called "*sesamum Africanum,*" brought to Jamaica under the name of *zezegary,* and Lunan reported that "the first time I saw the plant, it was growing in a negro's plantation, who told me, they ground the seed between two stones, and eat it as they do corn. Their seed-vessels, [are] full of small white seeds, which the negroes call *soonga,* or *wolongo.* The oil that is drawn from it is called *sergilim* oil. The seed is often mixed and ground with coco, to make chocolate" (Lunan 1814: 252). Sesame was prized as a source of oil, with good reason:

> [T]here are few which more deserve to be extensively cultivated into general domestic use, [to replace] that abominable rancid butter imported hither from Europe. Nothing but the grossest prejudice, in favor of old habits, can influence the inhabitants to persevere in the importation of that unwholesome, nauseous stuff, and to swallow it every day with their food, when they may supply themselves with so fine, nourishing and wholesome an oil, as the *sesamum,* for an ingredient in their pastry; nor are they less blamable, for continuing to import the olive oil, which is generally rancid before it arrives and fitter for perukes [wigs] than salads (Long 1774: 809).

II.E.5 Soybean

Description

The soybean plant belongs to the legume family *(Leguminosae),* the second largest family of flowering plants, with more than 14,000 species. Identifiable characteristics include a fruit located within a pod that dehisces along a seam from top to bottom. In the case of a soybean, the split takes place when the plant has matured and died to yield 2 to 4 seeds per pod that are easily removed without damage or loss.

The soybean's size, shape, and color is determined by the variety. Soybeans range in size from small (1 centimeter [cm]) to large (3.5 cm), can be flattened or oblong, and are colored yellow, green, brown, or black. They are approximately 8 percent hull, 90 percent cotyledon, and 2 percent hypocotyl (Wolf and Cowan 1971).

Terminology

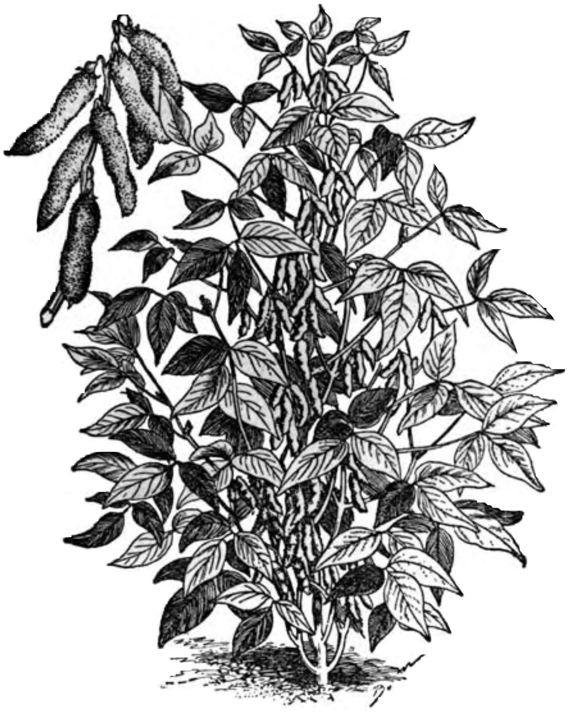
The terms "soy and "soya" are said to have derived from the Japanese word *shoyu* (or *sho-yu*) that designates a sauce made from salted beans. But the Japanese word may well have been inspired by the ancient Chinese name for the bean, which was *sou.* In Chinese, the word for soy sauce is *jiangyou* (or *chiang-yiu*). C. V. Piper and W. J. Morse (1923) have recorded more than 50 names for the soybean or its sauce in East Asia. In English the bean has been called soya bean, soya, soy, Chinese pea, Japanese pea, and Manchurian bean, to provide just a few of its appellations. For the purposes of this chapter, soya is used synonymously with the soybean and its many products.

Early History

Present-day soybean varieties *(Glycine max),* of which there are more than 20,000, can be traced to the wild soybean plant *Glycine soja* that grew in abundance in northeast China and Manchuria (Hymowitz and Newell 1981). Legends abound concerning the discovery and domestication of this food plant that today is the most widely used in the world (Toussaint-Samat 1993: 51). Around 2700 B.C., the legendary Chinese emperor Shen Nung is said to have ordered plants to be classified in terms of both food and medicinal value, and soybeans were among the five principal and sacred crops (Shih 1959). This dating squares nicely with the judgment of modern authorities on Asian plants that soybeans have been cultivated for at least 4,500 years (Herklots 1972). But there are other sources that indicate that the domesticated soybean (G. *max*) was introduced to China only around 1000 B.C. perhaps from the Jung people who lived in the northeast (Trager 1995).

The court poems of the *Book of Odes,* sixth century B.C., also indicate that the wild soybean came from northern China and that its cultivation began around the fifteenth century B.C. Confucius, who died in 479 B.C., left behind writings that mentioned at least 44 food plants used during Chou times; they included soybeans. But they do not seem to have been very popular in ancient times. Soybeans were said to cause flatulence and were viewed mostly as a food for the poor during years of bad harvests. Nonetheless, soybeans were recorded in the first century B.C. as one of the nine staples upon which the people of China depended, and certainly there were enough people. The first official census conducted in Han China at about that time counted 60 million people, and even if such a number seems implausibly high – especially in light of a census taken in A.D. 280 that showed only 16 million – it still suggests that Chinese agricultural policies were remarkably effective, both in feeding large numbers of people and, one suspects, in encouraging the growth of large numbers of people (Chang 1977: 71). The famine in China in the year A.D. 194 may have been the result of too many mouths to feed and thus responsible, at least partly, for the discrepancy in the two censuses. But in addition, famine forced the price of millet to skyrocket in relation to soybeans, resulting in an increased consumption of the latter – often in the form of bean *conjee* or gruel (Flannery 1969).

Soybean



Early Dissemination

Because the wild soybean was sensitive as to the amount of daylight it required, and because the length of growing seasons varied from region to region, domestication involved much experimental planting and breeding to match different varieties with different areas. That this was done so successfully is a tribute to ancient Chinese farmers who, as noted, were doubtless impelled by an ever-increasing need to feed larger and larger populations of humans and animals. Soybeans ground into meal and then compressed into cakes became food for travelers and soldiers on the move who, in turn, widened knowledge of the plant.

Buddhist priests, however, were perhaps as instrumental as anyone in the domestication of the soybean and absolutely vital to its dissemination (Yong and Wood 1974). As vegetarians, they were always interested in new foods and drinks (such as tea, which they also nurtured to an early success in China). In their monasteries, they experimented with soybean cultivation and usage and found flour, milk, curd, and sauce made from soy all welcome additions to their regimes. As missionaries, they carried the soybean wherever they went, and in the sixth century A.D., they introduced it to Japan from Korea, which they had reached in the first century. Buddhism merged with the native Shinto religion, and the plant quickly became a staple in the Japanese diet.

Not only missionaries but also soldiers, merchants, and travelers helped introduce soybeans to Asian countries. The northern half of Vietnam had soybean food products as early as 200 B.C. During the sixth through the tenth centuries A.D., Thailand received soybeans from southwest China, and India was exposed to them during the twelfth century by traders from Pakistan.

Recent History and Dissemination

The Portuguese began trading in East Asia during the sixteenth century, as did the Spanish and later the Dutch. Yet the soybean was not known in Europe until the end of the seventeenth century when Engelbert Kaempfer published his *Geschichte und Beschreibung von Japan,* an account of his visit to that country during the years 1692–4 as a guest of the Dutch East India Company. He wrote of the bean that the Japanese prized and used in so many different ways, and in 1712, he attempted, not very successfully as it turned out, to introduce this miracle plant to Europe. Its products simply did not fit into the various cuisines of the continent, which, in any event, were only then in the process of fully utilizing the relatively new American plants, such as maize and potatoes.

The botanists, however, were thrilled to have a new plant to study and classify, and Carolus Linnaeus, who described the soybean, gave it the name *Glycine max. Glycine* is the Greek word for "sweet," and "max" presumably refers to the large nodules on the root system, although other sources suggest that the word *max* is actually the result of a Portuguese transcription of the Persian name for the plant (Toussaint-Samat 1992: 52).

Because of scientific interest, the soybean was shuttled about the Continent during the eighteenth century for experimental purposes. In 1765, soybean seeds reached the American colonies with a sailor named Samuel Bowen, who was serving aboard an East India Company ship that had just visited China. Bowen did not return to the sea but instead acquired land in Savannah, Georgia, where he planted soybeans and processed his first crop into Chinese vetch, soy sauce, and a starchy substance incorrectly called sago. In North America as in Europe, however, soybean products did not go well with the various cuisines, and the bean remained little more than a curiosity until the twentieth century, despite efforts to reintroduce it.

By the mid–nineteenth century, the soybean was being rapidly disseminated around the globe as trade, imperialism, clipper ships, and then steamships all joined to knit the world more closely together. The expedition of Commodore Matthew Perry that opened Japan to trade in 1853–4 returned to the United States with the "Japan pea" – actually 2 soybean varieties that were subsequently distributed by the U.S. Commissioner of Patents to farmers for planting. But lacking knowledge of and experience with the plant, the recipients were apparently not successful in its cultivation.

During the American Civil War, when shipping was disrupted, soybeans were frequently substituted for coffee, especially by soldiers of the Union army (Crane 1933: 270). Interest also arose in soybean cultivation as a forage plant, and the Patent Office and the new Department of Agriculture (USDA) encouraged experimental planting. The USDA's role in promoting agricultural research, regulating the industry, and serving as an information generator for farmers proved invaluable to all farmers and certainly to those growing soybeans for the first time (Arntzen and Ritter 1994: 466).

There were 2 stages in processing the soybean plant as a forage crop or hay. The first was to cut the plants just before the leaves turned yellow but after the pods, containing semiripened seeds, had formed, thereby increasing the plants' protein value. In the second stage, the plants were windrowed and left to dry for a day or two, after which the windrows were raked into bunches and dried for another three or four days. Lastly, the bunches were stacked in barns right side up. The average yield of hay using this method was approximately 4 tons an acre, with a protein content of close to 11 percent.

In harvesting the soybean plant for silage, the process called for cutting the plants earlier – when their seedpods contained premature green seeds.

These were made into bundles of about 25 pounds each, then stored in barns until needed. This method traded some protein content for less leaf loss during harvesting.

Soybean plants, processed by either of these methods, lowered the cost of feeding livestock by replacing the more expensive grass hay and corn. Even a combination of soybean hay or silage and traditional feeds resulted in considerably reduced feed costs and supplied more protein than hay or corn alone could deliver.

At the turn of the twentieth century, the population of the United States was swelling with immigrants, and significant technological advances were spinning out of an ever-accelerating industrial process. An increased demand for food spurred soybean cultivation, and processing was facilitated by electric motors to power grinding equipment that made soybean meal more quickly and efficiently than ever before. Mechanized farm implements encouraged the planting of still more land in soybeans, while lowering the costs of harvesting.

The result was that soybeans produced in the United States became competitive with those grown in East Asia, despite the Asian application of very cheap labor. By 1911, the U.S. industry not only processed soybean meal into cakes for livestock feed but also began to press the beans into oil, as China was already doing. Indeed, the high oil content of the soybean (about 20 percent) was arousing substantial commercial interest.

Previously, a shortage of soybeans in the United States and the predominance of cottonseed oil (then called Wesson Oil after David Wesson, who, in 1899, developed a method for clarifying it) had retarded the development of soybean oil. But in 1915, cottonseed oil became scarce because the U.S. cotton was infested with boll weevils, and this in turn led to the processing of soy oil for human consumption. Cottonseed-processing plants quickly became soybean-processing plants, because the presses and other equipment worked equally well with soybeans. Moreover, a new method was discovered for extracting the oil by first grinding the beans, then soaking them in a solution of benzol, naphtha, and ether, which for every bushel (60 lbs.) of soybeans yielded 10.5 pounds of oil and 48 pounds of meal. Thus, soybean oil was efficiently produced at a time when World War I was creating more demand for oils.

None of these lessons in supply and demand were lost on southern farmers, who began to plant soybeans on land barren because of the boll weevil. The USDA also encouraged soybean cultivation in the states of the Midwest. In 1922, a soybean-processing plant was opened in Decatur, Illinois. To ensure a steady soybean supply, the "Peoria Plan" was developed to guarantee Illinois farmers a base price of $1.35 a bushel (Smith and Circle 1972). In addition, farmers throughout the nation were given an inducement to grow soybeans with the passage, in 1923, of the Smoot-Hawley Tariff, which placed import duties of 2 cents per pound on soybeans, 3.5 cents per pound on soybean oil, and $6.00 per ton on soybean meal.

Soybeans became the nation's "Cinderella" crop in the 1920s. Demand was high for soybean cakes, which continued to provide farmers with a high-protein, low-cost animal feed. But it was demand for soybean oil that stimulated still more production; soybeans yielded oil valued at 20 cents per pound, or $400.00 per ton, as opposed to meal worth only $20.00 a ton. Research supported by the processing plants helped plant breeders develop new soybean varieties with higher oil contents.

During the 1920s, this oil went into numerous industrial products, among them soaps, paints and varnishes, linoleum, ink, glycerin, explosives, celluloid, and a substitute for rubber. Moreover, the low cost of soybean production stimulated research to discover still more industrial uses. Yet, soybeans remained an underused food resource because of their relatively high saturated fat content, which made the oil solidify, as well as their high percentage of bad-tasting linolenic acid.

It was during the 1930s that research on soybean oil refinement, flavor reversion, and especially hydrogenation ultimately resolved these problems and opened the way for soybeans to be employed in food products (Toussaint-Samat 1993). Increasingly, the oil found its way into shortenings, margarine, salad dressings, and, of course, cooking oils. In fact, during the Great Depression years, soybean oil was well on its way to becoming the most important food oil in the United States, a status it achieved after World War II and never relinquished.

It is interesting to note that during that war, the only survival rations issued to Japanese soldiers had consisted of bags of soy flour, perhaps illustrative of the fact that despite the growing use of soybeans in the United States, they were still an Asian resource. Following the war, soybeans became the world's most important crop, not because of the Asian influence but because of productivity. Initially, much of the postwar surge of U.S. interest was due to the ability of soybeans to regenerate the soil when planted in rotation with corn (Pepper 1994: 193). During the war, soy margarine had replaced butter on most tables, a use that continued after 1945.

Making a transition to soybeans from a previous concentration on corn, wheat, cotton, or tobacco was scarcely a hardship for farmers because surpluses of these latter crops existed, and because with the passage of the Agriculture Adjustment Act in 1933, restrictions had been placed on the amount of acreage that could be devoted to them. Meanwhile, the government was promoting soybean products by, among other things, organizing the Regional Soybean Industrial Products Laboratory in 1938.

And once again research found industrial applications for soybeans – this time for using soy protein in the paper industry and for making plastics from oilcake residue in the automobile industry. At the same time, world food requirements in the 1950s increased demand for soy protein for both humans and domesticated animals. During this decade, American farmers responded by producing an annual average of 300 million bushels of soybeans for industrial and food use. In the process, the United States, which prior to World War II had been the world's biggest importer of fats, became its greatest exporter, accounting for fully 75 percent of the world's soybean crop.

Because of plant breeding, the soybean – once a subtropical plant – moved north as far as 52 degrees, and soybean fields became familiar sights from Minnesota to the Deep South. Soybean meal processed in the northern states was carried by rail to barges on the Mississippi River that transported it to New Orleans for shipment to world markets (Forrestal 1982).

In addition to the ease of bulk transportation, soybeans lend themselves to handling in many other ways. They can withstand long storage and shipment over long distances; they are easily harvested in an entirely mechanical procedure; and a growing season of only 15 weeks makes it easy to adjust production to world market demand. In short, as one food author has pointed out, supply can be virtually guaranteed, and if there is overproduction, there is no need to destroy the surplus (Toussaint-Samat 1993).

The people of Far Eastern countries receive, on average, about 12 percent of their protein requirements from soybean products. But despite the high protein content of the soybean and the high quality of that protein, attempts to introduce soya to many poor regions of the world, such as India, Africa, and Latin America, have historically met with little success, with southern South America a notable exception. For example, in Mexico in the 1940s the National Indian Institute handed out soybeans to the impoverished Otomi Indians living in the Mezquital valley. Although the legume flourished in the arid soil, the experiment failed when Otomi women were unable to hand-grind the soybeans to make a decent tortilla (Granberg 1970).

International efforts, however, continue to increase consumption, particularly in the soybean fortification of cereals on which many people rely. All of these cereals – rice, maize, barley, wheat, and rye – yield a protein that is incomplete, meaning that it does not contain all of the essential amino acids. Yet what they lack, soybeans contain, and soybeans are also high in the B vitamins, along with vitamin E, phosphorous, and iron. Thus, in cases where soya is used to supplement other cereals, as in Golden Elbow or Vitalia macaroni, Kupagani biscuits, ProNutro cereal, and Cerealina, the consumer receives a whole protein equal to that provided by meat, fish, and dairy products (Fortified foods 1970).

Processing, Preparation, and Products

The oldest methods of preparing green, immature soybeans for consumption was by roasting or by soaking, grinding, and cooking (Toussaint-Samat 1993). Mature soybeans were processed in much the same manner but with a longer cooking time.

Soybeans, paradoxically, have a very bland taste, which probably inspired the development of flavorful fermented soy products. Such soy processing began in China during the Chou dynasty (1122–246 B.C.) and subsequently spread to other areas of the Far East.

One of the first of these products, and the best known to Westerners, is *shoyu* or soy sauce – a dark brown liquid used extensively in Chinese food preparation – that is obtained by fermenting a combination of soybeans and wheat. The original process entailed first boiling soybeans with *koji (Aspergillus oryzae)* which, in this case, was a mold skimmed from the surface of cooked wheat that had cooled and fermented. Soy sauce has a salty taste and a subtle, but tantalizing, aroma that goes well with rice dishes.

Another product is soy paste, produced in a process similar to that which yields soy sauce, except that the *koji* is derived from barley or rice. Soy paste is also Chinese in origin and evolved from a paste of fish puree called *jiang* that was used before soya became popular. By the time of the Han dynasty in the third century, soy paste had become the important ingredient in *jiang.* Two or three centuries later, the Koreans were producing soy paste and the Japanese got the recipe from them. Today there are numerous such pastes, called *miso,* in everyday use in Japan. The color can vary, depending on the soybean-to-rice or barley ratio. The greater the amount of rice used, the lighter (and sweeter) the product. In the past, soy paste was stored in earthen jars for up to a year, which was said to improve the flavor.

Tempeh kedlee is a third soy product primarily confined to Indonesia, where more than half of the soybeans produced are devoted to it. It has a fine flavor, but not the longevity of other soy products. Also Indonesian in origin is *ontjom,* made by combining the residue of soybean milk with peanuts and allowing the mixture to ferment. The result is a kind of soy sauce with a nutlike flavor.

Still another product that originated in Indonesia (and Thailand as well) is *tao tjo,* made by combining cooked soybeans and roasted rice flour with *koji.* After about four days, a fungus covers the solution, whereupon the mixture is dried in the sun, then soaked in brine. A few days later, sugar and rice yeast are added and the sun, once again, is employed to dry the combined beans and flour. The end product is a sweet soy sauce to accompany vegetable, meat, or fish dishes.

A final Indonesian contribution is *ketjab,* in which bacteria are combined with cooked black beans, fermented, and then placed in salt brine for a week or so. The beans are drained and the residue is cooked several times. The extract that remains is sweetened with sugar and permitted to evaporate further.

A sixth soy product is *natto,* a gray-colored liquid with a strong, musty flavor, produced in Japan by wrapping cooked soybeans in rice straw and allowing the whole to ferment. The taste is something of an acquired one for Westerners and varies depending on locale.

Buddhist monks first developed *hamanatto* in their monasteries. This is still another fermented soy product, obtained in an elaborate procedure employed by the monks that began with soaking whole soybeans for up to 4 hours, then steaming them for 10 hours. Afterward, the beans were covered with *koji* and left to ferment for 20 hours, during which time a green mold developed to cover the beans. Next, they were dried in the sun to lower their moisture content, then placed in wooden buckets with strips of ginger on the bottom. After a year, the soybeans were once more dried in sun – this time until they turned black. The final product was a soybean sauce with a very sweet flavor and a pleasant aroma.

The major Korean contribution to soy products of the world is *kochu chang,* made by mashing boiled soybeans and beginning their fermentation with the addition of a bit of a previous batch, much like starter dough. This mixture was then placed in a sack and hung to dry in the sun for a couple of months, after which time the fermented mash was pulverized and mixed with salt and water. The final step was to put the mixture in an earthen jar to age for three months or so. After chilli peppers reached the East in the sixteenth century, they were added to the mash for additional flavor.

In addition to these sauces, soybeans have been processed by the Chinese and others of the Far East into bean curd, soybean milk, and bean bran. Soybean curd or *tou-fu* is made by wet-grinding the beans into a thin mixture that is strained, then coagulated with gypsum, which causes the proteins to precipitate. The mixture is strained a last time to become bean curd and soy milk, respectively. Bean curd thus provides the Asians with flour and milk, both very important foods in everyday life. The curd itself is often served with rice, meats, vegetables, and fish. It is also added to soups, mashed for making breads and cakes, and deep-fried.

Soybean milk – a vegetable milk – is obviously of considerable importance in a region of the world where little cattle raising takes place and where the human population seems to be uniformly lactose intolerant. In addition to serving as a beverage in its own right, soy milk is processed as a soft drink (Trager 1995).

The sprouts of soybean and mung beans *(Phaseolus aureus)* serve as an instant vegetable high in vitamin C and are also blanched and processed into cellophane noodles. Soybean sprouts are traditionally eaten on the Chinese New Year. Finally, young soybean pods are eaten boiled or roasted as a snack with soy sauce or sesame oil.

Nutrition

East Asians have long been dependent on soybeans for corrections of nutritional deficiencies. Soy sauces and other typical soy products are all concentrates of the B vitamins and contain significant amounts of the minerals calcium, iron, magnesium, phosphorous, and zinc. In addition, as we have already noted, they yield a very high quality protein, as well as important lipids, carbohydrates, and fiber.

Soy protein is also important nutritionally because of the ways in which it is employed in other food products for purposes of emulsion formation, promotion of fat and water absorption, and texture and color control. Foods benefiting from soy protein include bologna, frankfurters, breads, soups, cakes, pasta, gravies, whipped toppings, and simulated meats, vegetables, and fruits (Wolf and Cowan 1971: 52).

Soy flour usage, however, has not lived up to earlier expectations. The flour does have a nutty taste and very fragrant aroma; sweetened with sugar, it is baked into breads, muffins, cakes, cookies, and the like (Piper and Morse 1923). But unfortunately, it has a limited shelf life, which discourages production in large quantities.

It would not do to end this section on the nutritional value of soybeans without noting that they also contain various potentially toxic substances that can inhibit growth, reduce the absorption of fats, enlarge the pancreas, and decrease the energy yield of the diet (Norman 1978: 227). Among these antinutritional agents are trypsin, phytic acid, hemagglutinin, saponin, and phenolic constituents. Fortunately, the process of cooking eliminates the toxicity of soybeans.

II.E.6 ~ Sunflower

One of the most important of today's oil crops, the sunflower is a unique contribution of temperate North America to the world's major food plants. In addition to its superior oil, the seed of the sunflower is much appreciated as a food. Other parts of the plant were used for a variety of purposes by Native Americans. Today the species is also widely grown as an ornamental for its large showy heads.

Biology

Scientifically, the sunflower crop plant, known as *Helianthus annuus* var. *macrocarpus,* is a member of the family Asteraceae. It is an annual, is unbranched, grows from 1 to 3 meters tall, and bears a single large head up to 76 centimeters (cm) in diameter. Each head contains showy yellow sterile ray flowers and up to 8,000 smaller disk flowers. The latter produce the fruits, technically known as achenes, but commonly called seeds. The fruits, from 6 to 16 millimeters (mm) in length, contain a single seed.

In addition to the cultivated variety, the sunflower also includes branched, smaller-headed varieties *(Helianthus annuus* var. *annuus* and *Helianthus annuus* var. *lenticularis)* that are common as weeds or wild plants in North America from southern Canada to northern Mexico. Forms of the sunflower, particularly those with double flowers or red ray flowers, are cultivated as ornamentals, but more so in Europe than in North America (Heiser 1976).

The genus *Helianthus,* native to North America, comprises 49 species and is divided into four sections (Schilling and Heiser 1981). The sunflower is placed in the section *Helianthus* along with 11 other annual species, all of which are diploid with 17 pairs of chromosomes. The silverleaf sunflower *Helianthus argophyllus* of Texas is the closest relative of the sunflower. The other sections include mostly perennial species, which may be diploid, tetraploid, or hexaploid. One of the perennials, the Jerusalem artichoke, is also cultivated as a food plant for its edible tubers.

Several of the species, both annual and perennial, are occasionally cultivated as ornamentals for their showy flowers (Heiser et al. 1969). *Helianthus* × *laetiflorus* and *Helianthus* × *multiflorus* are particularly widely cultivated for this purpose.

Origin and Early History

In prehistoric times, Native Americans in western North America collected the seeds of wild sunflowers for food, a practice continued by some until early in the twentieth century. In addition to eating the seeds, they also used the plants for pigments. The flowers were employed in ceremonies, the dried stems utilized in construction and for fuel, and various other parts exploited for medicinal purposes.

It has been postulated that the wild sunflower, originally confined to western North America, was a camp-following weed carried to central and eastern North America by the Native Americans, where it became an encouraged weed and, eventually, a deliberately cultivated plant. Mutations occurred, giving rise to monocephalic forms with larger seeds. The archaeological recovery of seeds in eastern North America indicates that the sunflower was domesticated before 1500 B.C. and that it was fairly extensively cultivated before 500 B.C. Some of these prehistoric sunflowers were in no way inferior to modern varieties in size. Early historical records reveal that the sunflower was also cultivated in Mexico and the American Southwest where it is still grown by the Hopi and Havasupai (Heiser 1951).

Along with sumpweed *(Iva annua),* a chenopod *(Chenopodium berlandieri),* and a squash *(Cucurbita pepo),* the sunflower was domesticated in eastern North America before the arrival of maize and other cultivated plants from Mexico (Smith 1989; Gayle 1990). By the time of early historical observations, it seems that maize had become the major crop of Native Americans, although the sunflower was still widely cultivated as a minor crop; sumpweed had disappeared entirely from cultivation.

Sometime after 1492, the sunflower was carried to Europe, the earliest introductions probably being in Spain. The first clear-cut reference to the sunflower is in the herbal of Rembert Dodoens in 1568, where it is illustrated. The plant spread throughout much of Europe, reaching England before the end of the sixteenth century. The sunflower excited curiosity in some places because of its large size, but it was not an early success as a food plant. In fact, it was not until it reached Russia that the seeds became greatly appreciated.

The Holy Orthodox Church of Russia observed very strict dietary regulations during the 40 days of Lent and during Advent. In the early nineteenth century, the list of prohibited foods included nearly all of those rich in oil, but the sunflower, perhaps unknown to the church authorities, was not on the list. The Russian people eagerly adopted the sunflower seed, which could be used while still obeying the letter of the law (Gilmore 1931). The popularity of the sunflower was such that by midcentury or so Russia had become the world's leader in sunflower production.

Oil from sunflower seed was extracted in Russia from the early part of the nineteenth century onward. In addition to the heads, the stems were harvested as an important source of potash, some of which was exported (Putt 1978). Breeding to improve the crop plant commenced early in the twentieth century. Earlier-maturing and higher-yielding varieties were secured, and semidwarf varieties, which could be harvested mechanically, were developed. The oil content of the seeds was increased from 20 to more than 50 percent, and resistance to some pests and diseases was also incorporated into the plant.

Recent History

The two world wars led to great increases in sunflower production, particularly in Romania, Bulgaria, and Hungary. More recently, France and Spain have become major producers, but the former USSR has remained the world's leader and now produces more than half of the world's supply (Table II.E.6.1).

By far the most important sunflower-producing country in the Americas is Argentina, which became an exporter of the seeds early in the twentieth century. For many years, Argentina has been the world's second largest sunflower producer (see Table II.E.6.1).

Only recently, however, has the sunflower again become an important crop in its homeland. In both the United States and Canada, commercial sunflower cultivation was begun in the latter part of the nineteenth century, using varieties from Europe rather than native varieties. Indeed, North American production was, in part, the result of an introduction of improved varieties from the Soviet Union and the later adoption of higher-yielding hybrids (Putt 1978).

The sunflower was initially grown in the United States mostly for silage, but seed production has become increasingly important as people have replaced animal oils with those of plant origin in cooking. A quarter of a century ago, the sunflower, in some years, ranked second only to the soybean as one

Table II.E.6.1. *Sunflower production: Principal sunflower-producing countries in 1990 with 1960 figures for comparison (given in 1,000 metric tons)*

	1960	1990
Argentina	802	3,850
Bulgaria	279	365
Canada	17	115
China	–	1,500
France	3	2,314
Hungary	115	650
India	–	550
Italy	4	301
Morocco	–	160
Romania	529	556
South Africa	87	585
Spain	2	1,314
Turkey	128	900
United States	–	1,032
Former USSR	3,019	6,500
Former Yugoslavia	114	402
World	5,350	22,072

of the world's major oil crops. Lately, however, increased production of canola from rapeseed, particularly in Europe and Canada, has allowed this crop to take over the second position in oil production.

Agronomy

The sunflower is primarily a temperate zone crop. It has some tolerance to both high and low temperatures, and temperature may have an effect on oil composition. It is usually grown without irrigation, and although not highly drought tolerant, it often gives satisfactory yields when most other crops are damaged by drought. Sunflowers will grow in a variety of soil types, from clay to somewhat sandy, and respond well to fertilization, which may be done through soil or foliar treatments. Nitrogen is most often the limiting factor in their growth.

The plants may produce toxic residues in the soil so that crop rotation is essential for good growth. Weed control is also necessary, and herbicides are usually employed. In the northern United States, seeds are planted in late April or May. Later plantings affect oil composition adversely. The plants are ready for harvest in four months at which time considerable moisture is still present in the seeds. Thus, drying, usually by forcing air over the seeds, is required before the seeds are stored or transported (Robinson 1978; Schuler et al. 1978).

Pests and Diseases

Like most crops, the sunflower is subject to a number of insect pests, along with fungal and bacterial diseases. All parts of the plant may be attacked by insects. The most serious pest in the United States is the sunflower moth, which infests the head (Schulz 1978). Downy mildew, a rust, and scherotinia white mold are among the main pathogens that damage the crop (Zimmer and Hoes 1978). Sunflower seeds are a favorite food of many birds, and at times up to 30 percent of the crop is lost to them. The chief culprit in the United States is the blackbird. One method of reducing the loss to birds is to harvest the crop early while the moisture content of the seeds is still high (Besser 1978).

Oil and Protein

The sunflower has excellent nutritional properties. The oil contains high levels of linoleic acid, moderate levels of linolenic acid, and less than 15 percent fatty acids (Dorrell 1978). Extraction of the oil is by solvents after the kernel is crushed or rolled and then cooked. The oil is used for margarine and shortening, as well as for cooking and salad oils. At present, it is little used for industrial purposes but has potential for a number of such applications.

The seed meal left after the extraction of oil serves as animal feed. It has about 28 percent protein and a good balance of amino acids, although it is low in lysine. The hulls, another by-product of the extraction process, are ground and used as filler or roughage in livestock feed in the United States. In other countries, the hulls are also used as fuel (Doty 1978).

Other Uses of the Seed

Although most of the world's sunflower crop goes into oil production, some is used for confectionery food and for feed for birds and pets (Lofgren 1978). The varieties employed for these purposes generally have larger seeds with lower oil content than those grown for oil extraction. The confectionery seeds are used as snack foods, in salads, and in bakery goods. The seeds are frequently shelled, roasted, and salted before reaching the consumer. Large amounts are sold in the shell in the United States for the feeding of wild birds.

Breeding

In the middle of the twentieth century it was realized that utilization of hybrid vigor could produce great increases in the yield of sunflowers. Because of the nature of the flower, the only practical way of making hybrids would be through the employment of cytoplasmic male sterility, and in 1968, Patrice Leclercq of France announced the discovery of cytoplasmic male sterility in crosses of sunflower with *Helianthus petiolaris* (Fick 1978). Fertility restorers were subsequently identified by a number of investigators, and the commercial production of hybrids was soon under way. Yield increases of up to 20 percent resulted, making the sunflower more competitive with a number of other oil crops. Leclercq's cytoplasmic male sterility continues to be used for the creation of hybrids, but other sources of it are now available.

Sunflower breeding through traditional methods is being pursued in France, the United States, Russia, and a few other countries. In addition to increased yields, the principal objectives are to secure resistance to diseases and pests and to improve the oil content and composition. Both intra- and interspecific hybridization are being employed. The wild annual species have proved to be a particularly valuable source of disease resistance. The perennial species have, thus far, been little utilized.

Germ Plasm Reserves

Large seed collections that serve as a valuable reserve of genetic variation are maintained in Russia, the United States, and several other countries. Collections of the wild species are also available, and more than 2,000 accessions have been assembled in the United States (Seiler 1992). Wild *Helianthus annuus* still occurs naturally in large areas of North America, and several other annual species, particularly *Helianthus petiolaris,* have rather extensive distributions. Some of the other annual species occupy more restricted areas, but only one of them, *Helianthus paradoxus,* appears in imminent danger of extinction. Most of the perennial species are still readily available from wild populations in North America.

II.F

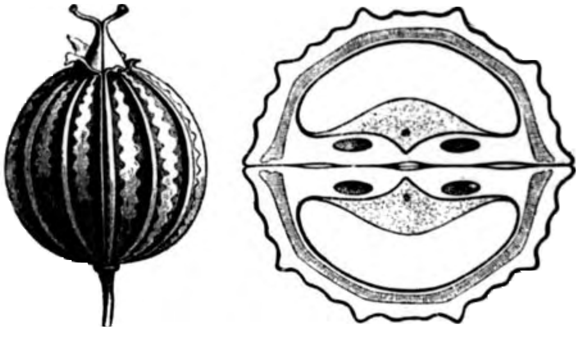
Trading in Tastes

II.F.1 Spices and Flavorings

Plants possess a wealth of different chemical ingredients, ranging from substances with simple structures to very complicated ones, such as terpene or benzoic derivatives. Some are poisonous, others are important raw materials in biochemistry and medicines, while still others are responsible for the appetizing odors we identify with certain foods.

Although the majority of spices are derived from plants, the most important spice is a mineral. Salt has been mined for culinary use (and perhaps, more importantly, as a food preservative) for more than 2,500 years, as well as secured at the seaside by the evaporation of seawater. Saltwater creatures, such as small herrings or other salty-tasting fish, have also been used as spices.

Among the spices of plant origin are such widely used spice plants as pepper and ginger. Other plants are frequently regarded as a flavoring, such as onions, peppers, carrots, and celery. Moreover, there are herbs, such as dandelions and daisies, which in the past were used as spices, as can be seen in old recipes. Although not normally considered to be spices, certain fruits and nuts, such as rowanberry, cranberry, and hazelnut, are also occasionally recommended in recipes as flavorings. In addition, plant stems, flowers, seeds, fruits, leaves, roots, and even pollen grains have been employed as spices.



Coriander

Although all spices do not necessarily figure significantly in nutrition, there are other sound reasons for cooking with them, not the least of which are the aromatic ingredients they contain that can influence the taste of food. But spices also have chemical ingredients that aid digestion and play a role in food conservation (as does salt) by inhibiting bacterial growth and rendering the food unpalatable for microbes and insects. Until relatively recently, most spices had been luxury items, and their usage was an indicator of well-established culinary traditions within a relatively long-standing (and presumably highly developed) culture (Stobart 1977; Küster 1987).

The Landscapes of Spices

Spice plants occur in all parts of the world, but some regions, such as the tropics and subtropics, have an abundance of them, reflecting the greater diversity of plant species there. In the subtropics, the number of spice plants was increased by an extensive grazing of grasslands over millennia. Thus, for example, on the steppe landscapes of the Near East, North Africa, and the Mediterranean, cattle, goats, and sheep preferred to graze on mild, nonpoisonous plants without spines and thorns. Such selective pressure on the plant life of a region eventually produced the kind of subtropic grazing areas observed today, one that is characterized by a wealth of spice plants, albeit often spiny ones that are sometimes poisonous if taken in overly large quantities. Thus, the aromas of thyme, lavender, and sage are always present in the Mediterranean air and in the atmosphere of similar landscapes in Asia, as well as in North American areas such as California, Texas, and Florida, where such plants have been introduced by human migrants.

Origins of Spices

It is often difficult to reconstruct the origin of certain spices because they have been introduced by humans to many habitations worldwide throughout the ages. In fact, it is sometimes difficult to determine whether a plant is indigenous or introduced to a specific area. The latter may well have occurred before written sources existed, but unfortunately, even in historic times individuals rarely wrote about the introduction of plants.

Some ancient scientists and writers, such as Aristotle, Virgil, and Pliny, mention plants in their manuscripts. But whether they personally knew of those they wrote about or whether they mentioned them only because other scholars in earlier texts had done so is another matter. An added complication is the difficulty of botanically equating the plants referred to by spice names in Greek or Latin texts with their modern equivalents. Put plainly, that a plant was present at a specific time in a specific region often can be determined only by an archaeobotanical analysis of plant materials derived from layers of accurately dated archaeological excavations.

Even when a plant is found among archaeological remains, however, it is often unclear that its use had been as a spice. This question can be definitively answered only with written sources. On the other hand, if pepper grains are found far outside their South Asian area of origin – in a Roman settlement in Europe, for instance – then this strongly suggests the liklihood that there had been a trade in pepper grains. And such a trade of pepper grains makes sense only if one assumes that they were used as spices in ancient Rome.

Having stressed the difficulties of reconstructing the ancient history of spices, we should also emphasize that most of the as-yet unresolved questions surrounding that history are now being addressed in the interdisciplinary work of botanists, archaeologists, and philologists. Such work has already deliniated the most likely areas of the origin of the various spices, as listed in Table II.F.1.1 – a table that also shows that all of the well-known ancient civilizations used a complement of typical spices. Thus, ginger, star anise, and soy were known in early Chinese culture, whereas black pepper was commonly used by ancients in India. In the basins of the Euphrates and Tigris rivers, licorice and coriander have been cultivated since early times; ancient cultures of the Mediterranean used sage and anise. And, of course, vanilla, chocolate, and chilli peppers from the New World have become well-known gifts of the Mesoamerican civilizations.

Table II.F.1.1. *The origin of spices used historically and today*

Spice	Latin name	Area of origin	Time of oldest cultivation/consumption	Parts of plants taken as spice
Ajowan	*Trachyspermum ammi*	NE Africa, S Asia	Unknown	Fruits
Alexanders	*Smyrnium olusatrum*	Mediterranean	Antiquity?	Leaves
Allspice	*Pimenta dioica*	Central America	Pre-Colombian	Fruits
Almond	*Amygdalus communis*	(W) Asia	2d millennium B.C.	Seeds
Angelica	*Angelica archangelica*	N Europe	Medieval	Stems, roots
Anise	*Pimpinella anisum*	S Europe	Bronze Age?	Fruits
Anise-pepper	*Xanthoxylum piperitum*	E Asia	Unknown	Fruits
Asafoetida	*Ferula asafoetida*	Persia, Afghanistan	2,000 B.C.	Dried mill
Avens	*Geum urbanum*	Widespread	Unknown	Roots
Balm	*Melissa officinalis*	E Mediterranean	Antiquity	Leaves
Basil	*Ocimum basilicum*	S Asia (India?)	Antiquity	Leaves
Bay	*Laurus nobilis*	Mediterranean	Antiquity	Leaves
Bergamot	*Monarda didyma*	N America	Unknown	Leaves
Black caraway	*Pimpinella saxifraga*	Europe, W Asia	Unknown	Leaves
Bog myrtle	*Myrica gale*	Northern Hemisphere	Medieval	Leaves
Borage	*Borago officinalis*	(W) Mediterranean	Middle Ages	Leaves, flowers
Burnet	*Sanguisorba* sp.	Europe	Unknown	Leaves
Calamus	*Acorus calamus*	SE Asia, N America	2d millennium B.C.	Roots
Caper	*Capparis spinosa*	Mediterranean, S,W Asia	2d millennium B.C.	Buds
Caraway	*Carum carvi*	Europe	Unknown	Fruits
Cardamom	*Elettaria cardamomum*	Tropical S Asia	3,000 B.C.	Seeds
Cassia	*Cinnamomum aromaticum*	China	3d millennium B.C.	Parts of bark
Cayenne peper	*Capsicum frutescens*	Tropical America	Unknown	Fruits
Celery	*Apium graveolens*	Widespread at seasides	Neolithic	Fruits, leaves
Chervil	*Anthriscus cerefolium*	SE Europe, W Asia	Antiquity	Leaves
Chive	*Allium schoenoprasum*	N hemisphere	Unknown	Leaves
Chocolate	*Theobroma cacao*	Tropical America	Unknown	Seeds
Cinnamon	*Cinnamomum verum*	Ceylon	Antiquity	Parts of bark
Citron	*Citrus medica*	SE Asia	Unknown	Fruit of skin

Table II.F.1.1. *(Continued)*

Spice	Latin name	Area of origin	Time of oldest cultivation/consumption	Parts of plants taken as spice
Clary	*Salvia sclarea*	Mediterranean, W Asia	Antiquity?	Leaves
Clove	*Syzygium aromaticum*	Molukkian Islands	Antiquity	Buds
Coriander	*Coriandrum sativum*	E Mediterranean, W Asia	Neolithic?	Fruits

Spices as Elements of an Urban Lifestyle

It would seem that those emerging from the Old World Neolithic Revolution who pioneered in employing most of the spices were not rural peasants but rather urban dwellers: Historical evidence suggests that it was only in those cultures which gave rise to concentrated settlements that spice use seems to have been known.

In most cases, that use was aimed not so much at making the food more tasty but rather at masking the taste of food that was no longer fresh, or even spoiled. Spoilage was not a major problem with cereal grains and legumes. But it was more of a problem with the less easy-to-conserve oil plant seeds and, of course, a major one with fish, fowl, meat, and animal products such as milk.

Although early humans appear to have been scavengers, it was presumably the ideal among their prehistoric hunter–gatherer successors to consume a hunted animal immediately after it had been killed. This, in turn, would have made the kill of any large animal a social event, with friends and relations joining the hunters in eating the meat while it was still fresh and unspoiled. After everybody had been fed, however, there was probably little interest in the remaining scraps, and because meat conservation technology had not been developed, it was necessary to kill again before meat once more entered the diet.

A similar approach to meat consumption was, doubtless, the case in the first farming communities. But as these early farmers increasingly derived more and more of their nutrients from crops, meat became less important in their diets – much less than it had been among their hunter–gatherer forebears.

Yet the relative dietary importance of various foods shifted again when the first towns or townlike settlements arose. Town dwellers depended for their food on rural settlements, and this demand was more readily met by meat than by grain. Clearly it was far easier for rural producers to drive cattle and sheep, moving under their own power, to a slaughterhouse inside a town than it was to haul bulky, not to mention heavy, containers of grains and legumes to town storage areas from the countryside.

Meat, as a consequence, became an important part of the diet in urban settlements, which led, in turn, to technology that permitted the utilization of the entire carcass. On the one hand, each part of the carcass had food value, and on the other, such utilization avoided the problem of carcass disposal inside or near the settlements, with the attendant difficulties of odors, pests, and even disease associated with the rotting remains.

The first techniques of meat conservation were those of smoking plus salting to preserve meats from insects and microbes that cannot live in a salty environment. However, even salted meat was often spoiled, or at least tasted spoiled, by the time it was consumed, and it was discovered that the spoiled taste could be covered by the addition of pungent spices. Moreover, although people might fall ill from the consumption of spoiled meat, it was learned that other spices could help prevent these consequences by making digestion easier.

Because of such growing knowledge, the people of the towns that demanded meat also demanded spices, and this was especially true of the upper classes. It came to be regarded as sophisticated to mask the taste of spoiled meat and fat in cookery and, thus, spices became a valuable item of exchange.

Elsewhere, and considerably later, other populations that had come to depend heavily on fish learned to preserve them by creating spicy sauces to accompany them. And later in the Americas, spices, especially chilli peppers, enlivened fare that in many cases was essentially vegetarian in nature. Clearly, then, contact with the spice trade that developed in the Eurasian world was not a prerequisite for spice usage. On the other hand, those with money who enjoyed such contact could choose from a variety of seasonings.

The Beginning of the Spice Trade

The spice trade began as early as the trade in precious metals and jewels and dyes and silks – which, along with spices, were ancient items traded over the silk and spice roads in the Near East. Spices first moved between Mesopotamia and Egypt; later, Indian spices were traded to the Levant, and Mesopotamian spices reached the Indus valley (see Table II.F.1.1 for areas of origin). All important trade centers were connected by spice roads, with such trade generally practiced by nomadic peoples, who in later times were the Arabs.

As the spice roads of the Near Eastern deserts were extended to Levantine harbors, spices began traveling by ship to Athens, Rome, Massilia, and other parts of the ancient world. The Greeks and Romans, in turn, added a number of Mediterranean spices to the trade and began to vie for dominance of the trade. In fact, control of the spice trade was one factor in the warfare among the Greeks and Romans and Near Eastern peoples.

Roman consumption of spices from all over the known world was enormous. In fact, the Roman demand for the spice silphion, which was grown in Kyrene in Northern Africa, was so great that it was overexploited until it became extinct. Today silphion is known only through historical documents, and its conventional designation as a member of the Apiaceae plant family can only be a tentative one (Küster 1987). Moreover, because the Romans took spices to all places on the globe where Roman soldiers were garrisoned, Roman cookery became the first cuisine that (at the risk of argument from Chinese historians) might be called "international." In addition, it was the Romans who established the first trade network across the known world to send spices, such as pepper, from Southeast Asia all the way to central Europe (Kucan 1984).

Use of Spices in Medieval Europe

During the European Middle Ages, Roman cookery and its use of spices had come to be well regarded, even in countries far more distant from the pepper-growing areas than ancient Rome had been. Spices, brought to western and northern Europe, were shipped along the western coast of Europe to England, Ireland, France, and the Netherlands. The Rhine river became an important shipping route as well. The Hanseatic merchants traded spices in the North Sea and the Baltic areas, and later, northern Italian and southern German merchants began to trade them overland and via the Alps. Harbor towns like Venice, Genoa, Lisbon, London, Dublin, Amsterdam, and Lübeck became wealthy as a result of the spice trade, as did inland towns like Constance, Augsburg, Nuremberg, and Cracow.

Indeed, at times, medieval European kings and emperors could not reign without the support of the spice merchants, who were very wealthy and exerted considerable political influence. The nickname "Pfeffersack" (pepper sack) was commonly used to refer to a merchant making very high profits from the spice trade. The use of black pepper, which could mask the scent of spoiled meat and fat, came to be regarded as a status symbol. Duke Karl of Bourgogne, regarded in his day as the richest man in Europe, ordered 380 pounds of pepper for his wedding dinner in 1468 (Küster 1987).

Ordinary people, however, could not afford to buy spices from Southeast Asia, which thus remained in short supply despite the trading networks. For this reason, there were often attempts to adulterate spices, which became a serious kind of crime that could result in a sentence of death by burning or decapitation. All of this, in turn, provided a strong motivation for people to discover pungent plants that were available locally and might be substituted for expensive imported spices. Among such finds were juniper, gentian, and caraway – plants that were unpalatable to livestock and, consequently, commonplace in the intensively grazed lands surrounding medieval towns. Gradually their seeds, leaves, fruits, and roots found their way into local cookery.

In Search of New Trading Routes

The Crusades marked the beginning of a crisis in the worldwide spice trade, especially in central Europe, as the significant trade between Arabs and Venetian merchants was disrupted. This development, in turn, produced what might be loosely termed "scientific" research into the origin of spices in central and western Europe. At that time, knowledge of the subject consisted of half-true tales passed down by Greek and Roman writers. But now physicians and others concerned with human health began to think about the active ingredients in herbs and spices, and an argument can be made that a shortage of spices was one of the stimuli that led to the development of Renaissance science.

The spice shortage also contributed to improvements in navigation technology, as several European nations competed to discover sea routes to India. In other words, this early exploration was not so much to bring Western civilization and Christianity to other peoples as to profit from the trade in precious stones, metals, and spices. Similarly, at a later time, ancient civilizations in Africa and Asia were set upon by European colonialists, and one of the precipitating factors for such imperialistic adventures was the competition of spice merchants from western and southern Europe.

The Portuguese found a sea route from Europe to India via the circumnavigation of Africa, which allowed them to bypass Arab intermediaries and bring such spices as pepper and cinnamon directly to Europe. They also discovered new spices, such as the "grains of paradise" *(Aframomum melegueta)* from western Africa, which they sold instead of pepper by bestowing upon the grains the enticing but misleading name "meleguetta pepper."

Meanwhile, Columbus and others had hypothesized that another possible trading route to India lay to the west, and stimulated in part by the desire to find new sea routes for the spice trade, the Spaniards "discovered" "Western India," or America. However, the Europeans found not pepper but (chilli) peppers, white cinnamon instead of cinnamon, Indian cress instead of cress, as well as chocolate and vanilla. Such American spices became an important part of the wealth of the New World to be exploited by the Old.

By the start of the sixteenth century, western European countries were beginning to assert their control over world trade and politics, largely due to their quest for spices. Thus, the spice trade figured prominently in European colonialism and imperialism and, consequently, in shaping the world political order of today.

The Internationalization of Spices

Since the sixteenth century, and especially since the nineteenth century, many Europeans and Asians have migrated to the Americas, taking with them their culinary traditions, including their knowledge of spices and how to use them. Because such knowledge was subsequently exchanged among different cultural groups, the use of particular spices became increasingly less identified with the cuisines that had originally incorporated them.

First iceboxes and then refrigerators diminished the risk of food spoilage, and thus erased the importance of spices in masking the taste of food going bad – the paramount reason for seeking them in the first place. But if spices were less necessary in cookery for covering up unpleasant tastes, they did provide pleasant flavors of their own, which strongly established them in cookery traditions. And this, coupled with the mass production and marketing that has made them so inexpensive, has ensured their continued widespread usage. Indeed, it is possible today to buy virtually any spice in the supermarkets of the world at an affordable price.

Of course, some national or regional cuisines can still be identified by their traditional spices. Restaurants that specialize in various types of international cuisine have proliferated – especially since the end of colonialism. North Africans who migrated to France established Algerian and Moroccan restaurants in Paris. Many Indonesian restaurants can be found in the Netherlands. Chinese and Indian restaurants have become popular in Great Britain and in the United States – to provide merely a few examples.

Somewhat later, a different development took place in Germany. During the 1950s and 1960s, a labor shortage in Germany induced many southern Europeans to venture northward seeking employment. And because of this migration, Italian, Balkan, and Greek restaurants with all their accompanying spices are now common in Germany.

Spices are so widely employed today that we scarcely notice their presence. Most understand and would agree that spices improve the taste of food and even aid digestion. But largely forgotten is the fact that the original purpose of spices was to mask bad tastes, rather than provide good ones; and almost completely forgotten is the role that the spice trade played in stimulating scientific thought during the Renaissance and the explorations and the empire building that followed.

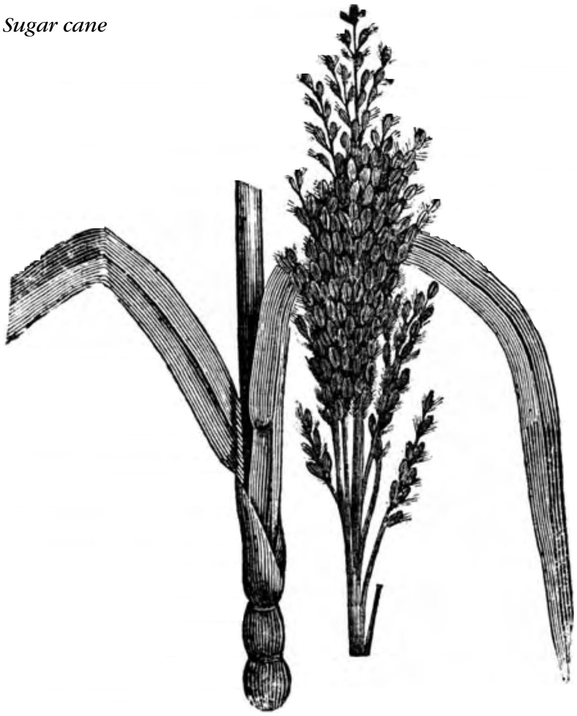
II.F.2 ⁂ Sugar

Sugar is the world's predominant sweetener. It satisfies the human appetite for sweetness and contributes calories to our diet. Sugar is used in cooking, in the preparation of commercially processed foods, and as an additive to drinks; it is also a preservative and fermenting agent. It sweetens without changing the flavor of food and drink. It is cheap to transport, easy to store, and relatively imperishable. These characteristics helped sugar to displace such sweeteners as fruit syrups, honey, and the sap of certain trees, the most famous of which is the North American maple.

Lack of data makes it difficult to establish when sugar became the principal sweetener in any given part of the world, but in every case this has occurred fairly recently. Illustrative are Europe and North America where it was only after 1700 that sugar was transformed from a luxury product into one of everyday use by even the poor. This took place as Brazil and the new West Indies colonies began producing sugar in such large quantities that price was significantly reduced. Lower prices led to increased consumption, which, in turn, fueled demand, with the result that the industry continued to expand in the Americas and later elsewhere in the tropical world.

Sugar cane



Since the eighteenth century, the rise in the per capita consumption of sugar has been closely associated with industrialization, increased personal income, the use of processed foods, and the consumption of beverages to which people add sugar, such as tea, coffee, and cocoa. In addition, the relatively recent popularity of soft drinks has also expanded the use of sugar. Annual per capita sugar consumption is now highest in its places of production, such as Brazil, Fiji, and Australia, where it exceeds 50 kilograms (kg). Consumption in Cuba has been exceptionally high, exceeding 80 kg per capita around the beginning of the 1990s. Subsequently, consumption has fallen to a still very high 60 kg per person.

With an annual per capita consumption of between 30 and 40 kg, the countries that were first industrialized in western Europe and North America constitute a second tier of sugar consumers. The poorer countries of the world make up a third group where consumption is low. The figure for China is 6.5 kg, and it is even lower for many countries in tropical Africa. Such a pattern reflects both differences in wealth and the ready availability of sugar to those in the countries of the first group. In the Western industrialized world, concerns about the effects of sugar on health, as well as the use of alternatives to sugar – such as high-fructose corn syrup and high-intensity, low-calorie sweeteners – have stabilized and, in some countries, lowered the use of sugar. Thus, it would seem that further expansion of the industry depends primarily on the poorer countries following the precedent of the richer ones by increasing consumption as standards of living improve. Secondarily, it depends on the ability of the sugar industry to meet competition from alternative sweeteners.

Sugar is the chemical sucrose that occurs naturally in plants. It is most richly concentrated in sugarcane and sugar beet, which are the sources of commercial sugar. Fully refined sugar, whether made from cane or beet, is pure sucrose, and the consumer cannot tell from which of the two plants it derives. But despite the identical end product, the sugarcane and the sugar beet industries differ greatly in methods of production and organization, and each has its own distinctive history and geography.

The Sugarcane Industry

The Raw Material

Sugarcane is a perennial grass of the humid tropics. It requires at least 1,000 millimeters of rain annually, which should fall year-round, although with irrigation the plant can also be grown in dry climates. Temperatures must be above 21° Celsius (C) for satisfactory growth, and the best results are obtained when the temperature exceeds 27° C. Cold temperatures, therefore, impose northern and southern limits on cultivation. Growth ceases when the temperature falls below 11–13° C; light frosts injure the plant, and a prolonged freeze will do serious damage. Sugarcane is tolerant of a wide range of soil conditions and grows well on both hillsides and flat land. With the mechanization of harvesting, a recent development that dates only from the 1950s, the industry has come to prefer flat land where the machines can function most effectively.

The principal parts of sugarcane are the roots and the stem that supports the leaves and the inflorescence. The stem in a mature plant can grow as high as 5 meters (m) and can be thick or thin, depending on the variety. Some stems have soft rinds and are easy to chew on; others have tough rinds, which makes for difficult milling. The color of the stems can range from green through shades of purple, and some varieties are leafy, whereas others are not. Despite these differences, the identification of varieties in the field is usually a matter for experts.

Commercial sugarcane is reproduced vegetatively. Until the late nineteenth century, the commercial varieties were thought to be infertile. Some are, although others set seed under certain climatic and day-length conditions. This discovery has been of basic importance for the breeding of new cane varieties, but commercial sugarcane is still reproduced in the traditional vegetative way. The stems have nodes spaced from 0.15 to 0.25 m apart, each of which contains root primordia and buds. A length of stem with at least one node is known variously as a sett, stem-cutting, or seed-piece. When setts are planted, roots develop from the primordia and a stem grows from the bud. Stems tiller at the root so that the bud in each sett produces several stems.

The first crop, known as plant cane, matures in 12 to 18 months, depending on the climate and variety of cane. The roots, left in the ground after the harvest, produce further crops known as ratoons. Some varieties produce better ratoons than others. As a perennial plant with a deep root system and with good ground coverage provided by the dense mat of stems and leaves, sugarcane protects the soil from erosion. Given adequate fertilizer and water, it can flourish year after year, and there are parts of the world in which sugarcane has been a cash crop for centuries.

All wild and domesticated varieties of sugarcane belong to the genus *Saccharum,* one of the many subdivisions of the large botanical family of *Gramineae.* Because these varieties interbreed, the genus has become a very complex one. Authorities recognize species of *Saccharum: S. robustum* Brandes and Jeswiet ex. Grassl., *S. edule* Hassk., *S. officinarum* L., *S. barberi* Jeswiet, *S. sinense* Roxb. emend. Jeswiet, and *S. spontaneum.* Speciation, however, of the genus is still in dispute.

The status of *S. edule* as a distinct species is problematic, and an argument exists for conflating *S. barberi* and *S. sinense.* There is also discussion as to the places of origin of the species. *S. barberi, S. sinense,* and *S. spontaneum* occur widely in southern Asia and may have originated there. New Guinea is thought by many to have been the place of origin of the other three species, although possibly *S. officinarum* evolved close by in the Halmahera/Celebes region of present-day Indonesia. Four of the species were cultivated for their sugar: *S. barberi* and *S. sinense,* respectively, in India and China; and *S. edule* and *S. officinarum* in New Guinea. *S. robustum* is too low in sucrose to be a useful source of sugar, but its tough fiber makes it valued in New Guinea for fencing and roofing. *S. officinarum* may have been cultivated as an important food for pigs in prehistoric New Guinea (Stevenson 1965: 31–2; Barnes 1974: 40–2; Blackburn 1984: 90–102; Daniels and Daniels 1993: 1–7).

S. officinarum is the species of basic importance to the history of the sugarcane industry. In New Guinea its evolution into an exceptionally sweet cane led to wide diffusion throughout the Pacific islands and eastward through southern Asia to Mediterranean Europe and America. Until the 1920s, nearly all the cane sugar that entered international commerce came from one or another variety of this species.[1] The varieties of *S. officinarum* are known collectively as noble canes, a name the Dutch gave them in the nineteenth century in appreciation of their importance to the sugar industry in Java.

Disease brought the era of the noble canes to an end. In the mid-nineteenth century, Bourbon cane, the standard commercially cultivated variety in the

Americas, had suffered occasional outbreaks of disease, but in the West Indies in the 1880s, disease in Bourbon cane became general and caused a serious reduction in yields. To use the jargon of the sugar trade, this variety "failed."

In the 1880s, disease also devastated the cane fields of Java. The initial response of planters was to replace the diseased cane with other "noble" varieties, but because these too might "fail," this solution was seen at best to be a temporary one. The long-term answer lay in breeding new varieties that would be resistant to disease and rich in sucrose. Cane-breeding research began simultaneously in the 1880s at the East Java Research Station (Proefstation Oost Java) and at Dodds Botanical Station in Barbados. Initially, researchers worked only with *S. officinarum.* Success came slowly, but during the first years of the twentieth century, newly bred varieties began to replace the naturally occurring ones, and substitution was complete in most regions by the 1930s.

In a second phase of research, which benefited from developments in genetics, attractive features from other species of sugarcane were combined with varieties of *S. officinarum.* This process, known as "nobilization," resulted in even further improvements in disease resistance and sucrose content. Nobilized varieties entered cultivation during the 1920s and gradually replaced the first generation of bred varieties (Galloway 1996).

The sugarcane industry has now been dependent on cane breeding for a century, and research remains necessary to the success of the industry. Because varieties "fail," reserve varieties must be on hand to replace them. Some of the aims of breeding programs are long-standing: resistance to disease, insects, and animal pests; suitability to different edaphic and climatic conditions; better ratooning; and high sucrose content. In recent years, additional considerations have come to the fore. Canes have to be able to tolerate herbicides, and in some countries they have to meet the needs of mechanical harvesters.

Cultivation and Harvest

Success in cane breeding gave the sugarcane industry a much improved raw material that enables it to meet more easily a basic requirement of survival in a competitive world, which is the sustainable production of cane rich in sucrose in different climatic and soil conditions. Cane breeding has also added flexibility in dealing with the constant of how best to manage the cane fields with a view to the needs of the mill and factory. A long harvest season is preferable to a short one because it permits the economic use of labor and machinery. Fields of cane, therefore, must mature in succession over a period of months. This can be achieved by staggering the planting of the fields and by cultivating a combination of quick-maturing and slow-maturing varieties. Cane ratoons complicate the operation because they mature more quickly than the plant cane.

Over the years, however, ratoon crops gradually decline in sugar yield, and eventually the roots have to be dug up and the field replanted. Breeding can improve the ratooning qualities of cane. The number of ratoon crops taken before replanting is a matter of judgment, involving the costs of planting and the yield of the crops. Practice over the centuries has ranged from none at all to 15 and even more. Where numerous ratoon crops are the custom, the introduction of new varieties is necessarily a slow process. Planting is still largely done by hand, although planting by machine has increased.

The harvesting of cane presents another set of problems. The cane must be carefully cut close to the ground (the sucrose content is usually highest at the base of the stems) but without damage to the roots. The leaves and inflorescence should not go to the mill where they will absorb sugar from the cane and so reduce the yield. Manual workers can cut carefully and strip the stems, but the work is arduous and expensive. The mechanization of harvesting has been made easier by the breeding of varieties that achieve uniform height and stand erect. The machines can cut and top (remove the inflorescence) with little waste.

Because it is very important to send clean cane to the mill with a minimum of trash, soil, or other debris, preharvest burning of the cane has become a common practice. This removes the living leaves as well as the dead, which lie on the ground and are known as "trash." Burning prepares a field for harvesting and does not damage the stems or reduce the yield of sugar, provided the stems reach the mill within 24 hours. But this last requirement is not new: Breeding has not been able to alter the fact that stems of cane are perishable and, once cut, must be milled quickly to avoid loss of juice and, hence, of sucrose and revenues. The perishable nature of the stems and the expense of transporting them still demand that the mills be located close to the fields where the cane is grown.

Where the owners of the mills also own the fields that supply the cane, coordination of cultivation and harvesting is a relatively easy matter, compared to a situation in which independent cane growers do the supplying. There are mills that rely on hundreds of cane growers, each cultivating a few hectares. In addition to logistical issues, the price the growers are to receive for their cane is a constant source of dispute (Blackburn 1984: 136–288; Fauconnier 1993: 75–132).

From Mill to Refinery

The aim in the mill is to extract the maximum amount of sucrose from the stems; the aim in the factory (usually attached to the mill) is to make maximum use of the sucrose to produce sugar quickly and efficiently. The opaque, dark-green juice that contains the sucrose flows from the mill to the factory where it is first heated and clarified, then condensed by boiling to a thick syrup in which sugar crystals form. This mix, known as a "massecuite," is then separated into sugar crystals and molasses. Early in the history of the industry, both milling and manufacture involved rather simple processes that by modern standards not only were slow and wasteful but also led to rather crude results. Now the milling and manufacture of sugar involve a series of highly sophisticated engineering and chemical operations and take place in what are, in fact, large industrial complexes. The daily grinding capacity of modern mills varies enormously, with the largest exceeding 20,000 metric tons (Chen 1985: 72).

Innovations in processing have never entirely replaced the old methods, and in India, Brazil, and many other countries modern factories coexist with traditional ones. The industry draws a distinction between the products of the two, based on the method of separating the crystals from the molasses. In traditional mills, the massecuite is placed in upright conical pots, and over a period of days, if not weeks, the molasses drains through a hole at the base of the cone, leaving a sugar loaf. In a modern mill, separation is accomplished rapidly in a centrifugal machine that was first employed in sugar factories in the mid-nineteenth century. The terms "centrifugal" and "noncentrifugal" are used in the sugar trade as a shorthand, referring to the products of very different processes of manufacture.

Noncentrifugal sugars are characteristically made for local markets by rural entrepreneurs with simple equipment and little capital. They appear for sale yellowed by molasses, and sometimes still moist, and compete in price with centrifugal sugar. They appeal to people who are especially fond of their taste. The noncentrifugal sugars include the *gur* of India, the *jaggery* of Nigeria, the *rapadura* of Brazil, and the *panela* of Colombia. (Indian *khandsari* sugar, an interesting anomaly, is produced by traditional methods, except that the crystals are separated in hand-held centrifuges.) The often remote location and modest scale of many noncentrifugal factories means that a proportion of world cane sugar production goes unreported.

Centrifugal sugar, the product of the modern factories, by contrast, enters world trade. The International Sugar Organization, as well as governments and sugar traders, track production; thus, there are detailed, country-by-country, annual statistics on production and consumption (Figure II.F.2.1). Commercial sugars are classified according to their purity, which is measured in degrees of polarization (pol.) with a polarimeter; purity ranges from 0° pol., signifying a total absence of sugar (as in distilled water, for example), to 100° pol., indicating pure sucrose. The basic centrifugal sugar of commerce is known as raw sugar, which, by international agreement, must have a polarization of at least 96°. Raw sugars are not quite pure sucrose and are intended for further processing, meaning that they are to be refined.

Refining is the final stage in the manufacture of sugar. The result is pure sucrose, with a pol. of 100°. The process of refining involves melting the raws, removal of the last impurities, and recrystallization of the sucrose under very careful sanitary conditions. The raws lose a very minor percentage of their weight in the transformation to refined sugar, the amount depending on the pol. of the raws and the technical ability of the refinery (Chen 1985: 634–6). This loss and the expense of refining are built into the selling price of refined sugar.

Refineries are located close to the market where the sugar is to be consumed, rather than the fields where the cane is grown. In the Western world, this

pattern was established several hundred years ago (Figure II.F.2.2). Transport in leaky sailing ships meant that sugar inevitably ran the risk of contamination from sea water, and in the hot, humid conditions of a long voyage across tropical seas, sugar crystals coalesced. Thus, there was no point in making a finished product if it was only going to be damaged in transit to the market. In addition, the lack of fuel in the cane-growing regions meant that it was rarely possible to produce the finished product there. The industry does make its own fuel, bagasse, which is the residue of the stems after milling, but during the early centuries of the industry, inefficient furnaces meant that it had to be supplemented with another kind of fuel, usually scarce timber.

In short, the location of refineries in the importing countries reflected the realities of the sugar trade of yesterday. Today, there are clean, rapid, purpose-designed ships, so that long voyages pose little risk of damage to the sugar. And fuel is no longer the problem it once was. A long record of improvements in the design of furnaces and machinery means that an efficiently operated factory produces a surplus of bagasse. Nevertheless, factors continue to favor the location of the refineries in the importing, temperate countries.

Perhaps most importantly, refineries are not limited by harvests but can operate year-round by buying their supplies of raws from producers throughout the world according to season and price. Since the nineteenth century, refineries in some countries have also had the option of adapting to domestic beet sugar. By contrast, a refinery in a cane-growing region, dependent on the local production of raws, can only operate seasonally, which is not cost-efficient unless it is possible to stockpile or import raws to keep the refinery constantly in operation.

Because of such developments, many sugar factories now skirt the issue of refining by making direct-consumption sugars which, as their name implies, require no further processing. Whites, also known as plantation whites, are the most important of this class of sugar, and have a pol. of up to 99.5°. Whites were intended originally only for local consumption, but they have now entered international commerce to compete with refined sugars (Blackburn 1984: 290–3, 313–14).

Despite what might seem as the diminution of their locational advantages, however, the importing refineries will not yield their role easily. Vested interests continue to be involved, but additional refining is the only value-added part in the sugarcane industry that can be transferred from the producing to the importing countries in order to create jobs. Such refineries also have a trump card – they are close to and know their markets and can create demand as well as deliver what the market wants.

A glance along grocery store shelves reveals the many products of the refineries. There are the standard granular sugars, ranging from coarse to fine, and powdered sugar for icing cakes. The familiar sugar cubes for tea and coffee have been there since as long ago as the mid-1870s (Chalmin 1983: 84). The brown and yellow sugars, whether granular or in lumps, are still called Demerara – named after an administrative division of British Guiana, where, in the mid-nineteenth century, partially modernized factories deliberately produced sugar still colored and flavored by molasses.

It became a recognized trade name that could only be applied to this type of sugar produced in Demerara until 1913, when a court of law in London accepted the argument that the term had become common usage for any brown sugar, whether or not it had been made in Demerara (Barnes 1974: 11). Today, Demeraras are, in general, refined sugars that have been colored and flavored.

Other Products

Sugar is the most important product of the sugarcane industry. But there are also others, one being fuel. Because sucrose can be fermented, as well as crystallized, it is turned into an alcohol that substitutes for gasoline in cars. A substantial portion of Brazil's annual sugarcane crop is used for this purpose. Another use is the creation of fancy molasses (made from clarified, concentrated, very sweet syrup-like juice from which no sucrose has been drawn). This is what is used in cooking, spread on bread and scones, and employed as a topping for pancakes. Fancy molasses was a specialty of Barbados, with North America once the major market, where it sold for less than maple syrup. Barbados still exports fancy molasses, and a similar product is made in several other countries.

In addition, there are by-products of the manufacture of sugar. The most important are molasses, alcoholic beverages, bagasse, and filter mud, each of which has several uses. The molasses that spins from the massecuite in the centrifuges of modern factories is known as final or blackstrap molasses. It contains unextractable sucrose, as well as glucose, fructose, water, and minerals, the composition varying according to the climate and soil in which the cane was grown. Relatively little of this type of molasses enters international trade. One local use is for animal feed (either fed directly to the animals or mixed with other foods). Other derivatives of molasses include industrial alcohol, citric acid, and yeast. But perhaps its best-known use is in the manufacture of alcoholic beverages.

Rum is the sugar industry's best-known drink, flavored and colored with burnt sugar. But there are numerous other cane liquors, such as the *cachaça* of Brazil. Moreover, in cane-growing countries, alcohol is now mixed with imported concentrates to make gin and even whisky. "Choice" molasses, the by-product of noncentrifugal sugar, is also distilled for alcoholic beverages.

Bagasse – the dried cane pulp remaining after the juice is extracted – is a fortuitous by-product of sugar manufacturing that finds important uses. In some countries it is a fuel that generates electricity for the national grid. Ongoing research has also pointed the way to other applications, and it is now employed in the production of compressed fiberboard, various types of paper, and plastics.

Much of the filter mud, the result of clarification of the cane juice, is returned to the cane fields as a fertilizer. But it is also possible to extract a crude wax from it that can be used in the manufacture of polishes. All of these by-products are major contributors to the profitability of the sugarcane industry (Barnes 1974: 446–69; Blackburn 1984: 314, 327–47).

Historical Geography[2]

The manufacture of crystal sugar from sugarcane is one of the world's oldest industries. Its history is markedly episodic, with periods of technological innovation and geographical expansion separating periods of comparatively little change. Sugar became closely linked to major forces in European history when the Portuguese, who, in the fifteenth century, were venturing along the west African coast, discovered that the production and sale of sugar grown on nearby islands, especially Madeira, could be a means of financing the enterprise of reaching the East Indies. In subsequent centuries, sugar became intimately associated with the European colonization of the tropical portions of the New World (Figure II.F.2.3). The demand for labor that it created led to the transatlantic slave trade that carried millions of Africans to the Americas. These were followed by East Indians and other Asians in still more international migrations.

Yet sugar was hardly confined to the Americas, and neither were the historical forces that have shaped the industry from the rise of capitalism through the industrial revolution to twentieth-century advances in science and technology. The first use of sugarcane by humans was doubtless to chew it to obtain the sweet juice, a practice that continues, especially among children. Later, in southern Asia at some unrecorded time, efforts were begun to extract the juice with a simple mill or press and to concentrate it by boiling into a sweet, viscous mass. The first evidence of crystal sugar production appears at about 500 B.C. in Sanskrit texts that indicate it took place in northern India. They describe in rather vague terms the making of several types of sugar for which the principal use seems to have been medicinal. Knowledge of this technique spread from northern India eastward to China and (along with the cultivation of sugarcane) westward into Persia, eventually reaching the east coast of the Mediterranean about A.D. 600.

Sugar making in India and China, however, remained a technologically conservative, small-scale, largely peasant activity until the twentieth century. In China, for reasons that are not entirely clear, sugar joined, rather than displaced, its competitors, becoming one more option in a cuisine that continued to value honey, manna, maltose, and sagwire palm sugar. Clearly, the history of sugar in the East stands in marked contrast to that which unfolded in the West.[3]

The sugar industry entered the Mediterranean basin as part of an agricultural revolution carried out by the Arabs. In the years following the founding of

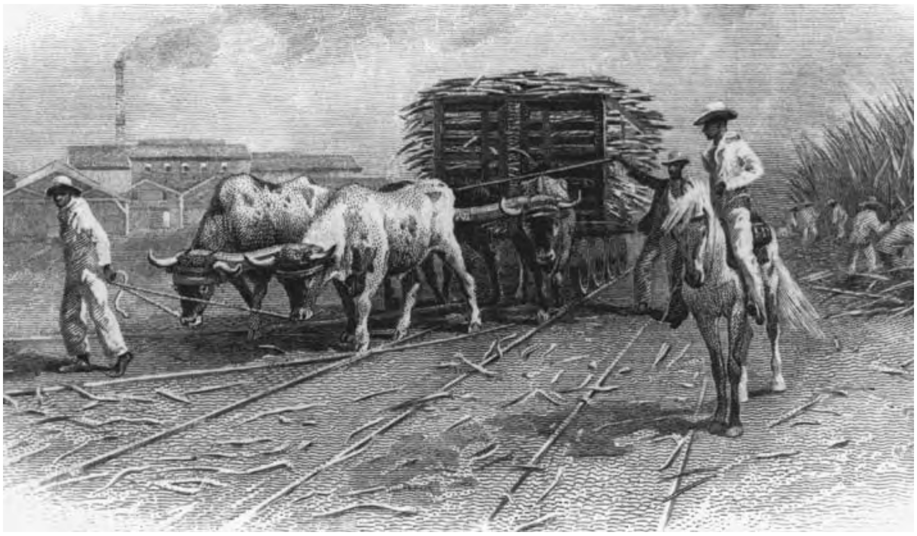

Figure II.F.2.3. Oxen drawing a cart of cane, with mill in background. (From a bond of the Eastern Cuba Sugar Corp., issued in 1922.)

Islam (Watson 1983), its adherents presided over the introduction of tropical and subtropical crops from Asia to the countries of the Mediterranean, as well as the techniques of irrigation that permitted cultivation throughout hot, dry summers.

To mill sugarcane, the burgeoning industry borrowed existing Mediterranean technology for extracting oil from olives and nuts and, in a second operation, used screw presses to obtain more juice from the bagasse. The juice was then clarified, reduced to the point of crystallization in open pans over furnaces, and the resulting syrup was placed in conical pots from which the molasses drained, leaving a loaf of sugar in each pot. The mills relied on water, animals, and men for power.

The risk of frost in the Mediterranean, together with the need for irrigation water, confined the cultivation of sugarcane to a few favored locations in the Levant, North Africa, Cyprus, Crete, Sicily, and Andalusia. Sugar production on the Atlantic islands of Portuguese Madeira and the Spanish Canaries was also Mediterranean in character. In its Mediterranean phase, however, the industry was labor-intensive, small-scale, and unable to produce large quantities of sugar, which therefore remained a luxury product. In short, there was little change in the technology of the Old World sugar industry between its introduction to the Mediterranean and its decline in the face of competition from the New World nearly 1,000 years later.

This Mediterranean phase did, nevertheless, foreshadow what was to come in the New World: Atlantic sugar was produced by slave labor brought from Africa to plantations in a system like that which would arise in the Americas. Moreover, the manner in which the Venetians and Genoese organized the supply of sugar to continental Europe during the Mediterranean phase also served as something of a blueprint for things to come. The capital of these Italian city-states established a colonial relationship with the producing regions. They built the first refineries in Bologna and Venice and also drew on slave labor from the coasts of the Black Sea. The Genoese came to concentrate their investments increasingly in the western Mediterranean and were later instrumental in helping to finance the transfer of the industry to the Americas.

The years between 1450 and 1680 mark that transfer, as well as the decline of the Mediterranean industry in the face of American competition. It was a phase not only of technological innovation but also of geographical expansion, with the sugar-producing islands of Madeira, the Canaries, and São Tomé serving as stepping stones across the Atlantic. The Spanish first cultivated sugarcane on Hispaniola in the early 1500s, but the Portuguese, beginning in Brazil during the 1520s, were initially far more successful. The English turned Barbados into a sugar colony during the 1640s, and the sugar industry gradually spread across the Caribbean and to other regions of the New World.

In tropical America, not only did the climatic conditions favor sugarcane cultivation but so did the abundance of land to grow it on and the forests needed to provide fuel for the factories. With these advantages, the American sugar industry assumed an altogether new scale in terms of number of mills, size of land holdings, and quantity of exports. Such an increased scope of activity created a large demand for labor, which the Portuguese, at first, tried to satisfy by employing the indigenous population. But as that population declined in the face of Old World diseases, they turned increasingly to Africa, and the entire American industry soon depended on slave labor from that continent, resulting in the importation of more than 10 million people (Curtin 1969).

Still another development was a technological revolution in the seventeenth century that saw the replacement of the inefficient Mediterranean-style mills used initially in the New World (Galloway 1993: 211–22). Perhaps the most important innovation was a mill which, in its basic design, consisted of three vertically mounted rollers that could be turned by animal, water, or wind power. Such a mill did not require the stems to be chopped into pieces before milling, and the efficiency of its operation made the use of presses redundant. It is interesting to note the strong evidence of the contribution of Chinese technology to this design (Daniels and Daniels 1988). More efficient milling demanded, in turn, more efficient manufacture of sugar, and notable improvements in the design of furnaces allowed a production-line organization for transforming cane juice into crystal sugar.

Sugar colonies with slave-run plantations characterized American industry in the eighteenth century, a period once again of relatively little change in technology, although planters did gradually introduce conservationist measures to preserve the fertility of the soil and supplies of fuel. The sugar colonies exported sugar and rum to Europe and North America and imported slaves and food. Such an economy supported the densest concentrations of population in colonial America.

With the nineteenth century, however, there began another era of innovation in methods of production and of geographical expansion. The successful slave revolt in the French colony of St. Domingue (now Haiti) during the 1790s heralded the beginning of the end of the old regime. Nonetheless, the process of abolition was only completed a century later when the slaves of Cuba and Brazil finally gained their freedom. Many of the former slaves continued to work on sugar plantations, but planters also sought other sources of labor. Between 1838 and 1917, the British recruited workers from their Indian empire and, in so doing, profoundly changed the ethnic composition of many of their colonies. Laborers also came from Madeira, China, Japan, and the Pacific islands to work in the cane fields.

Major nineteenth-century technical innovations included steam power and the replacement of the three-roller mills by horizontally laid iron rollers mounted in sets of three that could be linked with other sets to form a train of six, nine, and even more rollers. With some improvements, this basic design of the mill has continued to the present. Cane-sugar technology also borrowed from the beet industry, especially the use of vacuum pans, in which juice could be boiled at lower temperatures under reduced pressure to save fuel. The centrifuges for separating the crystals from the molasses were also borrowed, and large central factories, which could accommodate the new machinery, gradually replaced traditional mills.

Still another major development was the breeding of new sugarcane varieties. The new technology, coupled with improved varieties of the raw material, helped keep the sugarcane industry competitive with the sugar-beet industry. By the end of the nineteenth century, the manufacture of cane sugar was becoming a capital-intensive agribusiness that relied on continued improvements in technology and methods of cultivation to keep a competitive edge.

During the nineteenth century, the link between the sugar industry and European expansion continued. A rising prosperity among the growing populations of western Europe led to increased demand at a time when European territorial empires extended into Africa, southern Asia, and the Pacific. One result was that sugarcane industries were established in such places as South Africa, Java, Queensland, Fiji, Hawaii, and Taiwan. In southern Asia, the Western, industrial style of sugar production either replaced or operated alongside traditional noncentrifugal producers. By 1900, the sugarcane industry had become one of the major economic activities of the entire tropical world.

The Sugar-Beet Industry

The Raw Material

Sugar beet is a root crop of temperate lands in Eurasia and America that in recent years has also become an important winter crop in North Africa and the Middle East. Obviously, it has adapted to a wide range of climatic and soil conditions, even growing well in the short summers of Finland, the dampness of Ireland, the high altitudes of Iran and Sichua, and the hot, dry Imperial Valley of California. It benefits from irrigation and from long hours of daylight. Differences in temperature, day length, and rainfall do, of course, influence the sugar content of the roots. It is a biennial, storing food in its swollen roots to carry the plants through the first winter and the process of setting seed in the second year. Farmers harvest the roots that contain the sugar at the end of the first year's growing season, thus interrupting the plant's natural cycle. Toward the polar limits of the sugar beet's range, low summer temperatures and extended length of the day encourage some plants to set seed prematurely during the first year, resulting in poor development of the roots. Plants that do this are known as "bolters," which if present in significant numbers, lower the yield of sugar from a field.

Cultivated and wild beets belong to the genus *Beta,* of the family Chenopodiaceae. The species *Beta vulgaris* L. includes the common beet, the mangelwurzel, and the sugar beet. All three have descended from wild sea-beet, *Beta maritima,* by human selection. The Romans used beets, probably *Beta maritima,* as food for both humans and animals and thereby selected for its value as a vegetable. Cultivators in medieval and early modern Europe developed the roots for animal feed, and since the eighteenth century, the capacity of *Beta vulgaris* to store sucrose in its roots has been the focus of breeding. Selection in Germany increased the sugar content of the roots from 7 percent in the eighteenth century to between 11 and 12 percent by the 1850s. The sugar content is now up to 20 percent. In addition to this success, researchers also breed sugar beets to discourage "bolting," to resist disease, and for shape and fibrosity to help in harvesting and milling. Sugar beets provide an example of a rapidly domesticated plant that is still being modified and improved to suit a particular purpose (Bailey 1949: 353; Campbell 1976; Bosemark 1993; Evans 1993: 101–3, 107, 109).

The main stages in the extraction of sucrose from beet have remained basically the same over the last century or so, but there have been improvements in the efficiency of each stage. On arrival at the factory, the beets are washed to remove soil and stones and then sliced into thin, smooth pieces known as "cossettes." The aim is to maximize the surface area of the beet so as to facilitate the diffusion of the sucrose. The cossettes then enter a countercurrent diffuser through which they move against the flow of a hot water extractant. This operation transforms about 98 percent of the sugar from the beet into a raw juice. The juice, in turn, is purified, reduced by evaporation, and crystallized, and the crystals are separated in centrifuges from the mother liquor. Formerly, beet sugar factories produced a raw sugar that was further treated in a refinery; now many factories produce a white sugar that is 99.9 percent pure (Vukov 1977: 13, 421, 426–7; Reinefeld 1979: 131–49; Bichsel 1988).

More than 90 percent of the revenue of the sugar-beet industry comes from sugar. Alcohol production is the best financial alternative to making sugar, but researchers have been unable to generate other by-products that are very lucrative. The lime sludge from the purification process is sold for fertilizer. Citric acid and baker's yeast are produced by fermenting the molasses, and the exhausted cossettes can be used for animal feed (Blackburn 1984: 338–9; Tjebbes 1988: 139–45).

Historical Geography

The sugar-beet industry is only two centuries old. In 1747, a Berlin professor of chemistry, Andreas Marggraf (1709–82), succeeded in extracting a modest quantity of sugar from beet. Although he published the results of his research in French and German, he did not put them to commercial use (Baxa and Bruhns 1967: 95–9). However, his student Franz Carl Achard (1753–1821) was more practical. He improved the raw material by breeding the cultivated fodder beets for sugar content, and he evolved the white Silesian beet, which is the ancestor of all subsequent sugar-beet varieties (Oltmann 1989: 90, 107).

In the years around 1800, Achard was active in promoting the beet industry, and in 1801, with the financial assistance of the King of Prussia, he began to build what may have been the world's first sugar-beet factory (Baxa and Bruhns 1967: 113). Although it was not a financial success, other Prussians followed his initiative, building several small factories in Silesia and around Magdeburg. Russia was the second country to enter the industry: Its first sugar-beet factory opened in either 1801 or 1802 (Baxa and Bruhns 1967: 118; Munting 1984: 22), and the first factory in Austria opened in 1803. In the beginning, the French limited themselves to experiments, as did the Dutch, whose Society for the Encouragement of Agriculture offered a prize for extracting sugar from native plants (Slicher van Bath 1963: 276–7; Baxa and Bruhns 1967: 99–119).

These experimental and very small scale beginnings of the sugar-beet industry were given a considerable boost during the Napoleonic wars. In 1806, Napoleon's ban on the import of British goods and Britain's retaliatory blockade of his empire greatly reduced the supplies of cane sugar that reached continental Europe. Napoleon encouraged the production of beet sugar as a substitute, and landowners in France and the countries north of the Alps tried to respond.

The paucity of seed and unfamiliarity with the requirements of the crop led, however, to a disappointing supply of beet, part of which rotted on the way to the factory because of poor transportation. The number of factories illustrates the extent to which policy overreached reality: In France, in the season that spanned 1812 and 1813, only 158 factories of the 334 for which licenses had been given were actually in working order (Baxa and Bruhns 1967: 139). With the low yields of beet per hectare, low sucrose content, and a disappointing rate of recovery of the sucrose in the factories, beet sugar could not compete with cane once imports from the West Indies resumed after 1815. The beet industry disappeared from Europe except in France where it hung on until better times (Slicher van Bath 1963: 277; Baxa and Bruhns 1967: 134–45).

Those times began in the late 1830s and gathered force throughout the middle of the century, benefiting from improvements in both field and factory. In France, P. L. F. Levèque de Vilmorin (1816–60) was particularly successful in breeding varieties of beet for greater sugar content, with improvements continuing after his death (Baxa and Bruhns 1967: 190–1). In the first generation of sugar-beet factories, the juice was extracted by grinding the beet in animal-powered mills and then placing the pulp in presses (Baxa and Bruhns 1967: 148). In 1821, however, another Frenchman, Mathieu de Dombasle (1777–1843), proposed the procedure of slicing the beets and extracting the sucrose in a bath of water. He called the method maceration, but it is now known as the diffusion process. In 1860, Julius Robert (1826–88) became the first to employ it (Baxa and Bruhns 1967: 150, 176).

Diffusion replaced the mills and presses and remains to this day a standard part of the processing of sugar beet. Vacuum pans were first used in 1835 in a beet factory in Magdeburg, and centrifuges became part of factory equipment during the 1840s (Baxa and Bruhns 1967: 152, 172). An additional development encouraged the revival of the beet industry – the arrival of cheap Russian grain in western Europe where, from the 1820s onward, it caused a fall in grain prices. Western European farmers who had been growing grain now required a substitute crop, and beet was a good candidate. It could fit into the agricultural rotation, growing on land that would previously have been left fallow, and its leaves and roots provided feed for animals. This, in turn, made possible an increase in livestock numbers, which meant more manure. If the roots were sold to a factory, they earned the farmer cash, and the pulp could also be used for feed (Galloway 1989: 131).

Despite the advantages of sugar beet to the agricultural economy and improvements in its raw material as well as factory technology, the beet industry nevertheless was still not competitive with cane. Rather, its revival in the 1830s, and its continued growth, depended on government protection through tariffs on imported cane sugar and incentives of one sort or another, such as subsidized exports. The 1902 Brussels Convention attempted to bring some order to a scene characterized by a protected beet industry and a complaining sugarcane industry, yet protection for beet sugar remains in place (Chalmin 1984: 9–19; Munting 1984: 21–8; Perkins, 1984: 31–45).

The revival of sugar-beet cultivation began in northern France, where it had never entirely died out, and continued in Prussia and the other German states during the 1830s, in Austria-Hungary in the 1840s, and in Russia in the 1850s. By the 1850s, Germany had become the most important producer of beet sugar, responsible by the end of the century for rather more than a third of the European total. By this time, beet cultivation extended from southern Spain in a curve arching north and east through France, the Low Countries, Germany, and eastern Europe, and into the Balkans, Russia, and the Ukraine. It also extended into Denmark and southern Sweden. The industry was particularly important in northern France, in the Low Countries, around Magdeburg in Germany, in Bohemia, and around Kiev in the Ukraine. Great Britain was noticeably absent, refusing to subsidize a beet industry of its own, but rather buying sugar, whether cane or beet, wherever it was cheapest.

Sugar beet remained a predominantly European crop throughout the twentieth century. In the years approaching 1990, Europe accounted for about 80 percent of the world's production of beet sugar, with 40 percent of that production coming from the European Union. Since 1991, production in the countries of the former Soviet Union has lost ground, but this is probably a temporary situation. The geography of the European beet-sugar industry has also remained remarkably constant: Those regions that were important producers at the beginning of the twentieth century remained so at its end. There has been some modest expansion on the periphery into Ireland and Finland, and since the 1920s, Great Britain has finally developed a sugar-beet industry of its own. Two considerations led to the change in Britain's policy towards beet: World War I had revealed the difficulties of relying heavily on continental European producers of sugar and the awkwardness of such dependence. Moreover, sugar beet had the potential of being a useful cash crop for farmers in the agricultural depression that followed the war.

The North American sugar-beet industry dates from the 1880s and has increased steadily, producing nearly 4 million tonnes of sugar a year. The industry is overwhelmingly located in the United States. Beet is grown in the Midwest, but the bulk of the crop grows on irrigated land in the West. In Asia the industry became significant only in the 1920s and has seen rapid expansion since the 1960s (Baxa and Bruhns 1967: 192–201, 221–2, 262–94; International Sugar Organization 1994: 279–85).

Like the cane industry, the sugar-beet industry invests heavily in research. The breeding of new varieties, the methods of harvesting and planting, and improvements in factory technology are all important foci of attention.

The Contemporary Sugar Industry[4]

Production

At the beginning of the twentieth century, beet-sugar production exceeded that of cane sugar, with the total combined production of centrifugal sugar about 12 million metric tonnes raw value (mtrv). However, today cane accounts for most of the sugar produced (about two-thirds). Total combined production reached 100 million mtrv in the mid–1980s and rose to 120 million mtrv by the mid–1990s. This expansion has been fueled by increases in consumption of about 2 percent a year, resulting from a growing world population and improving standards of living in some of the less-developed countries of the world. Noncentrifugal sugar also continues to be an important sweetener: Statistics are almost certainly incomplete but show production in excess of 15 millions tonnes at present.

The sugar industry in some countries is highly protected. The United States, for example, maintains a domestic price for sugar well above the world price and controls the amount of sugar imported. The European Union protects its beet growers, and the industry in India is carefully regulated to control production and domestic prices. Clearly, the interventionist traditions in the industry established long ago remain very much alive.

India is the world's major producer of cane sugar, and its sugar industry continues to grow. Annual centrifugal production has reached 16 million mtrv, which includes nearly 1 million tonnes of khandsari sugar. India is also the world's major producer of noncentrifugal sugar, accounting for perhaps as much as two-thirds of the total. Practically all of this sugar is consumed in India; only rarely, after exceptionally good harvests, are small quantities exported.

Brazil's production has increased rapidly in recent years to reach 13 million mtrv, plus some small-scale production of noncentrifugal sugar known as *rapadura.* The country has the advantages of abundant land and a good climate, and its production is divided between the home sweetener market, fuel alcohol for automobiles, and exports. Brazil has the ability to direct sugar to exports or to fuel alcohol, depending on the world prices. Cuba and Thailand compete for the third and fourth rankings among the world's sugar producers. Cuba's annual production in the late 1980s was around 8 million mtrv, but collapsed to half this amount when the fall of communism in Eastern Europe brought about a loss of its major markets. The Cuban industry's ability to recover remains a major question. Thailand has only recently become an important sugar producer. Its industry is expanding, and production is now in excess of 6 million mtrv, of which two-thirds is exported.

The European Union is responsible for nearly half of the world's beet sugar, about 18 million mtrv annually. Germany and France are the main producers, although Ukraine and Poland produce close to 4 million and 2 million mtrv, respectively. By and large, the beet industry in eastern Europe suffers from poor management and a lack of investment in machinery, and because much land is still publicly owned. The region has enormous potential, however; several western European companies have taken advantage of privatization schemes to buy factories and begin the work of modernization. The United States, China, and Turkey are also major beet-sugar producers. The United States and China are among the relatively small number of countries which, because they extend across a wide range of climatic zones, are able to grow both cane and beet.

Trade

International trade in centrifugal sugar amounts to about 30 million mtrv, or about one-quarter of the total world production, meaning that most sugar is consumed in the country where it is produced. Much of the trade takes place under special arrangements, and only a small portion of the sugar traded internationally sells at the free-market price.

The European Union buys sugar at a preferential price from the former colonies of its member states; the United States allocates import quotas to a large number of countries. Cuba bartered sugar for oil with the former Soviet Union, and now barters with Russia on a more limited scale. These arrangements have had what might seem curious consequences. The European Union is both a major importer (1.8 million mtrv annually) of sugar from its former colonies and a major exporter (five million mtrv annually) because of its beet production. Some countries (Barbados, Jamaica, Guyana, and the Dominican Republic) export all, or nearly all, of their sugar at a premium price to meet contractual arrangements with the United States and the European Union, and they import at world market price for their own consumption. Refineries also import raw sugar, only to export it again in a practice known to the trade as tolling. This accounts for the presence of the United States on the list of sugar exporters. Quotas limit its imports, but tolling permits the use of otherwise surplus refining capacity and provides employment.

About 75 countries export sugar and about 130 import it – the numbers fluctuate a little from year to year. Most trade in small amounts, and many are minimal participants dealing in less than 10,000 tonnes a year. But the European Union, Ukraine, Cuba, Brazil, Thailand, and Australia all export more than 1 million mtrv annually. Together, these latter countries account for by far the greater part of sugar exports. By way of contrast, the European Union, Russia, Canada, the United States, Japan, and South Korea all import more than 1 million mtrv a year apiece, with Malaysia and Algeria not far behind. Such activities provide certainties, insofar as there can be any, in the sugar trade. The major sources of uncertainty are India and China. They may appear unexpectedly on the market as either importers or exporters if their policies change or if their policy makers misjudge the market situation. Weather is also an uncertainty. Poor or excellent harvests in a number of countries can cause shortages or create surpluses.

In most countries there are stocks of sugar held against sudden shortages and increases in price. The world stocks-to-use ratio in the mid–1990s was considered high, at about 19 percent (USDA 1996: 9). This translates into low free market prices because there are reserves to draw on in case of a sudden shortage. Sugar traders and some governments carefully monitor production, import, export, and consumption data in each country and calculate the buildup and/or drawdown of stocks with a view to predicting demand and prices. There is a very active trade in sugar futures.

Competition

For several hundred years, sucrose in the Western world has been without a serious competitor in the sweetener market, but recently this has changed. The leading caloric competitor is high-fructose corn syrup (HFCS). It is a liquid sweetener made from plants (especially maize) that contain a sufficient amount of starch, although sweeteners are also made from sweet potatoes and tapioca in Asia and from wheat and potatoes in Europe. HFCS appeared in the 1970s, during a period of high sugar prices, but continued in production after sugar prices fell. Sugar usually has a price advantage over HFCS, and HFCS is not always a good substitute for sugar. Bakers and manufacturers of confectionery and cereals prefer sugar because of its "bulking, texture and browning characteristics" (USDA 1995: 18). HFCS is most competitive in the manufacture of soft drinks. The United States is by far the largest producer of HFCS, with the European Union, Canada, Korea, Argentina, and Taiwan making very modest quantities. HFCS has captured rather less than 10 percent of the sweetener market and, in the immediate future, is not expected to expand beyond the liquid sweetener market in a few countries (USDA 1995: 15–20).

Low-calorie, high-intensity sweeteners have gained in significance since the 1980s and claim a small percentage of the sweetener market. Saccharin and aspartame are perhaps the best known. They are attractive to consumers concerned with diet and can compete in price with sugar. Both are used to sweeten coffee, tea, and other beverages ("table-top use"), but aspartame, benefiting from the demand for diet soft drinks, has received approval for a wider range of uses in the European Union, the United States, Canada, and Japan. This branch of the sweetener market is still evolving. Low-calorie sweeteners are used together in some applications, but they also compete with one another and, of course, they compete in the soft drink market with HFCS and sugar (Earley 1989; USDA 1995: 23–4).

The fact that the manufacture of sugar is one of the oldest industries in the world gives the sugar industry a special place in the cultural history of food, but other characteristics also give it a particular interest. It is unique among agro-industries in that it has both tropical and temperate sources of supply of its raw material. It has been responsive throughout its history to developments in science and technology and today continues to invest in research. Government intervention is a long-standing tradition. The importance of sugar to the finances of European imperialism was a great incentive for the colonial powers to attempt to manage the international trade in sugar for their own benefit. Governments continue to intervene to this day with subsidies and protective tariffs to defend vested interests.

The sugarcane industry has had profound economic and social consequences on those parts of the world in which it became a major crop. Indeed, perhaps no other crop has had such a formative influence on societies. The industry has divided societies, along class lines, between the owners of the factories (either local elites or – often nowadays – foreign companies) and the work force. Even where the factories have been nationalized, or are owned by cooperatives, disparities exist in income and prestige between managers and laborers. Because of its great demand for labor – satisfied first by African slavery, then by indentured workers, and finally by free laborers – the industry also produced multiethnic populations that frequently have complex internal politics. Another legacy is economic dependency. Although the empires are gone, many ex-colonies continue to grow sugar as a staple, relying on special arrangements with their former rulers (now members of the European Union), as well as with the United States, that enable them to sell their sugar at a premium above the low price that sugar generally commands on the open market.

The dilemma of dependency has had no easy resolution. Sugarcane producers have little bargaining power, given the oversupply of their product, and alternatives to the cultivation of sugarcane that can provide a better level of employment and income have been difficult to find. Dependency is keenly felt by the populations of the cane-growing countries, and where this sense of frustration is joined with the memory of slavery, as in the Caribbean, sugarcane is a very problematic crop.

J. H. Galloway

Notes

1. This statement requires one reservation. The medieval Mediterranean sugar industry and the early American industry cultivated only one variety of cane, known now in the literature as Creole cane. Opinion differs on the correct botanical identification of this cane. Most authorities accept that it was either a variety of *S. officinarum* (Blackburn 1984: 2, 91) or a hybrid of *S. barberi* and *S. officinarum* (Stevenson 1965: 41). However, Fauconnier (1993: 1) considers it to have been a variety of *S. barberi.*
2. In this section I draw heavily on Galloway 1989.
3. The authoritative discussion of sugar-making in China is that by Christian Daniels (1996).
4. I have used three sources for the statistics in this section: Czarnikow (1997): 55; the International Sugar Organization (1994); and the USDA (1997: 31–6). There are some differences in these data. For a brief discussion of the problems of collecting statistics on the sugar trade, see Ahlfeld and Hagelberg (1989: 59–65).

II.G

Important Foods from Animal Sources

II.G.1 American Bison

The American bison *(Bison bison)* is more closely related to cattle than to true buffalo, such as the water buffalo *(Bubalus bubalis).* Nonetheless, early European settlers called the unfamiliar animal they encountered in North America a "buffelo" *[sic]* and this misnomer has persisted to the present. Because we are so accustomed to thinking of the American bison as a buffalo, the terms are used interchangeably in this chapter.

Long perceived to be an environmental casualty of the conquest of the Great Plains, the American bison has gradually reasserted its presence in North America. Today, there are around 200,000 of the animals alive on the continent, and the danger of species extinction appears to have passed (Callenbach 1996). However, any further expansion of the population is likely to be linked, at least in part, to the animal's economic usefulness, especially as a food source. At present, only a limited number of people are acquainted with the taste of bison. For buffalo meat to become part of the national diet, the advertising and agricultural industries will have to reintroduce a food which, at an earlier time, was essential to many of the continent's inhabitants.

In size and appearance, the bison is imposing and distinctive. A mature male stands from 5 to 6 feet tall at the shoulder and may weigh from 1,800 to 2,400 pounds. Noticeably smaller, females seldom weigh more than 800 pounds. Despite its bulk, the bison is quick and agile and can sprint at speeds of up to 30 miles per hour. Like domestic cattle and sheep, it is cloven hooved; unlike them, both the male and female possess large, curved horns and a prominent hump at the shoulder. Buffalo are usually dark brown in color, although their hue lightens to brownish-yellow during the spring. The animals have two types of hair: a long, coarse, shaggy growth covering the neck, head, and shoulders, and a shorter, woolly growth found on the remainder of the body. During the spring, bison shed much of this hair, assisting the natural process by rubbing against rocks or trees. Only the head, hump, and forelegs retain hair throughout the year.

In the past, wild bison migrated with the seasons, from north to south and back. Although their diet consisted of various grasses (blue stem, grama, and bunch), it was buffalo grass *(Buchloe dactyloides)* that served as their primary staple. A short, fine plant, buffalo grass requires little water, tolerates extreme temperatures, and is resilient in the face of grazing and trampling. As the bison population declined, this species became scarce as well. Competing plant life that was no longer destroyed by the bison's hooves expanded throughout the plains, and without the wanderings of the bison to spread its seeds (either through manure or by attachment to the animal), buffalo grass was largely replaced by other grasses (Garretson 1938).

The buffalo's mating or "rutting" season commences in early June, reaches a peak in late July and early August, and gradually concludes by the end of September. There is violent competition among the bulls to impregnate the females, followed by a nine-month gestation period and the birth of a single calf (McHugh 1972). In general, the calves mature quickly and are able to mate by their second year, although the animals are not fully grown until the age of six. On the average, the bison's life span is between 20 and 30 years.

History of the Bison

When the European explorers first visited North America, large numbers of bison were present in perhaps 70 percent of the present-day continental United States, as well as in what are now the Canadian provinces of Alberta and Saskatchewan. Indeed, the pre-Columbian buffalo population is often estimated at some 60 million members. As a rule, the animals lived in groups of 20 to 40, gathering into larger herds only for rutting or migration.

Native Americans long utilized the bison as a food source; archaeological evidence suggests that buffalo hunting was practiced more than 10,000 years ago. However, for the peoples residing in the vast plains stretching from the Rocky Mountains to the Missouri River, the buffalo represented more than simply a source of food and clothing.

In a physical sense, the animal provided the plains inhabitants with many items essential to survival in this environment, in the form of blood, meat, hide, bone, sinew, and manure, that were used for food, rope, weapons, shelter, blankets, clothing, fuel, and medicine (Dary 1974). In a spiritual sense, the buffalo provided the first Americans with still more. Understanding the animal to be one of numerous earthly representatives of a higher power, the Native Americans honored it as a spirit that influenced fecundity, happiness, strength, protection, and healing. Within such tribes as the Assiniboin, Cheyenne, and Kiowa, buffalo skulls served as central totems in ceremonial activities. Particularly revered was the rare albino, or "White Buffalo," believed to be the sacred leader of all herds. Among the Plains Indians, an understanding of the buffalo was perceived as essential for understanding one's own place within the universe (McHugh 1972).

Methods of preparing bison as food were largely determined by the gender of the cooks. When eaten fresh, the meat was often cooked by the hunters, whereas meat curing and preservation were tasks reserved for women. Hunting parties would sometimes use the hide as a cauldron in which to boil the meat. Variations on this practice included lining a hole in the ground with the animal skin or suspending the hide aboveground on sticks over a fire. In addition to boiling, the meat was frequently roasted by rotating it over an open fire.

To cure buffalo meat, Indian women relied on the sun, rather than on salting or smoking – the European methods. Selecting the choicest parts, the women cut the meat into strips, across the grain, in order to maintain alternating layers of lean and fat. These strips were then suspended on elevated racks in full sunlight for several days. The result was a jerky that could be eaten in the dried form or rehydrated by lengthy boiling. When cured, the meat was lightweight and largely imperishable, an ideal staple for a mobile culture (Catlin 1842).

The jerky, however, could be even further condensed when transformed into pemmican, a food whose name is a word from the Cree language – *pimikân,* derived from *pimii,* meaning grease or fat. Pemmican is aptly named. To make it, the Indians placed pulverized jerky into sacks sewn from buffalo hide and then poured hot, liquid marrowfat over it. The fat would both combine with the dried meat and serve to seal the sack. While still molten, pemmican could be formed into shapes convenient for storage or transport. Mostly produced in the form of 90-pound blocks, it was a staple for the Plains Indians, as well as for the fur trappers and traders who spearheaded the Europeans' advance into the region.

As the Native Americans came to recognize pemmican's value in trade with the whites, additional ingredients were added to appeal to the latter's tastes. Although chokeberries became the most common supplement, some pemmican was flavored with cereals, sugar, and fruits. For trappers, this food was "the bread of the wilderness," a practical staple in terms of availability, stability, and nutrition. Whether the bison population was diminished as a result of such commerce is difficult to establish, although it is certainly probable (Binkerd, Kolari, and Tracy 1977).

Native Americans also incorporated buffalo into their diet in several ways other than as fresh and preserved meat. Various tribes developed methods of preparing blood soups and puddings. Roasted thigh bones were a popular source of tasty marrow, and the tongue was savored. Northern tribes enjoyed boiled fetal calves, and the Hidatsa specialized in grilled buffalo udders filled with milk. The Plains tribes occasionally dined on baked buffalo hides. However, this latter practice was infrequent as hides were generally more valuable for things other than food (McHugh 1972).

The Bison East of the Mississippi

Following the example of the first Americans, early European visitors utilized the buffalo as a source of steaks, stews, and marrow. Throughout the sixteenth century, Spanish explorers, such as Alvar Nuñez Cabeza de Vaca and Vincente de Zaldivar, wrote of consuming buffalo flesh during their adventures. The British, however, who settled east of the buffalo grounds, did not encounter the animal until they began to move inland at the beginning of the seventeenth century. By the end of the colonial era, the buffalo had virtually disappeared from the landscape east of the Appalachians.

The reasons for this disappearance are varied. Although settlers often hunted bison for food, it is doubtful that the human population of the time was numerous enough to eliminate great numbers of the animals. Rather, it seems more likely that as the whites transformed the landscape to meet their needs, the buffalo simply migrated westward away from people. In addition, as farmers began to raise more cattle, their grazing would have reduced the available food supply. Finally, it should be noted that the eastern herd was by no means as large as that of the west.

When European settlement expanded into the area between the Appalachians and the Mississippi, buffalo were once again on hand as a food source. In detailing his travels through Kentucky, Daniel Boone mentioned meals of fresh buffalo, and as other early frontiersmen penetrated the region, they often followed "buffalo roads" – narrow paths formed by herds in search of salt (Rorabacher 1970).

As had happened east of the Appalachians, however, as human settlement continued, buffalo east of the Mississippi became displaced by a changing economy. Initially, settlers relied heavily on bison for food; yet, once farms were established, the animals became nuisances, grazing on land more profitably used to raise cattle or crops. By 1830, the buffalo had disappeared from the East, and the American bison population was compressed into the Great Plains.

The Bison West of the Mississippi

Crowding into the plains created a variety of natural hazards for the buffalo. Food shortages were more common, and fatal diseases (particularly anthrax and bovine tuberculosis) could spread quickly and kill greater numbers as the herds grew more closely together (McHugh 1972).

Such consequences of the bison's westward migration, however, seem insignificant when compared with the destruction wrought by humans during the final third of the nineteenth century. It was then that the forces of economics and politics, as well as human greed, carelessness, and malice, came together in such a manner as almost to remove the American bison from the North American ecosystem. Between 1870 and 1873, the large buffalo herds of Kansas were destroyed. Next to go were the southern herds, and by 1878, the animals were absent from Texas to the edge of the prairie. The vast northern herds of the Dakotas and Montana survived a few years longer, perhaps into 1883. But by 1900, the herds of the Canadian plains were gone, and only about 300 of the animals remained in the United States.

Commercial hunting seems to have been the factor most significant in the buffalo's destruction. The earliest professional hunters in the West sought beavers, not bison, and required the latter only for food. By the early 1820s, however, commercial buffalo hunting had begun in southern Canada, with the primary aim of securing buffalo tongues (a popular delicacy) and hides for shipment to the East and abroad. Often, entrepreneurs recruited Native Americans to do such hunting in exchange for whiskey.

At least at this point, however, the bison's habit of shedding offered a degree of protection against excessive hunting. Because the sale of furry hides (for use as robes) produced the greatest revenue, and because the animals lost their furriness during the summer, hunting them was strictly seasonal. Nevertheless, the desire to trade for the white man's goods resulted in a Native American slaughter of buffalo that has been estimated as 30 percent greater annually than their personal needs required (Dobak 1996).

During the two decades prior to the Civil War, the Great Plains experienced a series of ecological changes that also hastened the disappearance of the bison. Foremost was the proliferation of open-range cattle ranching. Indeed, by 1850, the prairie had become home to more than 50 million cattle that were major competitors for the region's food supply. Moreover, ranchers were unhappy with the seasonal wanderings of the bison, arguing that their grazing rendered the land unfit for beef cattle for as long as two years afterward (Vestal 1952).

At the same time, as human settlement increased and transportation on the prairie improved, the slaughter of the buffalo for industrial purposes escalated. The trade in buffalo robes accelerated as more forts and trading posts dotted the western landscape: In 1850, around 100,000 robes reached the markets of St. Louis, a record total at that time. The increase in civilian and military populations on the plains also meant that still more of the animals were slaughtered for food (Dary 1974).

After 1865, the future of the bison became ever more precarious. With the conclusion of the American Civil War, both the U.S. Army and the railroad corporations sought to consolidate their positions on the plains. Troops were stationed in the West to pacify the Native Americans, and thousands of men migrated to the prairie to lay tracks for the Union Pacific and the Topeka & Santa Fe railroads. Fresh buffalo meat served as the primary fare for both the soldiers and the laborers. Moreover, once the railroads began service through the West, the buffalo again (as they had in the East) became nuisances, routinely wandering onto or across the tracks, blocking trains, and causing long delays. George Bird Grinnell recalled two such delays while traveling on the Kansas Pacific, one of which lasted for around three hours (Grinnell 1892).

In 1870, a refinement in tanning techniques became still another factor in the decrease of the American bison. The animal's summer hide had long been dismissed as economically worthless because there was no known method for transforming the skin into commercial leather. However, once Philadelphia tanners devised such a method, the bison became a year-round target, and the promise of easy money encouraged more and more men to become buffalo hunters (Cronon 1991).

This was especially the case following the financial panic of 1873, when the nation entered a five-year period of severe economic depression. As banks closed and millions of easterners were suddenly unemployed, the seemingly inexhaustible bison herds of the plains offered a chance to earn a living, and perhaps even to acquire wealth. Buffalo hides brought from 2 to 3 dollars each during the 1870s, and a successful hunter might kill more than 250 animals in a single day. In the 1950s, Frank H. Mayer, once a "buffalo runner" himself, recalled:

> The whole Western country went buffalo-wild. It was like a gold rush or a uranium rush. Men left jobs, businesses, wives, and children and

> future prospects to get into buffalo running. There were uncounted millions of the beasts – hundreds of millions, we forced ourselves to believe. And all we had to do was take these hides from their wearers. It was a harvest. We were the harvesters (Mayer and Roth 1958: 21).

Much of the time, hunters worked in gangs, with individuals specifically assigned to shoot or skin the animals. Larger parties would utilize horses to remove the hides quickly: After the buffalo's skin was loosened by making a series of cuts, it was tied to a horse which pulled the hide off the carcass (Wheeler 1923). The skins were awkward and bulky, often weighing more than 100 pounds each. Still, an experienced skinner could have the hide off an animal in about five minutes. Although the financial rewards encouraged efficiency, the animals' abundance more often produced carelessness and waste, and bison slain by commercial hunters were not really "harvested" at all but merely left to rot in the sun.

In general, the bison was easy prey. Seasoned hunters understood its habits and instincts and developed techniques to attack it when confused and vulnerable. Recalling the hunts of the 1870s, one participant stated that "[t]he stupidity of the buffalo was remarkable" (Wheeler 1923: 81). Although there was a modicum of risk in buffalo hunting, accidents were more often the result of human error than of aggressiveness on the part of the hunted. Many retired hunters later wrote about injuries caused by falling off horses or by rifles exploding. Occasionally, too, poor judgment during winter months resulted in death from exposure (Dodge 1959).

In addition to destruction by commercial hunters, the buffalo population was further decimated by increasingly numerous "sport-hunters." As early as the 1830s, such traveling gentlemen as Washington Irving began to test their marksmanship on the buffalo, and during the 1850s, an Irish nobleman, Sir George Goe, indulged in a highly publicized "safari" with 21 wagons and a staff of 40 servants. In a three-year period, his party killed 2,000 bison.

Such "sporting" expeditions became increasingly widespread as the century progressed, especially during the depression that ensued after the "Panic of 1873," when the railroads were determined to increase revenue by increasing the number of passengers going west. Rail executives hit upon the notion of catering to the sportsmen (who seemed to have money and time when most people did not) and advertised special "buffalo trains" that would transport easterners into areas populated by the animals. Upon arrival, the passengers could shoot bison from the comfort (and safety) of the railroad cars. More intrepid hunters might track them on horseback, although in general the procedure was to hire an experienced "scout" to minimize the danger.

The most renowned of such guides was William F. Cody, or "Buffalo Bill," a clever entrepreneur who later prospered as the creator of the traveling "Buffalo Bill's Wild West" show, on the road from 1883 to 1916. Much of Cody's initial fame had resulted from escorting prominent personalities, such as Gordon Bennett II (publisher of the *New York Herald*) and the son of Russian Tsar Alexander II (Aleksandre Nikolayevich), on hunts.

Such expeditions were bloody slaughters. Many hunters recalled ruining expensive rifles because of lengthy periods of continuous and rapid firing that caused them to overheat. If the hunters were successful in making a "stand" – a technique of tricking the buffalo into immobility – the potential for killing was limited only by their ammunition. Numerous parties recorded killing up to 200 animals per hunter per day.

The Final Buffalo Hunts

The impact of such slaughter was not unnoticed at the time. In 1871 and 1872, the territorial legislatures of Wyoming and Montana passed laws intended to reduce buffalo hunting. In the U.S. Senate (also during 1872), Cornelius Cole of California and Henry Wilson of Massachusetts attempted on separate occasions to enact federal protection for the bison. Both, however, were unsuccessful.

Two years later, U.S. Representative Greenburg L. Fort of Illinois sponsored national legislation prohibiting the killing of female bison by anyone not a Native American (Dary 1974). This bill triggered much debate that clearly indicated that its opponents saw in the extermination of the bison the most effective way of subduing the Plains Indians. Indeed, Secretary of the Interior Columbus Delano had endorsed such a position (in his annual report for 1873) by predicting that the disappearance of the bison would eliminate future Native American uprisings by reducing the Native Americans. One of the opponents of Fort's legislation, Samuel S. Cox, bluntly argued that the bill "favored Indians at the expense of white men," whereas only the reverse was desirable (Dary 1974: 127).

Despite strong opposition, the bill passed the House and Senate during the spring of 1874, only to have President Ulysses S. Grant employ a pocket veto that quietly killed it the following year. There seems little doubt that this was a political tactic inspired by the Bureau of Indian Affairs and by General Philip Sheridan.

In fact, Sheridan had clearly laid out a scheme whereby "the extermination of the buffalo herds by meat hunters for the construction gangs of the railroad, by hide-hunters, and finally by tourists shooting from palace-car windows" could hasten the submission of the Native Americans (Slotkin 1992: 426). In a frequently quoted 1875 speech to the Texas Legislature, Sheridan denounced efforts to save the buffalo, explaining that "the hide hunters were doing more to settle the Indian question than the entire Army had done in thirty years, by destroying the Indians' commissary" (Garretson 1938: 128).

If the American bison were not already doomed to near extinction by 1875, the failure of Fort's bill certainly brought it one step closer. Although within a decade a number of western states enacted laws to halt the slaughter, such regulations were rarely enforced, and even had they been, the laws probably appeared too late to reverse the decline of the species. In 1880, the Northern Pacific Railroad extended its lines through North Dakota, thus offering hide hunters ready access to the still-flourishing northern herds. Within three years, almost all of this population was destroyed.

By the end of the century, free-roaming buffalo had disappeared from the Great Plains and could be found only in a few protected situations: national parks, game reserves, and captivity. By 1913, when the "buffalo nickel" 5-cent coin (designed by James Earle Fraser) entered circulation, wild American bison had vanished from the landscape.

The Struggle for Conservation

The capability of the bison to breed in captivity was a critical factor in its escape from extinction. Following the demise of the wild herds at the end of the nineteenth century, a series of conservation measures were undertaken to preserve the species by controlled management of the few survivors. The initial attempt at government-sponsored protection dates from the beginning of the twentieth century and occurred at Yellowstone National Park, which contained the scant remnants of the northern herd. Although Congress had outlawed all buffalo hunting within the park, poaching was widespread and carried no serious penalty before 1894.

Far greater attention was accorded the buffalo following the 1902 appointment of Charles J. Jones as the warden of Yellowstone. Jones increased the size of the bison population by purchasing privately held animals from throughout the United States. Moreover, he segregated the animals into a "wild herd," which functioned with minimal supervision, and a "tame herd," which was closely monitored and given food and protection from deep snow during the winter. Newborn calves were frequently transferred from the wild to the tame herd to ensure their survival.

The publicity given to Jones's efforts subsequently resulted in the formation, in December 1905, of the American Bison Society (ABS). With Theodore Roosevelt serving as honorary president, and its membership composed of both naturalists and sportsmen, the society proved an effective association for the preservation of the buffalo. Working in conjunction with the New York Zoological Society, the ABS advocated the formation of additional federal herds to augment those in Yellowstone. Between 1907 and 1918, the societies assisted in the creation of buffalo reserves in Oklahoma, Montana, Nebraska, and North Dakota (U.S. Department of the Interior 1977).

In addition to such conservation agencies, many Native Americans have made efforts to reestablish the bison in North America. As early as 1873, Walking Coyote, of the Pend d'Oreille, noted the animals' decreasing numbers and attempted to raise a herd of his own from four calves captured in Montana. During the 1930s, both the Crow and Sioux established herds on reservation lands. More recently, in 1990, the Inter-Tribal Bison Cooperative (ITBC) was organized to assist bison-restoration projects undertaken by 31 tribes in 13 states. In viewing the bison as a natural part of the plains ecosystem, the ITBC argued that a return of the animal to its former home would improve the lives of the area's human inhabitants (Garretson 1938; Callenbach 1996).

The conservation strategies of the twentieth century have been remarkably successful. No longer endangered, the bison population has prospered to such a degree that the animal has entered commercial markets as a food item. During the 1970s, breeders created the "beefalo," an animal comprising three-eighths bison and five-eighths bovine parentage. Overall, this hybrid offered little beyond novelty; nutritionally, the meat was inferior to that of the buffalo, and the animal appeared susceptible to an array of diseases. The failure of this experiment suggests that, at least in the near future, the American bison is safe from any further genetic tinkering (National Buffalo Association 1990).

Bison as Food

As livestock, the bison provides a high yield of marketable meat, as well as a nutritious final product in the oven or on the stove. A major disadvantage in raising buffalo, however, is the high start-up cost: Prices of bison calves start at around $1,000, and because buffalo are classified as "exotic animals" by the U.S. Department of Agriculture, aspiring ranchers have less access than cattlemen to government assistance. One considerable advantage is that bison require less food, and far less water, than cattle. Although similar to other bovines in being ruminants capable of digesting other fodder, bison do not depend on succulent grasses. Instead, they prefer short, dry grass, which usually contains a higher percentage of protein. When grazing, bison will consume about 180 pounds less grass per month than cattle of comparable size.

The biggest advantage of the buffalo, however, is its high yield of nutritional meat. With lighter hides, heads, hooves, and tails than Hereford cattle, the buffalo provides a larger percentage of salable meat when dressed (Rorabacher 1970). In addition, when compared to domestic cattle, it is surprisingly disease free (although respiratory ailments, anthrax, and brucellosis appear as occasional illnesses), and as a result, the meat lacks most of the antibiotics and medications contained in commercial beef and is nonallergenic (National Buffalo Association 1990).

Unlike almost all the meat of other types of domesticated livestock, buffalo meat is low in fat (5 grams per half pound of raw bison, compared to more than 18 grams of fat in the same amount of beef). Clearly, in light of concerns for nutritional health, the bison has great potential as a healthful alternative to most other meats. In areas where butchered bison is readily available (primarily in, but not limited to, the American West), the meat is sold in cuts similar to those of beef: steaks, ribs, roasts, and ground meat. Although the per-pound cost of bison for consumers is often 50 percent greater than, or even double, that of beef, the lower ratio of fat means less shrinkage, and consequently, a pound of bison yields substantially more protein than an equal measure of beef or pork.

The nutritional argument notwithstanding, however, there are an assortment of economic and biological factors that will interact in any determination of whether the bison will again become a significant source of food. Currently, the species is raised on small- to medium-sized ranches in herds of 100 to 250 animals for large-scale production. But the buffalo would doubtless have to be fitted into the beef industry model.

Yet feeding, grazing, meat storage, and refrigeration are only a few of the practices within the cattle industry that would probably require modification to accommodate the buffalo. For example, bison are ill suited to feedlots – facilities used by cattlemen for the rapid increase in the size of their animals immediately preceding slaughter.The confinement created by such ranching tends both to increase fighting and to accelerate the spread of disease among bison. Buffalo, then, cannot be harvested with the same efficiency as cattle. Moreover, although proponents of bison exalt the animals' "natural" meat, free of the vitamins and antibiotics common in other foods, it seems possible, at least, that such additives in buffalo meat would be an eventual result of large-scale commercial production.

It is ironic that economic and cultural change, the same forces that nearly destroyed the bison during the nineteenth century, may hasten the ascendancy of the species in the future. For Native Americans, the buffalo was a sacred resource to be utilized according to human need. However, as the original inhabitants of North America were displaced by white settlers, the hunting of bison became an industry that rapidly diminished the animals' numbers.

At present, North Americans are involved in a cultural shift of sorts: Past understandings of what constitutes good nutrition are being rejected, and many people are reluctant to continue to consume the high-fat foods that have traditionally composed their diets. Low-fat red meat from the buffalo appears to be a viable replacement for much of the beef presently produced in America. Consequently, once again, harvesting the animals may offer vast financial rewards to humans. However, it is not difficult to envision large-scale bison ranching resulting in a noticeably different meat product from that presently provided by moderate-sized facilities, perhaps even in an unrecognizable buffalo.

II.G.2 Aquatic Animals

Pre-Christian Origins of Aquatic Husbandry

Primitive Fish Farming in China

Aquatic farming, like many other modern technologies, is credited to early Chinese societies well before 1000 B.C. In its rudest form, some systematic sowing and harvesting of fish in China have been inferred from marks on ancient "oracle bones" that have survived. Simple shapes of fish were perceived to predict favorable times in which to gather fish "seeds," particularly those of the common carp that abound in China's great rivers when the rainy seasons begin, and to sow them in convenient water bodies in floodplains nearer home.

More detailed records of fish husbandry are not found until early classic writings of the Chou Dynasty (1112–221 B.C.). It is not known, however, whether such husbandry was (1) in response to the symbolic cultural and social significance of fish in China, or (2) because of their importance in ornamental ponds built to beautify gardens of the rich, or (3) due to the simple expedient of having fresh food ready at hand each day. In probability, all three reasons are too closely linked to know with any conviction which came first. The common carp has long been a symbol of fortune in China and, therefore, a highly acceptable gift. Indeed, the offering of a live carp (or an image of the fish in jade or ivory rising out of the water to reach the gates of the dragon) recognized the importance of the recipient and bestowed great honor. It is not hard to imagine that both givers and receivers needed a place in which to keep fish alive, and ancient hand-painted scrolls often illustrate scenes from domestic life with tranquil exotic gardens and ornamental fishponds.

The earliest reference in Chinese literature to "aqua-husbandry" as a primitive technology is found in the writings of Fan Li in about 500 B.C. He wrote that culturing carp was one of five ways to make a good living in China, and he described techniques for constructing ponds and for breeding, feeding, and maintaining a healthy fish population. Based on Fan Li's guidelines, simple carp culture for food production flourished for the next thousand years until, quite fortuitously, an event occurred that revolutionized fish culture in China.

In about A.D. 618, during the Tang Dynasty, an emperor whose family name was Li came to the throne. As the name for common carp in Chinese sounded like "lee," the idea of culturing, killing, and eating "lee" was sacrilegious and, thus, banned. The crisis, however, compelled farmers to raise other fish and employ new husbandry practices. Soon four new species were cultured successfully, namely the "silver," "bighead," "mud," and "grass" carps. Furthermore, because of the very different nutritional niches that these fishes occupy in aquatic habitats, the four species could be cultured together in the same pond without competing for food, all of which significantly intensified unit production.

For the husbandry of these new species, farmers soon came to grasp the importance of using organic wastes to increase productivity, and fish culture, as a consequence, became more closely tied to animal and plant husbandry: Manure from pigs and poultry was deposited in fish ponds, and plants and vegetables were grown along their banks. Where ponds could be drained, the enriched sludge was excavated and used as fertilizer for crops. Yields increased dramatically, and polyculture of carp in these integrated farming systems became a key part of rural life in China. Today China annually produces more than 4 million tonnes of freshwater fish almost entirely through the polyculture of eight cyprinids and two or three other species. This figure nearly equals that of all aquatic farm production in the rest of the world.

The spread of fish culture throughout Asia is also credited to the Chinese and to their desire to give tribute, rather than to receive it or to trade. Powerful Chinese naval expeditions moved throughout every inhabited land bordering the China Sea and Indian Ocean for some 500 years before the Great Withdrawal of A.D. 1433, spreading word of the grandeur of each new dynasty, distributing treasures, and teaching skills. Because of their symbolism as valuable gifts, carp, together with simple lessons in fish husbandry, were probably a part of such largesse, especially because the fish are hardy travelers and tolerant of very poor conditions.

The Vivaria of Other Great Cultures

Simple fish husbandry was also practiced in most of the other great cultures. The Egyptians, for example, although not renowned fishermen, built vivaria as adjuncts to their temples and palaces. Their writings indicate that they understood the principles of migration and breeding of fish in the Nile, but there is no evidence of any attempted domestication. Although a staple in the commoners' diet, fish were eschewed by Egyptian kings and priests for symbolic reasons. Some fish were sacred, as they guided the boats that bore the dead to eternity, and others (probably muddy-tasting freshwater species from the waters of the delta) were regarded as unclean.

The Assyrians, on the other hand, including both Sumerians and Babylonians, were greatly addicted to fish and were skilled fishermen. They were known to keep large resources of fish in lakes created by the construction of irrigation dams on the Tigris and Euphrates, and they built vivaria for their temples and in most townships. Records from 422 B.C. describe fishponds belonging to rich merchants and civic prefects, operated for them by individuals under contract for one-half talent of silver and a daily supply of fish.

Vivaria in Sumerian temples can be traced back to 2500 B.C. Each had a keeper, who charged the public to fish these "piscinae" or stew-ponds. Further evidence indicates that piscinae became quite numerous among Assyrian commoners, although it is recorded that ponds built by "poor men" often drew poachers because their owners had no legal redress.

The neighboring Israelites, in spite of their liking for fish and their links with Egyptians and Assyrians, apparently never constructed vivaria. There is no record of such activity in all of their prolific writings until just before Christianity was born, when the Israelites were probably influenced by the practices of the Romans.

Wealthy Greeks and Romans feasted on all the common marine fish and shellfish of the Mediterranean for which, at times, they paid extraordinarily high prices. The Greeks appear to have been satisfied with what they could catch conveniently close at hand, and there is no record of their building vivaria. The Romans, on the other hand, transported seafoods, such as mullet, oysters, and cockles, great distances inland at significant cost and brought back species to Italy from all parts of their empire.

As a consequence, the Romans adopted the Egyptian and Assyrian vivarium, which became a necessary component of all the great estates. Many were constructed indoors, often adjacent to refectories to enable dinner guests to see and choose their own fish, and some were even built on board ships. Although costly to construct and maintain, vivaria proved extremely popular, and what had been intended to keep food fresh in a hot climate became a prestigious showpiece as well, complete with keeper.

The Roman vivaria remained the prerogative of the wealthy. However, the rich brackishwater lagoons and "valli" that surrounded the coast of Italy served the common people in similar fashion. They were especially good sources for mullet, sea bass, sea bream, and eels, which could be trapped inside them.

Whether the practice of keeping fish in vivaria was carried by the Romans throughout their empire is not known. The foundations of excavated Roman houses and fortifications outside Italy reveal pits that held water, but these may have been only for storing drinking water. Probably the defensive moats of larger walled fortifications and cities contained water enriched with human and kitchen wastes, which fell from the walls above and provided good nourishment for certain types of freshwater fish, such as carp. But, on the whole, freshwater fish were not popular with the Romans.

Subsistence Practices of the Middle Ages

Fish Ponds of Tribal Societies

Outside of China, early aquatic farming for food production developed mostly through tribal societies who fished for subsistence and survival. In most such societies, fishermen relied on a variety of fixed traps, in addition to spears and lines with hooks fashioned from bones for traditional fishing. These traps ranged from simple woven and baited baskets suspended in the water, to earthen ponds constructed along the shoreline, to complex labyrinths of fences made from bamboo and covered with reeds that enticed fish into ever-receding spaces from which there was no escape. Doubtless such fishermen also discovered that most fish could be held in captivity in these traps and kept fresh for several days or even longer if some feed was provided. From this discovery it was only a short step to locating places where seasonal resources of fry and fingerlings could be captured in large numbers, impounded in some way, and raised for future harvest.

As exemplified by surviving primitive societies, tribal fishermen have a good understanding of the natural behavior of their quarry and the influence of seasonal and lunar changes and diurnal conditions on their movements. Thus, the trapping and holding of brackishwater fish, such as milkfish and mullet, believed to have started in Indonesia in the fifteenth century, was possible because it was understood that every year, millions of young fish would migrate inshore in early spring to mangroves rich in food. Here they were caught and transferred to shallow ponds crudely fashioned around the estuaries and kept filled with water.

Records show that brackishwater ponds were also an important part of Polynesian societies throughout the Pacific islands at about the same time and that pond practices were quite sophisticated. The earliest recorded date for the construction of fishponds in the Hawaiian Islands is in the middle of the fifteenth century. These tidal ponds, shaped by stone and coral walls on top of reefs, were built around or adjacent to streams so that the fresh water attracted and fed young fish.

Most of the ponds had a system of one-way gates, through which water could be exchanged and small fish moved in (to feed and grow), and by which large fish were trapped at the full moon (as they tried to move out to spawn at sea). Other ponds had no gates, but water was exchanged through the permeable coral walls.

Ancient Polynesian walled fishponds were owned by chiefs and were symbols of importance, built by people drafted for the purpose. By the beginning of the nineteenth century, more than 200 ponds were recorded around the islands of Hawaii. Many were large, with walls from 2,000 to 5,000 feet in length. Each pond had keepers who fed the fish with taro and other vegetation and caught them for the chiefs and their immediate retinue.

Because the common people had no rights to fish in these ponds, they made their own "underwater ponds" in the sea by connecting coral heads with walls, thus trapping fish as the tide receded. They were also allowed to operate fishponds inland in wet areas where taro was grown. The Polynesians were a marine-dependent society, and the large variety of fish abundant around their islands in the Pacific was the principal animal protein in the everyday diet. They were not dependent on fish production in their ponds for subsistence, but used them as a source of food in bad weather and as a ready supply for feasts.

Coastal fishponds were probably built in Asia well before the fifteenth century. The islands of the Hawaiian chain and Tahiti, which lie almost at the limit of Polynesian extension in the Pacific, are known to have been well populated by A.D. 1000 by means of migrations of people descended from the Melanesians of the far western Pacific. Therefore, it is probable that the skills of catching fish and keeping them in captivity were carried from China, through Southeast Asia, into the Melanesian islands, and then on out into the Pacific between the tenth and thirteenth centuries.

The Stew-Ponds of Europe

At the same time that it was extending throughout Asia and the Pacific, the knowledge of fish husbandry also traveled westward into Europe. In the Middle Ages, so-called stew-ponds became increasingly common on large estates. They were a convenient source of fresh protein to alternate with a diet of dried, salted, and pickled foods, and particularly important in times of war and siege.

In similar fashion, coastal beds of common shellfish, such as oysters and mussels, were maintained as reserves of fresh protein. These were protected and conserved by selective harvesting, but there is no evidence of any effort at true domestication.

As with earlier cultures, stew-ponds in western and eastern Europe were associated with priests and nobles. They are evident in the earliest records of many of the religious orders founded in the twelfth century. For example, the original charter of the Kladruby Monastery in Bohemia, dated 1115, describes a fish production pond, and many others are still visible in the ruins of the earliest monasteries.

Stew-ponds were also a common feature of the great estates – most of which were constructed beside fish-laden rivers. In England, the eleventh-century Domesday Book records ownership of "vivariae piscinae" by many large estates and also by smaller landholdings of ordinary country squires and wealthy middle-class merchants. In his prologue to the *Canterbury Tales,* written in 1387–92, Geoffrey Chaucer describes the epicurean Franklin, a "householdere" who "hadde many a breem [bream] and many a luce [pike] in stuwe."

In contrast to such largesse, the feudal system of the European Middle Ages denied landownership and, therefore, stew-ponds, to peasants. All rivers and streams belonged to kings and their barons, who controlled large territories, as well as the game and fish in them. Poaching in rivers as well as in stew-ponds was generally punished by death, and thus fresh fish was a rare commodity for the lower classes and rural peasants. When ancient laws regarding fish and fishing were finally changed (some such statutes remained until the end of the nineteenth century, as in Hungary), the establishment of family stew-ponds was one of the first products of such change.

Toward the end of the Middle Ages, the fish typical of stew-ponds in Europe were native freshwater species, such as bream, perch, carp, barbel, roach, dace, and minnows. Predatory fish, such as pike, tench, eel, and lamprey, were excluded if possible. With the exception of such migratory fish as salmon, those which remained through the winter would probably reproduce in the following spring if the pond was suitable and large enough – thus replenishing the stocks naturally. From this point it was but one more step to the discovery that separate ponds were useful for storing during winter, breeding in spring, and fattening in summer and autumn.

By the middle of the fifteenth century, the construction and management of fishponds was a well-established and integral (but small) part of artisanal life, particularly in eastern Europe. Many towns in Bohemia and Moravia competed with the monasteries and nobles in pond construction, some of which were extraordinarily large. About 20,000 ponds were registered in the archives of this region in the sixteenth century, covering more than 75,000 hectares.

The technology, particularly of carp culture, became quite advanced. Many ponds were managed intensively, with production increasing steadily to between 75 and 100 kilograms per hectare. Techniques were described in books of the period. In 1547 Janus Dubravius, the Bishop of Olomouc, produced his treatise, *Jani Dubravil de Piscinis et Piscium qui in Illis Aluntur Libri Quinquae,* later translated into many languages. It included chapters on economics and diseases and described the work of fish-culture wardens and their organizational guild. Other works by John Taverner (1600) and Gervais Markham (1613) discuss in detail the practices of fish raising, including pond construction, pond fertility, management, feeding, and the best fish to raise. These authors also made observations on the breeding behavior of adults and the care of fry and fingerlings.

The beginning of the Renaissance coincided with the first peak in the early domestication of aquatic animals worldwide. By this time, thanks to the skills of the Chinese, most countries of Asia practiced breeding and propagation of several freshwater fish in captivity and had developed relatively sophisticated production practices. Island communities of the South China Sea and the Pacific Ocean substituted marine fish that could not be bred but that could be gathered in large numbers to stock coastal ponds.

The Europeans had also steadily advanced in management practices for the husbanding of freshwater fish in captivity and relied on natural breeding to supplement their stocks. But the next two hundred years saw stagnation and even decline in aquatic animal domestication. China closed its doors on the world, whereas in Europe there was growing competition for water and for land (Radcliffe 1926;Toussaint-Samat 1992).

The Impact of the Industrial Revolution

The Demise of Inland Fisheries in Europe

At the dawn of the nineteenth century in Europe, the demand for fish and shellfish was met by the traditional and dominant inland fisheries and by some modest estuarine and coastal fisheries. This adequately supplied a population widely dispersed among rural villages or grouped in small agricultural towns and a few principal cities that were trading centers.

Nineteenth-century industrialization, however, which mechanized fishing fleets and opened up large urban markets for iced fresh fish through networks of railways, expanded modest coastal fishing into marine fishery industries at unprecedented speed. Unfortunately, the same industrialization decimated the traditional freshwater fisheries.

The freshwater fisheries of coastal Europe were based mostly on migratory species, predominantly Atlantic salmon, sea trout, and, to a lesser extent, the eel. However, the Industrial Revolution produced an insatiable demand for fresh water, and almost every river and stream was affected. They were dammed to make reservoirs and drained by growing towns, polluted by manufacturing industries built along their banks, and diverted to fill new canals, and their catchments were stripped bare by deforestation.

Furthermore, those fish running the migratory gauntlet were poached with every conceivable trapping device, including explosives and poisons. Although protective fishery laws had been in existence since the fourteenth century, they were largely ignored and not enforced. Finally, adding to this relentless assault on the migratory fisheries, many large lakes and ponds of central Europe – operated since the Middle Ages as inland fisheries for the common carp and other cyprinids – were drained to meet the need for more agricultural land.

In a mere hundred years, and before parliamentarians finally recognized the problem and took action, the Industrial Revolution had polluted all the large and most productive estuaries and rivers in Europe or made them otherwise impassable to fish. Most remain so today. It is fortunate that toward the end of the nineteenth century, public and private organizations were formed to safeguard and monitor inland fisheries and to undertake scientific research to bring about their recovery.

Artificial propagation to replenish falling stocks was one small part of their regulatory response for the management of all fisheries, but this was not the only reason for such development. Another was a growing scientific curiosity in natural history inspired by the voyages of Charles Darwin and Alfred Wallace and also the new field of genetics discovered by the monk, Gregor Mendel.

Fish Propagation and the Hatchery Movement

The breeding of common brown trout was first described by William Yarrell in his *History of the British Fishes,* published in 1841. The book was based on a translation of an original paper written in 1763 by a German naturalist, which had gone largely ignored. The technique was rediscovered in 1844 by two French fishermen, Anton Géhin and Joseph Remy, who not only told of successful fertilization of trout eggs but also of stocking the progeny in the Moselotte River and raising them in a pond. Subsequently, Gottlieb Boccius wrote *A Treatise on the Production and Management of Fish in Freshwater by Artificial Spawning, Breeding, and Rearing,* with the sinister subtitle, *Shewing also the Cause of the Depletion of All Rivers and Streams* (1848).

Other works rapidly followed, notably those of Professor M. Coste in France. Following the publication of his *Instructions Pratiques sur la Pisciculture,* he was invited to lecture on fishery problems throughout Europe. These travels culminated in his publication (1861) of the *Voyage d'Exploration sur le Littoral de la France et de l'Italie,* which described the artificial culture of both fish and oysters. In addition to being generally credited with saving the oyster fisheries of France, he was also responsible for founding the first fish hatchery, built at Huningue, near Basle, in 1852. From this hatchery, eggs were distributed throughout France and other European countries to many rivers before these countries built their own hatcheries.

Coincidentally, there were similar developments in the New World. In Ohio, Theodatus Garlick artificially bred brook trout from eggs that he brought back from Canada in 1853. Within the next 20 years, eggs of a number of common freshwater fish had been reared under primitive laboratory conditions and the young fry put into their natural waters before they would have died in captivity.

The majority of these species were common salmonids, such as brook trout, brown trout, rainbow trout, Arctic char, and members of the large group of Pacific salmon, as well as other popular nonsalmonids, like the shad. All these fish had common attributes. They were readily caught, their eggs were large and visible, and the emergent fry had a plentiful supply of food from the yolk, which avoided the problem of feeding before release.

Many of these early efforts were supported by landowners and gentlemen sportfishermen. With independent financial resources to build hatcheries, these dilettantes started many small programs. In 1868 the first hatchery for Atlantic salmon was built by Samual Wilmot on his own property adjacent to Lake Ontario, Canada. There he released parr into the creek, and in 1867, with money from the government, the Wilmot's Creek hatchery was expanded to produce, in time, about 1 million salmon each year. This was, in all probability, the first actual ranching of salmon raised and released from a hatchery.

Soon fish hatcheries were common throughout North America. The first Pacific salmon hatcheries were built on the McCloud River in northern California in 1872 and in the Columbia Basin on the Clackamas River in Oregon in 1877. By the end of the century, the state of Washington alone had 14 salmon hatcheries, producing more than 58 million fry.

Experiments seemed to know no bounds. Rainbow and brook trout were transplanted from the western United States to trout hatcheries in Europe; and in the mid-1860s fast clippers carried the first shipments of trout and salmon eggs to India, New Zealand, and the new Chitose hatchery in Japan. In the early 1870s, Denmark built a hatchery to raise rainbow trout recently introduced from the United States. However, instead of releasing the young fish to enhance local rivers as others were doing, the Danes continued to keep the fish in captivity. This became the first land-based salmonid farming enterprise and led to Danish domination of the trout industry for the next hundred years.

The great 1883 International Fishery Exhibition in London, which devoted considerable space and attention to the new technology of fish (and shellfish) culture for enhancing declining fisheries, proved to be the springboard for worldwide interest. Many countries, including China, provided wonderfully illustrative and mechanical exhibits, and scientists and public figures alike returned home resolved to implement newly gained ideas.

One such man was Lachlan Maclean, whose successful introduction and acclimatization of trout in South Africa (although achieved only by persistence and endurance) led to other such attempts in all European colonies and overseas territories wherever there were cool mountain streams. Thus, trout were stocked in suitable upland areas throughout East Africa, from South Africa north to Kenya, and transferred to Australia, Tasmania, and New Zealand. They were also shipped to the Andean countries of South America.

In the end, however, most of these essentially private enterprises were not successful. There was still a great lack of understanding about the behavior, reproductive biology, nutrition, and diseases of salmonids; hatcheries were not simple facilities to construct and operate, and fish culture was not cheap. But, fortunately, by this time many governments had established fisheries policies, and fish propagation was an active part of fisheries management. Consequently, by the end of the century almost all private hatcheries had become publicly operated.

The First Propagation of Marine Species

In 1867, following an extensive survey of the oyster fisheries of Europe, the British naturalist Frank Buckland broadened his interest in freshwater perch to include oyster culture. His goal was not directly to produce food, but rather to use artificial culture of aquatic animals to enhance natural fisheries.

Several influential scientists, however, including Thomas Huxley, stated that farming the sea was useless as the sea fisheries were inexhaustible. But, as noted by one of Buckland's proponents, Ernest Holt, this was an overgeneralization. He believed that although the great fisheries for cod and herring and pilchard were beyond the influence of humans (either by overfishing or restocking), there were several smaller but important fisheries in the North Sea, such as that for flatfish, which could be enhanced. Holt showed with statistics the effects of overfishing on the plaice fishery, and in 1897 he proposed four solutions for management – one of which was artificial propagation.

The activity in fish propagation and fisheries research, triggered by the Great Exhibition of 1883, made it clear that temporary facilities for marine culture in fish-processing plants and water mills were totally inadequate. Propagation needed hatcheries, and fishery science needed institutes and laboratories. Consequently, one final contribution of the century to fish culture was the founding of many of today's most famous marine research stations, along with several professional societies.

France was one of the first countries to construct facilities directly in support of marine fish and shellfish culture. Following the successful efforts of Coste in salvaging the French oyster fisheries, coastal centers were built at Concarneau in 1859 and at Arcachon in 1863. In addition, a laboratory was built at Monaco, and in Naples, Italy, the famous Stazione Zooligica was constructed.

In the United States, Spencer Baird was appointed the first Commissioner of Fish and Fisheries in 1871, and fish culture became an official responsibility of the government. The first facility for work on the Atlantic cod was built in Gloucester, Massachusetts, and propagation was successfully achieved in 1878 using the technique developed by the Norwegian G. O. Sars in 1866. The successful propagation and release of other gadoids, and even herring, quickly followed, despite what would be described today as relatively poor conditions. Government funds were provided in 1885 to construct the first commercial marine fish hatchery at Woods Hole, where there was also a small group of scientists carrying out research on marine fish. The results were so good that the government built a second hatchery at Gloucester Harbor.

In the United Kingdom, the Marine Biological Association of England was founded in 1884 by the Royal Society of London, under the presidency of Thomas Huxley. In its first resolution, the society emphasized the necessity of establishing one or more laboratories on the coast of Britain where research could be conducted that would lead to the improvement of zoological and botanical science, and to an increase in knowledge about the resources of the sea.

The first laboratory was opened at Plymouth in 1888 with three professional staff, followed by one in Lowestoft. The new Lancashire and Western Fisheries Committee built laboratories at Port Erin on the Isle of Man and another at Piel Island near Barrow-in-Furness, both under the direction of Professor William Herdman from Liverpool. He began substantial propagation and release work not only with the flatfishes (plaice and flounder) but also with Atlantic cod and haddock.

The first marine hatchery in Scotland was built in 1894 at Dunbar, near Edinburgh, under the direction of James Cossor Ewart. The purpose of the Dunbar hatchery was to raise and release young marine fish to add directly to the fish supply. It began with the propagation of plaice to enhance the coastal fisheries. Ewart was helped by Harald Dannevig who, with his father Gunnar, had built the first commercial hatchery for Atlantic cod in Norway in 1882. Other facilities were built at St. Andrews and Aberdeen, and the newly formed Scottish Marine Biological Association constructed its new laboratory at Millport in the Firth of Clyde.

The fishery science carried out at all these coastal laboratories was well structured, largely because in 1899 and 1901, a gathering of illustrious scientists at Christiana, Sweden, established common methodologies for gathering information and identified specific cooperative programs for biological and hydrographic studies. The "Christiana Programme," as it became known, coordinated some of the first fisheries and marine research over an extensive area of the North Sea, the Northern Atlantic Ocean, and the Baltic Sea.

Early marine laboratories and fish hatcheries had large outdoor ponds or tidal basins for holding broodstock, modeled after those designed by the Dannevigs for cod. But it was soon clear that better control was required for incubation and for subsequent larval rearing, and in the United States initially, the "Chester jar" and then the larger "MacDonald tidal egg-hatching box" were adopted.

In Europe, the "rocking incubator" developed in Norway was more popular. But common to all hatcheries were cumbersome mechanical water systems, all soon blocked by biofouling. Worse still, their metal pipes and valves rapidly corroded, filling the tanks with rust and dangerous toxic ions. New hatcheries were built with dual pipe systems, settling tanks, and sand filters, substantially increasing their costs. Nevertheless, many such problems were not resolved for almost another half century with the advent of inert plastic materials.

Because they were concerned only with the early life stages of aquatic animals, marine hatcheries all over the world had no difficulty in realizing some large production numbers. Three hatcheries in Massachusetts, for example, accounted annually for 3,000 million fry of pollack and flounder. In Australia, under the expert eye of Harald Dannevig (who emigrated there in 1902), the hatchery at Gunnamatta Bay in New South Wales was producing 150 million fry annually; and this was emulated by the new Dunedin hatchery in New Zealand.

Unfortunately, however, despite these massive numbers, the releases had little beneficial effect on the local fisheries. This was because, unlike the eggs of freshwater fish, those of marine species are small and have little in the way of yolk reserves. The eggs hatch out quickly and the emergent larvae must feed almost immediately or die. Culturists knew little of the first feeding requirements of the emergent larvae and consequently, as there was no effort to provide the fry with small live-food organisms, their survival was almost immediately jeopardized.

The First Half of the Twentieth Century

The Influence of the Colonial Empires

In spite of the rapid progress in aquatic husbandry during the final 20 years of the nineteenth century, the first 50 years of the twentieth century were spent marking time. This was a period when efforts, intentional or not, went into building infrastructure, rather than converting scientific and technical advances into commercial production. But it was also a period when colonial and territorial influences in Asia and Africa were at their peak, and these had several useful benefits for the spread of existing technology around the world.

The new field of fisheries, and especially the idea of introducing and stocking familiar sports fish, was of considerable interest to many colonial administrators, who established fisheries departments, appointed fisheries officers, and built research centers and government farms. In many cases, an administrative organization was repeated at the state level. In India, for example, the first government fish farm was established in 1911 in the state of Sunkesula by the Fisheries Department of Madras, and this was followed by stations in Bengal, Punjab, Uttar Pradesh, Baroda, Mysore, and Hyderabad.

In India, not all of this activity was directed at the culture of sports fish, however. Eating meat was forbidden to large parts of the population by religious law, and meat was a scarce and costly commodity for many others. Hence, the possibility of increasing traditional fish production through culture was an attractive option. The gourami (first brought to India in 1841), Chinese carps, and some tilapia species were either introduced or reintroduced and became the basis of considerable practical research.

With its cultural background and strong tradition of fish and shellfish consumption, Japan was one of the earliest countries to establish regional research stations in support of national fisheries. The first was at Aichi, built in 1897, followed in the next 12 years by Shizuoka, Fukuoa, and Kuwana. This program was assisted by one of the earliest pieces of legislation in support of aquaculture, namely the Reclamation Subsidy Act, which designated large areas of land for reclamation for fish culture ponds. New ownership of these lands encouraged the capital investment required to develop them for eel culture, which increased the demand for wild elvers. The situation was further enlivened by a sudden recession in agriculture, which galvanized many farmers to convert their lands to fishponds.

The Japanese occupation of part of China, including Formosa (Taiwan), which was ceded by China in 1895, was accompanied by the transfer of Japanese interest in aquatic culture to the island. The Governor-General of Formosa established and organized an infrastructure for fisheries, much as it existed in Japan, and constructed a fish culture station at Tainan in 1910 under the distinguished scientist Takeo Aoki. Building first on the culture of milkfish (introduced centuries before by Dutch occupiers), the Japanese scientists worked on a variety of species. These included key marine species, such as the yellowtail, sea bream, and abalone, as well as freshwater eels and tilapia introduced from Indonesia. They built several other stations throughout the island, all of which were retroceded to the Republic of China in 1945.

In the colonial countries of Africa, particularly those belonging to Belgium and Great Britain, the priorities were for producing sports fish for recreational fishing and mosquito-eating fish for controlling malaria. The first recorded introductions of sports fish for culture in Africa (in particular, salmonids for cool mountain streams) were mostly confined to the rich agricultural countries with suitable upland areas. These stretched from Kenya down to South Africa and included Uganda, Nyasaland (Malawi), Rhodesia (Zimbabwe), and Swaziland. However, records also reveal the introduction of many other species, such as Chinese carps, and the liberal transfer of many native species, such as the cichlids.

In the north, as part of its continuing irrigation program in the Nile Delta, Egypt built the Barrage Farm in 1919 to receive introductions and produce seed for stocking its coastal lakes. The El Mex Farm was constructed in 1931 at the pumping station near Alexandria, and a number of marine species, such as Dover sole and shrimps, were introduced into inland high-saline waters, such as Lake Qarun.

Conservation and Compensation in the New World

Because of a lack of tangible benefits, North American interest (and investment) in the hatchery propagation of marine species was waning rapidly by the 1920s. But in the United States it was on the increase for freshwater species – especially Pacific salmonids – and, fortunately, the techniques of propagation were now highly reliable. It was fortunate because of the crisis that was beginning to develop in the salmon fisheries of the Pacific Northwest, and nowhere was the crisis more keenly felt than in the vast area of the Columbia River watershed.

The fisheries of the giant Columbia River had supported some 50,000 persons and yielded about 18 million pounds of fish each year. However, a number of factors combined to threaten the salmon resources of the Basin. Among these were the opening of the Pacific Northwest territories at the end of the century, the construction of hydroelectric dams, the diversion of water for irrigation, and poor logging and mining practices.

Fish hatcheries and fish ladders were constructed in the region to mitigate some of the losses, but it was not until the Federal Power Act of 1920 that fishways were required at all private power projects. The Fish and Wildlife Conservation Act of 1934 that followed was the most important legal authority for ensuring both protection and compensation for the salmon fisheries affected by federal water projects. Together, these two acts were responsible for more than 400 million U.S. dollars spent on fish passages and propagation hatcheries constructed in the Columbia Basin.

World War II

During the war, as the North Sea was closed, nearshore fishing was concentrated along the safe west coast in the British Isles. It was proposed that fish production could be supplemented by increasing productivity of some Scottish sea lochs with inorganic fertilizers and by increasing resources of fish through the transplantation of juveniles, particularly flatfish.

Led by Fabius Gross from the University of Edinburgh, a team of scientists began the fertilization of Loch Craiglin with sodium nitrate and commercial superphosphate fertilizers supplied by Imperial Chemical Industries Ltd., the largest national producer. The fertilizers increased productivity in the loch, but most of the nutrients were taken up by the phytoplankton and algae. Food organisms suitable for growing flatfish were also increased, but not with the consistency required to support large populations.

The economics of one of the first true attempts to farm the sea were never tested, however. As fishing vessels began to return to the seas in 1944 and 1945, the group was disbanded, and with the early and untimely death of Gross in 1947, all further technical interest was lost.

Another event concerning aquatic husbandry during the war years occurred in Africa, which was a major resource of raw materials for the allies. Mining in South Africa, and in other countries such as Zambia and Zaire, was greatly expanded, and large pools of labor worked the mines, built railways, and manned ports to maintain the flow of copper and iron ores. This labor force had to be fed and, for a time, meat was secured by large hunting parties and by deliveries of beef from South Africa.

It was not long, however, before local herds of wild game had been depleted and, to make the situation more critical, the beef was being redirected toward armies and to the hungry of Europe. British and Belgian colonial administrators reacted to the crisis by ordering the construction of ponds to produce fish for the miners and their families. Many thousands of small fish ponds were dug and stocked with tilapia and other native species for food. The effort proved successful and, at the end of the war, the Conference Piscicole Anglo-Belge was organized for further postwar development of aquaculture for food production.

A third event involving aquaculture had even more far-reaching importance. Fish farming in what would become Israel had been developed in 1934 by immigrants from central Europe, who brought with them experience in the culture of their traditional (and prized) fish, the common carp. The first kibbutz fish farm was established in 1938 at Nir David, and by the end of the war there were 30 productive kibbutz farms with a water surface of 800 hectares.

Initially, traditional methods were used on the farms, but as land and water became scarcer, new systems and practices were developed that were unique and highly productive for arid lands. In time, these would make Israel self-sufficient in fish production and even an exporter. In addition, the program made the country one of the most progressive in the field of fish culture.

The Birth of Modern Aquaculture

The Postwar Years

The wartime interest in fish farming for food production dimmed with the end of the war. Without extensive harvesting for many years, coastal and oceanic fisheries were ripe for such an effort, and world harvests increased steadily as old fleets of traditional fishery nations were modernized and expanded. In 1950, a world harvest equaling that of 1938 (about 20.5 million tonnes) was realized and this was soon doubled.

The early postwar years, however, were years in which many developing countries were newly independent with swelling populations, and "food self-sufficiency" and "animal protein" became prominent problems. European governments continued to contribute significantly to increasing food resources through production schemes and direct technical assistance. This had a valuable impact on the further development of fish and shellfish farming. Science was taken out of the laboratory and applied in the field.

The pioneers in this effort were trained in basic biological sciences and devoted the greater part of their lives to working overseas on almost every aspect of improving aquatic animal production. C. Fred Hickling, for example, like many of his colleagues from the British Museum, first worked on fisheries in East Africa. He studied the genetics of tilapias and produced the first all-male populations. Later he continued his work at the fish culture station at Malacca in Malaysia, which he expanded with its Latin square of research ponds, and where he contributed to advances in soil and water chemistry.

Similarly, Antoon De Bont and Marcel Huet, from Belgium, spent much of their lives in Central Africa and Indonesia, working on the breeding of tilapias, carps, and general limnology, while Jacques Bard, of France, worked in West Africa and later South America on tilapias and many indigenous species. Other such individuals included W. Schaperclaus from Germany and Elek Woynarovich from Hungary.

In the 1950s, many of these pioneers helped the fish culture staff of the Food and Agriculture Organization of the United Nations (FAO) to spread tilapia species throughout Asia and the Pacific region in an attempt to provide easily produced and readily available protein to the rural poor. Unfortunately, the project was to have long-lasting repercussions, as the fish rapidly replaced indigenous fauna and became pests wherever they were introduced.

After World War II, the pressing priority for food in Japan meant that all forms of agriculture received high priority during the reconstruction, and the old technical infrastructure was rapidly replaced, with emphasis on practical production.

Similarly in Taiwan, following independence in 1949, the old Japanese research stations were used to develop fish and shellfish culture under the Joint Commission on Rural Reconstruction, funded by the Rockefeller Foundation. Under the direction of T. P. Chen, fish culture in Taiwan became an important economic industry, principally for the efficient farming of milkfish and the fattening of eels for the Japanese market. There were also successful research developments, particularly the control of breeding and propagation of silver carp, grass carp, and grey mullet and, for the first time, species of marine shrimp.

In the United Kingdom throughout the late 1950s, the government supported two research projects as part of its general program on marine biological research. One, under James Shelbourne at Lowestoft, was concerned with the breeding and propagation of marine flatfish, whereas the other, under Duncan Waugh at Conway, focused on the propagation of oysters.

In 1961 the British White Fish Authority, a quasi-government organization operated by the fishing industry, instigated projects to carry promising research results from these projects through to commercial implementation. The authority constructed two experimental hatcheries. One, for marine flatfish, was located at Port Erin on the Isle of Man, while the other, for oysters, was situated at Conway. The successful operation of and yields from these hatcheries enabled follow-up efforts to be made at field stations in an attempt to accelerate growth rates. One was constructed in Scotland for the production of flatfish in an enclosed loch at Ardtoe. Another was located at Hunterston in Ayrshire, in the heated effluent from a nuclear electrical generating station.

Shelbourne's successful propagation of marine flatfish in England was possible because of an important earlier discovery made by Gustav Rollefson in 1939. Rollefson had found that the nauplius of the brine shrimp was a useful live-food and small enough for feeding marine fish larvae. Moreover, the eggs of brine shrimp were at times encysted, and they could be stored conveniently for subsequent use.

After the war, the natural production of cysts was first exploited at the Great Salt Lake in Utah for growing tropical fish for the aquarium trade. This was rapidly followed by more controlled production in the solar saltworks of San Francisco Bay. The availability of large and reliable quantities of instant live-food opened the way for marine fish and shellfish production on a hatchery scale, but this time with the potential to produce viable fry instead of fragile, starving larvae.

Uncontrolled Expansion of the 1970s

Throughout the 1960s, work by the White Fish Authority on marine flatfish in England, the growing production of yellowtail in Japan, and the successful farming of eels in Taiwan captured the interest of governments and scientists alike all over the world. The concept of farming the sea, an idea that had lain essentially dormant for more than 50 years, was suddenly reborn, and it was also an idea that reinjected new life into the passive efforts of farming freshwater species.

The 1970s witnessed an explosion of effort by marine biologists the world over. In Norway and England, attention was focused on the production of Atlantic salmon and rainbow trout. In the United States, scientists reinvigorated their work on Pacific salmon and the farming of catfish. Israel, in its continuing search for food self-sufficiency, stepped up its concentration on carp and tilapia production through integrated farming. Hungary produced and bred individual strains of carp and adopted Chinese methods for integrated farming with ducks.

In Japan and Taiwan, work intensified on the production of marine shrimps, followed by efforts in the United States, Panama, Ecuador, Thailand, the Philippines, Indonesia, and England. The Philippines and Indonesia improved their milkfish production. Thailand and the United States pioneered research and development of freshwater prawns. Japan expanded its efforts on abalone, sea bream, mackerels, and edible marine algae. Taiwan improved production of milkfish and bred mullet for the first time. Spain and the Netherlands produced prodigious quantities of mollusks, while France worked on sea bass, flatfish, and oysters, and Italy on sea bass and sea bream. In Europe, Denmark, England, and France revitalized their flagging trout industries, and Germany its eel industry.

Such a decade of intensive effort was assisted in no small way by complementary technologies. Plastics and fiberglass revolutionized hatcheries. Traditional cast-iron and glass piping and large concrete tanks, characteristic of the late nineteenth- and early twentieth-century hatcheries, were replaced by light and easily assembled plastic and fiberglass materials, which were inert and noncorrosive. Floating cages and rafts proved effective substitutes for costly excavated ponds and replaced the need to purchase expensive flat land. And, finally, modern scientific equipment enabled water conditions to be instantly monitored, bypassing lengthy laboratory analyses.

The domestication of aquatic animals was again viewed as a new and promising field of modern agriculture. Governments poured in development funds on promises of a technology to provide cheap protein for rural populations and profits for investors. Professional societies were formed, and the new field was now called "aquaculture," which, unfortunately, would experience still another dip in its progress curve.

The Realities of the 1980s

The optimistic view of the potential of aquaculture generated in the 1970s received a serious setback in the 1980s because when technical achievements in the laboratories were expanded to commercial endeavors, they were not profitable.

The logistics of manufacturing and delivering increasingly large quantities of artificial feed had not been adequately estimated, and such feed often proved to be nutritionally deficient. Thus, large losses of stock were encountered through poor nutrition, which exposed the animals to a variety of new diseases for which there was no treatment.

In addition, there were shortages of skilled labor, and many farms were victims of unforeseen disasters, running the gamut from storms and floods to toxic algal blooms, water pollution, and a general failure of equipment. Consequently, the sporadic quantity and quality of many farmed products were not competitive with those of natural products, and many investments were lost.

The 1980s, therefore, became a period of intensive research. In most cases it amounted to backtracking on matters of nutrition, pathology, and engineering. But research also advanced in new areas, such as induced breeding to improve egg quality and genetics. Work on many species was stopped, and efforts were focused on those species that could be produced reliably and in the quantities to make investments profitable.

Fish and Shellfish as Food

Large resources of protein in the flesh of fish and shellfish contain many readily available amino acids, such as lysine, methionine, and tryptophan, in quantities comparable with those in eggs, meat, and milk. Indeed, with their unsaturated fats, vitamins, minerals, and trace elements, fish and shellfish constitute a near-perfect food for the human body.

Obviously, however, quantitative differences in nutritional composition occur among the many large groups of species, and also within groups at different times of the year. In general, freshwater and brackishwater species contain about 14 to 25 percent protein, whereas marine species contain 9 to 26 percent.

Freshwater species have a low percentage of fat (less than 1 percent), whereas in some marine fish it may be as high as 20 percent. Compared with animal fat, fish oils contain more polyunsaturated fats and, therefore, can be beneficial in reducing the buildup of cholesterol in blood. In addition, fish and shellfish are good sources of calcium and phosphorus, especially when small fish and crustaceans are consumed whole. They also contain iron and traces of copper, as well as B-complex vitamins.

Preservation of Fish

Fish and shellfish offered early cultures a rich source of animal protein. But both were (and are) extremely perishable food commodities, subject to the activity of microorganisms (such as bacteria, molds, and yeasts) and internal chemical deterioration (such as rancidity from breakdown of oils and fats and enzymatic actions), as well as targets of insects and scavengers in storage. Preventive measures to slow down these many processes of deterioration were, therefore, required.

The traditional preservation methods of indigenous cultures around the world today are probably indicative of much trial and error that went on in primitive societies as they perfected their processes and built experience in storing food. Although drying, smoking, salting, boiling, and fermenting have been the five basic traditional methods of preservation or processing, there are many, often subtle, differences in method among and even within cultures. These are due to different preferences for taste, texture, smell, color of the flesh, and social custom. They are also due to the environment of the consumers, the habitation in which they live and store food, and the availability of materials for processing, such as the fish and shellfish themselves, sources of fuel for the fire, and the availability and composition of salt.

Early fishermen must also have learned the hard way that some species, or their body organs, were highly toxic and often lethal, and that such dangers could occur at different times of the year. For example, several mollusks can cause paralytic shellfish poisoning if harvested and consumed during incidences of intensive algal blooms in hot weather, and some individuals within common reef-fish species of the Pacific Ocean may induce ciguatera poisoning. Parts of the fish can also be highly toxic. The puffer fish, for example, which is popular in Japan, must have its poisonous gallbladder carefully removed by licensed handlers before it can be sold.

Food and Fish and Shellfish

The texture, taste, and color of fish and shellfish can be affected by their diet. Farmed fish, particularly those in accelerating temperature regimes, can be fatty. Excess fat, however, can be removed by greatly reducing the diet before harvest, and by increasing water circulation to increase energy utilization.

The direct absorption of geosmin from the water can affect the taste of the flesh. Geosmin is produced by some species of actinomycetes and cyanobacteria, which may bloom under certain chemical and physical conditions. They can produce the earthy-muddy flavors that are common in catfish and other freshwater pond fish and are now reported in some marine shrimps. But such flavors can be avoided if stocks are maintained in high-quality geosmin-free water conditions before harvesting. The color of the flesh is readily changed by additives in the diet. Salmonids, for example, are often fed carotenoid pigments prior to harvest to redden the flesh for increased marketing appeal.

The majority of captive aquatic animals are almost entirely dependent on artificially prepared feeds, although they also consume any natural foods that might be available in their enclosures. Artificial diets are invariably high in animal protein (15 to 40 percent, depending on the age and specific needs of the population), complemented by cereal proteins and carbohydrates, oils, and additives of minerals and vitamins.

In recent years the trend has been to formulate diets for fish containing only oils of polyunsaturated fats, and to include chemical attractants and growth promoters. Fish nutrition remains a primary area of research at present because of its direct influence on the quality of the finished product and because feed is the largest operational cost of farming.

The State of Aquaculture in the Present Day

Aquaculture Products on Today's Markets

The general global prosperity of the 1980s increased market demand for a variety of fish and fisheries products, which made the culture of several new species economically feasible. In addition, such demand stimulated production of those species traditionally associated with farming, such as trout, Chinese and Indian carp, and oysters and mussels.

Investments have also continued in the enterprises of raising aquatic animals for recreational use (sport fishing), for medicines and medical research, for biological assay, and for their many valuable by-products. Moreover, many species are cultured successfully for the ornamental fish trade, and in the last 10 years, some new and unusual species have been cultured.

According to the FAO, there are some 150 individual species or species groups under some form of domestic culture for human consumption worldwide, together with 60 more that are identified only by genera and family names. There are about 90 known species of fish currently farmed, 23 species of crustaceans, 35 species of mollusks, 4 species of algae, and miscellaneous aquatic animals (such as frogs, turtles, sea squirts, pearl oysters, and sponges). Of these, some 34 species may be considered the most important, as they are farmed over a wide geographic area, and their individual total production is more than 20,000 tonnes annually.

In Asia, and to a much lesser extent in Eastern Europe, freshwater fishes are the most popular farmed commodities among consumers. The most important are those that have traditional value and have been in great demand for centuries, particularly silver carp, bighead carp, and common carp.

In western Asia, the indigenous Indian carps remain traditional and important. About 7 million tonnes of Chinese and Indian carps are raised annually. They are relatively cheap because they are easily farmed and require few costly inputs. They are usually sold fresh and uncleaned, or "in the round," and many buyers prefer them still alive. The milkfish remains an important staple fish on traditional markets in the Philippines and Indonesia, but production has decreased as coastal ponds have been converted for raising high-value marine shrimp. Because of the bony nature of milkfish, the flesh is removed and reprocessed, but in recent years there has been an increase in the popularity of small kippered "boneless" fish.

In Africa, and to a lesser extent parts of Asia and Latin America, the tilapias are a cheap and widely available farmed commodity, as they are easily raised by small-scale rural farmers in rain-fed ponds. The Nile tilapia is the most popular species because of its larger size. A domestic hybrid, the red tilapia, is proving to be better for small-scale entrepreneurial farming in these regions and is capturing small but medium-value markets, even in the United States and Europe. Smaller species of tilapia raised in some African countries are used to concoct "relishes," to make leafy energy foods more palatable.

The diverse family of freshwater catfishes all have good medium value. Both local and institutional markets have been developed in the last decade of the twentieth century for these higher-priced species, particularly channel catfish in the United States and South America. Production of channel catfish is so reliable that there is a continuous availability of many product forms for consumers, including "fast foods."

In Europe and North America, the high-value salmonids, which have now been economically important for more than a century, continue to be in great demand. They are raised in both fresh and marine waters. The most popular product for the retail and restaurant trade is pan-size rainbow trout, but by the end of the twentieth century there was intense production of Atlantic salmon, even in Chile and New Zealand. Because of oversupply, prices have dropped considerably, and producers are seeking other markets with a variety of product forms, such as smoked salmon, in a variety of sizes.

The national markets of most developed countries have unmet demands for all farmed marine fish. Compared with freshwater fish, all marine species have medium-to-high value and most are economic to raise. The most popular species currently farmed are mullet, sea bass, bream, grouper, and many marine flatfishes, but progress in raising the volume remains slow.

The most remarkable achievement has been the massive growth in the production of marine shrimp to meet a continuously increasing demand for crustaceans as a whole by markets in Europe, Japan, and the United States. Some 17 of these high-value species are under culture, with the giant tiger prawn and fleshy prawn the most important. Farmed shrimp industries are now economically important to many Asian countries, particularly Indonesia, the Philippines, Thailand, and Taiwan, but they are also important to several countries of Central America and to Ecuador in South America.

Farmed shrimp have advantages in uniformity and, in addition to supplying a range of markets for size, they also satisfy markets for a variety of other product forms. Nonetheless, freshwater crustaceans have not benefited from the popularity of marine shrimps. Farmed species, such as the high-value giant river prawn, freshwater lobsters, and crayfish, are still confined to local markets and usually sold fresh.

Marine mollusks continue to have worldwide consumer appeal. They appear on the luxury markets of developed countries, yet are still farmed for subsistence in some of the poorest countries of Africa. Intensive farm production systems for both oysters and mussels have replaced traditional culture practices in European and Mediterranean countries and also in North America. In Asia, farmed production of the abalone, Japanese or Manila clam, and the blood cockle has been substantially increased by new and rapidly expanding culture fisheries.

Most developed countries have small luxury markets for a number of specialized aquatic groups. These include the meats of certain farmed reptiles, especially crocodilians and turtles (which also have valuable by-products, such as skins and shells), and of amphibians, particularly frogs, which are raised for their legs.

Summary

Aquaculture has proved to be a remarkable sector of economic growth in recent years. The 1992 value of cultured aquatic animals and plants for food was more than 32.5 billion U.S. dollars, almost triple the first estimate of 12 billion U.S. dollars in 1984. This is due mostly to rapid increases in farm production of aquatic animals, as well as rising prices. Since 1984, farm production of aquatic animals alone has increased by 90 percent. Individually, the production of crustaceans has increased by more than 250 percent, finfish by 105 percent, and mollusks by 55 percent.

Domesticated aquatic animal production contributes significantly to meeting an increasing worldwide food demand. Indeed, annual world demand for fishery products by the year 2000 had been predicted to be 110 to 120 million tonnes, of which about 30 percent is for industrial uses, such as oils and animal feeds. Farming of aquatic animals now contributes about 14 million tonnes annually, almost entirely for human consumption. Because most of these products are sold fresh or iced on local markets, such domestic production supplies about half the world's consumption of fresh fishery products.

In terms of quantity and distribution, the traditional species remain the most important. Like agriculture, aquaculture relies on a small number of "crops" for the greater part of its total production. Farming is still dominated by freshwater fish, particularly the cyprinids (which account for half the total aquatic animal production worldwide), followed by the salmonids and tilapines. The penaeids are the most important family of crustaceans, and mytilids and ostreids are the principal mollusks.

The narrow reliance on a few key crops has implications for the future of aquatic farming, particularly with the increasing involvement of bioengineering in the genetics of these species. On the one hand, there is a need to maintain genetic diversity for the viability of major food crops and the conservation of genetic resources. On the other hand, there is a pressing need for the domestication of farmed aquatic animals, similar to that of terrestrial animals and poultry. Most aquatic animals now farmed are still only one or two generations removed from natural (or wild) stocks.

Although there is great optimism for the future domestication of aquatic animals through genetic selection and other technical improvements, there are increasing pressures on the industry. In particular, these are the competition for suitable land and water with urban centers and agriculture activities; the impact of nutrient loading on the environment from intensive production; the spread of farm diseases to wild stocks; and the interbreeding of farmed stocks with wild stocks. Nonetheless, despite these growing issues, and a prolonged and shaky history stretching back over 2,000 years, the domestication of aquatic animals seems here to stay.

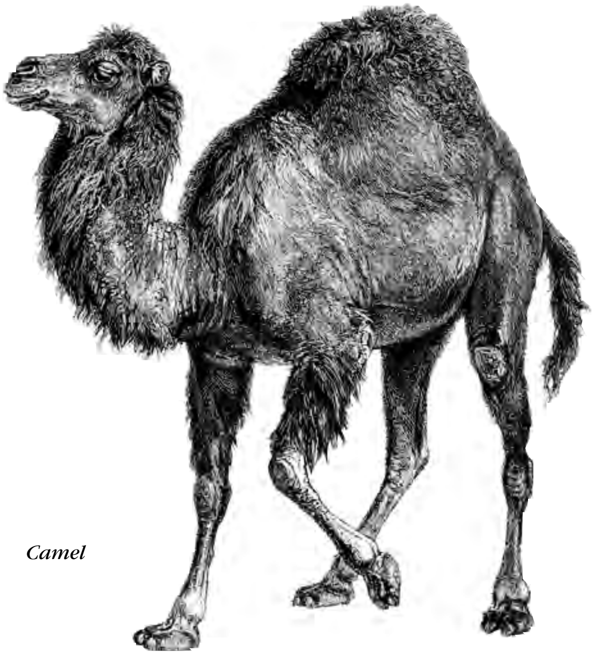
II.G.3 Camels

Camels are familiar to most of the English-speaking world only as beasts of burden, as Arab mounts on the silver screen, or as curiosities in the zoo. Camel meat and milk almost never find their way to the local grocer's shelves. In many parts of Africa and Asia, however, camel milk and meat are valuable sources of nutrition for many people. The following is a broad overview of the camel's current role as a food resource and a summary of evidence dealing with the early history of human reliance on camel products.



Camel

The people who keep camels for food are generally nomadic pastoralists, who rely primarily on livestock for their livelihood and move regularly in order to care for their animals, which, in addition to camels, may include other species such as sheep, goats, and cattle. In both Africa and Asia, camel pastoralists inhabit arid environments characterized by extreme, often unpredictable, fluctuations in temperature and rainfall. The latter may be restricted to one or two short seasons, may fail to happen in any given year, or may be localized in a very small geographic area, leaving vast stretches of the environment parched and barren. As a result, the productive potential of these ecosystems varies greatly over time and space, and those inhabiting such areas must be able to adapt quickly to variability in food, forage, and water availability. Camels are often a vital part of the pastoral strategy for coping with such harsh conditions. They cover great distances in search of limited and highly scattered forage and water, which is then efficiently converted into milk and meat for human consumption. In times of prolonged heat or drought, camels may be the only productive livestock and, consequently, are invaluable resources during critical months or seasons of scarcity.

Two Camel Species

There are two extant species of camel: the one-humped dromedary *(Camelus dromedarius)* of the hot deserts of Africa, Arabia, and India; and the two-humped bactrian *(Camelus bactrianus)* of the seasonally cold, higher deserts of the Iranian plateau, central Asia, China, and Mongolia (Figures II.G.3.1 and II.G.3.2). The camel's closest living relatives belong to the once species-rich suborder Tylopoda, which today includes the llama, alpaca, guanaco, and vicuña of South America. In this chapter, the generic term "camel" is used to refer to both species of Old World camels when it is not necessary to distinguish between them. However, it is the case that dromedaries and bactrians are uniquely adapted to the extremes of their native environments, resulting in important differences between them.

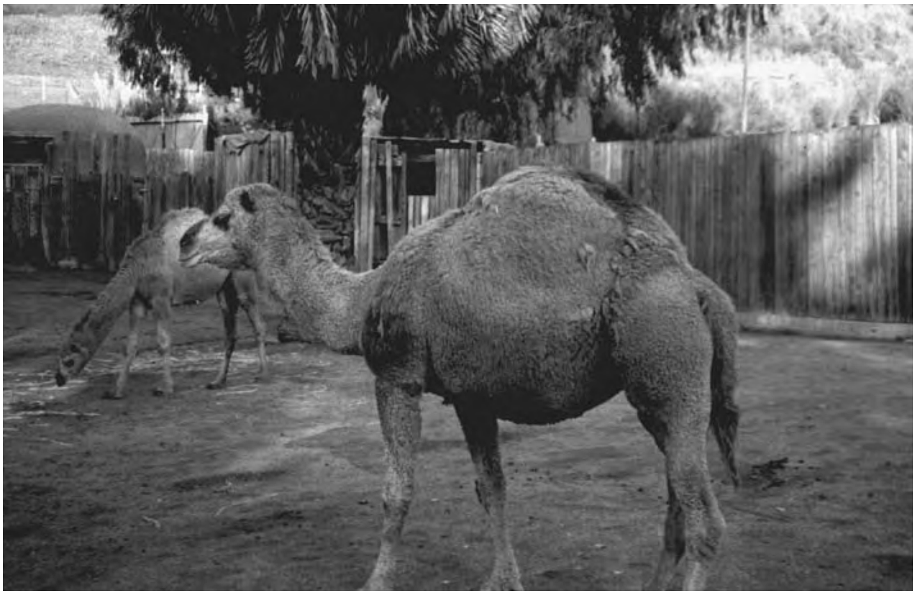


Figure II.G.3.1. *Camelus dromedarius*.

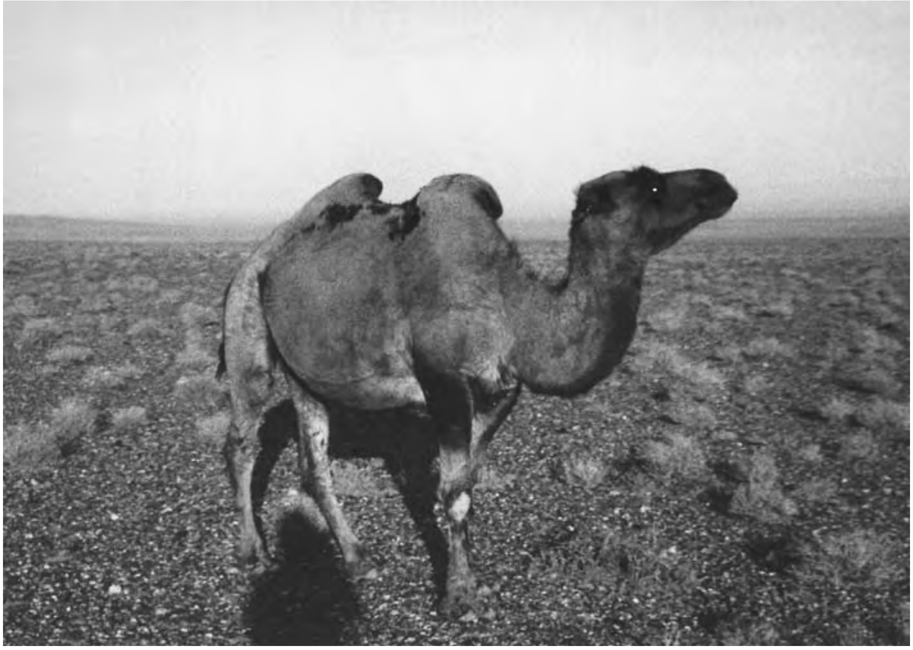

Figure II.G.3.2. *Camelus bactrianus.*

Dromedaries have longer legs, their winter coats are much thinner, and their summer coats are more reflective than those of bactrians. These traits are suited to surviving the intense and prolonged heat of the Arabian and African summers. Bactrians are also adapted to surviving in arid conditions, but their stockier builds and thick winter coats allow them to weather the icy winters of the highland deserts of Asia. In China, bactrians regularly experience temperatures of –30° C (–22° F) in the winter and 42° C (107.6° F) in the summer (Wei 1984). Although bactrians can survive in a wide range of temperatures, they are usually not found where the mean annual temperature is above 21° C (69.8° F) (Mason 1984).

Dromedaries and bactrians are not perfect biological species because they can (and do) mate. The resulting hybrids are larger than either parent and have one elongated hump. Unlike the hybrid offspring of horses and donkeys, first-generation camel hybrids are fertile (Gray 1954). However, if two first-generation hybrids are mated, the resulting second-generation hybrids display suboptimal qualities and are often infertile (Gray 1954; Bulliet 1975). Hybrid camels can be successfully mated with either a pure-blooded dromedary or a pure-blooded bactrian. The resulting offspring resemble the pure-blooded parent in size and number of humps (Bulliet 1975).

Historically, these first-generation hybrid camels were popular caravan animals due to their larger size and greater stamina than either purebred parent (Bulliet 1975; Toplyn 1995). Hybrid camels were also better able to survive the climatic extremes encountered at either end of the trade routes that connected China and the Iranian plateau with Arabia and Egypt. In order to maintain a constant supply of these large-bodied hybrids for caravan traffic, pastoralists had to continuously breed pure dromedary and bactrian parents so as to obtain viable hybrids. Today, hybrid camels are still being produced in the former Soviet Union, where dromedaries of the Turkmen tribes are bred with Kirghiz bactrian camels (Bulliet 1975).

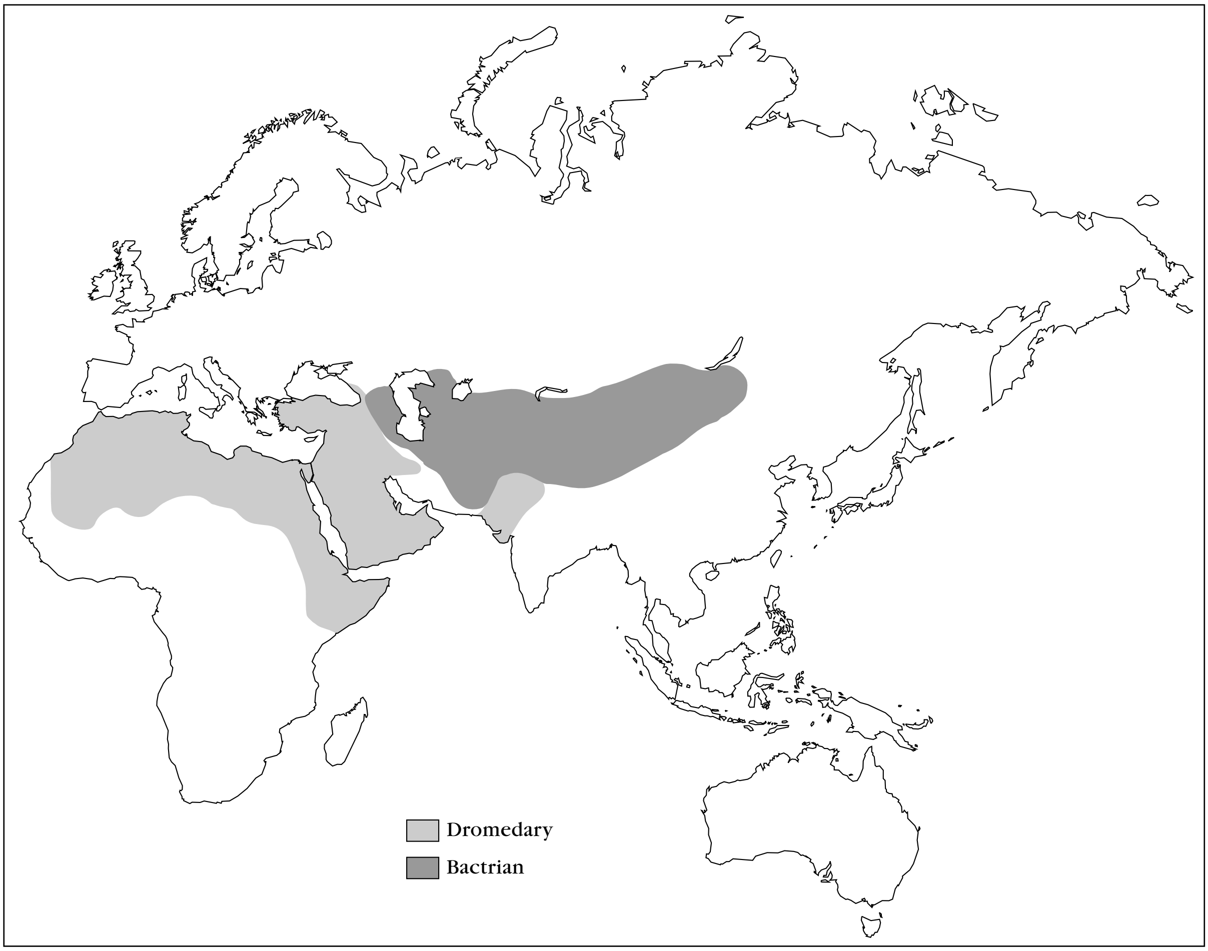
Geographic Distributions

It is not clear from archaeological and paleontological data whether the natural geographic ranges of dromedaries and bactrians overlap or whether their modern ranges are the result of human intervention. Like horses, camels originated in North America and migrated to Asia around 3 to 4 million years ago (Wilson 1984; Stanley, Kadwell, and Wheeler 1994). During the Pleistocene, many species of camel inhabited the Eurasian and African landmasses. Their bones have been recovered across Asia from Siberia to India, from Eastern Europe, and across North Africa as far south as Olduvai Gorge (Howell, Fichter, and Wolff 1969; Badam 1979; Wilson 1984; Dubrovo and Nigarov 1990; Germonpré and Lbova 1996).

Indeed, camels seem to have been successful animals that enjoyed a wide distribution until the beginning of the Holocene (about 10,000 years ago), after which their remains become extremely rare in the archaeological record of central and southwestern Asia (Bulliet 1975; Zarins 1978; Hoch 1979; Wapnish 1984; Uerpmann 1987; Tchnernov 1989; Germonpré and Lbova 1996). The few pieces of evidence from the early Holocene suggest that wild camels were confined to the southern part of the Arabian Peninsula and the deserts of central Asia, and it was not until about 1500 B.C. that domestic camels began to spread across southwestern and central Asia to occupy their current ranges.

In other words, prior to domestication, wild camels seem to have been close to extinction – inhabiting severely restricted ranges in southern Arabia and in parts of central Asia (Bulliet 1975; Russell 1988). But today, domestic camels inhabit the arid regions of North and East Africa, the Arabian Peninsula, parts of Israel, Jordan, Syria, Turkey, Iraq, Iran, Pakistan, Afghanistan, northwestern India, central Asia, northwestern China, and southern Mongolia (Map II.G.3.1). Dromedaries were also introduced into Australia in the late 1800s, and today 15,000 to 20,000 feral dromedaries roam the central and western parts of that continent (McKnight 1969).

Access to water seems to have played a pivotal role in the decline of wild camel populations and may have been a significant factor in their domestication. Despite the camel's ability to survive without drinking for extended periods (weeks to months depending on the water content of their forage), eventually they do have to replace their water losses. Studies of wild camels in China and Mongolia indicate that severe droughts force them to congregate around the few remaining sources of water, which, among other things, exposes them to increased predation by wolves (Tulgat and Schaller 1992). In fact, recent droughts have caused a sharp decline in the wild camel populations in these areas. Yet domestic camels seem to avoid the problems of drought and predation through their association with humans. In Africa, Arabia, and Mongolia, camels often rely on humans to access water in wells or cisterns, especially when rain-fed waterholes dry up (Yagil 1985). Some camels have been known to wait by a well for weeks in order to secure water.



Map II.G.3.1. The approximate modern distribution of camels.

Camels, however, cannot always afford to flee a drought-stricken area for greener pastures and more abundant water because moist environments can also be deadly, especially to dromedaries. Humid environments with standing water are often breeding grounds for tsetse flies that transmit trypanosomiasis and other diseases (Fratkin and Smith 1994), which kill many camels every year and limit the distribution of the dromedary in Africa and India (Wilson 1984; Yagil 1985). Pastoralists are keenly aware that certain swampy areas spread disease and will take their camels there for water only when no other options are available (Fratkin and Smith 1994).

In addition, camels are notoriously maladapted to wet, muddy ground, which, because of their unique physiology of long legs, unilateral gait, and large padded feet, makes them unstable. They often pull muscles, dislocate joints, or break limbs if forced to cross such areas (Russell 1988). Moreover, camels are "front-wheel-drive" animals. Unlike horses, camels use their forelimbs rather than their hind limbs for propulsion. This trait, in combination with padded rather than hoofed feet, leaves them at a severe disadvantage in rocky and mountainous areas (Sato 1980; Russell 1988).

Food and Water Requirements

Compared to other common domestic livestock, such as cattle, sheep, and goats, camels are the most efficient users of water, much of which they can obtain from their herbivorous diet. When necessary, they conserve water by producing a very concentrated urine and dry feces and by reducing water lost through perspiration. In response to solar radiation, dromedaries tolerate core body temperature fluctuations from 34° C to 42° C (93.2° F to 107.6° F) throughout a day (Schmidt-Neilsen 1964), thereby decreasing the need to sweat to regulate body temperature. They can also tolerate a loss of significantly more water relative to their body weight than other livestock, which reach critical limits when they lose 10 percent of their body water (Russell 1988). Dromedaries regularly lose one-third of their body weight in water and survive (Yagil 1985).

The camel's humps are fat deposits that also aid in water conservation. By concentrating fat along the back, the rest of the body is able to cool itself more efficiently. The dorsal fat concentrations not only are insulation against the brunt of solar radiation but also allow the body to radiate heat more efficiently than would be possible if fat were distributed evenly over the whole body. In addition, behavioral mechanisms aid in cooling. During the hottest part of the day, dromedaries tend to lie near each other, facing the sun, which minimizes body surface exposure to direct solar radiation. Calluses on the knees and chest of the camel allow it to rest on hot sands and to elevate its midsection, which enhances airflow beneath the body. Thus, the animal can reach a greater cooling potential. When water is available, a thirsty camel can replace even extensive water deficits by drinking as much as 200 liters in 3 minutes (Yagil 1985).

The camel's efficient use of water enables it to access seasonally and spatially dispersed high-quality forage that other livestock cannot. Often, forage protein content is inversely related to water availability (Russell 1988). Forage that is abundant after periodic rainfall or in areas around predictable water sources generally contains less protein than plants grown in drier areas. Camels move almost continuously as they graze, enabling them to cover many kilometers (km) each day; in fact, they can graze from 50 to 80 km away from water sources, whereas sheep and goats are limited to 20 to 30 km and cattle to 4 to 13 km (Dahl and Hjort 1976; Sato 1980; Russell 1988). As a result, camels are able to use the more concentrated packages of plant protein that are scattered across the landscape and located far enough away from water sources to be inaccessible to other livestock.

Camels are primarily browsers and are able to eat plant species that other livestock cannot, such as camel thorn, Acacia species, and saltbushes (Yagil 1982). When camels, cattle, sheep, and goats are herded together, they compete for some of the same plants, especially grasses (Sato 1980); consequently, camels are usually herded separately to ensure adequate forage for all livestock.

Although all livestock need salt in their diet, camels need more than sheep, goats, and cattle, and to meet these requirements, they must regularly visit areas with saline water or salt-rich plants (Sato 1980; Bernus 1990; Jabbur 1995). Alternatively, pastoralists may collect salt crystals or salt-rich earth to carry back to their camel herds.

In short, camels are well adapted to living in arid environments because they have evolved many mechanisms to conserve water and are able to consume a wide range of plant species. These adaptations decrease competition with other herbivores that share the same environments. From a husbandry standpoint, however, such adaptations often create extra work for pastoralists. If camels must be watered from a well, the human labor needed to satisfy their thirsts can be substantial, as even a small herd of 10 to 20 animals may need thousands of liters of water (Yagil 1985). This probably explains why, in the biblical story of Rebekah, Abraham's servant was so impressed by Rebekah's offer to water his 10 camels (Gen. 24:29).

Camels' Productive Potential: Labor and Food

Camels are physiologically much better adapted than humans to living in the deserts and semideserts of Africa and Asia, yet many people inhabit arid regions of the world. As part of their survival skills, humans have learned to use products from camels and to harness their power. However, not all people utilize camels and camel products the same way.

Labor

Historically, camels were very important for carrying loads over long distances and difficult terrain, and early long-distance trade flourished because of camel caravans. Exotic spices were transported from southern Arabia to the urban centers of Egypt and Mesopotamia during the first millennium B.C. Later, in the early centuries A.D., camels carried trade items along the Silk Route between Persia and China (Bulliet 1975). As mounts and water carriers, camels were also valuable in desert warfare. Some of the earliest literary accounts that mention domestic camels tell of mounted pastoralists from southern Arabia raiding villages to the north, and the animals continued as military mounts until as recently as the early part of the twentieth century in Arabia and India (Bulliet 1975). Camels have also served less dramatic but important roles in the daily lives of nomadic pastoralists, and still today, nomadic pastoralists use the animals to carry dwellings, household belongings, and old or very young people during regular migrations and relocations (Hobbs 1989).

With minimal loads, dromedaries can maintain a pace of 16 km (10 miles) per hour for up to 18 hours (Yagil 1985). Depending on the age, size, and health of the camel, a load of over 300 kilograms (kg) can be carried for several days, and up to 800 kg can be carried for short trips (Gauthier-Pilters and Dagg 1981). Bactrians in China continue to be used primarily as beasts of burden that can easily carry normal loads, averaging 40 percent of their live weight, 35 to 40 km in 24 hours (Wei 1984). Riding camels are also common in China and Mongolia; in fact, in the Chinese deserts, a bactrian camel is considered a more comfortable mount than a horse, and it maintains a pace of 5 to 10 km per hour (Wei 1984).

Today, however, the role of the camel as a transport animal is declining in many parts of the world. Except where automobiles and gasoline are still prohibitively expensive, camels are being replaced by motorized transport.

Milk Quality, Quantity, and Processing

Cross-culturally, milk is the most important edible product obtained from camels. Whether consumed fresh, processed for storage, or mixed with the milk of other livestock, this nutritious product is harvested by almost all pastoralists who keep camels. The absolute quantity and specific qualities of each camel's milk varies with the quantity and quality of available forage and water and the animal's health and age. The nutritional value of camel milk varies because of cultural norms regulating its collection, processing, and distribution within and outside of the pastoral group.

Milk quality. According to J. S. Jabbur (1995), camel milk is higher in vitamin C, fat, protein, and minerals than milk from other livestock raised under the same desert conditions. Certainly, this source of vitamin C is very important to people who inhabit areas where fresh fruits and vegetables are not available year-round. Camel milk contains between 5.7 and 9.8 mg of vitamin C, which is 3 times the amount found in cow's milk and 1.5 times the amount found in human milk (Yagil 1982).

The water content of camel milk varies inversely with the amount of available drinking water. Studies have found that when water was freely accessible, camels produced relatively concentrated milk, consisting of around 86 percent water; when drinking water was restricted, however, the milk became more diluted, with a water content of some 91 percent (Yagil 1982; el Amin 1984; Knoess 1984; Shalash 1984b). Such an adaptation is extremely valuable to both camel calves and people because, in conditions of heat stress and mild dehydration, the diluted milk serves as a source of needed liquid.

The fat content of camel milk also changes in response to the state of hydration of the animal. A hydrated dromedary produces milk with 3.0 percent to 5.38 percent fat, whereas the milk of one that is dehydrated may contain only 1.1 percent fat (Yagil 1982; el Amin 1984; Knoess 1984). Bactrian milkfat has been measured at slightly higher levels – 5.8 percent to 6.6 percent (Shalash 1984b). The various milks produced by other livestock species contain similar amounts of fat. Water buffalo, cows, goats, and sheep produce milk with 7.5, 3.5, 2.8, and 3.7 percent fat, respectively (Knoess 1984). Structurally, camel milkfat is somewhat different from cow, sheep, and goat milkfat in that it is distributed in very small globules (1.2 to 4.2 microns), which are also bound to proteins (Yagil 1982). This structure makes it very difficult to separate the fat from the milk and probably explains claims that butter cannot be made from camel milk. In fact, camel milk can be made into butter and cheese, but with some considerable difficulty, and consequently, when available, sheep, goats, and cattle are generally the preferred sources of milk for these products.

Lactose levels and protein concentrations do not vary with the hydration level of the animal. There are, however, individual and breed differences. Protein may constitute between 2 and 5.5 percent of camel milk, and some camels produce sweeter-tasting milk with lactose levels of 5.8 percent or more. Lower lactose levels are also common and give the milk a slightly sour taste (Yagil 1982). Buffalo, cow, goat, and sheep milk contain similar levels of lactose (Knoess 1984), although those of horse and human milk are higher (6.9 and 7.0 percent, respectively) (Shalash 1984b).

Milk quantity. It is difficult to compare milk yields between dromedaries and bactrians and between different populations of camels from around the world.

Daily milk yields seem to vary a great deal with the season, the age of the calf, and the availability of forage and water. Lactation begins when a camel gives birth, and its duration varies depending on food and water availability. Milk production will normally cease when the camel becomes pregnant again or if the calf dies, but pastoralists have developed ingenious methods of encouraging the camel to continue to produce milk when the latter occurs. For example, the camel is often tricked into thinking that her calf is still alive by the pastoralists' covering another calf with the skin and scent of the dead calf and encouraging it to suckle (Yagil 1982).

As a rule, bactrians lactate continuously for 14 to 16 months (Wei 1984), whereas dromedaries lactate for 12 to 20 months after a calf is born (Sato 1980; Yagil 1982). In parts of Africa, sheep and goats will give milk for only 3 to 4 months, and cattle for about 10 months (Sato 1980). Therefore, if people relied only on cattle or sheep and goats for milk, they would have to do without an important part of their diet for several months at a time.

Various methods of measuring camel milk yields have generated a wide range of daily and annual production estimates. Most of these are not explicit about whether the volume of milk obtained represents only the amount destined for human consumption or whether it also includes the amount normally consumed by the calf. Nevertheless, a survey of the literature indicates that dromedaries produce more milk on average than bactrians and that dromedary milk yields from across Asia, India, and Africa vary between 3.5 and 50 kg per day (Yagil 1982; Knoess 1984). In East Africa, camels produce an average of 3.5 to 4.0 liters of milk per day in the dry season and up to 10 liters per day in the wet season (Fratkin and Smith 1994). This quantity is quite impressive when compared to cattle in the same environment, which were able to produce only 1 liter per day in the wet season and 0 to 0.2 liters in the dry season. In northern Kenya, camels give twice as much milk as cattle and nine times that of sheep and goats (Sato 1980).

A camel's ability to produce milk is also influenced by the number of times it is milked per day, with more frequent milkings increasing a dam's total milk yield by 10 to 12 percent (Shalash 1984b). Milking frequency is a function of the herding practices employed and the household's need for milk. If camels must graze far away from the household, then they are milked less frequently than animals that graze nearby. In Sudan, hydrated camels yield 2.5 to 5 kg of milk at midday, and morning and evening milkings each yield 3.5 to 5 kg, which means a daily milk yield of 8.5 to 15 kg (Hjort and Dahl 1984). Raikas in India can obtain up to 10 liters of milk per day from their camels by milking them three to five times daily (Köhler-Rollefson 1992).

Bactrian camels produce an average of 5 kg of milk per day, although 15 to 20 kg have been obtained from specific animals. In China, most of the milk is left for the calf, and only about 2 kg is milked for human consumption (Yagil 1982).

Milk processing. Cultural practices can have a large effect on the nutritional benefits of camel milk, and many differences exist in milk-processing methods, the percentage of the diet derived from milk and milk products, and the distribution of the milk products within and outside the group. In most instances, camel milk is mixed with the milk of other lactating animals before it is consumed or processed, and if the milk is not to be consumed fresh, it is quickly processed to keep it from spoiling. Such processing usually results in those fermented milk products that are ubiquitous wherever milk is consumed. They are known by a variety of names around the world – such as kefir, *matzoon, dahdi,* yoghurt, and *lehben,* to name a few – but all are produced by the same basic method.

First, the milk is boiled for several minutes, which kills any pathogenic bacteria that may be in it. Once the milk has cooled to 79° F to 86° F, a starter culture from a previous batch of fermented milk is added. The milk is stirred and allowed to ferment overnight at room temperature, after which the resulting product can be safely stored for several days at room temperature (Yagil 1982). The fermentation process generally decreases the lactose content of the milk by converting it to either ethyl alcohol or lactic acid depending on the type of bacteria used. In human populations that do not maintain high lactase (the enzyme needed to digest lactose) levels as adults, soured or fermented milk is the preferred form for consumption (Simoons 1981). However, most human populations that have kept camels for centuries maintain high lactase levels as adults (Yagil 1982).

Another common method of preserving raw milk is to gently boil and evaporate it over a fire. The resulting solids (fats and proteins) are mixed with sugar to form a sweet, buttery, semisolid, cheese-like substance (Yagil 1982). To make butter requires up to 4 hours of churning or the use of a special blender, and the result generally has a greasy consistency. Most often, it is used for cooking, as a cosmetic, and for medicinal purposes. Buttermilk, left over from the butter-making process, often serves as a base for soup (Yagil 1982).

Milk as a Dietary Staple

G. Dahl and A. Hjort (1984) have calculated that 4 kg of camel milk will deliver an individual's daily caloric needs and more than enough protein, which means that a herd of 18 to 20 camels can supply the nutritional needs of a six-person family (two adults and four children). Most camel pastoralists, however, do not live on milk alone; domestic grains, hunted game, and gathered wild plants also contribute significantly to their diets (Hobbs 1989; Fratkin and Smith 1994; Jabbur 1995).

Cultural practices surrounding the use of camel milk vary greatly around the world. In India, for example, its consumption is limited to the camel-breeding caste known as the Raikas (Köhler-Rollefson 1996), and both the sale and the processing of camel milk into curds is taboo, although it may be given away (Köhler-Rollefson 1992). Raikas usually drink camel milk fresh, but on some occasions it is boiled and sweetened or made into rice pudding. Such practices and regulations ensure that most of the milk produced by Indian camels is not consumed by humans and that few Indian people outside of the Raika caste ever taste it.

In Arabia, Africa, and central Asia, however, the camel's milk-producing ability is fully utilized. The Rwala of Arabia claim (apparently correctly) that camel milk, supplemented with wild game, roots, and seeds, constitutes a sufficient diet (Lancaster and Lancaster 1990), although camel milk has recently become less important in the diets of Arabian Bedouins, who are being forced to settle permanently and sell their camel herds (Köhler-Rollefson 1993). For many in Africa, however, milk – including that of camels – is still a major dietary component. It supplies fully 75 percent of the daily calories in Rendille diets, 60 percent in Maasai diets, 60 to 70 percent in Boran diets, and 62 percent in Turkana diets (Fratkin and Roth 1990). In Kazakhstan, milk and milk products can supply up to 90 percent of the daily diet, and although this milk comes from several species of livestock, camels provide 37 percent of the total, sheep another 30 percent, yak 23 percent, and cows 10 percent (Yagil 1982).

Meat

Worldwide, labor and milk are the most important products obtained from camels, and often, camel pastoralists must choose husbandry strategies that optimize the production of milk and labor at the expense of meat yields. Such strategies emphasize the retention of adult females and the culling of young, unnecessary males, with labor supplied by nonpregnant females and/or castrated adult males (Wapnish 1984). The result is to limit the number of mature animals that can be harvested for meat. Generally, only old animals and young males not needed for breeding purposes are slaughtered. In many traditional societies, young camels are slaughtered only for special ceremonies and celebrations, and other unwanted animals are usually sold in commercial markets (Wapnish 1981; el Amin 1984; Köhler-Rollefson 1996).

In modern Sudan, however, pastoralists who raise camels rarely consume their meat but rather sell old animals to international markets for consumption in Egypt, Libya, and Saudi Arabia (el Amin 1984). Meat from old camels is tough and (save for their livers) not highly regarded among urban consumers, whereas meat from camels 5 years old and younger is as tender (and as highly valued) as beef; in fact, camel meat is said to taste like coarse, slightly sweet beef (el Amin 1984; Shalash 1984a).

The slaughter of an adult camel produces a large quantity of meat. Male dromedary carcasses may weigh more than 400 kg, whereas a bactrian may exceed 650 kg (Yagil 1982; Wei 1984). In general, a dressed dromedary carcass yields between 52.6 and 76.6 percent meat (el Amin 1984), and dressed bactrian carcasses have been reported to yield 35.4 to 51.7 percent (Wei 1984). The meat is generally very lean, with the total fat content of a carcass varying between 0 and 4.8 percent, depending on the age and nutritional status of the animal. The fat is concentrated in the hump and around the kidneys; that from the hump is melted and used instead of butter for cooking by some Arabian Bedouins (Jabbur 1995).

In addition to husbandry considerations, cultural and religious proscriptions limit the use of camel meat in many countries. In India, for example, Hindus will not eat camel meat, and it is also avoided by Christian Copts of Egypt, Christian Ethiopians, Zoroastrians of Iran, Mandaeans of Iraq and Iran, Nosaioris of Syria, and many Jews (Yagil 1982).

Blood

Several groups in eastern Africa use the blood of camels (as well as that of cattle) as a food resource that supplies valuable nutrients, including iron, salts, protein, and vitamin D (Yagil 1982). Blood may be drawn from a camel up to twice a month, and the animal can produce between 2 and 5.5 liters with each bleeding (Shalash 1984a; Bollig 1992). Blood is usually processed before consumption by first collecting it in a bowl and stirring it with a stick. Because fibrin, a blood-clotting protein, collects on the stick, it is easily separated from the rest of the blood and generally roasted before it is eaten. The remaining blood is either mixed with milk or boiled and mixed with maize flour (Bollig 1992).

Other Products

Camels provide many other valuable products, including wool, urine, and dung. In Sudan and India, dromedary wool is collected as the animals begin to molt and is used to make jackets, robes, tents, ropes, blankets, and carpets (el Amin 1984; Köhler-Rollefson 1992). In China and Mongolia, bactrian wool is a highly valued product that is often made into cushions, mattresses, bags, and ropes (Wei 1984). Among the Bedouins of Arabia, camel urine is used as a hair tonic (Jabbur 1995). Apparently its high salt content gives hair a reddish tint and prevents vermin infestations. Dung, also a valuable commodity, is often dried and stored for heating and cooking fuel (Jabbur 1995). And finally, if a person is lost in the desert and desperate for water, a camel may be slaughtered for the water contained in its stomach (Jabbur 1995).

Husbandry Considerations

Given the previous discussion of the camel's productive potential, one might wonder why camels are not more widely and intensively herded, or why people bother to herd other livestock with their camels. These questions are best answered by examining the camel's reproductive characteristics and the resulting husbandry strategies employed by camel pastoralists. Pastoralists have developed a variety of strategies that optimize the camel's productive potential in their particular social and ecological environment. Specifically (as already noted), pastoralists must balance the harvesting of camel products today against the need for future herd growth. This is usually calculated in terms of how much milk and meat can be taken for human consumption versus the amount of milk required by calves and the number of animals necessary to meet future production needs and to hedge against future unpredictable calamities.

Life History and Reproductive Characteristics

An animal's ability to reproduce quickly is a valuable trait to pastoralists. Reproductive potential depends on the age of first reproduction, the potential number of offspring per year, and infant mortality. A quick comparison of annual calving rates – 0.4 or less for camels, 0.4 to 0.8 for cattle, and 0.8 to 2.0 for sheep and goats – shows that camels are among the slowest reproducers of any domestic livestock species (Russell 1988; Herren 1992). Their low rate results from a 12- to 13-month gestation period (which is shorter for dromedaries than bactrians) and, typically, a 24- to 36-month span between births. Other factors that lower reproductive potential include the frequent restriction of breeding to rainy seasons and susceptibility to trypanosome, brucellosis, and pasteurellosis infections that trigger abortions.

The interval between births can be narrowed with intensive management practices, but this practice appears to shorten the female's life and limit the total number of offspring (Bollig 1992). Because camel herds increase at a rate of 8 percent or less annually, it takes a minimum of 15 years, and potentially as many as 50 years or more, for one to double in size (Dahl and Hjort 1976; Russell 1988; McCabe 1990). Such slow reproductive rates directly affect how people manage camel herds for food production and how they manage social obligations and their own reproductive rates (Galvin, Coppock, and Leslie 1994). Because camels will lactate only after giving birth and usually stop lactating shortly after becoming pregnant again, pastoralists carefully manage herds to ensure that at least some animals are lactating at any given time. But even with good luck and careful management, only 15 to 22 percent of the females may be lactating at one time. The camel's low calving rate also limits the number of young males that can be slaughtered for meat (Herren 1992). But the trade-off is that if a calf is slaughtered, all of the dam's milk becomes available for human consumption, providing, of course, that the dam can be tricked into continuing lactation.

Human Labor

Human-labor requirements are an important obstacle to the efficient utilization of domestic animals in pastoral societies because the availability of this labor limits the total number of livestock that can be herded by a single household. As we have seen, differing needs for food, water, preferred forage, rates of locomotion, duration of milk production, and breeding cycles prevent sheep, goats, cattle, and camels from being herded in a single group. Labor requirements are not constant throughout the year, but as herds are divided into milking and nonmilking and breeding and nonbreeding groups, more labor is required (Sato 1980; Roth 1990; Fratkin and Smith 1994). Pastoralists also face the constant problem of maintaining that delicate balance between labor requirements necessary to care for livestock and the number of people that can be supported by a given number of livestock (Fratkin and Smith 1994). To achieve and maintain this balance was doubtless at the root of the development of many inheritance, exchange, ritual, and human population control practices among camel pastoralists (Sato 1980; Fratkin and Smith 1994; Galvin et al. 1994).

Differences in livestock water requirements, forage plant species preferences, and grazing speed frequently force pastoral subsistence groups to split up for large portions of the year (Sato 1980; Sperling 1987; Bollig 1992; Fratkin and Smith 1994). This split often takes place along age or gender lines, resulting in dramatically different diets among members of the society (Sato 1980; Galvin et al. 1994). Illustrative are the Rendille of Kenya, who strictly delegate performance of the various herding tasks. Camels may be herded and milked only by young unmarried men; consequently, this segment of the Rendille population spends the longest time away from the main camp and covers the greatest distances during the grazing rounds. While on herding duty, these men subsist solely on camel milk and blood. Unmarried men and women herd small stock (sheep and goats) and consume both maize meal and milk while away from the base camp during the dry season. Adults, children, and the elderly, who remain at the base camp throughout the dry season, must subsist primarily on maize meal because few lactating animals can be supported on the meager forage available near the camp (Sato 1980).

Mixed Herding Strategies

Given that herding several different livestock species requires the division of pastoral societies and more herding labor than "camel-only" strategies, one might ask why so many pastoral societies go to such trouble. The answer is that a mixed pastoral system is an effective hedge against episodes of food scarcity. For example, if a camel herd is wiped out by a disease, it may take a lifetime to rebuild it. Alternatively, sheep and goats, although more likely to die during extended droughts, are able to quickly reproduce their numbers. Moreover, in most pastoral economies, sheep and goats satisfy immediate needs for meat and are often exchanged for grains.

Camels, however, are kept for the products that can be obtained from live animals during times of scarcity. In short, pastoralists use sheep and goats as we would use spending money, whereas camels are a form of stored wealth that might be equated with long-term stock or bond investments. In addition to maintaining diverse livestock herds, many pastoralists further diversify their resource base through trading relationships. They exchange animals and animal products for agricultural and industrial products and may also "loan" animals to relatives and neighbors or "adopt" children if herding requirements exceed the available labor (Russell 1988). These relationships can be used to optimize herd production and labor utilization over a greater geographic area.

Moreover, camels and other livestock can be viewed as a form of stored food for pastoralists. They not only represent food reserves that can be utilized on a regular basis but also serve to concentrate scattered or inedible nutrients into highly nutritious and accessible packages for human consumption (Russell 1988). Additionally, to return to the theme of stored wealth, the ability of camels to survive severe droughts better than other livestock, as well as their 30-year lifespan, makes them desirable "banks." For example, during a series of droughts in northern Africa between 1968 and 1973, the Tuareg lost 63 percent of their cattle and 47 percent of their sheep but only 38 percent of their camels (Bernus 1990). After a severe drought, camels can be sold or exchanged for necessities and to replace lost livestock.

The Camel in Antiquity

Very little is known about the earliest culinary uses of camels because of the nature of the archaeological record and because of the camel's preference for desert environments. The archaeological record is generally best preserved within structures such as buildings, cities, and natural enclosures such as caves. Camels, however, do not, and presumably did not, live in these environments. Not surprisingly, then, very few archaeological sites have produced evidence for the early use of camels. Before they were domesticated, camels were hunted for their meat, hides, and bones, and it is doubtful that they were exploited for their milk until after domestication.

But before humans could hunt wild camels or, later, milk domestic camels, humans first had to come into contact with them, and human–camel interaction is rarely documented in the archaeological record prior to the third millennium B.C. What little evidence of such contact is available comes from southwestern Asia (the presumed refuge of the wild dromedary) and (for the bactrian camel) from sites on the Iranian plateau, in central Asia, and in China (Map II.G.3.2).

Dromedary Domestication

Camel bones from Paleolithic sites (before 10,000 B.C.) in Egypt, Sudan, Jordan, Syria, and Israel attest to the wide distribution of a camel species – presumably the dromedary – prior to the Holocene. Subsequently, however, camel remains become much more rare, suggesting that they either were not in the vicinity of archaeological sites or, for some unknown reason, were not a regular food source.

Some of the earliest rock art, dated between 6000 and 3500 B.C., shows dromedaries and speared dromedaries (Anati 1970; Zarins 1989), and archaeological evidence confirms the presence of camels in southern Arabia at this time. At Sihi, a shell midden on the Red Sea coast, a camel mandible was recovered and directly radiocarbon-dated to about 7000 B.C. (Grigson 1989). Moreover, camel bones from southern Jordan were found in seventh-millennium-B.C. contexts (Köhler 1984), whereas other camel remains discovered in the United Arab Emirates were likely from the fourth millennium B.C. (Uerpmann 1987).

In southern Arabia, rock art images showing hunting scenes, hunting parties, and the use of bows and arrows provide pictographic evidence that local hunters were responsible for the camel bones found at several of the area's sites and dating from between 3500 and 1900 B.C. (Zarins 1989). Third-millennium-B.C. sites along the Gulf coast of the United Arab Emirates have also yielded numerous such bones (Hoch 1979; Uerpmann 1987), including those from the island site of Umm an-Nar, where, although it is not clear whether the camels were wild or domesticated, they were most certainly introduced by humans (Hoch 1979).

The long history of human–camel interaction in southern Arabia indicates a likely environment for the occurrence of domestication but does not document exactly when such an event might have happened. However, it would seem that we can actually spy early domestic camels to the north of Arabia. In the Sinai and the Levant, camel images are absent from rock art traditions (suggesting that wild camels were unknown), but their bones nonetheless begin to appear in second-millennium-B.C. urban sites (Lernau 1978; Hakker-Orion 1984; Zarins 1989). For an explanation, we return to southern Arabia, where people for millennia had kept sheep, goats, and cattle and lived in permanent structures made of stone. But then, presumably, the ecological changes caused by desiccation and a concomitant expansion of the desert forced the adoption of a more mobile lifestyle. It is believed, in other words, that the bones found on

the northern edge of the desert were those of domesticated camels, upon which the now mobile pastoralists from southern Arabia had begun to visit the urban centers of the north (Tchnernov 1989; Zarins 1989).

Bactrian Domestication

The early history of human–bactrian interaction is poorly understood at present. This is partly because of a limited amount of archaeological investigation of central Asian sites and partly because of the inaccessibility of most Russian and Chinese documents to outside researchers. Although evidence for the use of bactrian camels in Neolithic China is practically nonexistent (because few animal bones were ever saved or studied), an exception is one camel bone from a site near Lake Burkol in the northeastern part of Xinjiang Province; this bone has been radiocarbon-dated to 3000 B.C. (Olsen 1988). Rock art from northern China and Inner Mongolia also attests to the presence of bactrians; however, dates for this art are highly speculative. Not until the Zhou Dynasty (c. 1100–771 B.C.) do Chinese literary sources confirm that bactrian camels were domesticated and employed as beasts of burden (Olsen 1988).

Early evidence for the presence of camels on the Iranian plateau is found at the site of Shar-i Sokhta (Compagnoni and Tosi 1978), where bones, dung (contained in a ceramic jar), and hair (woven into a piece of fabric), dating from roughly 2600 B.C., were found. These discoveries suggest that people were already utilizing several valuable resources from camels that presumably lived near the site. Other finds indicate that camels in the Indus Valley at the site of Mohenjo-daro by 2300 B.C. (Meadow 1984) were bactrians. A pottery shard from a contemporary site on the Iranian plateau depicted a bactrian, and no images of dromedaries have been found from this period (Compagnoni and Tosi 1978). However, there is no consensus on whether the bones from these areas are those of dromedaries or bactrians (Compagnoni and Tosi 1978; Meadow 1984; Wapnish 1984), largely because there is evidence of extensive trading between the Arabian Peninsula and Iran by the first half of the third millennium B.C. (Hoch 1979), and dromedaries could have been introduced to the Iranian sites from Arabia the trading network.

Domestication as Beasts of Burden

The distribution of camel bones at Tell Jemmeh, an urban site in southern Israel, may reveal when and why camels finally became an important domestic animal across southwestern Asia. Their bones are absent from the earliest levels of this site – the Chalcolithic (c. 3200 B.C.) and Middle Bronze II (c. 1650–1550 B.C.) (Wapnish 1981), with the first deposits of camel remains dating from between approximately 1400 and 800 B.C. But over this 600-year period, only 7 camel bones were left behind to be recovered. Eight more showed up for the following century, when the Assyrians began to exert their influence at the site through military campaigns, and 40 bones were deposited between 675 and 600 B.C. – a 75-year period that corresponds to the city's association with the Assyrian invasions of Egypt. Then, from the beginning of the sixth century B.C. until occupation of the site ended at around 200 B.C., over 273 camel bones were left behind. These last four centuries witnessed periods of political instability as first neo-Babylonians, then Persians, and finally Alexander the Great took control of the site.

The question of why camel remains steadily increased in this urban center – if it was well supplied with meat from domestic cattle, donkeys, sheep, goats, pigs, and wild game – may be answered by the fact that camels found increasing economic and political importance as beasts of burden. The long-distance trade in incense and spices from southern Arabia to the Levant and beyond had become lucrative. Empires wanted to control and profit from this trade but needed to be able to supply and move troops in these arid regions. Both enterprises depended on the camel's unique ability to haul heavy loads over long distances while consuming little water, and a whole economy grew up around this ability (Wapnish 1981). Archaeological investigations at two other sites in the region also support this interpretation. Camel bones from Wadi Arabah No. 2 and Timna, two copper-production sites (1350–1150 B.C.), indicate that camels were used to transport this valuable product to urban markets (Rothenberg 1972; Zarins 1989).

At the site of Tal-e Malyan, in present-day Iran, a similar pattern of camel introduction is evident. Although the site was occupied from at least 3400 B.C. and has yielded thousands of animal bones, those of camels do not appear until the Middle Elamite period (1600–1000 B.C.) (Zeder 1984). Regional political instability may have led to the city's decline during these centuries, encouraging people to abandon their urban lifestyles for a more mobile pastoral existence. Camels introduced to the region by caravaneers figured prominently in the new pastoral system.

The Assyrians were instrumental in introducing camels to people across Southwest Asia, although not always peacefully, and their texts and monuments provide us with much of the available evidence about the historical use and distribution of dromedaries and bactrians. Some of the earliest written accounts of dromedaries come from an Assyrian cuneiform text, written between 1074 and 1057 B.C., which mentions that the animals were brought to Nineveh and exhibited with other exotic animals (Zarins 1989). Two bactrian camels are depicted on the Black Obelisk of Shalmaneser III of Assyria, which has been dated to 856 B.C. (Bulliet 1975).

All of the preceding tends to fit rather nicely with a synthetic hypothesis of the origins of dromedary pastoralism proposed by J. Zarins (1989). The camel was probably hunted for its meat in southern Arabia until around 2200 B.C., when dromedaries were domesticated and kept for milking purposes. However, they were not ridden or used as beasts of burden until around 1500 B.C. – about the time when saddles were developed for them. Afterward, camels were increasingly employed for riding and as pack animals for overland trade. After about 1000 B.C., saddle technology was improved, and camels became very important in warfare as mounts for armed soldiers (Bulliet 1975).

The origin of domesticated bactrians is more obscure. Presumably, the process of their domestication followed a similar path, although we do not know if they were domesticated earlier or around the same time as dromedaries. It is clear, however, that by the first millennium B.C., if not earlier, bactrians, too, were being used as pack animals (Bulliet 1975).

The archaeological record also plainly indicates that overland trade and warfare introduced camels to peoples who lived beyond the animals' native deserts. Apparently, these people appreciated the camel's ability to produce copious amounts of milk year-round and to carry large burdens over great distances in environments that were inhospitable to most other livestock. Moreover, the late appearance of indisputably domesticated camels suggests that they were incorporated into already-established pastoral lifestyles with sheep, goats, and cattle.

Our understanding of the origins of the use of camels as a food resource should improve as current efforts in identifying and studying the archaeological traces of early pastoralists are completed and published. In addition, ethnographic studies of modern camel pastoralists that attempt to quantify the costs and benefits of camel husbandry under specified ecological and social conditions would enhance our understanding of the origins of such practices. And finally, an ongoing study of camels' genetic variability may someday help to trace the origins and subsequent dispersal of camels and the pastoral systems associated with camel husbandry.

Elizabeth A. Stephens

A Jacob Javits Fellowship and the Haury Educational Fund for Archaeology generously funded research leading to the production of this chapter. Fieldwork was graciously supported by Dr. John Olsen. I would also like to thank Dr. Mary Stiner, Dr. Carol Kramer, Dr. Stephen Zegura, Dr. Michael Hammer, Jeff Brantingham, Lane Therrell, Dr. Andrew Standeven, and anonymous reviewers for their help, encouragement, and valuable comments on my research.

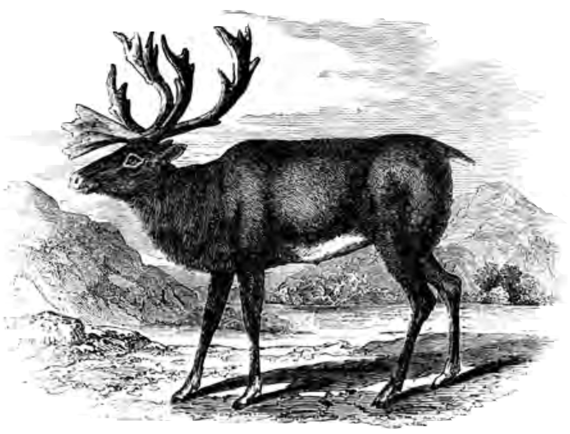
II.G.4 Caribou and Reindeer

The terms "caribou" and "reindeer" refer to a species of cervid, *Rangifer tarandus,* which has Holarctic distribution. "Reindeer," however, is somewhat ambiguous, as it is used to refer to both the wild and domesticated forms of this species, whereas "caribou" always designates the wild form. Yet "reindeer" is generally preferred in the Old World for both. (The term "wild reindeer" is also sometimes used as a synonym for "caribou," to differentiate from the domesticated animal.) In addition, a separate species of Paleoarctic (Old World) reindeer, *Rangifer arcticus,* was once recognized, but the fact that caribou and reindeer interbreed successfully and produce fertile offspring, particularly in Alaskan herds, led to general unification of the taxon (Banfield 1961).



Reindeer

At least six major modern subspecies of caribou are recognized. Two of these are Paleoarctic in distribution: *Rangifer tarandus tarandus,* the European tundra reindeer, and *Rangifer tarandus fennicus,* the Eurasian forest reindeer. Three are Neoarctic in distribution: *Rangifer tarandus grant* of Arctic Alaska and westernmost Canada, *Rangifer tarandus pearyi* (the "Peary caribou") of eastern Arctic Canada, and *Rangifer tarandus groenlandicus* of Greenland and Baffin Island (Meldgaard 1986). One subspecies, *Rangifer tarandus caribou,* is endemic to the subarctic boreal forest, originally ranging from Alaska to eastern Canada and the northernmost United States but now more limited in distribution. Other varieties are more restricted geographically: *Rangifer tarandus platyrhynchus* lives only on Spitzbergen, and *Rangifer tarandus dawsoni* is confined to the Queen Charlotte Islands.

Prehistory of Caribou/Wild Reindeer Utilization

The genus *Rangifer* exists in the paleontological record throughout the middle to late Pleistocene or Ice Age period and has a probable antiquity of at least 400,000 years. The relative prevalence of caribou remains in paleontological and archaeological sites from this period serves as a sensitive indicator of climatic and vegetational change (Parker 1971; Messier et al. 1988). This is because caribou are tied to arctic tundra or subarctic taiga (open coniferous forest) habitats, which provide their chief foods: lichens, particularly of the genera *Cladonia* and *Alectoria,* and a wide variety of low browse or groundcover plants, including forbs, fungi, willow and birch shoots, and grass and sedge shoots (Kelsall 1968). Thus, the presence of caribou during glacial periods (and their absence during interglacial periods) in central Europe and other parts of northern Eurasia is linked to the expansion and regression of the Scandinavian ice sheet to which these arctic and subarctic environments were tied (Bouchud 1966).

Remains of *R. tarandus* are initially associated with late *Homo erectus* or archaic *Homo sapiens* sites in Europe and, more frequently, with Neanderthal sites. *Rangifer tarandus* existed as a recognizable taxon throughout the Upper Paleolithic period from 40,000 to 10,000 years ago (Banfield 1961). It is a conservative taxon, with little change occurring in caribou throughout the late Ice Age and postglacial periods. During the Upper Paleolithic period, many northern Eurasian hunting populations became specialized in hunting wild reindeer (Sturdy 1975; Mellars 1996; Burke and Pike-Tay 1997). The caribou was probably the most important game animal in western Europe during the Upper Paleolithic, and European cave deposits contain large amounts of caribou bones (Delpech and Heintz 1976; Delpech 1983; Boyle 1990, 1993; Straus 1997; Thacker 1997). Caribou also figure prominently in Ice Age art, as at Lascaux Cave, and some depictions (as at Trois Frères) suggest that they played an important role in ritual and perhaps shamanistic activities. In the New World, caribou were important to Paleo-Indian hunters throughout North America (Cleland 1965; Funk, Fisher, and Reilly 1970; Spiess, Curran, and Grimes 1985; Peers 1986; Jackson 1988).

After the end of the Ice Age, caribou populations retreated northward to areas offering suitable habitat, such as northern Germany and southern Scandinavia, and many parts of Russia, Alaska, Canada, and Greenland. They were an important focus of Epipaleolithic or Mesolithic hunters throughout this region; their bones are found in archaeological sites, and they were depicted in rock art in each of these areas. With evolving post-Pleistocene climates, caribou became restricted to areas of northern Scandinavia, Siberia, parts of the Russian Far East, and the more northerly areas of Canada and Alaska (Yesner 1995). They have continued to be hunted by various aboriginal populations in all of these regions until the present time (e.g., Birket-Smith 1929; Lips 1947; Chard 1963; Gubser 1965; Nelleman 1970; Simchenko 1976; Irimoto 1981; Hall 1989; Krupnik 1993).

Methods of Caribou/Wild Reindeer Exploitation

Since Upper Paleolithic times, caribou have been a historically important food resource for northern Eurasian hunting peoples for three reasons: the dense aggregation of the animals in bands and herds, their ease of capture, and their nutritional value. Modern caribou tend to congregate in large numbers ranging from dozens (bands) to thousands (herds). Their migratory habits minimize their impact on the relatively delicate plant communities upon which they depend. These migrations may shift groups between forested and open (tundra) environments on a seasonal basis. They frequently involve movement between seasonally important hunting grounds and spring "calving grounds," where females give birth. Contemporary migration distances range from relatively short (for example, on Spitzbergen and islands of the Canadian High Arctic) to very long (in western Canada and Alaska). Factors involved in the distance and location of migration include available forage, protection against predators, and insect infestations (Pruitt 1960; Skoog 1968; Heard 1997).

The nature of caribou migration patterns of the past is unclear. Zooarchaeological data from late Ice Age sites in southwestern France suggest that year-round occupation of some areas was possible by specialized caribou hunters, which may be related to shorter-distance migrations by the animals, as well as to the fact that they existed in significant numbers (Gordon 1988; David and Enloe 1992; Enloe and David 1997; Spiess in press). In comparison with their Arctic habitats of today, southwestern France would have provided a smaller physical area but much greater environmental (particularly altitudinal) diversity, thereby helping to support larger groups of animals. In addition, beginning around 20,000 years ago, caribou were hunted with efficient tools such as spears and atlatls (Bouchud 1966; Delpech 1983; Pike-Tay and Bricker 1993).

In places where they were less available, such as in open forest areas, caribou were a seasonally important resource; their dietary significance seems to have varied in relation to the specificity of the habitat for caribou and the length of local caribou migration routes. Among historically known caribou hunting groups, some maintained a herd-following strategy, whereas others remained in specific areas, usually near annual migration routes, exploiting other resources until the caribou showed up.

The former pattern seems to have been more typical of places where few alternative resources existed, such as the Canadian High Arctic (Gordon 1975), and may also have been true of Scandinavia before the domestication of reindeer (Blehr 1990). The second pattern was more typical of places where alternative resources existed, where annual migration routes were fairly precise, and where caribou could be taken in sufficiently large numbers that their meat could be stored for a considerable time period; such a location was the Brooks Range of northern Alaska (Burch 1972). Situations in which caribou composed the predominant element in the diet yet failed to materialize along a particular migration route in a given year have been well documented; the result was usually starvation for the hunters (Mowat 1952).

Human groups hunting caribou have employed a wide variety of techniques, which Arthur Spiess (1979), Otto Blehr (1990), and Bryan Gordon (1990) have discussed in detail. There are basically two approaches: One involved "mass killing" techniques, in which large numbers of animals were taken from a band or herd at one time, whereas the other saw individual caribou or small numbers of individuals killed. The former tended to be used for hunting large bands or herds (as during seasonal aggregations) when large numbers of humans were available to hunt and where caribou meat was particularly important in the diet. Mass killing techniques involved logistic planning, whereas individual hunting techniques were largely based on opportunistic encounters.

Mass killing techniques were historically used by many groups, including coastal and interior Eskimos, various Athapaskan peoples of interior Alaska and western Canada, some Algonquian groups in the eastern Canadian Subarctic, the Saami peoples of northern Scandinavia, some Siberian groups, and a few of the Rocky Mountain groups of western Canada. Algonquians of northern New England and peoples of the Russian Far East seem to have used individualistic hunting techniques almost entirely. Mass killing techniques were of two types. On land, they involved drives into traps, snares, fences, corrals, or human "surrounds"; in general, this type included any technique in which the caribou were lured into a small area to be killed and butchered (Anell 1969; Morrison 1982). The caribou were also driven into water, with the use of boats, in areas where rivers or lakes lay near migration routes (Arima 1975; Greenman and Stanley 1977; Yesner 1980). Male and female humans of all ages participated in these activities, with which forms of sociopolitical leadership were often associated. These may have ranged from simple task leadership to the involvement of more general leaders or village headmen (for example, the *umialik* or whaling boat captains in North Alaskan villages).

By contrast, individualistic hunting was usually done by men using singly set snares, stalking, and "running down" of game. Killing was done with atlatls, spears, bows and arrows, and the rifles introduced into many indigenous caribou hunting groups during the nineteenth century. For both mass and individualistic hunting various aids were employed, such as decoys (antlers, reindeer skins, calls) and mock caribou made of wood or stone. Some of these approaches may be reflected in the archaeological record; examples might include the caribou headdress from Trois Frères or certain depictions in Scandinavian rock art. Mass killing efforts tended to yield nonselective age and sex groups of caribou, whereas individual hunting techniques were more effective at different times of year to take particular ages or sexes of the animals. The archaeological record indicates that bulls were generally preferred for meat, and today they are larger and have more fat, particularly during the autumn (Yesner 1980). Calves were also sought for their high fat content, and female adults became the preferred prey in early winter, when the bulls were in rut (see Figure II.G.4.1).

Individualistic hunting techniques were also used to take animals at specific times of the year for nonfood purposes, such as in late summer and fall, when the quality of reindeer fur was particularly suitable for clothing manufacture. Cows and calves were often sought for their skins. Animals of varying ages and sexes were targeted for the manufacture of specific items of clothing: skin bags, rawhide or "babiche" for snowshoe lacings, as well as covers for dwellings, caches, and sleds (Smith 1978). In addition, antlers were an important resource for tool manufacture. If already shed, antlers could be scavenged, but they could also be taken from animals, particularly males, and generally from adults over 4 years of age, as they produce significantly larger antlers.

Dietary Importance of Caribou/Wild Reindeer

The fact that specialized caribou hunting has been possible among some groups for 40,000 years indicates that the animal is capable of satisfying human subsistence requirements (Burch 1972). However, rarely did historically known groups subsist solely on

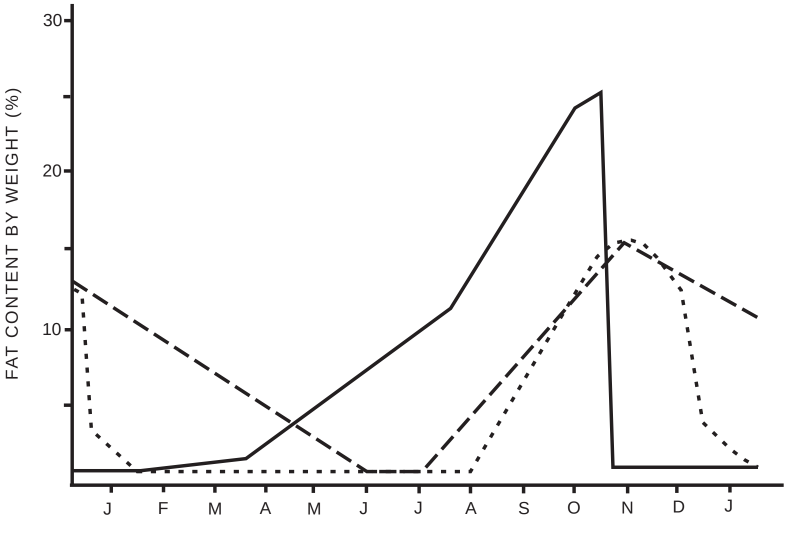


Figure II.G.4.1. Seasonal variation in the fat content of caribou. Mature bulls are represented by a solid line, mature females by a dashed line, and young bulls by a dotted line. (From Spiess 1979: 28; used by permission of Academic Press.)

a caribou meat diet. Past caribou-hunting specialists of the arctic region, such as the Arctic Small Tool peoples (also known as the Denbigh peoples in Alaska and the Dorset peoples in Canada), were historically replaced by more efficient coastal hunters, such as the Thule peoples (ancestral to modern Arctic Eskimos), who combined caribou and sea-mammal hunting. There is also historical and archaeological evidence suggesting that contemporary groups – such as the Nunamiut Eskimos of Alaska, the Caribou Eskimos of Canada, and even the so-called Reindeer Lapps of northern Scandinavia – have developed their specialized lifeways only in the past few hundred years, and that until recently, they migrated between coastal and interior regions, combining caribou hunting with fishing and sea-mammal hunting.

The Caribou Eskimos, living to the west of Hudson Bay in an area where whaling or walrus hunting is less possible today than in other areas (and where shorefast ice requires individual stalking of seals in winter), have been particularly dependent on caribou. They are, however, a group with smaller human populations, simpler technologies, and less complex political structures than other Eskimo peoples. Similarly, among Alaskan Athapaskan groups, those involved primarily with caribou hunting (for example, the Gwich'in) have been more mobile, with a simpler technology, and have been fewer in numbers than other groups that were also involved with salmon fishing and/or seal hunting. Such caribou-dependent groups tends to be very mobile, occupying in the course of a year several different base camps, where they have utilized relatively unsophisticated dwellings such as caribou-hide tents (or even brush lean-tos).

Widespread concern over the availability of caribou was especially characteristic of groups occupying boreal forest regions, where the animals were often scarce (cf. Smith 1978). Such concern took the form of specialized ritual and may have stimulated the development of divination as a technique in caribou hunting. The effect of divination was to randomize the impact of such hunting and therefore minimize the likelihood of overexploitation (Moore 1969). Some authors have even linked the so-called Windigo Psychosis of subarctic Cree peoples to concerns over starvation in the boreal forest.

That caribou-hunting groups occasionally met with starvation is well documented in the ethnographic record. In part, this was a result of the naturally cyclical patterns of caribou abundance in arctic regions. Although it is difficult to establish the antiquity of these patterns, there is some suggestion that they go back hundreds of years in interior Alaska (Yesner 1980), Labrador (Fitzhugh 1972), and Greenland (Gronnow, Meldgaard, and Nielsen 1983; Meldgaard 1983), and they may even have occurred during the Upper Paleolithic in France (David 1973). During caribou population highs, such as in late-nineteenth-century Alaska, intensification of hunting, including widespread construction of "caribou fences," seems to have taken place. At times of population lows, caribou-hunting groups apparently shifted to a more diverse diet that included small game and birds (Yesner 1989). Within the last 150 years, habitat disturbance has led to population expansion of other cervids such as the moose, which subsequently filled the dietary niche formerly occupied by caribou in some parts of interior Alaska.

Because higher metabolic rates are required for human survival under cold conditions, dietary requirements of high-caloric foods are significantly greater in the Arctic region (Draper 1974). Calories are usually provided by fats, which have twice the caloric density of protein or carbohydrates (about 9 calories per gram). However, except for deposits around viscera, under the skin, and in bone marrow, caribou are generally lean, yielding fat at only 10 percent of body weight (Hall 1971). Between 40 and 55 percent of a caribou carcass is meat (White 1953; Hill 1967; Binford 1978). Caribou weights vary from about 35 kilograms (kg) for a juvenile to 150 kg for a large adult male (Kelsall 1968). Such a range provides from 20 to 80 kg of meat but only 3 to 10 kg of fat (Table II.G.4.1).

There is some physical evidence that nutritional deprivation was occasionally associated with those groups that were more caribou-dependent. In the Canadian High Arctic, for example, a greater dependence on caribou may be linked to relatively shorter statures in that region (Laughlin 1966). Although there is evidence for episodic nutritional stress in human skeletons from throughout the Arctic and Subarctic (Yesner 1994), the Caribou Eskimos have shown some of the strongest patterns of development of growth arrest lines, indicative of starvation, of any Eskimo peoples (Buikstra 1976). In addition, studies by the Alaska Dietary Survey (Mann et al. 1962) and by Edward Foulks (1972) have suggested that a caribou diet may be deficient in thiamine and other vitamins.

Caribou/Reindeer Butchery and Consumption

Caribou butchery practices have varied widely among groups. However, common variables in the butchery process have involved transportation requirements and whether immediate or short-term consumption or storage of meat was anticipated. The size of the packages of meat produced would often be related to whether humans, dogs, or sleds (or, today, snowmobiles) were used for transportation. If carcasses were to be used for long-term caching (storage in an underground or rock-lined chamber), they would only be beheaded, eviscerated, and quartered, with further butchery taking place before consumption at a later time. Butchery procedures may also have been affected by whether the animal was being used for purposes other than human consumption (such as clothing manufacture, dog food, or bait for traps).

Table II.G.4.1. *Weights and edible weights for caribou* (Rangifer tarandus)

Age/Size Group	Weight (kg)	Percentage edible	Meat (kg)	Fat (kg)	Viscera (kg)
Fawn	11	58	3.8	1.1	2.2
Juvenile	34	57	11.8	3.4	6.8
Young adult (female)	57	56	19.8	5.7	11.4
Young adult (male)	81	56	28.1	8.1	16.2
Average adult (female)	72	50	25.5	7.3	14.5
Average adult (male)	110	50	38.2	10.9	21.8
Old adult (female)	84	39	29.2	8.4	16.8
Old adult (male)	153	39	53.1	15.3	30.6

Arctic peoples compensated for the relative leanness of caribou meat by the way in which the animal was butchered, cooked, and prepared. The final preparation of food sections was strongly related to preference for body parts. These were (and are) fairly constant cross-culturally and were based on the amounts of meat in different parts of the carcass, particularly on fat concentrations and the reliability of those concentrations. In general, because of higher fat content, portions nearer the axial skeleton (ribs and vertebrae), including rib steaks and roasts, were highly desired. Also high on the preference list was the backstrap (backbone musculature), followed by front (brisket, short ribs) and back (pelvis) portions. Rear haunches were generally preferred to front shanks for the same reasons. Kidneys were also prized above other viscera because of higher fat content, followed by the heart and lungs. The most desirable smaller parts included those of the head, particularly the brain, the tongue, and the fat behind the eyes. Intestinal fat was also consumed (Spiess 1979).

If alternative resources were few, a variety of techniques were employed to maximize the nutritional yield from caribou carcasses. One was the smashing or cracking of the articular ends of long bones to obtain marrow, a high-fat, high-protein substance enjoyed by hunting peoples. Afterward, the marrow and bone fragments were sometimes boiled to produce "bone juice." Data from Eskimo informants suggest that marrow was cherished as a source of fat because of high concentrations of low-melting-point fats, particularly oleic acid (Binford 1978). Bones chosen first for marrow extraction were the tibia, the "cannon bones" (metacarpals and metatarsals), the radiocubitis, the femur, and the humerus (Binford 1978: 42). Less desirable as sources of marrow were the pelvis, phalanges, mandible, scapula, and ribs. Thin animals (including nursing females or rut-depleted males) were often avoided because starvation removes fat reserves from the bone marrow.

Both marrow and caribou back-fat have been key ingredients in the traditional dish akutuk, an excellent source of vitamins as well as protein and fat. This dish, colloquially known as "Eskimo ice cream," was prepared in the past by mixing caribou tallow with berries of various types and snow. Depending on the availability of other fats, fish, or sea mammals, oils might also have been added. Today, sugar has become another ingredient in the mix.

A second major nutritional resource obtained by carcass reduction was caribou "bone grease," that is, fats obtained from bone tissue itself (Leechman 1951). These were rendered by first smashing bones into small fragments, then simmering them in a pot of water and skimming off the fat. If not consumed immediately, the fat was generally stored in a cleaned caribou stomach. The best bone grease, referred to as "white" bone grease by Eskimo informants (Binford 1978), was rendered from long bones, whereas the axial skeleton, mandible, sternum, and pelvis were used to produce a less desired "yellow grease." Obtaining both marrow and bone grease could also have been part of the same procedure that employed long bones for tool manufacture (Yesner and Bonnichsen 1979). Carcass reduction for marrow and bone grease most likely took place at times of the year when caribou were scarce and/or stored resources were depleted, particularly in the late winter and early spring.

A final resource that could sometimes be obtained from caribou or reindeer were the stomach contents, that is, fermented plants of various sorts, including lichens. Although these plants cannot be readily digested by humans because of their high cellulose content, they are edible if fermented in the caribou rumen. As such, they can be an excellent source of ascorbic acid (vitamin C), otherwise obtainable only from berries (fresh, frozen, or preserved in fish or sea-mammal oils) or raw meat.

Food Storage and "Social Storage"

Many groups stored their caribou meat. Variables affecting storage included the quantity of meat to be butchered or transported and the ambient temperature at the time of the kill and afterward. There were two basic practices: the caching of unbutchered or roughly butchered meat sections and storage following butchering of the animals. Caching was likely to occur when large numbers of caribou were killed at one time and the carcasses could not be consumed or transported immediately. This generally took place in late fall or winter, and landmarks were left behind so that the meat could be recovered even if the caches were covered by snow. Meat sections were recovered when the area was revisited during an annual round, whereupon secondary butchering would take place. Unbutchered, cached meat sections were sometimes fed to the dogs, particularly during the winter.

In situations where butchering preceded storage, the hunters employed drying and also (when possible) freezing. Specific butchery methods depended on storage techniques. Drying methods utilized drying racks (Figure II.G.4.2), whereas frozen storage required deep ice cellars, often delved out of the permafrost, that could only be used during winter or spring.

Widespread food sharing was also a technique that helped to maximize both the nutrition obtained from the caribou and the survivability of the caribou-hunting group. In groups using mass killing techniques, the individuals in charge of the hunt often acted as decision makers regarding the division of the meat. Sharing beyond the nuclear family was less likely during periods of relative abundance, but at other times of year (when individual hunting took place) food sharing was ubiquitous. It was widely recognized by various caribou-hunting groups that men differed significantly in their hunting abilities (or luck), and kills were shared with all other members of the group. In such cases, the successful hunter was often in charge of meat distribution.

Finally, trade was a mechanism by which caribou hunters obtained other foods. Among the Nunamiut of northern Alaska and the Tareumiut peoples on the North Alaskan coast, for example, long-distance trading partnerships were developed. During annual ses-

sions, frequently held during summer months, caribou hides were traded for dried fish, seal meat, and fish and sea-mammal oils. Similar patterns evolved in Scandinavia and Russia.

The Domestication of Reindeer

The domestication of reindeer marked a considerable departure from previous dependence on wild reindeer (caribou). Although human manipulation of caribou populations is thousands of years old, true domestication of reindeer began no more than 400 to 500 years ago in northern Scandinavia and Siberia (Anderson 1958; Vorren and Manker 1962; Levin and Potapov 1964). O. Magnus (1555) is probably the earliest historical source referring to reindeer domestication by Saami (Lapps). However, there is some archaeological evidence from medieval Scandinavia to suggest that this transition may have taken place as early as the beginning of the fifteenth century (Simonsen 1972; Hambleton and Rowly-Conwy 1997). Historical sources suggest that reindeer domestication began with the expansion of peoples from the south into the territory of these northern peoples, including Norse populations in Scandinavia and Evenks (Tungus) in Siberia. These expansions were probably coincident with a climatic optimum in the sixteenth century. The result was removal of reindeer habitat, increased density of northern peoples, and overhunting of reindeer populations, in part resulting from the introduction of firearms. Domestication apparently occurred in order to provide northern groups with a reliable source of food in the face of the decline of reindeer populations. Unlike other northern groups, the Saami regularly milked their reindeer, producing a kind of cheese (Magnus 1555; Utsi 1948). By the seventeenth century, Saami peoples were regularly trading reindeer hides for grain, salt, metal objects, cloth, and alcohol (Schefferus 1674). In part, this trading was to pay for the taxation of reindeer herds imposed by Norse authorities.

Historical sources also indicate that initially the domestication of reindeer (and their herding and use as draft animals) was undertaken as an aid to hunting before it became a sustainable livelihood. Also, in some areas, such as parts of northern Siberia, reindeer herding remained a hunting aid and/or source of reserve food into the twentieth century. Later, more closely supervised and intensive herding took place, beginning no more than 200 years ago. Such herding involved draft reindeer for carrying loads and for riding. As with wild reindeer hunting, domesticated reindeer herding has involved the use of a wide variety of techniques for corralling and killing animals, including, as already mentioned, the use of rifles since the late nineteenth century. At the same time, like cattle herding, it has also involved the use of a wide variety of techniques for breaking animals and for indicating ownership (for example, ear notching).

The necessity for continuous human contact in herding, caring for, and driving reindeer populations created an ever increasing dependence of humans on the animals. This, in turn, necessitated greater reindeer-herding specialization, a more sedentary lifestyle, and, in some cases, a discontinuance of customary transhumant movements into coastal or riverine zones for fishing and/or sea-mammal hunting. The result was the differentiation in Scandinavia between the so-called Mountain Lapps or Reindeer Lapps (focused on reindeer herding), the Forest Lapps, and the Coast Lapps or Fisher Lapps. In Siberia, a similar process can be seen in the evolution of the "Reindeer Chukchi." Development of discrete groups of herders also took place, with differences in reindeer paraphernalia identifying such groups. Problems have also developed in mating or interaction between domesticated reindeer herds and wild reindeer populations, necessitating special efforts to separate these groups.

Reindeer Husbandry in the Twentieth Century

In northwestern Alaska, reindeer herding began in the 1920s with the noted Protestant minister Sheldon Jackson, who introduced the animals into the area (Scheffer 1951; Stern et al. 1980). Jackson believed that reindeer would help to augment the diet of the Bering Strait Inupiat (Northern Eskimo) people, some of whose other resources, especially large baleen whales, had been depleted by the ingress of other populations since the mid-nineteenth century. Jackson brought in Saami (Lapp) herders to help the Alaskan natives learn about reindeer (Vorren 1994). Although the herds depleted some habitats and caused disruption of traditional settlement patterns and lifestyles, reindeer herding continues today in that part of Alaska, where it is a successful enterprise managed by the Northwest Alaska Native Association (NANA).

In the former Soviet Union, large cooperatives, equivalent to communal farms, were established for the marketing and distribution of reindeer meat. Thus, much of the meat was not consumed by local peoples but by others in the region. Payments for reindeer meat were handled by local officials, assisted by Communist Party advisory groups. Such practices have been terminated with the fall of the Soviet Union.

In the latter part of the twentieth century, more extensive and larger-scale reindeer husbandry or ranching has been developed in a number of places, including Alaska, northwestern Canada, western Greenland, and Siberia (Strickon 1965; Sturdy 1972; Ingold 1980). This development has everywhere required the use of modern mechanized equipment, including trucks, airplanes, and particularly snowmobiles (Pelto 1973; Beach 1981; Paine 1994). There have been problems in adapting mechanized systems to reindeer herding because of the traditional skittishness of the animals. Such systems have also continued to transform traditional settlement patterns and lifestyles. The marketing and sale of meat has been initiated in a number of locales, particularly in Scandinavia, Greenland, and Russia. The sale of reindeer meat is more restricted in Canada and Alaska; in the latter region, however, it is a key ingredient in "reindeer sausage," which is widely marketed. The meat is frequently leaner and milder in flavor than that of wild caribou and is preferred by many non-native consumers for that reason. A key reason for the present-day maintenance of reindeer herds in a number of places, including Alaska and Russia, is the strong demand for – and purchase of – reindeer antlers in East Asia. There, the antlers, alleged to possess the properties of a stimulant and an aphrodisiac, are ground to a pharmaceutical powder and retailed to the public.

Table II.G.4.2 *Age distribution of caribou from an Alaskan archaeological site*

Age	Number of individuals
0–12 months (0–1 yr)	14
12–24 months (1–2 yr)	10
24–36 months (2–3 yr)	9
36–48 months (3–4 yr)	27
48–60 months (4–5 yr)	10
60–72 months (5–6 yr)	6
72–96 months (6–8 yr)	8
96–120 months (8–10 yr)	1
120–156 months (10-13 yr)	3
156–180 months (13–15 yr)	5
180–204 months (15–17 yr)	1
204+ months (17+ yr)	1
	N = 87

Survival of a Subsistence Based on Caribou/Reindeer

Both herding and hunting of reindeer have continued to provide meat for indigenous peoples throughout the northern circumpolar region and have proven to be important local sources of human nutrition. To a lesser extent, caribou or wild reindeer are also an important resource for non-native peoples who hunt them and consume their meat. Thus, in Alaska, special permits are required for non-native caribou hunting, and preference is given to those who can demonstrate past reliance on this meat to feed their families. The use of caribou and reindeer is governed by local and national laws. In addition, international treaties, such as that between the United States and Canada, govern the management and exploitation of caribou herds that cross national boundaries. In Scandinavia, such treaties have ensured the movement of traditional Saami herds and herders across the northern part of the region.

Unfortunately, there are a number of threats to the continued use and consumption of caribou and reindeer meat by northern peoples. Habitat disruption has probably had the greatest effect on both wild and domestic reindeer. For example, even in those areas where traditional caribou hunting persists, there is a significant difference between the hunting patterns of the past and those of today. Illustrative is Alaskan archaeological data, which demonstrates that traditional peoples hunted caribou as much as 15 or more years old, but animals of this age are rarely seen in wild populations today (Yesner 1980) (see Table II.G.4.2).

Significant alterations of caribou and reindeer habitats are the result of a number of factors: the increased movement of non-native peoples into arctic regions; the development of oil, mining, and other industries in the Arctic (particularly in Alaska and Russia); and the construction of large hydroelectric projects (particularly in Canada and Scandinavia). The latter has had a particularly strong impact by flooding large areas of the traditional caribou range. In addition, air pollution, particularly that resulting from the Chernobyl reactor accident in the former Soviet Union, has affected the caribou. It is too early to determine the long-term consequences for the subsistence of northern peoples, particularly in Scandinavia and Russia, but reindeer meat will probably continue to be important in these regions for some time. In Alaska and Canada, although some herds have been reduced, others still number in the hundreds of thousands. It is to be hoped that reindeer and caribou will continue to be significant dietary resources well into the twenty-first century.

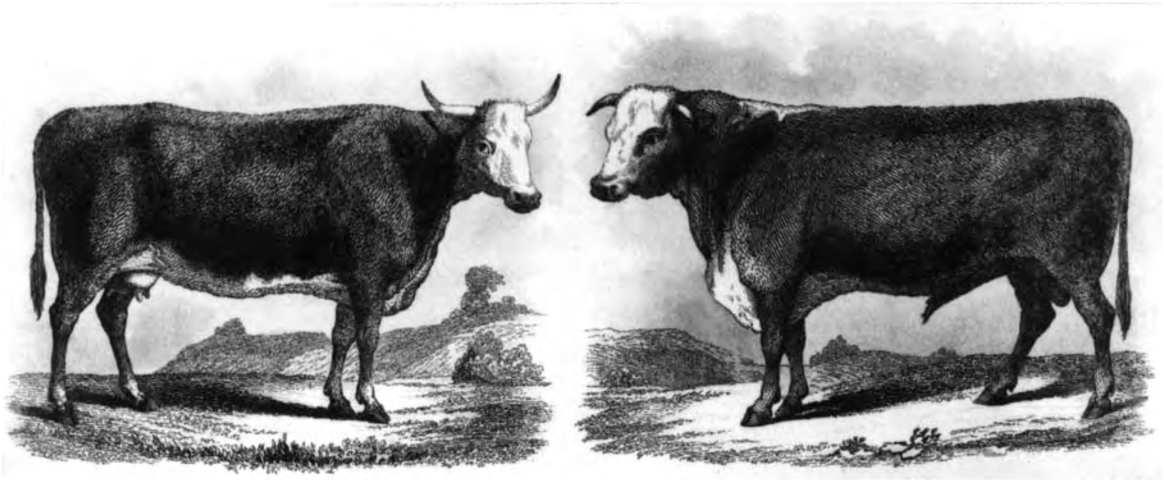
II.G.5 ~ Cattle

Although cattle have been domesticated for less than 10,000 years, they are the world's most important animals, as judged by their multiple contributions of draft power, meat, milk, hides, and dung. In Asia and Africa, the tie between man and beast is much more than economic (as it is in the West), and domestication itself seems to have occurred for noneconomic reasons. Cattle, like other ruminants, convert cellulose-rich materials



Cattle

– that are otherwise useless to humans as food – into carbohydrates, fats, and proteins. (In industrialized countries, however, cattle are fed grains from cultivated land and consequently can be viewed as competing for foods that could go directly to humans.)

The term "cattle" can have a broad or narrow meaning. One usage subsumes all five domesticated species in the genus *Bos* as cattle. The other restricts the term to only the two main bovines in this genus: European cattle *(Bos taurus)* and zebu cattle *(Bos indicus).* Both animals were derived from the same wild ancestor, the aurochs *(Bos primigenius),* and they can interbreed to produce fertile offspring. Three much more localized Asian species sometimes fall under the rubric of domesticated cattle: mithan *(Bos frontalis,* yak *(Bos grunniens),* and banteng *(Bos javanicus).* The mithan is found in a forested region that encompasses northeast India, northwest Burma, and Bhutan. Its ancestor is the wild gaur *(Bos gaurus).* The yak of Nepal and Tibet was derived from the wild yak *(Bos mutus),* whereas the banteng ("Bali cattle"), found on several islands of the Indonesian archipelago, was domesticated from the wild banteng of the same species. Unless otherwise qualified, the term "cattle" in this chapter refers to the two main species derived from the aurochs.

Domestication

Evidence for the domestication of cattle dates from between 8,000 and 7,000 years ago in southwestern Asia. Such dating suggests that cattle were not domesticated until cereal domestication had taken place, whereas sheep and goats entered the barnyard of humans with the beginning of agriculture. Although the aurochs has been extinct since the seventeenth century, its role as the wild ancestor of cattle has never been seriously disputed. This impressive beast occurred throughout Eurasia south of the taiga and north of the desert and tropical forest. Paleolithic cave paintings at Lascaux and Altamira in Europe convey a sense of its fierce nobility, which must have awed hunters. At Mesolithic sites in Eurasia, the relative paucity of aurochs bones compared to those of wild sheep – a difficult quarry – and goats suggests a major differential in hunting success.

That humans with primitive technology would have even attempted to tame such a ferocious animal becomes plausible only if one constructs a lure scenario. This setting would have the creation of artificial salt licks to entice the aurochs to a place where the opportunity might present itself to steal a calf from its mother. A young animal, of course, could have been captured and tamed much more easily than an adult.

It is probable that the aurochs underwent transformation into cattle more than once in the prehistory of the Old World. Mitochondrial DNA research indicates that zebu cattle of India were domesticated independently from European cattle and from a different subspecies of the aurochs (Loftus et al. 1994). The clustering of all African zebu within the *B. taurus* lineage is based on the assumption that a zebu ancestor crossbred with earlier *B. taurus* in Africa, and the zebu cattle themselves may have had more than one place of origin. A humped bovid on a Near Eastern figurine dates from the late Bronze Age and corresponds to a similar kind of animal found at Mehrgarh in Pakistan. At that site, both zebu and European cattle are found and together comprise more than 50 percent of the mammalian assemblage (Meadows 1984). Although their origins seem to have been outside the tropics, zebu are well adapted to hot climates, perhaps because much of their early husbandry was in India. Domestication may have enhanced the zebu's characteristic hump, dewlap, generally white color, and alert nature.

Early Neolithic cattle keeping in northern Africa points to a possible separate domestication there as well (Close and Wendorf 1992), and S. Bökönyi (1976) has gone so far as to assert that domestication of cattle from the wild happened repeatedly as late as the classical period of history. Indeed, the first-century-B.C. Roman poet Virgil stated that after a virulent disease had decimated the herds, peasants transformed the aurochs into a domesticated bovine to replace their previous stock. Discrete domestications may have occurred in several places, but the diffusion of domesticated cattle would have been a much more important overall process than repeatedly transforming a ferocious creature over many generations.

As with sheep and goats, the process of domesticating cattle resulted in animals smaller than the wild progenitor. Dated osteological material from Neolithic sites establishes the transition from wild to domesticated, although the sexual dimorphism between the male and female aurochs was not originally appreciated, and the "wild" label was misapplied to the former and "domesticated" to the latter (Grigson 1969). The Fertile Crescent has long been considered the place of initial cattle domestication, but that view tends to reflect the large number of excavations made there. Early signs of Neolithic cattle keeping have also been found in Anatolia (Turkey), where the osteological material at Catal Hüyük provides evidence of the transition from the aurochs of 8,400 years ago to cattle by 7,800 years ago. In short, it is still premature to specify where the first cattle were domesticated.

The extraordinary usefulness of cattle would superficially seem to have been the motivation for their domestication. In other words, given all the benefits that cattle impart, it was logical that the aurochs would come under human control, which is an extension of a deeply rooted Western concept that nature exists to serve the practical needs of people and that necessity has always elicited human ingenuity to provide technical solutions.

However, an alternative to such a materialistic perspective was first proposed by Eduard Hahn (1896), a German geographer-ethnologist. Hahn probed beneath the shallow surface of materialistic motives to see noneconomic forces at work in transforming the animal into what is essentially an artifact of artificial selection. He noted that the curved horns of the aurochs resembled the lunar crescent, which symbolized the Moon Goddess, and suggested that the original reason for domestication was to sacrifice these animals as a reenactment of the goddess's death, with such sacrifices perhaps performed at each waning of the moon.

Such a practice would have required a supply of animals that was initially met by capturing them from the wild. But in the holding pens, some captive bulls and cows (both with long horns) bred, and from these matings, calves occasionally were born that had physical characteristics different from their parents. Their overall size was smaller, their temperament more docile, and their markings and hide color had unusual variations. Viewed as special, these aurochs born in captivity were also kept as objects of sacrifice but were allowed to breed, and phenotypic distinctiveness enhanced their sacred status.

Some of the next generation to follow may have reinforced the characteristics of the parents, and a gene pool that distinguished these bovines from their wild forebears gradually formed. No longer were they aurochs, but rather cattle, whose sacred roles included pulling ceremonial wagons in religious processions and symbolically plowing the land in fertility rites. Their milk was perceived to be a ritual gift from the goddess, and the most docile cows let themselves be milked by a priest in the presence of their calves. Gradually, the economic usefulness of cattle asserted itself for plowing fields, pulling wagons, and for the meat, milk, and hides, which came to be highly prized. But these were later and secondary benefits of bovine manipulation that initially was prompted by the early mythology of Near Eastern religion. The Eurasian religion of the Upper Paleolithic was supplanted by goddess cults that evolved with the emergence of agriculture and livestock husbandry into fertility cults meant to ensure the prosperity of crops and herds (Isaac 1970).

Evidence for the prehistoric importance of cattle in ritual and the noneconomic motives for domestication comes from Catal Hüyük, a Neolithic archaeological site 50 kilometers south of Konya, Turkey (Mellaart 1967). Many shrines at this reconstructed site, including the earliest one found, have bulls' heads, and an abundance of cattle horn displays suggests that they were venerated as fertility symbols. In another kind of representation, a goddess is shown as having given birth to a bull. Moving to modern times, the previously mentioned mithan (or "Indian bison," as it is sometimes called) is a domesticated animal, but it is not used for draft, meat, or milk. Rather, it is kept as an object of ritual and sacrifice, providing a contemporary example of domestication for noneconomic reasons (Simoons and Simoons 1968). Mithans – periodically killed in ritual sacrifices – occur across a continuum varying from very tame to untamed forest-dwelling animals, and salt, for which they have an insatiable craving, is the enticement that humans employ to attract them.

Early Civilizations

In Mesopotamia, Egypt, and the Indus Valley, cattle served humans as objects of ritual and sources of meat, milk, and draft power, and in all three civilizations, they were the objects of much more intensive human attention than were sheep or goats. Draft animals were indispensable for working irrigated plots in desert and semiarid regions. Cattle required water and grass and needed considerable care. Using cattle for meat seems to have been less important than for draft. During the third Ur dynasty (2112–2004 B.C.), cattle products supplied only 10 percent of total meat needs (Adams 1981). In Mesopotamia, state authority was involved in the organization of cattle keeping, and cattle were called by different terms depending on their function (Zeder 1991).

Ritual use of cattle has been a Eurasian continuity. In ancient Egypt, cattle were regarded as sacred by several cults, particularly that of the goddess Isis, and in Crete, friezes more than 4,000 years old display evidence of bovine importance. At the palace of Minos, for example, the royal couple dressed up as a bull and a cow, and the Minoans also watched specially trained athletes who jousted bulls with acrobatic daring. The Phoenician cult of Baal had a god of fertility represented as a bull – a cult which spread to their colonies as far west as present-day Spain. The early Hebrews worshiped the bull, and in Canaan, the Baal cult was fused with the worship of Yahweh. During King Solomon's reign, the temple housed bulls of bronze and horned sculptures.

In classical antiquity, there is a rich history of bulls offered in ritual sacrifice. Some of these rituals in Greece provided a mechanism to reaffirm the social hierarchy of the polis. Sacred cattle were kept at Eleusis where Demeter was worshiped. In ancient Rome, a white bull was sacrificed at the annual *Feriae Latinae,* and its meat was distributed in proportion to the relative importance of the member cities of the Latin League. In Europe and the Middle East, Judaism, Christianity, and Islam all suppressed such sacred cattle cults as pagan manifestations that competed with their messages, although a lingering remnant is the contemporary Spanish bullfight, which reenacts a sacrifice to symbolize the eternal struggle between humans and nature. In its evolution, bullfighting lost its obvious religious content, which may explain its survival through 2,000 years of Christianity.

Europe

The westward diffusion of cattle throughout Europe was tied to the invention of the wooden plow. The harnessing of a powerful animal to that device made it possible to greatly extend cultivation without a corresponding increase in human population. At the same time, in any one community it freed surplus labor for other activities, which enabled the group to develop greater socioeconomic complexity. Castration of the bull to create an ox was a key element in the spread of the plow. Steady and strong – but docile – the ox made enormous contributions to agriculture. Osteometric evidence shows that oxen were already in use during the fourth millennium B.C., and a figure from Nemea in Greece shows yoked oxen dating from the third millennium B.C. (Pullen 1992).

Farther north in Europe, where wet summers provided abundant forage, cattle had a bigger role to play in livestock husbandry. Following the Middle Ages, an appetite for beef grew, and, in fact, the Europeans' frenetic quest for spices was related to their growing carnivorous tastes. Until the late eighteenth century, cattle were the most important livestock in the uplands of the British Isles, where they grazed mainly on commonly owned natural pastures and secondarily were fed hay cut and stored for winter use. Other animals – sheep, pigs, goats, and horses – were made a part of a land-use system that also favored dairying and the cultivation of grains.

The relative isolation of each region resulted in locally limited gene pools for *B. taurus,* which led to different cattle phenotypes. Three of these, Aberdeen Angus, Shorthorn, and Hereford, have diffused overseas to become modern ranching stock in the Americas; other breeds, such as Devon, Skye, Galloway, Kerry, and Durham, are now rare. Characteristic of British livestock tradition was the close management and selective breeding that imparted a generally docile behavior to the animal. Fat cattle were the aesthetic ideal but also a practical outcome of the high value placed on tallow. Emphasis on pure bloodlines reflected, in part, competition among the landed gentry to produce the best animals, and, in fact, purebred cattle became a symbol of the British ruling class that dominated the world in the nineteenth century. Moreover, that class extended its insistence on purity to its own members as a way of separating the rulers from the ruled in the vast British Empire.

Africa

African bovines kept by humans are usually presumed to have originated as domesticated animals in southwestern Asia, with cattle funneled into Africa through the Sinai Peninsula and, possibly, the Straits of Bab-el Mandeb across the Red Sea, eventually spreading over vast areas of the continent. There is, however, an alternative explanation anchored in the possibility of an independent domestication of cattle in Africa. Evidence that this may have been the case has been found in the northern Sahara, in Algeria, where cave paintings dating from 5,000 to 6,000 years ago indicate a pastoral way of life based on domesticated cattle (Simoons 1971). More recently, an argument has been made for independent cattle domestication in the eastern Sahara as well (Close and Wendorf 1992). Bovid bones found in faunal assemblages have been interpreted to be the remains of domesticated stock kept for milk and blood. Deep wells, dated from the ninth millennium B.C., provided the water without which these cattle could not have survived.

In Africa, more than on any other continent, cattle raising follows a paleotechnic, precapitalistic mode that depends on the natural vegetation of common lands. The transcendental importance of cattle is most apparent in the sub-Saharan eastern half of the continent, where more than 80 million head may be found in an arc across Sudan, Ethiopia, Uganda, Kenya, and Tanzania. Numbers would be much higher than that if nagana disease (spread by tsetse flies) did not make large areas unsuitable for cattle. The ethnographic significance of this geographic concentration was realized only after Melville Herskovits (1926) published his landmark study on the "cattle complex" in East Africa. Subsequent research among different tribal groups – the Karamajong, Nandi, Dodot, Masai, Pakot, and Turkana, among others – validated his contentions of the centrality of cattle in East African life.

Some groups are strongly pastoralist, others may also engage in agriculture. In either case, cattle, whose prestige value surpasses their economic contribution, dominate the pastoral life as well as the social and spiritual activities of each group. Every animal is named and categorized: Among the Masai, for example, each individual animal can be classified according to its matriarchal bovine lineage, a spatial pattern organized by households, and a color/age/sex physical description. A major reason for the naming of cattle in East Africa is that it manifests the affection felt toward bovines as members of the family.

Native religion in East Africa involves cattle sacrifice. Bruce Lincoln (1981) has explained this practice in terms of a "cattle cycle," in which a celestial deity gave cattle to his people. When these animals were stolen by an enemy group (less common today), warriors were enlisted to recover the stolen cattle. The cycle was completed when priests subsequently sacrificed some of the cattle in order to propitiate the celestial deity.

A textbook example of how central cattle can be to the material and social existence of a people can be seen in the Nuer people of the Sudan (Cranstone 1969). Their language is rich in terms that describe and categorize cattle by horn shape, hide color, and age. Milk is a staple food, along with millet, and cattle blood is consumed. Rawhide provides tongs, drums, shields, and bedding, and cattle bones become scrapers, pounders, and beaters. The horns are used to make spoons and spearheads. Cattle dung can be a fuel, but it is also employed in plastering walls, dressing wounds, and, when dried, as a tooth powder. Cow urine is used in washing, cheese making, and dressing skins. The meat and fat of cattle are eaten, but the ritual involved in the slaughter is as important as the food.

Fewer cattle are kept in West Africa than in East Africa, in part because it embraces more desert and forest. The relative importance of cattle varies from tribe to tribe. For example, a dearth of grass and water in the southern Sahara encourages the Tuareg to herd many more goats than cattle, but farther south in the Sahel zone, the Fulani (or Peul) people have become cattle specialists with a spiritual link to their bovines. Each nuclear family owns a herd and knows each animal by name. The Fulani have solved the problem of forage through a symbiosis with their agricultural neighbors to the south. In the dry season, they move their herds south to graze on the stubble of harvested fields. In recompense, the cattle leave manure as fertilizer. Like the tribal peoples of East Africa, the Fulani measure prestige in terms of numbers of animals. They use common pastures, but overstocking has led to range deterioration. One solution for this problem would be the introduction of a commercial system to regularly market young cattle.

India

India has about 200 million head of cattle, more than any other country. Cattle are of great importance as draft animals and as a source of dairy products (milk, curds, ghee), which constitute a significant element of the Indian diet. Cow dung has multiple uses as fuel, fertilizer, and as a ritualistic medium; even cow urine has its sacred applications. The Hindu religion bans the exploitation of cattle for meat and for hides, and to deliberately kill a cow is considered a serious offense in a country whose politicians are committed to protecting the animals. Veneration of cattle is also reflected in the institutions elaborated to protect old cows (Lodrick 1981). At the same time, compliance has its exceptions. Certain tribal groups and some lower-caste Hindus do slaughter cattle and eat their meat.

The cow has elicited much controversy in Hinduism about its origins, for its elevation to sacred status came only after Hinduism was established. One view is that the sacredness of cattle reflects the concept of the sanctity of life *(ahimsa)* that reached Hinduism through Buddhism (Simoons 1994). Opposing this idealistic perspective is the materialist argument that cow protection was ultimately imposed to assure an ongoing pool of plow animals, without which Indian agriculture could not effectively function (Harris 1966).

The New World

Latin America

Cattle began reaching the Western Hemisphere with the second voyage of Christopher Columbus in 1494, when a few head were landed on the island of Hispaniola. They multiplied rapidly – at the same time becoming feral – and eventually were more hunted than herded. Pirates, for example, organized roundups when they wanted fresh meat. From Hispaniola, cattle were taken to other islands and to the mainlands of Central, North, and South America.

In Latin America, cattle raising became an important use of land, especially in the sparsely populated *cerrado* of Brazil, the pampas of Argentina, and the llanos of Venezuela and Colombia. The business was organized in an extensive manner, with fenceless expanses, semiferal animals, mounted cowboys, and low productivity – a system that still prevails over large areas from Mexico to northern Argentina, although the zebu now tends to be more numerous than European cattle. Since the 1970s, cattle ranching has been responsible for most tropical deforestation, especially in Amazonia and Central America, where aggressively spreading grasses of African origin, among them *Panicum, Hyparrhenia,* and *Pennisetum,* have become the forage for millions of cattle. This herbaceous invasion has been termed the "Africanization of the New World tropics," and the expansion of ranching into these areas has been called the "scourge of cows" (Parsons 1970, 1988). Moreover, cattle raising as a "complex" of economic, nutritional, and social factors, and the effects of this complex on the environment and human health, has been denounced as "a new kind of malevolent force in the world" (Rifkin 1992). But from the point of view of their owners, cattle are "walking bank accounts," which become fat on grasses that grow without planting or care.

After the middle of the nineteenth century, cattle ranching moved toward an intensive British style of management on the pampas of Argentina and Uruguay. Throughout the colonial period and beyond, cattle had been raised to make dried and salted beef *(tasajo)* and for hides and tallow. But the nineteenth-century invention of evaporating beef broth to make bouillon cubes provided a new export product to stimulate cattle production, and around 1860, the pampas began to be transformed. The arrival of the Shorthorn, Aberdeen Angus, and Hereford breeds; the introduction of barbed wire fencing; the cultivation of alfalfa; the use of eolian windmills to provide pumped water; and the invention and installation of refrigerated chambers on ships – all set the conditions for the export of high-quality chilled meat to Europe. Since the 1880s, beef exports have underwritten the economies of Uruguay and Argentina.

North America

North American cattle raising has its roots in two very different ranching traditions (Jordan 1993). One came from Andalusia in Spain, specifically from the Guadalquivir marshes, where bovines grazed year-round and were tended by mounted cowboys who used lassos. Transferred from Spain to the Caribbean Islands, this style of ranching was taken to the Carolinas, to the Louisiana coastal plain, and to the Mexican east coast. From Mexico, it diffused northward to southern Texas, with longhorn cattle belonging to the same breed still raised along the Guadalquivir today. Elsewhere in North America, where cold winters intervened, pastoral practices were influenced by those of the British Isles. Thus, the midwestern prairies had a cattle-raising complex that included British breeds of cattle and the use of haying, fencing, barns, and intensive herd management to create docile animals.

Most cattle in North America are "finished off" on grain in feed lots; indeed, more than 70 percent of the grain produced in the United States is fed to cattle and other livestock. A slaughtered steer yields about 60 percent of its weight in beef products, some of which is used as pet food, but most is for human consumption. The remaining 40 percent consists of fat, bones, viscera, and hide that go into a variety of industrial and household products. Cattle tend to be much leaner today than they were a century ago. Demand for low-cholesterol meat, and the use of petroleum-based detergents rather than soaps made from tallow, have greatly reduced the market for both fatty beef and beef fat.

A growing application of animal-raising technologies can be expected to increase the efficiency of cattle raising in the United States and other industrialized countries. Artificial insemination was a common practice by the 1950s, and more recent reproductive techniques include embryo transfer, estrous cycle regulation, embryo splitting, in vitro fertilization, sperm sexing, and cloning. Other techniques promote growth: Anabolic steroids have been used on beef cattle since 1954, and fully 90 percent of feedlot cattle in the United States receive these drugs. In the European Union, steroids are still banned, which has complicated the export of American beef into that large market. For dairy cattle, bovine somatotropin, a protein hormone, increases milk production by about 12 percent. Other technologies relate to processing and marketing. Irradiation of meat kills microorganisms and extends shelf life, and the extraction of water from milk to reduce transportation costs will greatly increase the milkshed range of cities.

Consumption of Bovine Flesh

Except in the few cultures that shun beef as food, bovine flesh has often been regarded as the ultimate measure of a good diet. As Europe regained its prosperity in the three decades after World War II, per capita consumption of beef increased several times. Now, more than 40 percent of all the meat produced in Western Europe is beef. Consumers in some European countries – especially Italy, France, and Austria – are exceptionally fond of veal, which is very young bovine flesh.

In Europe, veal typically comes from calves less than 6 months old that are fed on whole milk or on a formula that includes milk products. Close to half of the bovines slaughtered in France are calves, which yield veal that normally retails for 20 percent more than beef. Veal, tender and subtly flavorful, lends itself to imaginative sauces or accompaniments: Scallopini, osso buco, saltimbocca, and Wiener schnitzel are all well-known veal dishes. In Europe, calves also provide much of the most desirable organ meats: liver, sweetbreads, kidneys, brains, and tongue. In both France and Italy, veal consumption is about one-third that of beef – four times more veal, on a per capita basis, than is eaten in the United States, where beef has been the preferred meat since the nineteenth century.

Today, more than 40 percent of beef consumed in the United States is ground, mostly for hamburgers. The hamburger has become an icon of American popular culture, even though it is said to have originated in Hamburg, Germany. "Hamburger steak" was on Delmonico's menu as early as 1836, and there are numerous claimants for the invention of the hamburger sandwich, including a German immigrant said to have brought the idea to the United States in 1892. Certainly, it was the case that the hamburger began to be nationally known at the 1904 St. Louis World's Fair, where the sandwiches were sold by German immigrants (Trager 1995).

The hamburger – as a snack or a meal – fits into the American quest for efficiency. It cooks thoroughly in less than 8 minutes, and today, fast-food operators normally cook it even before the customer places an order. Hamburger restaurants appeared in American cities beginning in the 1920s, but their organization to maximize efficiency dates from four decades later. Giant franchise corporations with headquarters in the United States have now spread over a major part of the industrialized world. At an international level, these restaurants communicate American values of efficiency, service, and cleanliness, but for many, they also define the failure of the American culinary imagination.

The American middle class is also fond of steak, and well informed about the best cuts. Steak is a favorite restaurant choice, but it is frequently cooked at home as well, often on an outdoor grill. (In 1995, 77 percent of American households owned at least one such grill.) The United States Department of Agriculture (USDA) grading system for beef has its greatest application in steak. "Prime," with the most fat marbling, is the most flavorful, tender, and costly. Only 2 percent of all the beef produced in the country is of prime grade. "Choice" is the most widely sold grade, whereas "select" is leaner, cheaper, and not as tender. Several other countries in the world – notably Argentina – have a much higher per capita consumption of beef than the United States, but this statistic probably includes considerable amounts of organ meats. By contrast, bovine organ meat attracts few consumers in the United States.

In Japan, beef consumption is a relatively recent phenomenon. Meat eating was prohibited until shortly after the Meiji Restoration in 1882. Buddhist beliefs and Shinto influences had banned the killing and eating of four-legged animals, but fish and fowl were consumed, and the Japanese still obtain most of their protein from fish and soybeans. Sukiyaki – thinly sliced, highly marbled sirloin in soy sauce, accompanied by vegetables – has been the preferred beef dish. In the preparation of sukiyaki, the sight of blood, unacceptable in Japanese culture, was avoided. But after World War II, American influences and increasing prosperity introduced hamburger, beef chunks in curry sauce, and skewered beef, and most recently, steak has become accepted in Japan.

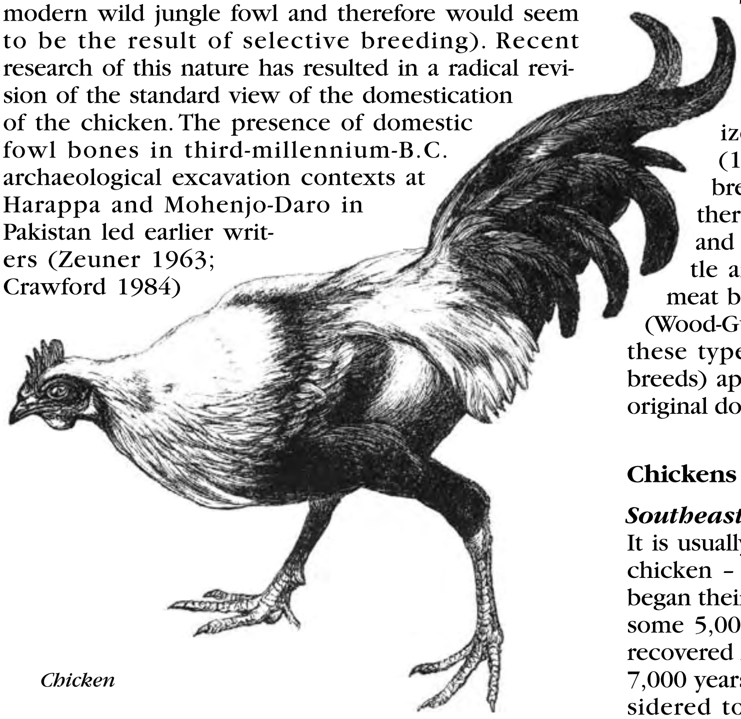
II.G.6 ~ Chickens

Origins

The chicken *(Gallus gallus* or *Gallus domesticus)* is generally considered to have evolved from the jungle fowl *(G. gallus),* which ranges throughout the area between eastern India and Java. Within the nomenclature, *G. domesticus* is normally used by scholars who believe in a polyphyletic origin for the domestic chicken (from *G. gallus, Gallus sonnerati,* and *Gallus lafayettei*), whereas *G. gallus* is used by those who support a unique origin from the various subspecies of wild *G. gallus.* Debates regarding the origin and spread of the domestic chicken focus both on its genetic basis and the "hearth area" of its initial domestication.

The osteological identification of domestic chickens has been made both on a contextual basis (i.e., the occurrence of *Gallus* bones outside of the birds' normal wild range) and on osteometric grounds (i.e., the occurrence of bones that are larger than those of modern wild jungle fowl and therefore would seem to be the result of selective breeding). Recent research of this nature has resulted in a radical revision of the standard view of the domestication of the chicken. The presence of domestic fowl bones in third-millennium-B.C. archaeological excavation contexts at Harappa and Mohenjo-Daro in Pakistan led earlier writers (Zeuner 1963; Crawford 1984) to assume that the chicken was first domesticated in this area. However, in 1988, B. West and B.-X. Zhou presented archaeological data showing domestic chickens to be present at China's Yangshao and Peiligan Neolithic sites, which dated from circa 6000 to 4000 B.C. As a consequence, because wild forms of *Gallus* are entirely absent in China, and as the climate would have been inimical to them in the early Holocene, it seems likely that chickens were domesticated elsewhere at an even earlier date. In the absence of evidence from India, Southeast Asia (i.e., Thailand) has been put forward as a likely hearth area (West and Zhou 1988).



Chicken

Such a hypothesis seems to square nicely with some recent research on the genetic origins of chickens. In the past, a polyphyletic view often predominated because of the phenotypic diversity of modern chickens (Crawford 1984). But quite recently, A. Fumihito and colleagues (1994) have shown convincingly that all modern chicken genes can be derived from the subspecies of *Gallus* found in northeast Thailand. This demonstration provides a geographical origin for the chicken that harmonizes with the archaeological data and, at least for the moment, disposes of the argument for polygenesis.

Uses

Although chickens are strongly associated with egg production in European and neo-European cultures, elsewhere they have very different associations. In much of Southeast and East Asia they have been bred both for fighting and as decoration; in Japan, for example, there is little evidence for the exploitation of chickens as food until the nineteenth century. On the basis of the present locations of these specialized breeds, I. G. Moiseeva and colleagues (1996) have postulated three centers of breed origin, to which we would add two further categories for highly productive egg layers and meat–egg compromise breeds. Both Aristotle and Pliny referred to distinct fighting and meat breeds at the beginning of the Christian era (Wood-Gush 1959). However, the origin of most of these types (save the intermediate and egg-laying breeds) appears to have been near the zone of their original domestication.

Chickens and Geography

Southeast Asia and Oceania

It is usually conceded that the Austronesians had the chicken – along with the dog and pig – when they began their epic voyages of colonization in the Pacific some 5,000 or more years ago. Chickens have been recovered from Hemudu in Southeast China, dating to 7,000 years ago, and such settlements are usually considered to be ancestral to the main Austronesian expansion (Bellwood 1995). Although direct evidence is lacking for chickens in the Austronesian area until much later, linguistic evidence argues that the fowl traveled with the Austronesians (Zorc 1994).

Central Asia

The chicken has been well documented osteologically from the Harappan civilization of the Indus Valley, where it was introduced by 2500 B.C. (Zeuner 1963). However, in view of both archaeological and linguistic evidence, it appears that chickens did not spread through India but rather around it – heading northeastward from China and through central Asia north of the Himalayas (Nishi 1990; Moiseeva et al. 1996). The fowl was certainly introduced into Iran about this period; Zoroastrian literature makes extensive reference to its crowing at dawn (Wood-Gush 1959).

Linguistics can complement the results of archaeology in tracking the route of the chicken's diffusion. If words for chicken, cock, and chick are compiled for the Old World, some intriguing patterns emerge. There are two extremely widespread roots, ka(C)i and tax(V).[1] The latter is spread from Korea across central Asia to the Near East, North Africa, and south to Lake Chad. This suggests not only that the chicken diffused westward from China as far as central Africa, but that it did so after the principal language phyla were established, as the vernacular terms form a chain of loanwords.

Europe

The discovery of bones – collated by West and Zhou (1988) – in central Asia seems to indicate that the chicken had reached the borders of Europe by 3000 B.C. The earliest finds come from Romania, Turkey, and Greece, where there are at least eight late Neolithic and early Bronze Age sites from which bones have been dated to the third millennium B.C. These finds, contemporary with or slightly earlier than those of the Indus Valley, appear to demonstrate that the initial dispersion of the chicken from Southeast Asia effectively bypassed the Indian subcontinent. This conclusion would seem to be further borne out by "culturally dated" fourth-millennium-B.C. finds in the vicinity of Kiev (Ukraine) that were published in the 1950s, although a great deal of research remains to be done in the area.

The subsequent rate of dispersion of the chicken in Europe appears to have slowed substantially, with most early western and northern European bone discoveries dated to the middle to late first millennium B.C. Indeed, F. Hernandez-Carrasquilla (1992) has sounded a note of caution by refuting all pre–first-millennium-B.C. identifications from Spain as intrusions or errors in attribution and has once again credited the Phoenicians with the domestic fowl's introduction into Iberia.

Chicken domestication became well established in Europe during the Iron Age, and by the time of the Romans, superior breeding or animal husbandry strategies had resulted in substantial size increases in the domestic fowl (Thesing 1977). During the medieval period, the dietary importance of chickens increased relative to that of mammals, with chicken rearing in towns becoming increasingly common (Astill and Grant 1988; Benecke 1993). Unfortunately, chickens were often left to forage amid domestic waste, and less labor-intensive poultry-rearing techniques resulted in a general size reduction for domestic fowl (Thesing 1977), although birds bred in rural areas may have fared better. In Europe, there is little evidence for a great diversity of breeds until the late Middle Ages, or even later; in parts of the Netherlands and Poland, however, there is osteological evidence for both a small and a large breed of chicken in early medieval times (Benecke 1993).

Southwestern Asia and North Africa

In the Levant, there are only a few early chicken identifications, with the earliest finds, from Tell Sweyhat in northern Syria, dating to the late third millennium B.C. (Buitenhuis 1983). The bird does not appear to have been common further south until the first millennium B.C. (West and Zhou 1988). A seal found at Nimrud, dated to 800 B.C., shows a cock (Zeuner 1963). One of the uses of early chickens in this region is indicated by the seventh-century-B.C. representation of fighting cocks on seals and potsherds from Israel/Palestine (Taran 1975).

A much-reproduced painted limestone fragment from the tomb of Tutankhamen clearly illustrates a cock, and several other representations suggest the occasional presence of fowl as exotics in Egypt during the New Kingdom (1425–1123 B.C.) (Carter 1923; Darby, Ghalioungui, and Grivetti 1977, 1: 297 ff.; Crawford 1984). However, they then disappear from the graphic record until about 650 B.C., after which they are represented in abundance (Coltherd 1966). Osteologically, despite several early misattributions, the earliest chicken bones found in Egypt date only to the beginning of the Greco–Roman period (332 B.C. to A.D. 200) (MacDonald and Edwards 1993). It would thus appear likely that the chicken was at first imported into Egypt as an exotic menagerie and fighting bird and gained economic importance only during the late first millennium B.C. – in Ptolemaic times.

Sub-Saharan Africa

Although chickens are central to African culture throughout the continent, the morphology of local fowls remains undescribed, and the routes by which they entered the continent – as well as the dates when that took place – remain poorly known. Archaeologists have tended to favor a rather recent date (MacDonald 1992, 1995; MacDonald and Edwards 1993), whereas linguists have argued for much earlier dates, based on the degree of the embedding of words for chicken (Johnston 1886; Manessy 1972; Blench 1995; Williamson in press).

Osteological evidence of chickens in Africa has become increasingly abundant during the 1990s. The earliest known remains are from the middle of the first millennium A.D., with finds from Mali (MacDonald 1992), Nubia (MacDonald and Edwards 1993), the East African coast (Mudida and Horton 1996), and South Africa (Plug 1996) all dating to this period. No earlier remains are known as yet, and archaeozoologists hypothesize that chickens most likely entered Africa either via the Nile Valley or through an early Greco-Roman east-coast trade between about A.D. 100 and 500. A trans-Saharan introduction (at an earlier date via Phoenician Carthage), however, cannot be excluded.

The linguistic evidence rather strongly suggests multiple introductions: across the Sahara, via the Berbers, on the east coast, and, possibly, a separate introduction to Ethiopia via the Red Sea coast. In addition, early reports of chickens in Mozambique suggest black-feathered types, resembling those in India.

Because, in most cases, African chickens were left to find their own food and were allowed to mate at random, there are no significant African breeds (Kuit, Traore, and Wilson 1986; MacDonald 1992).

The New World

One of the most intriguing controversies in the history of chickens is the question of whether they were present in the New World in pre-European times. Both G. F. Carter (1971) and R. Langdon (1990) have argued strongly that they were, at least in parts of the West Coast. Linguistics (in the sense that chickens do not have names borrowed from European languages), morphology (the distinctive blue eggs of some New World breeds, otherwise known only from China), and the improbable speed of transmission inland that would be required by the assumption of a European introduction all suggest a pre-Columbian introduction from Asia (see also Carpenter 1985). Against this theory, however, is the fact that no undisputed early chicken bones have ever been found in a mainland site. Langdon (1990) has cited reports of blue-egg fowls on Easter Island, which he considers to strengthen evidence of trans-Pacific contact with the South American mainland.

Future Understanding

We know very little about past developments in five geographical areas that are crucial to understanding the domestication and subsequent spread of the domestic fowl: Thailand, Russia/Ukraine, the Indian subcontinent, Southwest Asia, and sub-Saharan Africa. It is crucial that specialized archaeozoologists examine temporally relevant avian skeletal materials from these zones and that they be well apprised of potentially confusing local wild taxa – especially birds such as guinea fowl, pheasants, and larger francolins – and the criteria for their differentiation (MacDonald 1992).

Complementary results can be obtained from more detailed genetic work on traditional chicken breeds using both DNA and phenotypic characters. Although the chicken is usually considered to be well known, compilations such as those by Ronan Loftus and Beate Scherf (1993) show that there are many poorly described breeds of chicken on the verge of extinction that are kept by traditional societies. A broader view of the origins and distribution of chicken breeds in the world should help us to understand more clearly their role in both subsistence and the interaction of human cultures.

Roger Blench and Kevin C. MacDonald

Note

1. The authors are grateful to Zev Handel and James Matisoff for providing unpublished documentation of chicken names in Sino-Tibetan languages.

II.G.7 Chicken Eggs

Hickety Pickety, my black hen
She lays eggs for gentlemen
Gentlemen come here every day
To see what my hen doth lay

Anonymous

History

Eggs from many species of fowl have doubtless been consumed since the very beginning of humankind's stay on earth. In historical times, ancient Romans ate peafowl eggs, and the Chinese were fond of pigeon eggs. Ostrich eggs have been eaten since the days of the Phoenicians, whereas quail eggs, as hard-cooked, shelf-stable, packaged products, are now featured on many gourmet food counters in the United States and Japan. Other eggs consumed by various ethnic groups include those from plovers, partridges, gulls, turkeys, pelicans, ducks, and geese. Turtle eggs have been highly prized, and in starvation situations, any eggs, even those of alligators, have been relied upon.

In this chapter, however, only avian eggs (and these mostly from the chicken) are discussed. Avian eggs in themselves constitute a huge subject: In 1949, A. L. Romanoff and A. J. Romanoff published a book in which they attempted to compile all the facts known, at the time, about the eggs of birds. It contained over 2,400 reference citations.

It is almost obligatory in writing about eggs to first deal with that age-old question: Which came first, the chicken or the egg? Those who believe in creationism rely on holy books, like the Bible, which specify that animals were created. Thus, the chicken came first. But, as Harold McGee has pointed out, the eggs of reptiles preceded by far the evolution of the first birds; consequently, "[e]ggs . . . are millions of years older than birds." He added that "*Gallus domesticus,* the chicken, more or less as we know it, is only 4 to 5 thousand years old, a latecomer even among the domesticated animals" (1984: 55).

McGee placed the ancestors of *Gallus domesticus* (as the Romans named it) in Southeast Asia or India.

Maguelonne Toussaint-Samat was a bit more specific in writing that the chicken is "a descendant of a bird from the Malaysian jungle" (1992: 351). Still others have designated Burma and quite recently Thailand as its homeland, and there has been an argument for multiple origins with as many as four different species of jungle fowl contributing to the modern chicken (Smith and Daniel 1982; Fumihito et al. 1994; Simoons 1994).

The chicken was not only a tardy arrival as a food animal; it may have been domesticated not for food purposes at all but rather because of a perceived need for an on-hand supply of birds for sacrifice and divination. Frederick Simoons (1994) pointed out that these have been traditional uses of the chicken in Southeast Asia and are still roles the bird is called upon to fill by many peoples of the region.

Another early, but nonfood, use for the chicken in Southeast Asia was the sport of cockfighting – a sport that to this day remains immensely popular there, despite thousands of years of opposition by religions such as Hinduism and Buddhism (Simoons 1994).

But cockfighting was not confined to Southeast Asia, and as interest in it spread, so did the chicken. Although there was mention of the bird in Egypt in the early fourteenth century B.C., there seems to be no subsequent mention of it for many centuries thereafter, prompting speculation that it may have disappeared after its initial introduction (Smith and Daniel 1982). The chicken, however, was also in Persia at an early date, and from there it (along with cockfighting) spread out into ancient Greece, where it joined ducks, geese, and guinea fowl in poultry yards around the fifth century B.C. (Toussaint-Samat 1992).

Although a few recipes from the Greeks indicate that eggs were used for baking, and the physicians who compiled the Hippocratic Corpus recommended lightly cooked eggs as the most nourishing way to prepare them, and Aristotle systematically opened eggs at different points in their incubation to describe what he saw, it is doubtful that egg production was, initially at least, a very important reason for maintaining the bird (Smith and Daniel 1982; Toussaint-Samat 1992).

In the Roman period, however, although cockfighting remained a primary reason for keeping chickens, eggs were finally beginning to catch on in the kitchen. The recipes of Apicius (25 B.C.) reveal custards, omelets, and eggs used in a variety of other dishes, as well as by themselves in hard-boiled form (McGee 1984; Touissant-Samat 1994). The Roman physician Galen, however, condemned fried eggs, saying they "have bad juice and corrupt even the foods mixed with them" (cited in Smith and Daniel 1982: 366).

Yet in other parts of the world at about this time, it would appear that egg consumption was avoided more often than not. In part this was because eggs (as well as chickens) were used for divination, in part because eggs were regarded as a filthy food (the product of the semen of a cock), in part because of food taboos (such as those that regulated the diets of pregnant women and their youngsters), and often because it was believed wasteful to eat the egg instead of waiting for the chicken.

China, however, constituted a very large exception to egg avoidance. Both chickens and eggs were important sources of animal protein, and the Chinese are said to have encouraged their use throughout the rest of East Asia. In Southeast Asia and in the Pacific Islands (where the chicken was distributed early on by Asian colonizers), as well as in China, a taste was developed for brooded eggs (with well-developed fetuses). In addition, the Chinese became partial to "100-year-old" eggs that tend to make Westerners gag. But despite the name, the eggs are buried for only a few months in a mixture of saltpeter, clay, tea leaves, and other materials that cause the shells to turn black. The interiors of such eggs take on a "hard-boiled" appearance with green veins running through them (Toussaint-Samat 1992; Simoons 1994).

Moving from the East back to the West after the fall of Rome, darkness descended on both Europe and the chicken, and little is known about the use of eggs on the Continent until the sixteenth century. In the meantime, the Iberians had discovered the New World, triggering many debates for scholars – among them the question of whether chickens were on hand in the Americas when Columbus first arrived in 1492. The answer seems to be no, at least as far as the West Indies (where the Spaniards introduced them) are concerned, but may very possibly be yes, as far as South America is concerned. There, the native people had names of their own for a kind of chicken – and the only one in the world that lays blue and green eggs (Smith and Daniel 1982). Page Smith and Charles Daniel have speculated that this South American *araucana* was not an "indigenous chicken" but instead the product of a union of American grouse with Asian chickens that reached South America with earlier, unrecorded voyagers (1982: 31), most likely Pacific Islanders.

European literature is not completely silent on eggs prior to the Renaissance; we are warned in *Don Quixote de la Mancha* (by Miguel de Cervantes [1547–1616]) not to put them all in one basket, and Francis Bacon (1561–1626) commented on those who would burn their houses down just to roast an egg. Throughout the preceding Middle Ages, however, eggs were mostly mentioned in nursery rhymes. In large part, one suspects that this considerable silence was because eggs were classified as meat by the Church; what with Fridays, Lent, and numerous other days when meat was proscribed, eggs were off the menu about half of the days of the year. As a consequence, most eggs were either used for hatching or were saved to be eaten at Easter. To keep them from spoiling, they were dipped in either liquid fat or wax and then decorated to make them more attractive – hence the custom of "Easter eggs" (Toussaint-Samat 1992).

Although some French and English recipe books from the late fourteenth century contain directions for making custards, omelets, and baked eggs (McGee 1984), Smith and Daniel (1982) suggest that the renaissance of the chicken came only in the sixteenth century with the work of Ulisse Aldrovandi (1522–1605), an Italian who wrote nine volumes on animals, including one on chickens. It was the dawn of a new age of science, and as Aristotle had done some 1,800 years earlier, Aldrovandi systematically examined the egg while at the same time adroitly dodging "that trite and thus otiose . . . question, whether the hen exists before the egg or vice versa" (quoted in Smith and Daniel 1982: 45). It might have been a new age of science, but the Church still had a firm answer for this old riddle.

The egg had made considerable culinary headway by 1651, when Pierre François de la Varenne published *Le cuisinier françois,* a cookbook that provided 60 recipes for eggs (Tannahill 1989). But it is the era embracing the eighteenth and early nineteenth centuries that has been characterized as "The Century of the Chicken" (Smith and Daniel 1982) because of the considerable amount of scientific interest the bird generated. Upon learning about elaborate hatching ovens in Egypt, the French naturalist René de Reaumur wrote a treatise on the subject, and breeding chickens became a preoccupation of European (and North American) country squires with a scientific turn of mind (McGee 1984).

This effort was given considerable impetus in the nineteenth century with the opening of the Chinese port of Canton (in 1834) to foreign traders. One of the first English vessels in the new trade returned with a few chickens of a Chinese breed – "Cochin" fowl, as they were ultimately called – as a present for Queen Victoria. In addition to their startlingly spectacular appearance, the Cochin chickens were superior in meat and egg production to established Mediterranean and European breeds. When they were first exhibited in England, tens of thousands of people showed up to stare, and all breeders had to have one. The same phenomenon took place at the Boston Poultry Show of 1849, where the birds again attracted crowds in the thousands, and even Daniel Webster attended to heap praise on the fowl.

Chickens had suddenly gained a new prominence among barnyard animals, and others of the great Asian breeds followed the Cochin to the West to perpetuate the chicken craze (Smith and Daniel 1982; McGee 1984). Breeding for show – with major emphasis on feather coloring and comb type – continued throughout much of the rest of the nineteenth century, with over 100 different breeds and color variations the result.

The "Century of the Chicken" was also a century of the egg, during which it was incorporated into diets as never before. Boiled eggs for breakfast became a favorite of many, and it was said that entire families of Parisians crowded around every Sunday to admire the dexterity of their sovereign, Louis XIV, who could knock off the small end of an egg with his fork in a single stroke (Toussaint-Samat 1992). The king was also very fond of meringues. Cookbooks provided careful instructions for the preparation of omelets and the poaching of eggs; mayonnaise was invented in the middle of the eighteenth century; the Americans followed the English example of marrying bacon with eggs; and the baking industry boomed (Trager 1995). Consequently, as the end of the nineteenth century approached, eggs were very much in demand in the West, and the emphasis in chicken breeding shifted from show-bird characteristics to productive capacity for eggs, or meat, or both.

Early in the twentieth century, Artemus Ward, in *The Grocer's Encyclopedia,* indicated something of the way that demand was being met. He wrote of "large poultry farms [where] eggs are produced and handled very much as the product of any other factory . . . but," he added, "the greater part of the country's egg supply is still represented by accumulations from thousands of general farmers scattered all over the country" (1911: 223).

This is hardly the case today. Poultry sheds have become meat and egg factories with automated hatcheries (McGee 1984). Major steps in this direction took place in the 1930s and 1940s as John Tyson pioneered the vertical integration of the poultry industry. In 1956, the animal health-products division of Merck Pharmaceutical Company began production of a drug that prevented flock-destroying epidemics of coccidiosis. These events were accompanied by the development of high-protein feeds, after which chicken and egg production became truly automated industries (Trager 1995).

The egg is a fine (and cheap) source of high-quality protein, as well as iron, vitamins E and B_{12}, folacin, riboflavin, and phosphorous, and was long regarded as a near-perfect food. But the egg's yolk is also a source of considerable cholesterol, and with the implication of this substance in blocking heart arteries, demand for fresh eggs fell by almost 25 percent in the decade of the 1980s. In addition, eggs have been blamed of late (with some regularity) for outbreaks of salmonellosis. But although the use of fresh eggs has fallen off, the sale of food products containing eggs has risen significantly (Margen et al. 1992). The industry is hardly a dying one.

The Shell Egg Industry

The egg industry in most of the world is based on chicken eggs. In Southeast Asia there is also a duck egg market. As ethnic populations move, the food products they desire move with them. With the rather large number of Southeast Asian natives now living in other parts of the world, a geographically widespread demand for duck eggs has become a relatively recent phenomenon.

Table II.G.7.1 *Egg production of several countries of the world (in millions of eggs)*

Country	1969	1979	1989
United States	68,700	69,228	67,042
Former Soviet Union	37,000	65,585	84,600
Japan	27,565	33,150	40,383
Germany[a]	15,036	14,962	12,275
United Kingdom	18,450	18,555	17,834
France	11,200	13,840	15,150
Italy	10,281	11,037	11,223
Brazil	7,140	11,035	10,140
Spain	9,670	7,200	12,174
Poland	6,400	8,670	8,200
Mexico	5,657	10,390	14,700
Canada	5,655	5,551	5,500
Netherlands	4,370	8,187	10,711
Belgium, Luxembourg	3,900	3,453	2,724
Czechoslovakia	3,410	4,225	5,628
Romania	3,200	7,085	7,600
Argentina	2,940	3,350	3,350
Hungary	2,600	4,450	4,250
Australia	2,380	3,395	3,286
Republic of South Africa	2,028	3,083	4,012

[a] Production for East and West Germany was combined.

Table II.G.7.1, which includes only the markets for chicken eggs, lists the countries leading in egg production. Data on egg production in China, prior to 1989, are not available, but production there has always been extensive. Prior to 1940, China was the leading nation in the export of dried egg products. In Turkey and Korea, egg production has recently become significant. Figures for Eastern European countries for the 20-year period 1969 to 1989 show an increase in egg production in most of the countries, especially in the former Soviet Union. In countries with production controls, such as Canada, Australia, and the United Kingdom, there was almost no increase. The lower production in the United Kingdom for 1989 was likely influenced significantly by bad publicity relative to the safety of eggs during the mid-1980s. Overall, most countries listed in Table II.G.7.1 had an increase in egg production in excess of population increase.

The concentration of egg production has moved rapidly to larger units in the United States. In 1959, over 49 percent of all eggs in the United States were produced by flocks of less than 1,600 hens. By 1974, only 5.44 percent of all eggs were produced by such small flocks. In 1990, less than 1,000 companies produced over 97 percent of all eggs, with the smallest of these commercial farms having over 30,000 layers.

Egg consumption figures for countries around the world can be approximated by dividing human population figures for each country into the production figures listed in Table II.G.7.1. There is an international trade for eggs, but in most countries it is a relatively small percentage of total production. The Netherlands might be an exception, as they export many eggs to other European Economic Community (EEC) countries. Shell egg consumption in the United States has been declining since about 1950, when annual consumption was about 400 eggs per person with over 95 percent being in shell egg form. The 1990 consumption of shell eggs had decreased to about 200 per capita, with egg products accounting for over 40 more eggs per person. The use of egg products and eggs in prepared form has been increasing by 1 to 2 percent annually for the last several years. Publicity about potential danger from bacteria in shell eggs will likely result in a continuation of the shift to pasteurized egg products, particularly by institutional feeding establishments.

The egg products industry in the United States is expanding in numbers of companies involved and in volume from each company. The basic products are liquid, frozen, or dried whole egg, egg white, and egg yolk. For reasons of convenience, the shift has been from frozen and dried to liquid products. Developments in pasteurizing procedures and in the aseptic handling of liquids suggest that the shift to liquid will accelerate.

The egg industry is in a growth phase worldwide and will continue to expand because of the wide acceptance of eggs as food of a high nutritional value, especially in terms of protein quality, which makes the egg such a valuable food source for the expanding world population. Research and technology are striving to overcome the problems presented by cholesterol content and microbiological safety.

Egg Formation

At the time of hatching, the female chicken has a rudimentary ovary with over 2,000 ovules or immature egg yolks called oocytes. The egg yolk develops while in a follicle of the ovary. The remainder of the egg, especially the white, or albumen, and the shell, is formed in the oviduct. From these values it is apparent that major changes in the size of the reproductive system take place in relatively short time periods.

It is generally acknowledged that a hen forms an egg in about two weeks. This is true except for the very small core of the yolk. The yolk of the egg is formed in three stages: (1) the part formed during embryonic development of the female chick; (2) the normal slow development of the ovum from the time of hatching to a point in sexual maturity some 10 days prior to ovulation; and (3) the accelerated growth period during the last 10 days before ovulation (release of the ovum or yolk into the oviduct) (Stadelman and Cotterill 1995). The yolk increases in size during the rapid growth stage by the deposition

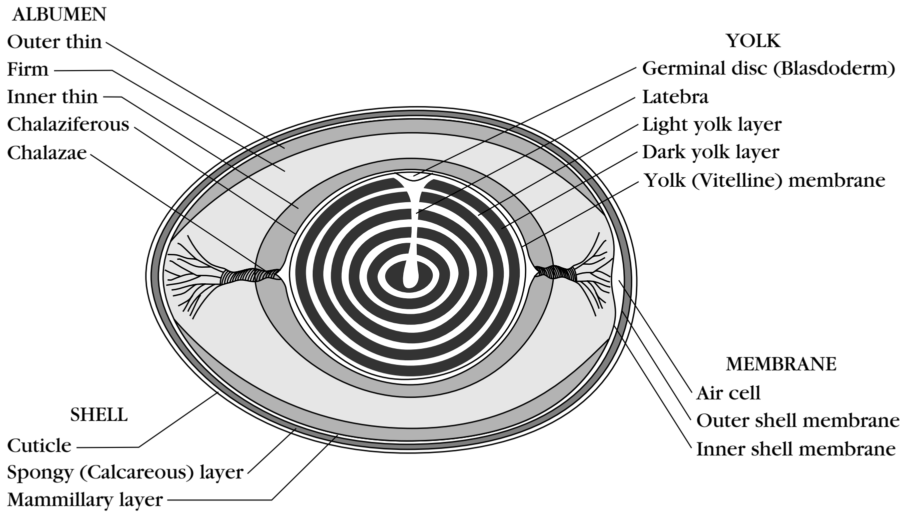

Figure II.G.7.1. Structure of the chicken egg.

of layers of yolk material. The concentric rings of growth remain intact until the yolk membrane, the vitelline membrane, is broken. The yolk of a normal chicken egg makes up 27 to 33 percent of the total egg weight.

In the oviduct the albumen, or white portion, of the egg, which accounts for about 60 percent of the total egg weight, is deposited around the yolk in about 4.5 hours. The oviduct is made up of five distinct regions. The yolk is released from the ovarian follicle into the infundibulum. A small amount of thick albumen rich in mucin fibers is deposited around the yolk during its 20-minute time of passage, due to peristolic action, into the magnum section of the oviduct. In the magnum section, the yolk collects the rest of the thick albumen and some thin albumen. The developing egg spends about 3 hours in the magnum section prior to entering the isthmus section where the shell membranes and remaining thin white are added during about a 1-hour stay.

The edible portion of the egg is now complete, but about 19 hours is spent in the uterus section where the shell is deposited over the shell membranes. In the posterior section of the uterus the pigments of colored egg shells are deposited on the shell just prior to movement of the intact egg through the vagina.

From the time the first thick albumen is deposited on the yolk until the shell membranes are in place, the yolk spins due to the peristolic movements of the oviduct. The spinning motion causes mucin fibers of the thick albumen to be twisted on opposite sides of the yolk into the chalaza. The chalaza forms a tight mesh over the yolk surface with the loose ends enmeshed in the layers of thick albumen. The chalaza aids in keeping the yolk centered in the albumen.

Another part of the egg often observed is the air cell. This forms between the inner and outer shell membranes after the egg is laid and is usually found in the large end. At the time of lay, the egg is at the body temperature of the hen, about 107° F (42° C), but as it cools, the volume shrinks, which starts the air cell. During the time the egg is held, there is a continual loss of moisture from the egg albumen, which results in an ever increasing air cell size. The rate at which moisture is lost is controlled by atmospheric humidity and porosity of the shell.

Egg Structure

The parts of the egg are shown in Figure II.G.7.1. As discussed in the section on the formation of the egg, the ovum starts development during the embryonic growth of the female chick. The female germ cell is in this structure. During the rapid growth phase of egg formation, the latebra grows to keep the germinal disk on the surface of the yolk. The vitelline membrane expands quickly during the rapid growth phase of yolk development. In a fully developed yolk the vitelline membrane is about 0.024 millimeter (mm) thick (Needham 1931). Depending on the methods used in histological examination of the membrane, there are either two or three layers (Romanoff and Romanoff 1949).

The yolk is deposited in concentric layers during formation. In hard-cooked egg yolks it is possible to differentiate light and dark rings when highly pigmented feedstuffs are fed for a limited period of time each day. The size of the yolk varies directly with egg size. The percentage of the total egg in the yolk varies from 27 to 33 percent. The percentage of the egg as yolk varies with egg size (Marion et al. 1964), with strains laying smaller eggs having a higher percentage of the egg as yolk. According to F. E. Cunningham, O. J. Cotterill, and E. M. Funk (1960), as hens age, the percentage of yolk in the egg increases. Cotterill and

G. S. Geiger (1977) studied yield records from the Missouri Random Sample test and found that the yolk size in eggs decreased from 1965 to 1975. W. W. Marion and others (1964) suggested that all deviations in egg component part percentages are covariates of egg size.

The size of the yolk increases slowly during storage due to a very slow balancing of osmotic pressures between the yolk and albumen. A series of papers by J. Needham and M. Smith (1931), Smith and J. Shepherd (1931), Smith (1931), J. Needham, M. Stephenson, and D. M. Needham (1931), and J. Needham (1931) reported on the relations of yolk to albumen in the hen's egg. The vitelline membrane is a unique entity in its ability to maintain about 50 percent solids in the yolk, with only 13 percent solids in the albumen over many months of storage. At this time, a proven explanation for this phenomenon is not available.

The albumen of the hen's egg consists of four layers that can be identified in the broken-out freshly laid egg. The location of the layers in the intact egg is indicated in Figure II.G.7.1. The inner thick, or chalaziferous, layer is next to the vitelline membrane. This layer of albumen is rich in mucin fibers that are generally lacking in the thin white layers. The outer thick layer is a complex of lysozyme-mucin proteins. This complex disintegrates over time when eggs are in storage.

The shell membranes, inner and outer, are composed of keratin fibers arranged in a web pattern to form a barrier to microbial invasion of the egg contents. The inner membrane is about one-third the thickness of the outer membrane (Romanoff and Romanoff 1949). The combined thickness of the two membranes is about 0.1 mm. Passage of gases or liquids through the membranes occurs largely by osmosis or diffusion.

The egg shell must meet a number of requirements. It must be strong enough and rigid enough to withstand the weight of the adult hen. It must be porous enough to allow respiration for the developing embryo during incubation and still compact enough to prevent microbial invasion or the escape of too much moisture. Additionally, the shell serves as a supply of minerals for the nutrition of the embryo. The outer surface of the egg is the shell, which consists of four layers, all composed primarily of calcium carbonate. The thickness of the egg shell varies among hens. It is normally thickest for hens just starting egg production; thickness decreases as the hens extend their egg-laying cycle. A hot environmental temperature also results in thinner egg shells, as does a low level of calcium in the hen's diet.

Egg Quality Evaluation and Preservation

The basis for quality determination of eggs by nondestructive means in the United States is the *Egg Grading Manual* (U.S. Department of Agriculture 1977). The same characteristics laid out in the manual are used in all countries with various degrees of emphasis on the several quality factors. Quality determinations are divided into external and internal factors. External quality factors are soundness of the shell, cleanliness, and egg shape. The internal factors are air cell size, albumen viscosity, and yolk shadow. The internal factors are judged by passing the egg in front of a bright light source. Other internal factors are freedom from blood spots, bloody albumen, meat spots, or other inclusions. Equipment is currently available that allows for quality evaluation by candling at rates in excess of 72,000 eggs per hour.

In 1981, the quality standards for grades of eggs in the United States were modified (U.S. Department of Agriculture 1981). The grades of eggs that can be offered for sale at retail are AA, A, B, and B*, referred to as B star. The requirements for each grade are detailed for each external and internal quality factor. The application of these standards are discussed by W. J. Stadelman and Cotterill (1995).

Numerous laboratory methods for quality evaluation of eggs have been prepared. Most of these methods are destructive in that the shell is broken and measurements are made on the liquid contents. The most widely accepted method is the Haugh Unit for expressing the albumen condition. This measurement was presented by R. R. Haugh (1937) and modified by A. W. Brant, A. W. Otte, and K. H. Norris (1951). A lesser used system is the United States Department of Agriculture (USDA) score as suggested by Brant and colleagues (1951), which attempts to correlate visual appearance of the broken-out egg, Haugh Units, and candled grade.

Evaluation of shell quality is on the basis of shell strength. The breaking strength has been found to be closely related to shell thickness. On broken-out eggs, measurement of shell thickness is a common method. As the specific gravity of freshly laid eggs is determined primarily by shell thickness, a nondestructive estimation of shell thickness can be made by determining specific gravity of the intact egg.

In terms of quality preservation, the most frequently considered item is albumen condition, which is often expressed as Haugh Units. For a high-quality or grade AA egg, the Haugh Units should be above 78. This value lowers over time as the thick albumen thins. The rate of albumen thinning is a function of temperature. The breakdown or thinning of albumen is relatively rapid at high temperatures, 40° Celsius (C), and slows to almost no change at 1° C. Other than temperature, the carbon dioxide content of the atmosphere surrounding the egg affects the rate of carbon dioxide loss from the egg. With the loss of carbon dioxide, the pH of the albumen rises from about 7.6 in a fresh egg to 9.7 in a stale egg.

Humidity of the atmosphere influences rate of water loss from the egg, which results in increased air cell size. Ideal conditions for long-term storage of eggs are a temperature between 1° C and 3° C and a relative humidity of about 80 percent. For long-term storage, egg shells are usually coated with a colorless, odorless mineral oil that seals the pores of the shell.

A frequently neglected consideration in quality preservation is maintaining cleanliness and soundness of the shells. In summary, egg quality preservation is a function of time, temperature, humidity, and handling.

Egg Sizes

In most parts of the world egg sizes are based on metric weights, with each size up or down being with a 5-gram grouping. Eggs are sold by the dozen in the United States. Egg sizes are based on weight per dozen ranging from pee wee (15 ounces [oz]), small (18 oz), medium (21 oz), large (24 oz), extra large (27 oz), to jumbo (30 oz). For consumer satisfaction it is desirable to pack cartons holding a dozen with uniform-sized eggs of the appropriate weight. Many of the jumbo-sized eggs will contain two yolks.

Egg Chemistry

Shell eggs consist of about 9.5 percent shell, 63 percent albumen, and 27.5 percent yolk, according to Cotterill and Geiger (1977). The total solids of the albumen, yolk, and whole egg are about 12 percent, 52 percent, and 24 percent, respectively. Reviews of the chemistry of egg components were written by R. E. Feeney (1964), T. L. Parkinson (1966), Stadelman (1976), and W. D. Powrie and S. Nakai (1990). Extensive analytical data on the nutrient composition of eggs are given in a publication by the U.S. Department of Agriculture (1989).

The shell membranes are composed of protein fibers, mostly keratin with some mucin, arranged in net fashion to form a semipermeable membrane. The shell membranes provide a significant barrier to bacterial invasion of the albumen.

The egg white consists of a number of proteins, a small amount (less than 1 percent) of carbohydrates and minerals, and no lipids. The composition of the albumen of a freshly laid egg is about 87 percent moisture, 11.5 percent protein, 0.8 percent ash, and 0.7 percent carbohydrates. The carbohydrates are the sugars in glycoproteins. The predominant protein is ovalbumin. The complete amino acid sequence with 385 residues has been determined by A. D. Nisbet and others (1981). The molecular weight of the polypeptide chain is 42,699.

The pH of the albumen in a freshly laid egg is about 7.6, which increases during storage to as high as pH 9.7. The rate of pH change is influenced by temperature, air movement, and shell quality. The pH increase is the result of carbon dioxide loss from the albumen. The pH of the albumen depends on the equilibrium between the dissolved carbon dioxide, bicarbonate ion, carbonate ion, and proteins.

The protein ovotransferrin is referred to as conalbumin in older literature. Its unique characteristic is its ability to bind multivalent metallic ions. With aluminum salts a white precipitate is formed; with copper, the flocculant is yellow; and with ferric iron a red color results. The ovotransferrin is one of the most heat-labile proteins of the albumen. Powrie and Nakai (1990) discuss methods for the isolation of each of the proteins.

Egg yolk might be described as a complex system containing a variety of particles suspended in a protein solution. Another description is that it is an oil-in-water emulsion, with lecithin and the lysoproteins aiding in maintaining a stable emulsion. The yolk consists of a plasma with suspended granules. Fresh egg yolk contains about 52 percent solids and has a pH of 6.0, which rises during storage to 6.9.

Nutritional Value

Eggs are a popular food in all countries of the world and have been since ancient times. Before agriculture developed, eggs were gathered from birds' nests for human food. Although eggs contain about 75 percent water, they are a rich source of high-quality protein and are often used as the protein against which other protein sources are compared. Eggs are also important sources of unsaturated fatty acids, iron, phosphorus, trace minerals, vitamins A, E, and K, and all B vitamins. As a natural source of vitamin D, eggs rank second only to fish oils. Eggs are low in calcium, as the shell is not eaten, and they are devoid of vitamin C (Stadelman and Pratt 1989). The high nutrient density of eggs relative to their caloric content makes them an excellent food for many people with special dietary needs (Stadelman et al. 1988).

Much has been written concerning the relationship of plasma cholesterol level to coronary problems in humans, yet some individuals do not adequately differentiate between plasma, or serum, cholesterol and dietary cholesterol. For most people it would seem that there is only a very slight relationship between the level of cholesterol in their diet and the serum cholesterol level in their blood.

Microbiology

The egg contents at the time of laying are generally free of microbial contamination. During the 1980s it was found that a few eggs, estimated at 1 in 20,000, might contain a bacteria, *Salmonella enteriditis,* in the yolk at the time of production. This bacteria is of great concern to health officials and the egg-producing industry because the organism can cause food poisoning in humans.

The egg has a number of barriers to bacterial invasion. The shell and shell membranes act as physical barriers. In the albumen there are several proteins that influence the ability of organisms to colonize in the egg. Lysozyme will digest cell walls of some bacteria. Avidin removes biotin from the available nutrients for bacteria, and ovotransferrin chelates with ions of iron, making it unavailable. When eggs are cooked, the tying up of biotin or iron is eliminated so these materials are readily available for microorganisms or humans.

Packaging

As egg shells are subject to cracking, packaging has been developed to minimize this loss. In early days eggs were loosely packed in rigid containers using whole grain oats to keep the eggs from contacting the sides of the container or each other. A step forward in innovation was the use of fillers and flats made of cardboard to keep eggs in individual cells in wooden cases. The wooden case was standardized to hold 30 dozen eggs. The next move was to fiberboard cases and a pulp paper filler flat. These cases are now in use for domestic shipments. Most export shipments are still in wooden cases using the filler flat.

For the retailing of eggs, many packages have been and are still being used. The poorest of these, as far as protecting the egg, is a bulk display with paper bags to carry a dozen or more eggs. Pulp paper cartons have been developed to hold from 2 to 18 eggs. These may be coming back into use because of environmental concerns regarding plastic foam cartons.

The Liquid Egg Industry

Shell eggs are converted to liquid products by the removal of the shell. It is required in the United States and some other countries that the shells be removed with no commingling of the shell and liquid portions. The liquid content of the egg is handled as albumen, yolk, whole egg, and various blends of yolk and albumen. Commercial equipment can break and separate yolks from albumen at rates in excess of 36,000 eggs per hour.

Processing Liquid Eggs

The steps of processing liquid eggs include pasteurization, homogenization, packaging, and refrigeration. The liquid products may be converted to frozen, dehydrated, or dried products. An excellent historical review covering early development of the United States egg-products industry was prepared by J. W. Koudele and E. C. Heinsohn (1960).

The pasteurization of eggs is accomplished by heating the liquid to a sufficiently high temperature for a long enough time to kill any pathogenic microorganisms that might be present. As egg proteins coagulate when heated, the pasteurization temperatures and times must be carefully controlled in order to obtain the bacterial reduction with minimal damage to the functional properties of the egg product. Heat damage can be minimized by maintaining a high degree of turbulence in the egg product during the pasteurization process. For whole eggs in the United States, a temperature of 60° C (140° F) for a minimum of 3.5 minutes is required. Higher temperatures for a shorter holding time are accepted. C. R. Murdock and others (1960) compiled information on minimal accepted pasteurization times and temperatures in several countries. In Poland whole egg pasteurization requires 66.1° C to 67.8° C for 3 minutes, in China 63.3° C for 2.5 minutes and in Australia 62.5° C for 2.5 minutes.

Pasteurization temperatures for albumen are sometimes lower than for the whole egg, using longer holding times. The addition of aluminum salts to the albumen results in chelation, with the ovotransferrin allowing the use of higher pasteurization temperatures for albumen (Lineweaver and Cunningham 1966). Ovotransferrin is the most heat-labile of all proteins in the albumen. Egg yolk is rather heat-stable and can be pasteurized by using slightly higher temperatures or longer times than for the whole egg. Cunningham (1990) reported detailed procedures for the pasteurization of different liquid egg products.

A procedure for the ultrapasteurizing of liquid whole eggs was described by H. R. Ball, Jr., and colleagues (1987), and by K. R. Swartzel, Ball, and M. Hamid-Samimi (1989). They utilized temperatures that are higher than the minimum required in the United States with high turbulence in the holding tubes and projected a usable shelf life of the ultrapasteurized whole egg products of up to 24 weeks when stored at 4° C or lower. The commercialization of this procedure will reduce the need for frozen products.

The homogenization of liquid whole egg may be done either before or after pasteurization. It usually follows pasteurization so that any clumping of materials due to the heating would be dispersed in the homogenization operation.

The packaging of egg products is an ever changing operation. The early processors, from the late nineteenth century until the mid-twentieth century, used metal cans, each containing about 30 pounds of product. The next package was a rigid plastic bucket of either 10- or 30-pound capacity. This was followed by the use of waxed cardboard boxes of 4- or 5-pound capacity. Small quantities were packaged in half-pint cardboard containers in a futile attempt at selling the egg products in retail food stores. At present the industry is moving toward the use of flexible film packages with an aseptic packaging technology.

Before the introduction of ultrapasteurization and aseptic packaging, the shelf life of liquid eggs was about 6 days. But now, with a predicted shelf life of up to 24 weeks (Swartzel et al. 1989), it may be possible to sell liquid product at retail. In earlier years much of the liquid product was packaged as indicated and frozen for distribution to food manufacturers.

During World War II there was a great demand for dried egg products for military feeding and to supply civilian populations of countries in the war zones. The usual method of drying was by using a spray drier. Small amounts were pan-dried and freeze-dried. In the drying of eggs it was necessary to remove the reducing sugars normally present in egg albumen to minimize the discoloration that would result from a reaction between such sugars and amino acids abundant in the egg liquid. Desugaring is accomplished by a controlled bacterial or yeast fermentation, by a spontaneous microbial fermentation, or by an enzymatic fermentation using glucose oxidase.

W. M. Hill and M. Sebring (1990) reviewed methods for desugaring liquid eggs. D. H. Bergquist (1990) outlined procedures for the dehydration of liquid eggs and listed seven advantages of the dried products. These are as follows:

1. A low storage cost.
2. A low transportation cost.
3. The ease of sanitary handling.
4. The lack of susceptibility to bacterial growth during storage.
5. An allowance for more precise formulation.
6. The uniformity of product.
7. An allowance for development of new convenience foods.

During the last 20 years a number of additional processed egg products have been introduced in the marketplace, as described by Stadelman and others (1988). The most widely marketed to date have been hard-cooked egg products. They are available as peeled hard-cooked eggs, diced eggs, long eggs, and Scotch eggs. It was estimated that about 1 percent of all eggs sold in the United States in 1990 were in hard-cooked form. Generally, the hard-cooked egg sales are to restaurants rather than at retail.

In summary, eggs have long served as a food for humankind. They have a high-density nutritional value, especially with respect to the protein quality. They contain all nutrients required by humans except vitamin C, but as we do not utilize the shell, the egg is also deficient in calcium. Eggs are usually one of the first solid foods given to infants and frequently constitute a significant portion of the diet of the elderly. Valued for their versatility, they are employed to coagulate, to foam, to emulsify, to color, to flavor, and to control sugar crystallization in some candies. With this wide range of use, eggs remain one of our most economical food staples.

II.G.8 Dogs

The Dog as Human Food

The difficulty that confronts one at the very beginning of a study of the dog as human food is the lack of convincing evidence relating to the use of dogs *(Canis familiaris)* as food by early humans. Most of the discussions in published articles are either speculative or employ relatively recent evidence of dog consumption and extrapolate these data to the distant past.

There are some fine published discussions that relate to the eating of dogs in more recent times. One of the best is by Margaret Titcomb (1969), who documents the importance of the dog to human cultures in the ancient Pacific area. Titcomb believes (as do I) that the dog of the Pacific Islands was originally carried by canoe from the Asian mainland along with the pig and chicken for food on the voyage.

It was fed carefully upon vegetables such as taro and breadfruit so that its flesh was palatable to its human owners. Captain James Cook noted in his journal of 1784 that dogs were fed and herded with the hogs. Titcomb (1969) relates that they were fattened on poi and that an informant remembered that relatives penned up puppies to keep them from eating unclean food. They were fed three times a day on poi and broth until fattened. Natives considered baked dog a great delicacy, but they never offered it to foreigners, who held dog meat in great abhorrence, according to the wife of a missionary in 1820.

Preparation of dogs as food is abstracted by Titcomb (1969), who writes: "Like the pig, the dog was killed by strangulation in order not to lose the blood. The blood was poured into a calabash (gourd) used for cooking, and red hot stones were added, causing the blood to coagulate; it was then ready to eat." The meat might be baked or cut up and wrapped in *ti* leaf bundles and cooked in boiling water. An informant stated that the upper part of the backbone was preferred by many diners, although some liked the ribs best, and others preferred the brain. The latter has been attested to by dog skulls, with holes in the crania, found in archaeological excavations.

There is some indication of the numbers of dogs that were used as food from the dance anklets, made of dog teeth, that survive in museum collections. Dog canine teeth were drilled for attachment to fabric bands and worn as dance rattles. One, in the Bishop Museum, has 11,218 teeth; it has been estimated that 2,805 dogs were required to produce the artifact.

Domestic dogs found their way from island to island across the Pacific Ocean. A major reason for their success as immigrants in the region was a total absence of competition from wolves, jackals, and foxes. Pacific Island canids themselves did not become feral, probably due mainly to a lack of adequate food in the wild, which meant they had to rely on their human owners for subsistence.

Today dogs are employed as food for human consumption in many parts of Asia, and China in particular, but the origins and reasons for this practice are not well documented, or if they are, they are probably recorded in one or more of the many Asian sources not yet translated.

Dog Fossils and Their Interpretation

Dog consumption practices in the Pacific and Asia notwithstanding, the dog's main attraction to humans, historically, has been its ability to hunt other animals selected as food by humans rather than serving as a source of food itself.

Over the past 50 years that I have been examining animal bones from archaeological sites, I have yet to see the bones of dogs bearing cut or butcher marks that would indicate that dogs had unquestionably been butchered for food. In the southwestern United States, for example, and particularly in Arizona, there are literally hundreds of articulated prehistoric dog burials and many more isolated postcranial bones. The latter often show evidence of cutting, but it is evident that they were being prepared for bone artifacts. Most represent the shafts of humeri or femora and were scored by flint blades in transverse directions below the proximal articular condyle or the distal articular condyle, resulting in a bone tube when the articular ends were removed. Many of these artifacts, or "tubes," have been recovered from archaeological sites along with the discarded ends of the bones.

Some archaeologists have used the evidence of burned or charred dog bones to indicate meal preparation. However, experiments with fresh material have proven that burned or charred bone is the result of grilling to the point where edible flesh has been completely destroyed. Indeed, it must be destroyed before any change is apparent on the bones.

Generally, the sample size of dog burials is inadequate to determine their value to the associated human population. However, there are several occurrences of multiple dog burials that suggest reasons other than culinary for the buried animals. In Askelon, Persia, 1,238 dog skeletons of all ages, associated with a period dated between 822 and 428 B.C., were excavated and examined by archaeologists (Wapnish and Hesse 1993). There was no evidence of butchering or food preparation associated with these dogs.

Similarly, a site of puppy burials from the first-century-A.D. Roman villa at Lugnano, Italy, was excavated in June 1992. At least some of these dogs were associated with child burials, which may have had some ritual significance. In fact, dogs in association with human burials are not uncommon. Intentional burials of dogs, both separately and with humans, are known from Chinese sites (Figure II.G.8.1). Some of the dogs are in the same coffins with the humans; others have their own separate burial boxes.

Indeed, there is always a danger of misinterpreting dog remains when only bones are present. One of the best examples of this potential for misinterpretation is connected with a 1901 photograph taken on the shore of Penzhina Bay, in eastern Siberia on the Sea of Okhotsk. The photograph shows four large sled dogs hanging by their necks atop long poles that were set into the frozen earth (Perkins 1981). Waldemar Jochelson, the photographer (on what was an American Museum of Natural History expedition), explained:

> All along the bank of the Paren River were stakes driven into the snow, with dogs hanging on them, their muzzles pointing upward. In the light of the spring sun, this long row of dog-sacrifices offered a queer and sad sight. I found out that the greater part of the dogs had been killed by the drivers of the sledges in gratitude for their safe return from Gizhiginsk, and to guard their villages from the measles, which a year previous had come to them from that little town. (Perkins 1981)

The dogs were eventually cut down from the poles and buried, and there was no evidence left indicating the circumstances that led to their deaths. It is doubtful that any excavators of the dogs would be able to glean the method of their execution or the reason for their demise. The point is that ritual sacrifices of dogs are not generally recorded. One example is a fenced brick-lined pit, off to one side of the market in Kathmandu in Nepal, whose purpose is for the sacrifice and dismembering of dogs. If it were not for the tourist photographs taken when the rituals are in progress, the small fenced pit might be mistaken for a dry fountain.

At sites in Egypt and prehistoric southwestern North America, dog mummies have been recovered. In the former region, humans did the mummifying, whereas natural causes were responsible in the latter. From these discoveries we can derive information about dog size and color of pelage and can make comparisons with surviving breeds of dogs. Two of the best-preserved animals are a small black-and-white dog and a yellowish-white one (Figure II.G.8.2) from a Basketmaker site at Marsh Pass, Arizona.

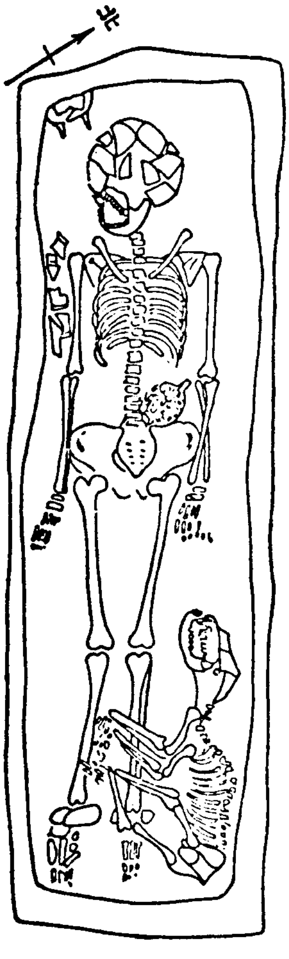

Figure II.G.8.1. Intentional burials of domestic dogs and humans. Neolithic of China; Xiawanggang c. 4000 B.P. (Illustration courtesy of Qi Guo-gin.)

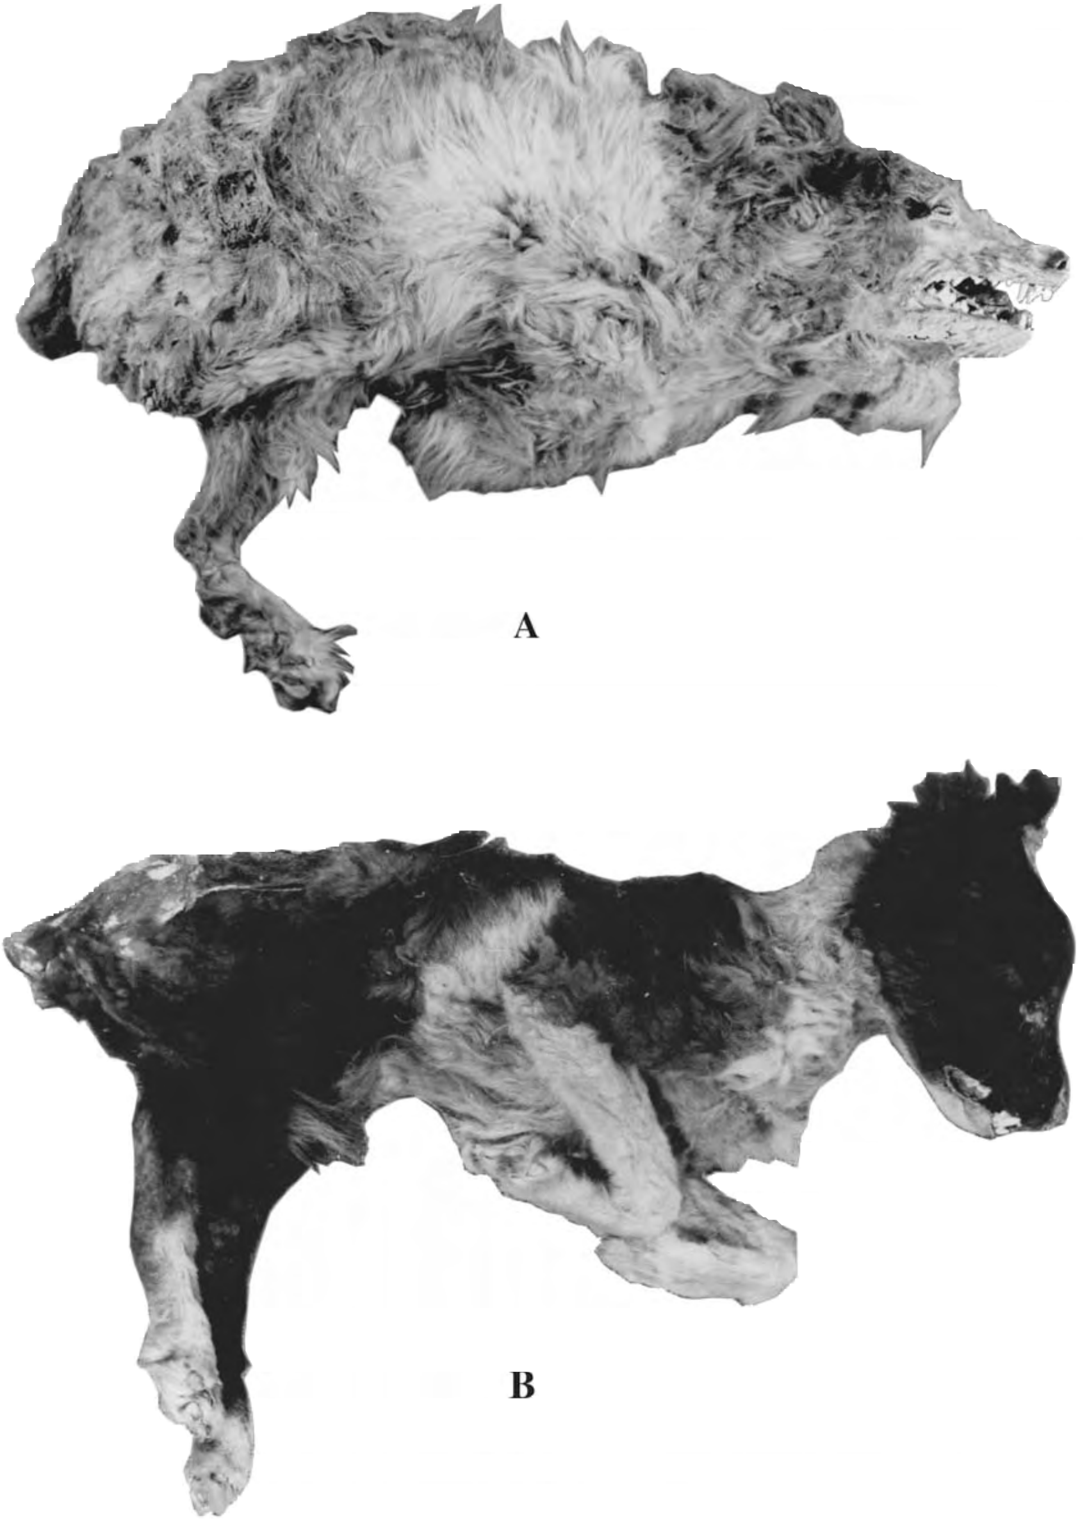

Figure II.G.8.2. Indian dogs, 2,000 years old, early Basketmaker. Natural mummies from White Dog Cave, Marsh Pass, Arizona: (A) yellow-white domestic dog; (B) black-and-white domestic dog. Both are *Canis familiaris*. (Photograph by John W. Olsen.)

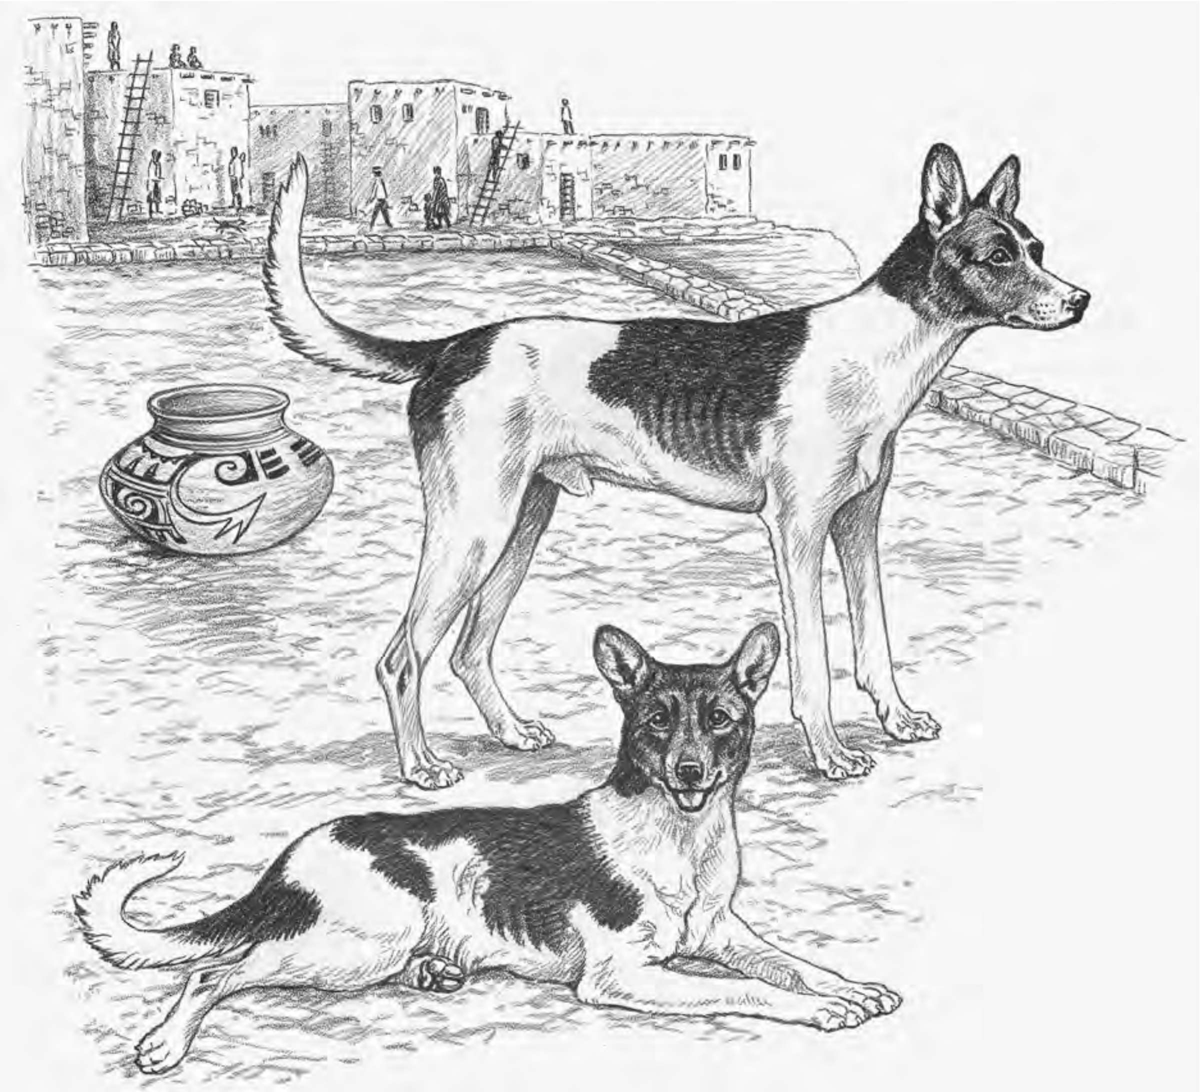

Figure II.G.8.3. Typical long-legged Basketmaker domestic dogs, *Canis familiaris,* from vicinity of Marsh Pass, Arizona, 2,000 B.P. (Drawing by Wallace Hughes.)

These dogs were mummified naturally in the hot, dry environment and placed in White Dog Cave with a mummified Pueblo Indian wrapped in a woven shroud. The dogs were a bit longer legged than the mongrels found in the vicinity today, but the color patterning and small size are rather common in the general area of Marsh Pass (Figure II.G.8.3).

Dog Domestication

If the pages of the past are blurred with respect to the use of the dog as food, they are equally hard to read in matters of dog domestication, which constitutes the burden of most of the remainder of this chapter. Much of what has been and is being published on the events leading to canid taming and domestication is based more on supposition than on hard evidence. Woven into what follows is my own version of this process (based on Olsen 1985).

Studies relating to the social structures of both humans and wolves shed some light on what *may* have taken place in the initial development and relationship of these two groups of early hunters that eventually culminated in the close relationship between dogs and humans prevailing today throughout much of the world. Foremost among these studies are those by L. D. Mech (1970), M. W. Fox (1971), and B. H. López (1978). Perhaps the best compilation that relates to this relationship is a series of papers edited by R. L. Hall and H. S. Sharp (1978). Several theories dealing with the attitudes of humans toward wolves and of wolves toward humans are discussed in detail in their volume.

Human hunter–gatherer societies and wolf packs were similar in a number of respects. Both comprised social units that were relatively small in number. Both were capable of hunting over open ground or wooded areas, pursuing rather large game and exerting considerable physical effort and energy over prolonged periods to accomplish their goals. Both used hunting methods that required a pack or team effort as opposed to the tactics of a lone hunter.

Faunal evidence from paleoanthropological sites of the late Pleistocene age (c. 10,000 B.C.) indicates that *Homo sapiens,* at this stage of development, depended on a diet that included a sizable portion of game animals. As carnivores, the wolves of this period also depended on wild game, and because hunting game by running it down takes a good deal more time than consuming the kill, one of the characteristics of both these predator groups would have been sharing the spoils of the hunt. Such socialization would have developed independently among both wolves and humans (Hall and Sharp 1978).

Another social feature shared by wolves and humans would have been that gender did not necessarily determine who did the hunting. Rather, such a determination would have depended on the individual's maturity and ability to hunt successfully. The nonhunters of the pack (immature animals), therefore, would gather in rendezvous areas that were selected for regrouping and for the sharing of freshly killed game provided by the active hunting members of the pack (Mech 1970; Hall and Sharp 1978; López 1978). The wolf packs' methods of obtaining game appear to be well organized and planned and should be briefly abstracted here as a possible model of how human hunting societies may have obtained game during the Pleistocene.

As pack hunters, wolves are able to capture and kill animals much larger than themselves. Artiodactyls such as deer, mountain sheep, elk, caribou, and even the moose, a formidable adversary, are all chosen prey. Rabbits, beaver, and (at times) fish in shallow water, as well as other small mammals, are also caught and eaten (Mech 1970). Wolves have been observed to change their hunting tactics more to suit the terrain and weather conditions than to suit the habits of a particular animal that they are pursuing. Their ability to procure food is not always successful; rather, feast or famine may be more the norm for these animals.

The selected prey in an ungulate herd may be an old or weakened animal, but this is not necessarily the case. Healthy, prime adults, as well as immature animals, are also selected and killed by wolves (Mech 1970). The method of bringing down such an animal is for the wolf to run alongside, slashing and tearing at its hindquarters, flanks, and abdomen until it is weak enough from its injuries to be dispatched (López 1978). Wolves may grab an animal, such as the moose or caribou, by the nose, holding on, while other members of the pack close in for the kill (Mech 1970; Hall and Sharp 1978; López 1978).

It is the case, however, that wolves generally choose animals that are easier to procure than healthy, active prey. Animals that are injured, infected by parasites to such a degree that they are weakened, or foundering in deep snow are all known to have been selected by wolf packs for food (López 1978). Animals in this condition, of course, signal their plight to some degree; these signals would not be lost on keen observers, such as wolves (or humans), and the weakened prey would be relatively easy to dispatch.

If a prey animal runs, it is certain to be pursued, especially if it is a lone individual (Mech 1970). To weaken such an animal, particularly if it appears to the wolf to be a strong and healthy adult, the practice of relay hunting may be put into practice, taking advantage of the terrain to wind the pursued. The hunt may end in a rush, terminating the animal's struggles in a few moments, or the dogged pursuit may go on for miles before the pack closes in. Alternatively, a wolf pack of four to six animals may send out two wolves to herd a lone victim into an ambush of the remaining members of the group (Mech 1970).

Wolves that have maintained a territory for a considerable length of time may know the terrain well enough to use shortcuts to intercept running prey. They are also known to hunt into the wind when approaching a feeding herd of artiodactyls.

The similar pack-hunting methods and social structures of early humans and wolves would not, in themselves, have been responsible for the first taming and domestication of the wolf. Perhaps humans observed the wolf's ability to track successfully by scent, or its ability to cover ground swiftly enough to elude human pursuit. It is possible that hungry wolves were enticed (not necessarily by human design) to come close to a campfire, where meat was being cooked and the refuse discarded in the immediate vicinity of the camp. Perhaps wolves that had attached themselves loosely to human habitation areas would consider such camps as their home territory, and their warning growls toward intruders would also warn the human inhabitants of the approach of such outsiders. If such an association occurred, it is not unreasonable to assume that these events would bring about firmer ties between wolves and humans to their mutual advantage. Unfortunately, evidence of the kind needed to prove or disprove this speculation is not the sort that could be preserved in the archaeological record.

If a hunter were to have initiated a closer association with wolves by taking a wolf pup from its den (possibly if a pup's parents were killed), this action would have encouraged imprinting of the substitute human family leader on the young wolf's behavior pattern as it developed and matured in close association with the human hunting group. Thus, J. P. Scott (1950) wrote:

> Behavior studies seem to indicate that the reason for the apparently easy and successful domestication of the wolf lies in the fact that it is a species with highly developed patterns of social behavior and that a large number of these patterns are sufficiently similar to human ones to permit mutual social adjustment between man and wolf. The primary stimuli are so similar in the two species that appropriate and recognizable social behavior is evoked.

But it is also quite possible that there existed a mutual respect between the wolf and human of 10,000 to 15,000 years ago for the hunting prowess of the other. At such a time, humans were themselves probably as rugged and aggressive as the wolves with which they shared a hunting territory.

In order for any animal, including wolves, to be successfully tamed and domesticated, it must be able to suppress its natural or normal living pattern and subjugate it to that which is dictated to it by humans. The wolf (in most instances), and the resulting domestic dog, have been able to do this, as have all of the common domestic animals that are familiar to us. But some animals cannot cross this bridge from wild to domestic. Records extending as far back as early dynastic Egypt indicate that many animals that seemed potential domesticates did not fulfill that potential. Some Egyptians experimented with hyenas, gazelles, and foxes, but they had little success in molding them into household animals. Similarly, the cape hunting dog (not a dog in the true sense of the word), the coyote, the jackal, and all of the large, wild felids were never brought beyond the tame or semitame stage. The modern wolf, however, appears to be an animal that will easily and fully accept the companionship of humans in a manner that nearly approaches that of a domesticated dog.

Since we are discussing the possibilities of the first friendly contacts between wolves and humans, it is appropriate to mention at this point the evidence we have for early domestication through osteological changes in the wolf. It is generally known and accepted by workers concerned with early canid domestication that the first observable changes take place in the skulls, jaws, and dentition of these tamed canids. More specifically, these alterations include the foreshortening of the muzzle, or rostrum, and the crowding of the tooth rows, along with a comparative overall reduction in the size of the teeth.

As domestication occurred, the mandibles deepened midway along the horizontal ramus, with a more convex inferior margin than that found in similar-sized wild wolves. These are all characteristics found in most domestic dogs of wolf size. The coronal apex takes a decided backward turn, a condition found in some Chinese wolves *(Canis lupus chanco)* but generally absent in wolves from other geographic areas (Olsen and Olsen 1977). The foreshortening of the muzzle, or rostral, area of the skull has been observed in the remains of wolves recovered from geographically widely separated paleontological and archaeological sites of late Pleistocene age and later.

One of the earliest documentations of this foreshortening of wolf skulls was made by J. G. Pidoplichko (1969), who described short-faced, and possibly tamed, wolves. Their fossils were collected from excavations conducted in 1954 at a late Paleolithic campsite of mammoth hunters at Mezin in the Chernigov region of the Ukraine. They were found in association with a lithic assemblage amid the remains of 116 individuals of woolly mammoths (*Mammuthus primigenius*). The remains of wolves with proportions of those living in that area today (*Canis lupus albus*) were also found, along with the three or four short-faced animals.

Pidoplichko coined the taxonomic designation *Canis lupus domesticus* for these short-faced wolves. I, however, would propose to change the taxonomic assignment to *Canis lupus familiaris* for these and other similarly differing wolves and to use the name designated for the domestic dog to identify this Pleistocene race or subspecies, rather than create a new trinomial designation. The use of *familiaris* follows the correct taxonomic progression from a wild wolf, through taming, to the domestic dog. This term seems to be less confusing than the name *domesticus,* which has commonly been used as the scientific name for the domestic cat *(Felis domesticus,* now *Felis cattus).*

For a number of years, particularly during the 1930s, the Frick Laboratory of the American Museum of Natural History in New York City had field representatives stationed in the Fairbanks area of Alaska. They were there to cooperate with the University of Alaska and the Fairbanks Exploration Company in collecting faunal remains as they were uncovered in muck deposits by hydraulic gold-mining operations. Such placer-mining methods, however, made it impossible to determine the stratigraphic context of a particular bone or artifact, because many had been collected by the gold-dredge crews from the spoil dumps of reworked and discarded matrix.

In fact, there is a general consensus that artifacts from such areas, which may originally have been on the surface, were subsequently relocated several meters below the ground level and mixed with the bones of extinct animals (Rainey 1939). Thus, it might have been possible to find some artifacts in association with the older, extinct animals if different methods of mining had been practiced when the bulk of known Pleistocene vertebrate material was collected in the 1930s.

Between the years 1932 and 1953, 28 more or less complete wolf skulls were obtained from the muck deposits in an area north and west of Fairbanks. The age of the deposits from which these wolf skulls were obtained has been determined as Upper Pleistocene, Wisconsin Age (about 10,000 B.C.). The geologist T. L. Péwé published two reports (1975a, 1975b) on the geology and stratigraphy of this area and the associated recovered fauna. The wolf skulls were collected from dredging operations on Ester Creek, Cripple Creek, Engineer Creek, and Little Eldorado Creek. All of these creeks also yielded Paleolithic artifacts (Rainey 1939). However, the association of these artifacts with the skeletal remains of extinct animals is problematical, because the mechanical mixing of artifacts and bones, just discussed, prevented the collectors from obtaining any evidence that might have existed of a contemporary association of Pleistocene wolves with humans.

T. Galusha, of the Department of Vertebrate Paleontology at the American Museum of Natural History in New York City, worked for many years on the wolf remains from the Fairbanks dredging operations. He noted that a number of the skulls were extremely short-faced for wild wolves and approached modern Eskimo dogs in facial proportions, although they were considerably larger animals overall.

He turned the project over to me shortly before his death, and I continued his studies and compared this collection with a large series of both Pleistocene and Holocene wolves as well as with Eskimo dogs from both Greenland and Siberia. I feel confident at this point in stating that the short-faced wolves from the Fairbanks area appear to be forerunners of the later, domesticated Eskimo dogs.

The proportions of the skulls of these wolves that vary do so in the rostral area. The area of the skull that is anterior to the infraorbital foramen is noticeably foreshortened and constricted laterally in several of the skulls. Two of them (F:AM70933 and F:AM67156) lack anterior premolars. Several others have the full complement of teeth in the abbreviated dental margin. The dentition of F:AM67153 is considerably smaller than the average wolf of that area and approaches the overall tooth size found in the Eskimo dog.

Dishing of the rostrum, when viewed laterally, is evident in all of the short-faced skulls identified as *Canis lupus* from the Fairbanks gold fields. The occipital and supraoccipital crests are noticeably diminished compared to those found in average specimens of *C. lupus.* The occipital overhang of these crests, a wolf characteristic, is about equal in both groups of *C. lupus.* Multivariate analysis of all of the wolves from the Fairbanks collection separated the collection into two groups, based on either their predominant wolf-like or dog-like characteristics. Yet, as has already been noted, it may never be possible to establish if there was a close human association with the Alaskan Pleistocene wolves, because of the types of deposits in which both the wolves and the lithic assemblages occur and the conditions under which both were collected.

In 1939 and 1940 an Eskimo village site was uncovered that dated from the first millennium B.C. This village, named Ipiutak, is believed to represent an occupation of early Eskimo immigrants from Siberia. The artifacts suggest a Neolithic culture (Larsen and Rainey 1948). The site is located on the tip of Point Hope, Alaska, approximately 125 miles north of the Arctic Circle, and is at the westernmost point of the continent north of the Bering Strait.

At least five more or less complete *Canis* skulls were recovered from the archaeological excavations at Ipiutak. These were studied and reported on by O. J. Murie in an appendix to the site report by H. Larsen and E. Rainey (1948). After comparing these skulls to those of wolves, Eskimo dogs, and other large domestic dogs, Murie decided that they fell into the Siberian class of dogs. Any slight differences between the Ipiutak dog skulls and the Siberian and Alaskan dog skulls with which they were compared were within the size variation considered to be normal for domesticated dogs of this type.

One animal in particular (No. H43) was considered to be a dog–wolf hybrid, as the large size and heavier mandible and teeth approached those of a wolf rather than a dog. Murie concluded that two of the skulls represented the so-called Siberian husky type, three may have been variants of this same type, and the other animal (No. H43) was the hybrid just mentioned. He believed that there was adequate evidence that the Ipiutak dogs were of Asian origin.

Both sides of the Bering Strait have seen numerous explorations and excavations searching for the earliest evidence of habitation sites of the Asian migrants who reached the North American continent. Unfortunately, very little relating to vertebrate remains has been reported. This may be partly because of the poor preservational conditions that characterize this region and that have resulted in an extremely small sample upon which to base our interpretations. However, the subordinate role of organic remains in many early archaeological interpretations has also had a great deal to do with this gap in our knowledge of fossil vertebrates of all taxa from archaeological contexts.

An example of this subordinate role can be seen in the 331-page report on the archaeology of Cape Denbigh (Giddings 1964). The text and 73 plates are devoted to a thorough coverage of nearly all aspects of the excavations on Cape Denbigh, but the recovered faunal remains are listed in a table of only seven lines in one paragraph. No scientific taxonomy is given for these animals, and some remains are classified simply as "bird" or "other." Obviously, it is quite possible to overlook many comparatively small canid fragments if one's interests are funneled in other directions. It is also possible that canids were not collected because it may have been assumed that they represented the common, local wolves, when in actuality they might have represented primitive dogs, as well as wolves or crosses between wolves and dogs.

An intriguing collection of seven large canid skulls that may represent both domestic dogs and wolves or even wolf–dog crosses were found at the Bagnell site, which is a two-component village situated on the edge of a terrace above the Missouri River flood plain just north of Sanger, North Dakota. The dates of the proveniences from which the skulls were collected are from as early as circa A.D. 1590, with the latest occupation from the earliest layer yielding two skulls of domestic dogs of wolf size. Two more of the skulls are definitely those of wolves, but from the later time of occupation; one skull is of a domestic dog, also of wolf size, and the remaining two are of wolves. A most intriguing observation is that one of the domestic dog skulls from the early layer possesses two strong wolf characteristics and seven morphological characteristics that are typical of large, domestic dogs. Admittedly there is a problem of temporal control for these proveniences; however, at this time it does not seem likely that the earliest proveniences contain any intrusive mixtures of dogs that were introduced by Europeans. Large, wolf-sized dogs, particularly those that appear to be wolf–dog hybrids, are so rare in an archaeological context that these Bagnell canids are worthy of considerable note.

Another published account of a large, hybrid cross of a wolf and a dog is that contained in the report of excavations of a bison-kill site in southwestern New Mexico (Speth and Parry 1980). This find, a single canid skull, is illustrated and analyzed in the report, but unfortunately no provenience is given for this specimen. The overall range of dates for all proveniences on the site are from as early as A.D. 1420 ± 125 to A.D. 1845 ± 100. This canid would be of interest in relation to early taming of the wolf and, perhaps, its crossing with smaller Indian dogs, but only if it could be established that it was collected from a provenience that predated the European introduction of large mastiffs or hounds. Since the range of dates is so great, it could easily be the result of a more recent crossing of a European dog and local wolf. (The occurrence is recorded here as a plea to future workers to include all pertinent data and not just that which pertains to comparative zoology.)

To date, the oldest substantiated finds of prehistoric domestic dogs in North America are those from Jaguar Cave, Idaho. Fossil fragments, consisting of incomplete mandibles, a single left mandible, and a small portion of a left maxilla, were all collected from excavations in an early Holocene rock-shelter in the Beaverhead Mountains of Lemhi County, Idaho. The excavations were conducted by a joint expedition of the Peabody Museum of Archaeology and Ethnology at Harvard University and the Idaho State Museum at the Idaho State University in 1961 and 1962. Carbon-14 (14C) dates indicate that the age of the deposits ranges from about 9500 to 8400 B.C. (Lawrence 1967). The site was determined to be a hunting camp (Sadek-Kooros 1972).

An interesting aspect that remains unexplained concerning the canid from this site is its unwolflike appearance (Lawrence 1967), which suggests there may be an even earlier form, as yet undiscovered, that may link these Jaguar Cave dogs with a wild, ancestral form. One would not expect to find these early dogs in a locality so far south as the Jaguar Cave rock-shelter without finding similar remains in sites closer to the Bering Strait. The morphological features that are present in the Jaguar Cave dog fragments are characteristically the same as those that are present in known specimens of *C. familiaris.* For example, critical measurements taken of all fragments indicate that they are too small to be derived from the wolf. They were then compared to the coyote, but they differ from this smaller, wild canid in being more massive, deeper dorsoventrally, and thicker lateromedially. The tooth rows are short when compared to the size of the individual teeth, and this shortening of the jaws is accompanied by crowding of the tooth row. This aspect is particularly noticeable in the area of anterior premolars, where the alveoli do not lie in a straight line; they are, rather, set obliquely. The muzzle, as far as could be projected from the fragments, is more shortened than in the coyote, and this characteristic seems to be well developed, as in later domestic dogs.

Some lower jaws of what are surely coyotes also occurred in the same site. These were determined to be of the local subspecies *Canis latrans lestes.* Canid material from a considerably later site (also in Birch Creek Valley, Idaho), having a 14C date not earlier than 2500 B.C., was also described by B. Lawrence (1967) as belonging to domestic dogs. The specimens included four nearly complete mandibles, a number of mandibular fragments, one broken skull, and two cranial fragments. The specimens from this later site were determined to be very similar in form and size to Eskimo dogs, with which they were compared in the Museum of Comparative Zoology at Harvard University. By inference, the specimens from Jaguar Cave were also from this group of dogs.

There exists a considerable temporal gap between the Jaguar Cave dogs and later prehistoric dogs from other areas in North America. Fossils from areas in the Southwest date from at least the time of Christ (Guernsey and Kidder 1921). From other areas they date perhaps from 8400 B.C. (McMillan 1970). A dog from the Koster site in Illinois (Struever and Holton 1979) has an assigned date of 6500 B.C., and dogs from White's Mound in Richmond County, Georgia, have been given a date of about 500 B.C. (Olsen 1970). F. C. Hill (1972) briefly noted a Middle Archaic dog burial from Illinois with an accompanying date of 5000 B.C.

G. M. Allen (1920) published the first comprehensive discussion of early dogs that were associated with the prehistoric peoples of the Western Hemisphere.

This publication, unfortunately, is now out of date as well as out of print. Most of the critical finds relating to the development of the domestic dog were made subsequent to Allen's work. W. G. Haag (1948) based his evaluations of an osteometric analysis of some eastern prehistoric dogs on Allen's early publication, but Haag's monograph is also out of date.

The monograph by Allen was for many years the standard work that was used to classify domestic dogs found in association with prehistoric human cultures. The author listed these dogs as falling into the following groups, determined by comparative skull measurements and form: "(1) a large, broad-muzzled Eskimo dog, (2) a larger and (3) a smaller Indian dog, from which are probably to be derived several distinct local breeds. Of the larger style of dog, as many as eleven varieties may be distinguished; of the smaller, five" (Allen 1920: 503).

Some years ago I placed southwestern prehistoric dogs into two assemblages, small and large, following, more or less, Allen's classification. The animals in the small group were fox terrier–sized and were further refined or separated into small, short-faced, and small, long-faced dogs. The animals in the large group were long-faced and were comparable in size to the local coyote but a bit heavier in overall proportions. This latter group was referred to by Allen as the large Pueblo Indian dog, or the Plains Indian dog.

However, after examining later published reports and newer finds and reexamining the older finds made during Allen's career, I now conclude that these groupings are, in a sense, artificial – particularly for dogs from the southwestern United States. In fact, the groups actually grade into one another in size, form, and amount of morphological variation, if a large enough collection is examined. The result is a more or less single mongrel group of southwestern Indian dogs, although the entire range of size and form variation is not found in every archaeological site. It is still possible to find representatives of only a part of the spectrum – either small, short-faced or long-faced dogs, or large Pueblo Indian dogs – at specified sites. The overlap is at the extremes of each of these size groups and is quite logical, because the prehistoric Indian dogs were hardly registered American Kennel Club breeds but were, instead, free-breeding, socializing mongrels.

It is, of course, quite simple to pick out representative animals of these differing groups from collections of excavated canids if there are enough individuals assembled from a large number of archaeological sites. The Basketmaker and early Pueblo Indian dogs of the Southwest and those from White's Mound, Georgia, as well as the dogs from the shell heaps of Kentucky or Alabama, all show a close similarity in size and form. But these animals were quite advanced domestic dogs, and most were of a comparatively small size, although – as stated earlier – there are exceptions to this rule (for example, both small and large forms of dogs are found in the same stratigraphic level at the Jaguar Cave site).

Many early and later Pueblo Indian sites have yielded dog remains. In particular, reference is made to immature puppies as well as adults found in levels dating from about A.D. 1125 to 1175 at Antelope House in Canyon de Chelly, Arizona (Kelley 1975). At the Grasshopper Pueblo, built during the fourteenth century in east central Arizona, a number of small domestic dogs were recovered during 16 years of excavation by the University of Arizona Archaeological Field School (Olsen 1980). A unique find of an immature gray wolf, *C. lupus,* consisting of a right premaxilla and deciduous dentition, was also recovered from one of the rooms of this pueblo. This fragment of a wolf pup suggests that it may have been kept as a pet, perhaps with a view toward taming, although this is only speculation.

It is the case, however, that nearly every Pueblo excavation in the southwestern United States has produced some evidence of the domestication of the dog. These sites date from the eleventh through the fourteenth centuries and range in size from Cliff Palace Ruin in Mesa Verde National Park, Colorado (with its multistoried masonry construction of many rooms and great stone towers), to the more modest pueblos at Keetseel and Betatakin in the area of Monument Valley, Arizona. Tree-ring dates for Keetseel range between A.D. 1274 and A.D. 1284; those for Betatakin are between A.D. 1260 and A.D. 1277. By the time of these late dates, the domestic dogs were well advanced and were morphologically the same as present-day dogs.

As of this writing, however, we have yet to recover the ancestral forms of *C. familiaris* that would help to bridge the gap between the small, late Paleolithic wolves and the early Neolithic dogs from Asia and from Jaguar Cave, Idaho, on the one hand, and, on the other hand, the gap between the Jaguar Cave dogs and the well-known series of dogs of the southwestern United States that date from some 2,000 years ago and are still in existence today.

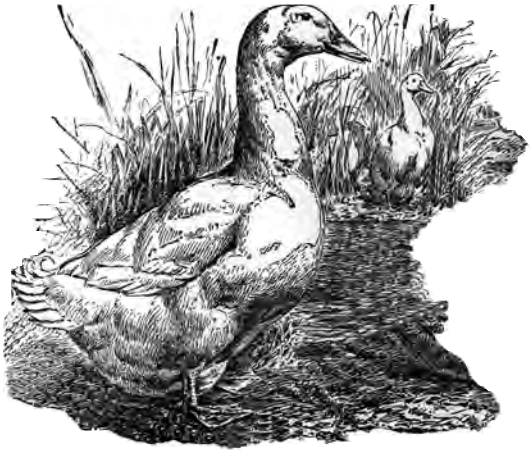
II.G.9 Ducks

The mallard, *Anas platyrhynchos,* is the most ubiquitous taxon in the subfamily *Anatinae* of the family *Anatidae.* It is the ancestor of most domestic ducks, the males of which still sport the ancestral curling feathers of the upper tail (Delacour 1956–64; Gooders 1975; Gooders and Boyer 1986). Because the wild mallard is so widespread in the Northern Hemisphere, it is extremely likely that it was widely utilized by humans and probably domesticated in different areas at different times. The amount of variability in the domestic duck is very small compared with that found in the domestic chicken (Thomson 1964), and it would seem that present-day domestic ducks evolved gradually (Woelfle 1967), in the process becoming larger than the wild type, with much more variety in color, size, and gait (Clayton 1984). Domestic ducks have also lost the ability to fly.

The excellent flavor of duck flesh (as well as the eggs) has been enjoyed from prehistoric times to the present day. An important incentive in breeding ducks for meat has been the fact that they have a fast growth rate and can be killed as young as 6 to 7 weeks of age and still be palatable. A disadvantage, however, is that duck carcasses are very fatty (Clayton 1984).

Ducks are raised in large numbers in many Western countries, such as the Netherlands, Britain, and the United States, although intensive duck production has occurred only in the last 20 years (Clayton 1984). In Britain, most commercial ducks are found in Norfolk (although some are kept in Aberdeen and Dumfries), but these constitute only about 1 percent of all poultry in the country (Urquhart 1983). Ducks are less prone to disease than hens but eat more food. Unfortunately, their eggs are unpopular with British consumers because they are thought to be unclean. Ducks destined for the supermarkets are killed when they are from 7 to 9 weeks old.

It is in the East where fully 75 percent of domestic ducks are found, especially in the Asian countries of Vietnam, Indonesia, Thailand, China, Bangladesh, the Philippines, and Burma. Duck meat contains a high percentage (up to 35 percent) of fat, which is in short supply in many Asian diets, and in China, where less meat is consumed on a regular basis than in the Western world, selection is for ducks with a high fat content (Clayton 1984).



Peking Duck

Present-day domestic ducks range from the small Call, weighing less than 1 kilogram (kg), to the larger strains of Peking and Aylesbury, weighing up to 6 kg. Ducks can be grouped into three categories: meat producers (Rouen and Aylesbury), egg layers (Indian Runner and Khaki Campbell), and ornamental birds (the tiny Call and Crested ducks) (Delacour 1956–64). The Normandy or Rouen duck is quite similar to the wild mallard and, although common worldwide, is of greatest economic importance in Southeast Asia. The bird has a gamy flavor and in France is traditionally killed by strangulation or smothering, thus ensuring that the flesh retains all of its blood and flavor (David 1970).

Most domestic breeds have a characteristic horizontal posture, but some (as, for example, the Indian Runner), are much more erect, which allows them to run very quickly. The selective pressures that encouraged this erectness are not known, nor are the anatomical changes that brought it about, although droving, common for centuries in the Far East, may be a possibility (Clayton 1972, 1984).

Ducks in the Prehistoric Period

The earliest work on bird bones from archaeological sites was carried out in the mid-nineteenth century at shell mounds in Jutland, Denmark (Steenstrup 1855). Little attention, however, was given to the identification of bird bones from archaeological sites in the Northern Hemisphere until the 1980s, and scant research has been undertaken on the taphonomy of bird bones (Ericson 1987; Livingston 1989). Another problem is that morphological differences between similar bones of different taxa of the *Anatidae* are not always distinct and clear-cut. Measurements of bones can help to separate them, but frequently no specific identification can be made, especially if the material is fragmentary. Nevertheless, attempts at distinguishing wild and domestic mallard bones have been made, although there are also zooarchaeological problems in such an undertaking. Anatomical differences that may be associated with domestication have been recognized in several late Saxon faunal collections in Britain, including that of Northampton (Coy 1981, 1989). The flattened facet on the anterior aspect of the *caput femoris,* employed by J. Lepiksaar (1969) for the identification of domestic geese, can also be used for ducks. J. Ekman (1973) applied this technique to remains in seventeenth- or eighteenth-century deposits in Gothenburg, Sweden.

The wild mallard is (and was) highly migratory, with flocks of several thousand birds not unusual (Gooders 1975). Ideally, wild birds are hunted in the late summer and early fall, just after they have grown plump on summer feeding, and prehistoric fowlers generally took the birds at this, their most defenseless period, or while they were molting or nesting in the spring (Clark 1948).

Some Danish Mesolithic wetland sites demonstrate human exploitation aimed almost solely at birds and, in certain cases, seasonal exploitation of just one or a few species. For example, the Mesolithic site of Aggersund on the Limfjord was a specialized camp for the procurement of whooper swans (Grigson 1989).

There are two distinct types of Danish Mesolithic sites. One is the inland bog, associated with the Maglemosian culture of the Boreal age, whereas the other is the coastal midden of the Ertebolle culture of the Atlantic age. The chief Maglemosian sites on Zealand (Mullerup, Svaerdborg, Holmegaard, and Øgaarde) have yielded bird bone assemblages in which the most abundantly represented birds are wild ducks and mute swans. Also represented are grebes, coots, and some sea birds, including cormorants, gulls, and divers of various species (Clark 1948). Marine birds are more strongly represented in the Ertebolle middens. Because of a lack of winter migrants, the Maglemosian sites were probably occupied only during the summer months, but fruitfully so, as evidenced by the presence of cranes and numerous mute swans, as well as young cormorants and sea eagles.

The mute swan and mallard are both resident taxa and remain very common in present-day Denmark (Grigson 1989). Mallards breed all over inland Denmark and molt during the summer in most wetland habitats, usually in small flocks, but occasionally several hundred individuals congregate on large lakes and in densely vegetated marshland.

In addition to the work done in Denmark, we know from efforts in Germany (at Friesack, Landkreis Nauen) that the Mesolithic (9,700 to 7,000 years ago) bird bone assemblage is dominated by the mallard in all phases (Teichert 1993). In Neolithic eastern Europe (western Russia, the northeastern Baltic region, and northern Poland), numerous bird bones have been excavated from wetland settlements. It is thought that some of these may have been specialized waterfowling sites (Zvelebil 1987). Eighty-nine percent of the bone sample at Narva-Riigikula 3 is composed of waterfowl, mainly ducks. The site is situated on a sandy dune separating a lagoon from the open sea and is on the route of the annual migration of waterfowl between their breeding grounds in the Arctic and their winter quarters in southern Scandinavia and northwestern Europe. These wetland sites are of immense importance in preserving bone and plant remains as well as food-processing tool kits – in this case, wooden projectiles with blunted tips – thus making it possible to reconstruct the subsistence strategies of forest-zone hunter-gatherers in a much more comprehensive way than at dry sites.

As was the case in Poland, the wild duck was the chief quarry of the Iron Age inhabitants of Glastonbury Lake Village in Somerset, England. There, the birds were probably dispatched by clay pellets (also excavated from the site) that were well adapted for use with a sling (Andrews 1917).

Ducks in the Historical Period

The Evidence of Domestication

Southeast Asia is claimed to have been a major center of duck domestication (Zeuner 1963; Wood-Gush 1964), especially southern China, where the birds were kept during the Earlier Han Dynasty (206 B.C. to A.D. 220). The first written records of domestic ducks date back to the Warring States period (475–221 B.C.) (Weishu 1989). But according to one authority, the Chinese have had domesticated ducks for at least 3,000 years (Yeh 1980, cited in Clayton 1984), and it is the case that Chinese pottery models of ducks and geese, dating from about 2500 B.C., have been excavated (Watson 1969). However, archaeological evidence of a faunal nature is also needed before any firm conclusions about the antiquity of domestic ducks in China can be reached.

As already noted, Southeast Asia continues today as an important duck-raising area where domestic ducks surpass chickens in economic importance (Zeuner 1963). The duck thrives in watery environments, which promote clean plumage and increased disease resistance. Moreover, in warm, humid climates, with abundant rice paddies and waterways, ducks forage more successfully and produce more eggs than do chickens, which are not fond of this sort of environment (Clayton 1984).

In China, ducks are particularly important in the control of land crabs (which can devastate rice crops); the birds eat the crab nymphs that eat rice seedlings. Ducks are also released into paddy fields to consume locust nymphs, which, unlike adult locusts, are unable to fly. The recognition that ducks are effective instruments in combatting insect pests is probably of great antiquity (Needham 1986).

The main duck taxa winter in southern China and, except during the breeding season, move in large flocks, each consisting of hundreds – or even thousands – of birds. Although many different species of domestic duck have evolved in Jiangsu and other provinces south of the Yangtze River, where duck raising is common, their shapes, colors, and wings still bear much resemblance to those of their ancestors. The well-known Peking duck, for example, evolved through domestication of the mallard. Its feathers have whitened over a long period, but the curling central tail feather shows that the bird is descended from the same ancestor as the domestic ducks in the south (Weishu 1989).

True domestication elsewhere, however, seems to have come much later. Surveying the limited textual evidence (from Aristotle in the fourth century B.C. up to the ninth century A.D.), J. Harper concluded that ducks did not become fully domesticated outside of China until possibly the Middle Ages (Harper 1972).

The pintail *(Anas acuta)* is the most frequently represented taxon of waterfowl in ancient Egyptian art and hieroglyphics (Houlihan 1986), and such illustrations include depictions of pintails being force-fed. These birds can be tamed easily and remain able to breed (Delacour 1956–64). The widespread marshes of the Nile Delta would have provided excellent wintering grounds for both ducks and geese and, therefore, fowling opportunities for humans. But although geese, chickens, and pigeons are frequently mentioned in Egyptian papyri from the fifth century B.C. onward, ducks are noted only rarely.

Aristotle discussed only chickens and geese in his *Natural History,* and although Theophrastus mentioned tame ducks, he failed to indicate whether they were bred in captivity (Harper 1972). F. E. Zeuner (1963) has asserted that the keeping of domestic ducks in Greek and Roman times was unusual, though not unknown. Duck-shaped vases have been recovered at Rhodes and Cyprus, both centers of the cult of Aphrodite; they were dedicated to the goddess and to her companion, Eros. Ducks may have been on these islands for religious purposes only.

Several species were kept in captivity by the Romans, who maintained aviaries *(nessotrophia)* of wild ducks, probably to fatten them for the table (Toynbee 1973). Varro, writing in 37 B.C., was the first to mention duck raising by the Romans, pointing out that ducks should be enclosed to protect them from eagles as well as to prevent their escape (Hooper and Ash 1935). In the first century A.D., Lucius Junius Moderatus Columella provided advice on keeping ducks (mallard, teal, and pochard) and other waterfowl in captivity, which was considered much more difficult than caring for more traditional domestic fowl (Forster and Heffner 1954).

Columella, along with Marcus Tullius Cicero and Pliny the Elder, recommended that the eggs of wild ducks be gathered and placed under hens to hatch. Columella claimed that ducks raised in this way would breed readily in captivity, whereas birds taken as adults would be slow to commence laying. He also stated that duck keeping was more expensive than the raising of geese, which fed mainly on grass (Forster and Heffner 1954). Marcus Porcius Cato mentioned the fattening of hens, geese, and squabs for the market, but not ducks (Hooper and Ash 1935).

Moving from Rome to other parts of Europe, we find that metrical data from Colchester, England (from the first to the fourth centuries A.D.), indicate that length and breadth measurements of mallard wing and leg bones are within the range of variation for wild mallards (Luff unpublished). Similarly, measurements of mallard remains from the Roman fort of Velsen I in the Netherlands were considered to be of the wild variety; length and width measurements of the mallard bones fit perfectly within the ranges of recent wild mallards studied by H. Reichstein and H. Pieper (1986; also see Prummel 1987).

The Saxons may have had domestic ducks, but as yet the evidence is unclear. Remains unearthed at Saxon Hamwih (Southampton) could have been those of domesticated ducks but could also have been those of wild birds (Bourdillon and Coy 1980). However, J. P. Coy (1989) has suggested that the low proportion of wildfowl at Saxon sites in Britain is indicative of the economic importance of domestic birds such as ducks and chickens.

A bit later, in Carolingian France (the eighth to the tenth centuries A.D.), estate surveys listing payments due feudal lords indicate that chickens and geese served as tender far more frequently than ducks (Harper 1972). Similarly, in Germany, the *Capitularium de Villis* grouped ducks with ornamental birds such as peafowl, pheasants, and partridges, but not with chickens and geese, kept for purely economic reasons (Franz 1967).

The scarcity of wildfowl was most likely significant in hastening domestication. Early medieval England, for example, had apparently witnessed a wholesale slaughter of wildfowl in spite of Acts of Parliament specifically aimed at their conservation, and in 1209, King John, finding insufficient game for his personal falconry, issued a proclamation forbidding the taking of wildfowl by any means (Macpherson 1897). Statutes were also passed by Henry V, and again by Henry VIII, against the destruction of wildfowl. Interestingly, in the price controls of the Poulters' Guild in London, dated to 1370, a distinction was drawn between wild and tame mallards (Jones 1965). Wild mallards were more expensive than tame ones, which suggests that wild birds were more prized than farmyard birds and indicates their general scarcity at that time.

Jean Delacour (1956–64) has suggested that the mallard may have become truly domesticated in Europe only in the medieval period – although, of course, prior to the distinction made by St. Hildegaard (twelfth century) between wild *(silvestris)* and domestic *(domesticus)* ducks (Figure II.G.9.1). Certainly, the latter were being reared in France by the end of the fourteenth century, when the Ménagier de Paris (c. 1390) also distinguished between wild and domesticated ducks (Prummel 1983).

Nonetheless, ducks of domestic origin are uncommon in archaeological contexts of the medieval period (Eastham 1977; Maltby 1979). At early medieval Dorestad (Netherlands), some ducks were larger than others, indicating that they might well have been domesticates (Prummel 1983). However, the majority of remains at that site probably derived from wild specimens, because their measurements fall within the range for modern wild mallards (Woelfle 1967). Many mallard remains from late medieval Amsterdam measured even larger than those from Dorestad, once again suggesting the presence of domestic ducks among the Dutch (Prummel 1983). But by contrast, at Haithabu in northern Germany, duck remains have been firmly identified as deriving from the wild variety (Requate 1960; Reichstein 1974), which was also the case at eleventh- and twelfth-century Grand-Besle, Buchy, Normandy (Lepiksaar 1966–8).

Although domestic ducks are often identified in archaeological deposits from the sixteenth century onward, they did not increase dramatically in size until the eighteenth and nineteenth centuries, when distinct varieties were recorded. Methods of rearing ducks were modeled on those mentioned by classical authors. G. Markham, for example, in the seventeenth century described ways of keeping wild mallards, teals, widgeons, shellducks, and lapwings that were very similar to those mentioned by Columella (Markham 1614).

In the eighteenth century, breeders began to promote and further develop certain traits for frequent egg laying or rapid growth for meat production, and sometimes breeds were crossed to produce hybrids suitable for both purposes (Batty 1985). Other varieties were used mainly as ornamental birds to decorate gardens and park ponds.

Aspects of Domestication

S. Bökönyi has emphasized the differences between "animal keeping" and "animal breeding," with the former occurring without purposeful selection or the control of feeding, whereas the latter involves the deliberate selecting of specific traits for animal breeding and also control of nutritional intake (Bökönyi 1969).

There are a number of possible reasons why duck domestication in the West lagged so far behind that of the goose and chicken. One is that goslings accept the first living creature that they see as their mother, whereas mallards, who imprint through sound, do not do this. For them it is the call note of the mother that is important in identifying her (Lorenz 1964). Consequently, ducks were much less amenable to domestication, and the Roman idea of placing wild duck eggs under hens to hatch them into domesticity was off the mark because it did not go far enough.

Interestingly, the Comte de Buffon (Georges Louis Leclerc), who authored 32 volumes of *Natural History,* explained how such a procedure did work:

> Eggs taken from the reeds and rushes amidst the water, and set under an adopted mother, first produced, in our farm-yards, wild, shy, fugitive birds, perpetually roving and unsettled, and impatient to regain the abodes of liberty. These however after they had bred and reared their own young in the domestic asylum became attached to the spot and their descendants in process of time grew more and more gentle and tractable, till at last they appear to have relinquished and forgotten the prerogatives of the savage state, although they still retain a strong propensity to wander abroad. (quoted in Bewick 1826)

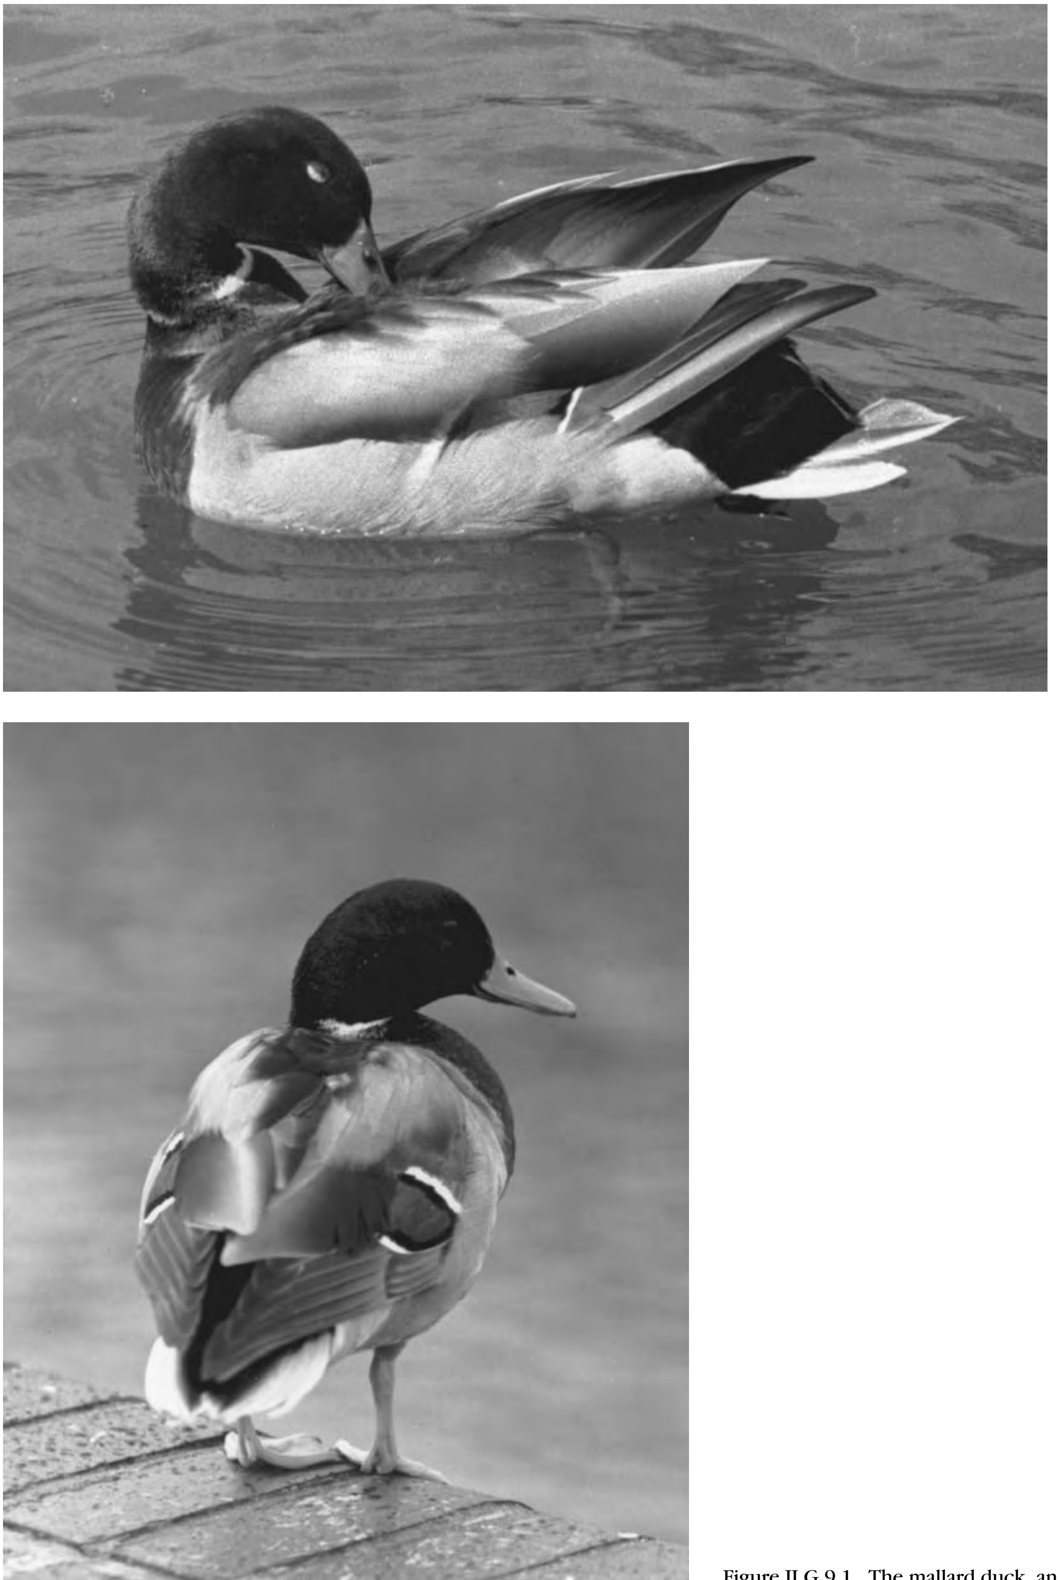


Figure II.G.9.1. The mallard duck, ancestor of most domestic ducks.

Another reason for what appears to have been tardy domestication in the West has to do with temperature. S. Bottema (1989) has pointed out that domestic fowl in the Near East always have larger numbers of young than those in more temperate regions, which is the result of a higher survival rate connected not with greater clutch size but with higher temperatures.

Temperature, in turn, is linked to diet. If eggs of the teal *(Anas crecca)* are hatched when temperatures are low, the young may not survive, even though teal ducklings in the wild are not affected by cold weather. The reason is that a natural diet in the wild compensates for a lack of body warmth, but in captivity, with a suboptimal diet, a warm temperature becomes a critical factor (Bottema 1989). In fact, it is for this reason that Bottema (1989) has proposed that areas with high spring temperatures (such as much of Asia) would have been the locus for initial duck domestication.

Charles Darwin (1875) was one of the first researchers to deal with morphological changes in domestication. Using a small sample of wild mallard, Aylesbury, Tufted, Penguin, and Call ducks, he found that: (1) In comparison with the wild duck, the domestic duck experienced universal but slight reduction in the length of the bones of the wing relative to those of the legs; and (2) the prominence of the crest of the sternum relative to its length was much reduced in all domestic breeds. In addition, E. Brown (1906: 5), citing Edward Hewitt's breeding of wild ducks in 1862, has commented that "the beautiful carriage of the wild mallard and his mate changes to the easy, well-to-do, comfortable deportment of a small Rouen, for they at each reproduction become much larger."

Yet although most researchers, such as Darwin and Brown, have equated domestication with a size increase, E. P. Allison has suggested that there was a size decrease in mute swans from the Neolithic to the Bronze Age in Cambridgeshire, and that the birds were, on average, significantly larger than recent specimens. This phenomenon is not related to climatic change (Northcote 1981, 1983). But it is related to confinement, which can produce smaller birds that have not been selected for intentionally, such as the shellduck *(Tadorna tadorna)* or the male pintail *(A. acuta).* It is also related to food conditions in captivity, which can bring about a size decrease (Bottema 1989).

Confinement and food conditions in captivity may also have affected ducks in ways we have yet to understand. Another confounding factor in faunal analysis of mallards from riverine urban sites is that they may have arisen from a number of different populations, including wild, domestic, and scavenging ducks, with the latter most likely to interbreed with the former (O'Connor 1993). Thus, it is debatable just how pure the strains of present-day river mallards are, as they are obviously the product of considerable inbreeding. Ducks can hybridize (doubtless this was responsible for genetic contributions to domestic stock), and, in fact, all breeds of domestic duck can interbreed.

Also bearing on the history of duck domestication has been the birds' fussiness (much greater than that of chickens), which forestalls their development in caged coops because they have large appetites and because their feet are not tolerant of the wire floors. Ducks produce proportionately larger eggs than gallinaceous birds (and their young seem more resistant to starvation) (Marcström 1966), but selection under domestication has been for a larger bird and not for a larger egg. Moreover, duck eggs, as already noted, have never been in high demand in Europe; they are strong in flavor and lack the palatability of hens' eggs (Brown 1930). This is unfortunate, as ducks are naturally prolific layers and the eggs are highly nutritious.

Summary

Current evidence suggests that the origin of duck domestication was in Southeast Asia, and particularly in China. This region is still an important center for duck breeding and consumption, and one where captive, newly hatched ducklings have a greater chance of survival because of relatively higher temperatures.

It is true that more zooarchaeological data – in the form of bones – would be helpful in determining the origins of duck domestication. But because distinctions between the wild and domestic types of ducks are slight, such evidence alone would probably not pinpoint these origins.

Although the Egyptians, Greeks, and Romans kept ducks in captivity, they never truly domesticated them. Compelling evidence for domestication outside of Southeast Asia has only been found for the medieval period and later. In Europe, and particularly in Britain, the widespread pursuit and destruction of waterfowl by the nobility during the early Middle Ages (and probably earlier) may well have provided the impetus for duck domestication.

Because ducks have voracious appetites, feeding them may often have been a problem during winter months, when food shortages were common in nonindustrial societies – especially after a poor harvest. Consequently, it is likely that even though tamed, ducks were frequently left to forage as best they could. This inference also suggests that breeding was not controlled, with tame ducks interbreeding with members of the wild population. It was only in the eighteenth and nineteenth centuries that specialized breeds of domestic ducks were reared for meat, eggs, and ornamentation.

II.G.10 Game

Evolutionary Underpinnings

Game (defined here as the meat of wild mammals, birds, and terrestrial reptiles) has been an important component of the human diet since earliest times. A signal difference between the digestive system of humans and those of their closest primate relatives is the modification of the guts of the former for the processing of a diet containing substantial quantities of meat (Chivers 1992). Until the last few thousand years, all meat-producing animals were wild. The continuing cultural significance of hunting as an activity, and game as an element of the diet, must be seen in the light of the age-old importance of game animals in human biological and cultural evolution.

Although little doubt exists that early hominids consumed appreciable quantities of game, lively debate lingers over whether our remote ancestors were primarily hunters or scavengers (e.g., Shipman 1986; Binford 1988). Nevertheless, there is abundant evidence that by the time of the appearance of early modern humans – between 50,000 and 100,000 years ago – hunting was one of humankind's major activities. It may have been so for uncounted previous millennia.

A striking sexual division of subsistence labor characterizes most contemporary hunting and gathering peoples, with men hunting and women gathering (but see later discussion). Typically, gathered foods more or less reliably provide the bulk of the calories in the diet, mainly as carbohydrates, whereas game (and/or fish) contributes the undependable and sometimes limiting protein fraction. It has been proposed (Isaac 1978; Isaac and Crader 1981) that this bifurcation in foraging tasks and products is ancient and is implicated in the coevolution of food sharing, tool use, paternal investment in offspring, and related features of the unique human constellation of social behaviors.

Game, particularly large game, is often shared widely, whereas gathered foods tend to be acquired and consumed within the family. Meat is usually more valued than vegetable foods, and hunting is typically a more prestigious activity than gathering (Kent 1989). These correlations, too, may be ancient. The ancestral associations of men with hunting, of hunting with high social status, and of game with generosity and display, are an important part of the background of the presence of game in the human diet.

Subsistence Hunting

Global Trends

Studies of the hunting and gathering societies have identified geographic regularities in the quantity of game in the diet of these foraging peoples for whom wild foods are the foundation of life (Lee 1968; Jochim 1981). Behind these regularities are climatically determined abundances and availabilities of game animals relative to other potential human foods.

Close to the North Pole, inedible (for humans) tundra grasses dominate the vegetation, whereas much of the faunal biomass is in grazing animals (caribou, reindeer) with large herds and highly palatable flesh. Because much of the circumpolar region is coastal, terrestrial game can often be supplemented by large sea mammals (seals and whales). Thus, most of the few high-latitude foraging peoples (Eskimos, native Siberians) live largely or almost exclusively on game; the only real alternative food is fish (and that solely for inhabitants of uncommonly well-favored seaboards).

A good number of cool-temperate hunting and gathering peoples (40°–60° latitude) have fish as the primary element in the diet, particularly anadromous fish (fish that run upriver from the ocean to spawn, frequently in enormous numbers; see Schalk 1977). These peoples, however, also consume considerable game. Well-known ethnographic examples are the inhabitants of the northwest coast of North America and the coastal islands of northeast Asia, locations endowed with rivers supporting reliable and abundant fish runs. Other cool-temperate foraging peoples (that is, the Cree and Ojibwa of eastern Canada and several bison-hunting tribes of the North American Great Plains) make game the basis of their diet and eat distinctly lesser quantities of fish and vegetable foods. Cool-temperate regions are mainly forested or covered with prairie grasses, and wild vegetable foods are seasonally scarce and often not abundant at the best of times. With the exception of the North American bison, most of the large game tends to be relatively solitary and the availability of fish and game in a locality usually decides the base of the diet.

Hunting and gathering peoples living within 40° of the equator – the majority of all foraging peoples, and the great majority of those for whom we have reliable dietary information – derive most of their diet from gathered vegetable foods. Tubers, nuts, and seeds tend to be abundant and reliable relative to fish and game at these latitudes. Nevertheless, game remains for these peoples the most desirable part of the diet. Its capture attracts more effort and attention than the harvest of vegetable foods, and its procurers are often rewarded with favorable attention ranging from subtle deference to sexual favors (Hawkes 1990).

It is frequently assumed that game's desirability to these lower-latitude foragers derives from its role as the only major source of limiting nutrients, particularly the eight essential amino acids found in animal protein. However, complete inventories and nutritional analyses of these foragers' gathered wild foods remain scarce. That game and fish do supply much (usually most) of their protein is clear; that alternative invertebrate and vegetable protein foods are actually lacking is less clear. Well-documented demonstrations that gathered foods could not supply a protein-adequate diet are still too few to establish the generality of the impression that game is strictly necessary to provide protein for low-latitude hunters and gatherers.

Cultural Evolutionary Trends

Within the last 10,000 years (perhaps a bit earlier in Southeast Asia) plants and animals were domesticated on all continents except Australia. In some regions (e.g., eastern North America, lowland South America), the major edible domesticates were all plants. Here, wild game and fish continued to supply the meat in everyone's diet, not only in early agricultural times but even after domestication had permitted the emergence of stratified societies. In these New World stratified societies, the mighty were differentiated from the lowly in diet as in other aspects of life. However, it was the amount of game, the species of game, and the cuts of meat that distinguished the larders of the haves from those of the have-nots; there was no significant substitution of domestic flesh for wild game.

In other regions (that is, Europe, western Asia), large herd animals were domesticated at around the same time(s) as plants, and livestock became important early in the history of food production. Nevertheless, even though domesticated animals and their products (milk, blood) quickly became major elements in the diet of these mixed farmer-herders, game remained in the diet. The hunt continued in parallel with stock raising throughout most of early village life in the Old World, with wild animals often important in the diet. As food production led eventually to the development of Old World complex societies, hunting survived. At that point, however, the reasons for its persistence – previously a straightforward matter of obtaining food – became divergent.

By the early days of stratified societies, a pattern had been established (e.g., Trigger 1965) that continued through much of history and into the modern world: Hunting, and the presence of game in the diet, was most prominent in the lives of people at the very top and the very bottom of the social hierarchy. Among rulers, hunting lingered as recreation and ostensive display, a demonstration of not needing to rely on the efficient meat production of domesticated animals. Among the peripheral and the poor, hunting persisted because people could not afford domestic animals. The conflict of these classes over access to game lies behind such beloved folklore as the legend of Robin Hood. Among both classes, and into modern times, hunting is pleasurable, and game is a prestige food, although there are higher prestige foods among the impoverished.

Sexual Division of Labor

Although numerous societies have produced the occasional female hunter, and many cultures recognize goddesses of the hunt (the Grecian Artemis or the Indian Chandi), hunting remains predominantly (often exclusively) a male pursuit in almost all societies. Reasons proposed for masculine dominion of the chase range from the advantage in mean strength and speed enjoyed by male hunters to the disadvantages in combining hunting with pregnancy and child care incurred by female hunters. In this connection, the evidence of the tropical forest Agta people of the Philippines is crucial: Among some bands of the hunting, gathering, casually horticultural, and trading Agta, women regularly hunt, and their hunting includes dangerous game – like the wild pig – that they kill close up with machetes and improvised spears.

It is significant, then, that among the Agta, most women's hunting involves dogs; that "during late pregnancy and for the first few months of nursing, a woman will not hunt" (Estioko-Griffin and Griffin 1981: 131); and that "[y]oung mothers . . . are not the major women hunters; mature women with self sufficient children secure most of the game animals considered [of those taken by women] both by number and by weight" (Griffin and Griffin 1992: 310). Although the sexual division of labor appears remarkably weak among the Agta, and the generalization that women are mainly confined to gathering is overthrown by this case, hunting, nonetheless, remains more associated with men than with women.

Optimal Foraging Theory

A body of ecological theory known as Optimal Foraging Theory or OFT (Stephens and Krebs 1986) generates predictions as to the prey species that should be included in the diet of a predator. The general rule is that the predator should choose to pursue individuals of a particular species only when the predator cannot expect to get more or better food for its hunting time by disregarding that species. If there is a statistically reliable expectation that members of more valuable prey species will be taken in the time that would otherwise have been dedicated to the pursuit of members of a less valuable species, then that less valuable species is not in the optimal diet.

For example, if hares in a grassland are difficult to catch, but gazelles are plump and easy to kill, the optimal forager ignores the small and time-costly hares, even when he sees them bounding away, as long as gazelles are plentiful. Time spent chasing a hare is time taken away from searching for gazelles. Hares enter the optimal diet only when gazelles have become so rare that it becomes cost-effective to chase hares. When the mean encounter rate with individuals of each potential game species is known, along with the average time it takes to pursue and kill them and the average amount of meat they provide, then the optimal diet set can be predicted with considerable precision.

Predictions can also be made as to the predator's order of preference for the animals included in the optimal diet set. Predicted choices are easily summarized: Hunters should favor large animals over small and easily killed animals over those that require much time to hunt down and often escape.

Optimal diet set predictions have been tested for a number of subsistence hunters, with observed hunting behavior generally agreeing with the OFT model (Hill and Hawkes 1983; Kuchikura 1988; Kaplan and Hill 1992). Preferred game orderings have also been examined from an OFT perspective. Again, subsistence hunters appear in general to conform to theoretical predictions (Altman 1987; Hawkes, O'Connell, and Blurton-Jones 1991).

Game Allocation

The goal of subsistence hunting is game to eat. However, it is seldom if ever the case that all animals are considered game or that all parts of all game animals are eaten randomly by all members of a society. Rules governing the allocation of game are highly variable cross-culturally. Indeed, the issue of who makes the distribution is far from uniform from one culture to another. In many egalitarian cultures, the game belongs to the man (or woman) who killed it; in others, to the hunter who first wounded it; and in still others, to the person who made the arrow or other weapon with which the kill was accomplished, independent of that person's participation in the hunt. In ranked or stratified societies, the right to distribute the game may belong to the head of the lineage to which the successful hunter belongs, or to a village chief, or to another official.

Among the egalitarian, hunting and gathering !Kung Bushmen of southern Africa, the hunter whose arrow first hit the animal makes the initial distribution of meat, which is to the other hunters in his party. These hunters, in turn, distribute shares to their kin. All the hunters' kin who receive meat have additional kin obligations, and eventually everyone in the camp receives some meat, although portions may be small for individuals genealogically distant from the members of the hunting party (Marshall 1965).

But distribution methods aside, there are often rules of striking salience as to where different parts of animals are directed. Among the egalitarian, horticultural Anggor of New Guinea, when a wild pig is killed, the carcass, once cooked, is parceled out in a detailed way: The extremities are given to local clans; the hunter's clan gets the viscera; old women eat the fetus of a pregnant sow; old men receive cooked blood; and so on (Hurber 1980).

Parts (or all) of particular animals may be reserved for or prohibited to particular people or all people. Among the egalitarian, horticultural Barí of Colombia and Venezuela, the head and tripe of howler monkey are not eaten by anyone, whereas the head of spider monkey is eaten, along with the liver and some other organ meats. Peccary heads are reserved for old men; children are not allowed to consume any part of a bear; and no one eats jaguar.

People in particular statuses may have privileges or prohibitions connected with consumption of designated parts of game animals. Excavations at sites belonging to the late prehistoric Mississippian chiefdom centered at Moundville, Alabama, indicate that preferred cuts of deer meat were sent from outlying areas to elite centers, presumably for consumption by chiefs, their families, and retainers (Welch 1991).

Entire game species may be associated with social statuses. Among contemporary Anglo-Americans, consumption of opossum meat is restricted to rural lower classes, although venison is acceptable at both extremes of the social ladder, and smaller game birds are eaten largely by people of means.

There are a few general principles known for game distribution: (1) Many cultures assign carnivores and scavengers to an "inedible" category; (2) in egalitarian societies, the larger and more unpredictably obtained a game animal is, the more likely it is to be shared widely; (3) in ranked and stratified societies, the largest and most desirable game animals and the best cuts typically go to the most important members of society; and (4) the reproductive parts of otherwise edible animals are often prohibited to some if not all members of a society. Beyond these empirical generalizations, a general theory of food allocations, prescriptions, and proscriptions remains to be constructed.

Game in the Diet

The amount of game in the victuals of subsistence hunting peoples varies from a small fraction, as among many peoples with domestic food animals who also hunt when the opportunity arises (many societies in Oceania are of this type), to virtually the entire diet, as among some Eskimo groups. Some regional trends were mentioned previously. Within subsistence hunting societies, the distribution of game may or may not also be highly variable, with some or all game animals widely distributed and consumed or effectively confined to a minority of the society's members. In general, the higher the proportion of game in the aggregate diet, the weaker the exclusion of classes of individuals within the society from game consumption.

Prestige, Recreational, and Commercial Hunting

Prestige Hunting

Rulers of antiquity were often conspicuous hunters. Near the dawn of recorded history,"the Middle Assyrian king Tiglath-pileser I claimed . . . to have killed 4 wild bulls, 10 elephants and 920 lions – 800 from his chariot and 120 on foot" (Roaf 1990: 154).

Millennia later, in December A.D. 799, on a different continent, Charlemagne and his three sons killed a wolf, 2 European bison, 6 aurochs, 66 boars, and 80 deer in the space of two hours, to the applause of the queen and princesses, at a hunt organized by a count and his foresters. The royal party feasted later that day on the choicest parts of the kill (Halleux 1988).

Marco Polo's description, nearly 500 years later still, of Kublai Khan's yearly round illustrates a number of the features of prestige hunting: its prominence in royal life; its ostensive display; its employment of sumptuary laws; and its ranking of game animals by their suitability as royal prey. For six months of the year, hunting figured large in the life of Kublai Khan's court:

> The three months of December, January, and February, during which the Emperor resides at his Capital City, are assigned for hunting and fowling, to the extent of some 40 days' journey round the city; and it is ordained that the larger game taken be sent to the Court. To be more particular: of all the larger beasts of the chase, such as boars, stags, lions, bears, etc., the greater part of what is taken has to be sent, and feathered game likewise. . . .
>
> After he has stopped at his capital city those three months . . . he starts off on the 1st day of March, and travels eastward towards the Ocean Sea, a journey of two days. He takes with him full 10,000 falconers and some 500 gerfalcons besides peregrines, sakers, and other hawks in great numbers; and goshawks also to fly at the water fowl. . . . The Emperor himself is carried upon four elephants in a fine chamber made of timber, lined inside with plates of beaten gold, and outside with lion' skins. . . . He always keeps beside him a dozen of his choicest gerfalcons, and is attended by several of his Barons, who ride on horseback alongside. . . . And when he has travelled till he reaches a place called Katar Modun, there he finds his tents pitched . . . full 10,000 tents in all. . . . The Lord remains encamped there until the spring [May] and all that time he does nothing but go hawking round and among the canebreaks . . . and across fine plains . . . for 20 days journey round the spot nobody is allowed . . . to keep hawks or hounds . . . and furthermore throughout all the emperor's territories, nobody however audacious dares to hunt . . . hare, stag, buck and roe, from . . . March to . . . October. (Polo 1927: 127, 129–33)

Recreational Hunting

Much prestige hunting is clearly recreational, but hunting for enjoyment is not limited to royalty. Indeed, most hunting, even explicitly commercial hunting, has a pleasurable aspect. Although the recreational chase of the upper classes is nowadays often more a matter of public socializing or trophy skins than of table meat (British fox hunting, international big cat hunting), a notable proportion of the recreational hunting of all classes produces edible game such as duck and deer. In modern times, ethical considerations may impel the consumption of this game as a justification for the enjoyment of the hunt, even when the hunter finds it less palatable than the highly processed food to which he is accustomed. Generations of North American boys have learned a version of the "You shoot it, you eat it" hunter's code from their fathers. The pleasures of the hunt may paradoxically cause moderns to eat game they would otherwise omit from their diets.

Commercial Hunting

Hunting in order to sell or barter game has roots more ancient than commonly recognized. There are no contemporary tropical forest hunters and gatherers who do not maintain trading relations – most often game for crops – with agricultural neighbors. It has been proposed that humans did not enter the tropical forest until the invention of agriculture made this interchange possible (Headland 1987; Headland and Bailey 1991). The Pygmies of the Congo Basin have been trading game for crops with their Bantu neighbors for centuries, if not millennia. Similar relations, possibly of comparable antiquity, are maintained with agriculturalists by the hunting and gathering Makú of the Amazon region, the Agta of the Philippines, and a number of Hill Tribes in India. The game-producing hunters and gatherers are typically considered by their agricultural trading partners to be serfs or slaves.

In Western industrial societies commercial meat hunters are also marginal people. Guides and "white hunters" are glamorous figures in fiction and may, in fact, make considerable money, but they provide recreational and prestige hunting for others. They do not make a living by selling the game they hunt themselves. In a sense, contemporary individuals who sell game can be looked at as the cultural descendants of the peripheral individuals who continued to hunt for food while more affluent members of their societies obtained animal protein from domesticated animals.

Game is usually tougher than the meat of domesticated animals, but many consider it to be tastier. Its generally lower fat content has led some to believe that it is healthier as well.

It is indicative of the persistence of social evolutionary trends noted earlier that in the Western world, restaurants habitually serving wild game are of two kinds – the most expensive establishments in major metropolitan centers and small, "mom and pop" places in rural areas. Many people frequenting both kinds of establishments eat game in considerable measure for its status marker value, although of course the prestige of consuming game differs widely in association as well as scope between one type of restaurant and the other. In the former, game is affiliated with wealth and display, whereas in the latter it is primarily linked with recreation and the manly virtues.

Aside from its survival in this and similar commercial contexts, game has largely disappeared from the diet in modern industrial societies. Areas where it is still a notable part of yearly food consumption are uncommon. These include tribal enclaves, a few rural areas where subsistence hunting traditions are strong, and a very few spots where recreational and prestige hunting are major components of the local economy. In prospect, it seems that whatever amount of game remains in the diet of humans in the developed world will be retained for its association with the prestige of the hunt rather than for the nutritional value of the meat itself.

II.G.11 Geese

The common domestic geese are derived from two wild species, the greylag, *Anser anser,* and the swan goose, *Anser cygnoides.* The wild greylag is found seasonally throughout most of Eurasia and North Africa, although it is not known to breed south of 45° latitude. The swan goose is confined to East Asia, although the two can freely hybridize at the meeting point of their ranges. It has been argued that the Indian bar-headed goose, *Anser indicus,* also played a part in the evolution of domestic geese, because it is interfertile with the aforementioned species (Crawford 1984).

Geese are easily domesticated, and this process probably occurred numerous times. Moreover, the continuing presence of the greylag suggests that there was constant introgression from the wild form, accounting for Charles Darwin's observation that "the amount of variation that it has undergone, as compared with that of most domesticated animals, is singularly small" (cited in Crawford 1984: 345).

Other species of geese have been domesticated on an experimental basis in ancient or modern times. These are:

Canada goose	*Branta canadensis*
White-fronted goose	*Anser albifrons*
Egyptian goose	*Alopochen aegyptiaca*
Spur-winged goose	*Plectopterus gambensis*

However, none of these birds have attained commercial importance.

Despite their distribution, domestic geese are poorly documented across their range, especially the Chinese swan goose, which is virtually absent from all discussions of Chinese animal husbandry. Geese bones, due to their greater size and fragility, are often more comminuted in archaeological deposits than those of chickens and small game birds. Nonetheless, the lack of reports of goose bones from archaeological sites may reflect more the prejudices of archaeology than a real absence.

Geese in Domestication

Not only are geese easily domesticated, but when rendered flightless by their weight, they can be herded long distances. It has been hypothesized that the process of domestication probably began with the capture of wild specimens that were subsequently force-fed to make them too heavy to fly. The fattening of geese for their liver (foie gras) seems to have been known at least from Roman times, when birds were given a mixture of flour, milk, and honey (Zeuner 1963).

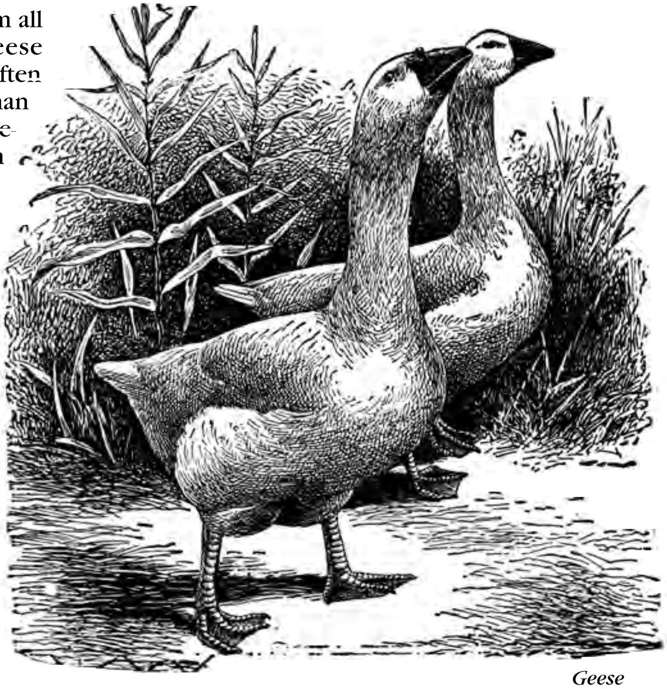
Goose eggs, in addition to goose flesh, were eaten in ancient Macedonia and Rome. Like chickens, the birds were also bred for fighting, especially in Russia (Dmitriev and Ernst 1989). Geese are known in fable for raising the alarm that saved Rome from Gallic invasion in 390 B.C., and they were recorded ethnographically in Europe and South America as guard animals (Zeuner 1963; Crawford 1984). Geese are still reared for their quills, which were once of major importance for writing implements and remain sought after for some musical instruments. Geese are also kept for their down, which is used to stuff pillows, bedclothes, and clothing because of its insulating qualities.

Historical Distribution

Egypt and Southwest Asia

R. D. Crawford (1984) hypothesized that the greylag goose was probably first domesticated in southeastern Europe around 3000 B.C. However, in the absence of any tangible evidence from this region, archaeological findings now indicate Egypt as the first known center of goose domestication. The earliest evidence comes from the Old Kingdom (2723–2300 B.C.), in the form of representations of geese confined in poultry yards, kept in cages, and being herded. The pictures are sufficiently imprecise that it is uncertain whether the greylag goose or the white-fronted goose, *A. albifrons,* is being depicted. Both were trapped and eaten and, on occasion, hand-fed to increase their plumpness for the table (Houlihan and Goodman 1986: 54 ff.).

Arguably domesticated, greylag geese begin to occur osteologically in temple or funerary offerings only during the Middle Kingdom. For instance, they



Geese

have been documented from the queen's burial chambers in the Twelfth Dynasty pyramid of Amenemhat III (1850–1800 B.C.) (Darby, Ghalioungui, and Grivetti 1977; Houlihan and Goodman 1986; Katzmann 1990). Greylag geese were certainly fully domesticated by the Eighteenth Dynasty (1450–1341 B.C.), when tomb paintings showed the distinctive heterogeneous colorings of domesticated *A. anser* flocks (Boessneck 1991). If, however, the white-fronted goose *(A. albifrons)* was domesticated at that time, this practice did not persist, whereas the rearing of the greylag goose spread westward along the North African littoral and into the Near East and Europe. Despite its belligerent nature, the Egyptian goose, *A. aegyptiaca,* was also apparently domesticated for the table in the Old Kingdom, although no trace of this bird remains today (Houlihan and Goodman 1986: 64).

J. Boessneck (1991) has pointed out that the geese remains from Egypt suggest very large animals, exceeding even modern commercial breeds. These "huge domestic geese" are known from the late dynastic periods at Tell el-Maskuta (c. 600 B.C. to A.D. 200), which has yielded close to 1,000 identifiable elements. As with chickens, it may be that domestic geese were originally high-status or cult animals in Egypt and were commonly consumed only in late Dynastic or Ptolemaic times.

Geese are also represented in Mesopotamian art from the early Dynastic period onward, and it appears that in neo-Babylonian times they were farmed out to breeders on a profit-sharing basis (Zeuner 1963: 469).

Europe

The ultimate antiquity of the domestic goose in Europe cannot be effectively determined from the sparse archaeozoological literature. Domestic geese are mentioned in textual sources from the first millennium B.C. onward, as for example in *The Odyssey,* or as depicted on Macedonian coinage (Zeuner 1963: 466–7). These dates are relatively late, however, suggesting that domestic geese may not have been as ancient in Europe as many earlier scholars assumed (e.g., Zeuner 1963; Crawford 1984). Against this interpretation, various authors have noted the antiquity of the term for goose in Indo-European languages (e.g., Hahn 1926). But recent scholarship has shown that Indo-European reconstructions of terms for goose may refer just as easily to wild as to domestic birds (Gamgrelize and Ivanov 1995).

Archaeozoological evidence indicates that the domestic goose did not become widespread in Europe until Roman times. Julius Caesar noted that the Britons did not eat goose because they considered it a sacred bird (Zeuner 1963). After the decline of Rome, the popularity of geese continued to increase and their spread in medieval northern Europe seems to have owed a great deal to the Normans. Geese were of minor importance in the Anglo-Saxon and Viking economies of the British Isles but became almost central after the coming of the Normans in the eleventh to thirteenth centuries (Allison 1985; MacDonald, MacDonald, and Ryan 1993).

The economic importance of geese relative to chickens seems to have depended greatly upon local environment, with high percentages of goose bones showing up in excavations of the medieval fenland cities of East Anglia (e.g., Lincoln and Kings Lynn) (Astill and Grant 1988: 163). Likewise, geese seemed to be the most important small livestock component of the Anglo-Norman economy in parts of Ireland (e.g., Dublin) (MacDonald et al. 1993). Geese had three advantages over chickens: (1) they could be driven rather than carried to market; (2) they could thrive on food of poorer quality than that required by other domestic fowl; and (3) they would have been more significant calorifically under traditional management than chickens. As a consequence of these advantages, evidence suggests that geese made a substantially greater dietary contribution in medieval towns than they did in rural areas (Astill and Grant 1988). However, this once important European food species has been displaced in recent years by the turkey, which is more amenable to modern factory farming techniques (Crawford 1984).

Africa

Sture Lagercrantz (1950: 82–7) reviewed references to geese in Africa and concluded that almost all reports of greylag geese are connected with direct European or Arab contact. It is generally assumed that the domestic goose did not cross the Sahara. It is true that the Songhay people in Mali have geese (Rouch 1954: 21), but this may be the result of relatively recent contacts with Morocco. Al-Umari mentioned that under Mansa Musa, the ruler of Mali in the fourteenth century, the peoples of the "Sudan" kept geese (Levtzion and Hopkins 1981: 267). It is possible, however, these were not *A. anser* but rather another species of goose, domesticated or tamed. The spur-winged goose, *P. gambensis,* has been recorded at San, Bamako, and Segou in Mali, where it is kept as a backyard species, as well as in northeast Nigeria (RIM 1992: 2).

Central and East Asia

The distribution and importance of the domestic form of the Chinese goose appears to be virtually undocumented. No information, either cultural or archaeozoological, is available for the swan goose, though all writers assert that it is embedded in Chinese culture. J. Delacour (1954) stated that goose rearing probably began in China more than 3,000 years ago, and William Watson (1969: 394) referred to pottery models of geese, probably representing domestic individuals, found at Hupei, a Lung Shan site in China.

The most complete documentation of geese in central Asia is in the work of N. G. Dmitriev and L. K. Ernst (1989), describing the livestock of the former Soviet Union. Originally, Chinese geese were widespread in the eastern part of the nation, whereas greylags were in the west with a number of stabilized crosses developing in the center of the country. However, breeding stations have imported numerous European breeds and crossed them with indigenous stock, leading to substantial introgression in local races. Breeds were originally developed specifically for fighting and to resist extremely low temperatures.

Future Research

Information concerning the history of the domestic goose is very sparse. Obviously, an important avenue for the creation of new data on this subject rests with archaeozoology. The greatest difficulty for archaeologists with small and often comminuted assemblages is to sort out wild from domestic geese by means other than inference alone. Fortunately, various criteria have been put forward that seem to reliably differentiate wild and domestic geese in larger bird bone assemblages. These criteria include:

1. A reduction in the length and robusticity in the wing of domestic *A. anser,* coupled with an increase in lower limb robusticity relative to wild taxa (Reichstein and Pieper 1986).
2. A reduction in the wing musculature of flightless, overfed, or clipped *A. anser* with osteological effects, such as the profound reduction of feather attachments on the ulna *(papillae remigales caudales)* (MacDonald et al. 1993).
3. The presence of a flattened facet on the anterior surface of the femoral head, a pathology resulting from an overdependence on the legs for locomotion (MacDonald et al. 1993).

Apart from archaeological inquiry, ethnographic, linguistic, and textual research are also necessary, especially in East Asia. The place of the goose in Chinese culture should be reviewed through examination of iconographic and written sources as well as collation of synchronic descriptions of goose management. Virtually no work has yet been undertaken on the historical genetics of geese, making the task of tracing their diffusion across the Old World extremely problematic. These lacunae probably reflect the lack of current economic significance accorded geese rather than their historical role in human nutrition.

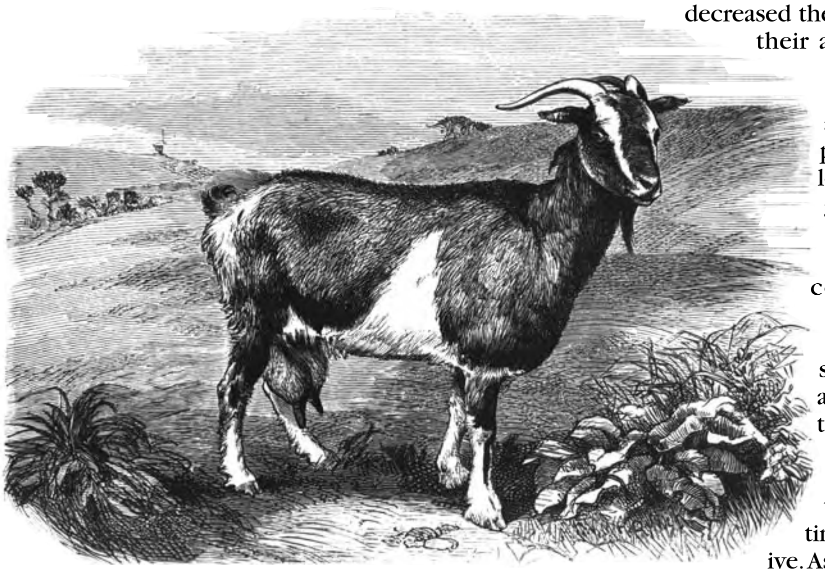
II.G.12 Goats

The domesticated goat *(Capra hircus)* is an animal that, although of extraordinary usefulness to humans, experiences sharply different levels of acceptance around the world. Its ruminant ability to digest cellulose is the key to its success as a form of livestock, but its browsing efficiency can often be harmful to marginal environments.



Goat

Origin and Domestication

Goats were domesticated in the Near East from *Capra aegagrus,* known variously as the Persian wild goat, bezoar goat, or *padang.* The males of this ungulate species of the rugged terrain of western Asia have long, scimitar-shaped horns; the females' horns are similarly shaped but shorter. The bezoar goat has been a prey of hunters, in part, at least, because its stomach concretions (also called "bezoars" by physicians) have a widespread but medically unfounded reputation as an antidote for poison. The foothills of the Zagros Mountains is the most plausible area for the origin of goat domestication. Early Neolithic sites contain evidence of goat keeping from as long as 9,000 years ago. Such dating would seem to make the goat a candidate for the world's oldest domesticated herd animal. Brian Hesse (1982) analyzed the abundant goat bones at the site of Ganj Dareh on the cold Iranian plateau and determined that the smaller size of the bones corresponded to domestic goats. Other sites, dated several hundred years later, have yielded further evidence of early goat keeping in the eastern half of the Fertile Crescent. At Jarmo, goats were the most numerous domesticate. At Tepe Ali Kosh, domestic goats preceded domestic sheep. From the east, the domesticated caprine spread westward into the Mediterranean. For example, at Natufian sites in the Levant, the domesticated goat appeared only later as a significant animal in the life of the people. There, and in Egypt, goats have been present for about 7,000 years. In the Nile Valley, goats were integrated into a sedentary agricultural system, but they also could be sustained in the non-irrigated desert beyond.

As with sheep, the domestication process decreased the average size of goats from that of their ancestors. Although the domestic goat bore a horned resemblance to the bezoar, smaller horns gradually evolved, and a number of polled breeds also emerged. The lop ears and twisted horns of some goat breeds reveal human selection of mutations. As with other domesticated animals, the coat colors and patterns of domestic goats are more diverse than those of their wild ancestors. Unlike sheep, goats have maintained the agility, intelligence, and curiosity of the wild animal. These features enable domestic goats to bond with humans much more strongly than do sheep and, at the same time, to be more willful and combative. As was the case with other animals, domestication increased libido; the adjective "goatish" means "lustful." Although goats and sheep belong to the same family (Bovidae), and even the same tribe (Caprini), these two different genera do not hybridize.

Domestication may not have been for the economic reasons that seem so seductively straightforward today. The need for food was not necessarily a plausible mother of invention, for domestication is a process that occurs over many generations. A quite different motive seems more worthy of consideration. As with sheep and other domesticates, taming and reproduction in captivity may well have begun for the purpose of maintaining a steady supply of sacrificial animals. This theory is suggested by the important role that goats played in religious ritual, often as symbols of fecundity and virility. In Sumer, the deity known as "Enki" had the tail of a fish and the head of a goat. The Israelites sacrificed goats to Yahweh. The well-known figurative concept of the "scapegoat" came from the practice of priests' placing their hands on the heads of goats and recounting the sins of the people.

The importance of sacrifice probably motivated early cult masters to keep a ready supply of animals for this purpose, and controlling reproduction ensured a flow of live animals that the vagaries of hunting could not. Several other religions, such as Zoroastrianism and Hinduism, have sacrificed goats. In the latter case, goats are sacrificed to "Kali," the Hindu goddess of time, who is much revered in the Bengal region of India (Samanta 1994). A healthy male goat, black in color, is prepared for sacrifice through purification rites. Then the animal is decapitated in conjunction with the invocation of Kali, "who thirsts for blood." The blood is ritually drunk; the rest of the goat is then immolated, and sometimes the cooked flesh is eaten.

In the art of ancient Greece, satyrs were the attendants of Dionysus and Pan and had goat-like attributes. They had the legs and hindquarters of a goat, small horns, and goat-like ears. The gods themselves were goat-like: Pan had a man's body and head, but the hooves and horns of a goat; Dionysus, who assumed the form of a goat, was, like Zeus, raised on goat's milk. The cults of Zeus, Apollo, Hera, Hermes, and Artemis all manifested caprine elements. Aphrodite was sometimes depicted as riding a goat. In ancient Rome, goats were sacrificed during the feast of Lupercalia. Goat imagery of the classical period was the source of goat-like demons of the Middle Ages. Witchcraft has used the goat as a symbol of evil. The Biblical metaphor of the sheep (those chosen by God) and the goats (the damned) has doubtless influenced Western thinking about the relative worth of these two animals.

Goat Distribution

The world's pattern of goat keeping is very uneven. The animals play a major role in subsistence economies, where they provide useful products in return for a minimal investment of capital and labor. Thus, nonindustrial countries contain more than 90 percent of the half-billion goats in the world (FAO 1995). Goats adapt well to both dry and wet conditions and to tropical and midlatitude climates, and culture also helps to explain the importance the goat is accorded in the developing world. Islamic societies of the Middle East and North Africa have ennobled the goat as a source of food, and the Arab conquest of North Africa greatly expanded pastoralism as a way of life and the goat's role in it. By contrast, the Romans in North Africa emphasized farming to a much greater extent. Yet the Islamic factor must also be weighed by the ability of the goat to thrive in a subhumid environment. Thus, for example, the rural folk of both Greece and Turkey have paid much attention to goat keeping. The summer drought of the Mediterranean climate has always made it difficult to supply the large amounts of better-quality fodder needed to sustain herds of cattle. Keeping goats as an alternative avoids this constraint.

Though only partly semiarid and Islamic, Nigeria has more goats – about 250 million – than any other country in Africa. No controlled breeding is practiced, and the typical herd comprised several different kinds, including dwarf goats, which stand less than 50 centimeters high (Epstein 1971). Goats constitute about half of the domestic grazing livestock in Nigeria and provide about one-quarter of the meat consumed in that country. Goat meat supplies protein, mostly to rural people, who also sell live animals in markets as a source of income. The animals generally fend for themselves, subsisting largely on browse discovered within a radius of their dwelling compound. Sometimes they are fed vegetable waste from the kitchen, and their owners typically provide water. Night shelter within the compound protects them from predators and thieves. During the planting season, goats are often tethered to prevent crop destruction. Most of the animals have parasites, and their mortality rate from disease is high.

Goats are also part of the rural tradition in Mexico. Most of the 9 million goats there browse the sparsely vegetated slopes throughout the country. Poor Mexican farmers have long counted on their *cabras* as sources of animal protein and income. The *criollo* breed, which evolved from goats brought from Spain in the sixteenth century, is well adapted to the hot, dry landscape. However, it is low-yielding in edible products and is a carrier of brucellosis, a disease of domestic animals often transmitted to humans. Goat keeping in Mexico today has the reputation of a backward livestock activity, and environmentalists blame free-ranging animals for much of the erosion of the hill lands.

Uses of Goats

Goats provide four major products for human use: meat, milk, fiber, and skins. In nonindustrialized societies, owners typically make use of all four. In Europe, North America, and some other places, goats are normally kept only for their milk.

Meat

Goat meat is a vital addition to the diets of millions of people, although such consumption is not accurately recorded by official market statistics because a goat is often raised and butchered by the same family that consumes it. The small carcass size of a goat allows the animal to be consumed by a household in two or three days, and meat spoilage is consequently less than if a family butchered a cow.

Goat flesh is especially important in rural Africa, the Middle East, and South Asia; in India, members of a number of Hindu castes eat it with equanimity. In several Asian countries, goat and sheep meats are not differentiated, and, in fact, some languages do not distinguish between the two. By contrast, northern Europeans and North Americans generally avoid goat meat, with readily available meat alternatives as well as negative feelings about goats as human food constituting the explanation. In the United States, the flesh has a reputation for being smelly and tough, an opinion based on the cultural prejudices of those who have never eaten it. One major exception, however, is the attitude among people of Latin American origin, who have created a specialized ethnic demand for goat flesh. Superannuated dairy goats are slaughtered for this market, and in southern Texas meat goats are raised for sale (Glimp 1995).

Compared to other forms of livestock, goats have a structural disadvantage in that their higher metabolic rate makes them less efficient meat producers. A 350-kilogram (kg) cow requires the same amount of energy as six goats – each weighing only 25 kg. Moreover, slaughtered goats have a lower percentage of useful parts and, correspondingly, more offal. That same 350-kg cow yields 189 kg of product, whereas the six goats together yield only 81 kg (McDowell and Woodward 1982).

Another problem is that goat meat tends to be dry because the animal has its fat deposited around the viscera rather than in marbled fashion, as do cattle and sheep. Age and sex are also factors. A young doe is palatable, but the tough meat from an old billy goat is not. Adult males have a scent gland that can make the strong flavor of their meat unacceptable to consumers. Kids, however, either as sucklings or when weaned, produce a meat of tender texture and delicate flavor. In France, kid is the only form of goat meat that finds a ready market.

Some goat dealers in the western United States have tried to distribute goat meat commercially under the euphemism of "chevon." Because goat meat is low in fat, producers have sought to capitalize on the national concern about fat in the diet. Sensory experiments have demonstrated that it is possible to use goat meat, alone or in combination with beef, to produce lowfat meat products for consumers who would not ordinarily consume goat meat (James and Berry 1997). More attention to breeding quality meat animals may have a long-term effect in a gradual American acceptance of goats as food. The Boer goat, originally from South Africa, is considered to be the best meat breed.

Milk

Milk is an important product of the goat, and in some areas dairy products constitute the only reason for keeping the animals. Yet from a commercial point of view, goats cannot compete with cows. Milk yields per lactation, duration of lactation, percentage of protein, persistency of milk yield, and the suitability of milking machines are all measures in which cows perform better than goats. Moreover, the need to maintain many more goats than cows for milk production entails more work in milking, more health problems, and more record keeping. However, in the overall perspective of single-family subsistence, the goat's small size fits in better with a family's needs than that of the much larger cow, and goats have a strong home instinct and require less herding than cattle. Compared to sheep, goats have a higher level of milk production, perhaps because the incidence of twinning is high in all breeds.

In Africa and western Asia, milk production is an important aspect of keeping goats. At a country level, India is the world leader in producing goat milk; other producers include Iran, Pakistan, Somalia, and Sudan. The Nubian goat, red or black in color, is an important milking breed of the Old World. It is recognized by its Roman nose, short hair, long legs, and lack of horns.

In zones of Western culture, goat's milk is now less important than in other parts of the world. In Latin America, Mexico and Brazil are the two main producers of goat milk. *Dulce de leche,* a caramelized concoction of sugar and goat's milk, is a much-appreciated sweet in countries settled by Spaniards. In the Mediterranean region, goat's milk is locally available, especially in small villages. In Greece, about one-fourth of the milk supply is still provided by goats.

Moving north, both France and Switzerland produce substantial quantities of goat milk. The Alps have an old caprine tradition, which has given rise to seven dairy-goat breeds, the best known of which are Toggenburg, Saanen, and French-Alpine. Norway is also famous for its high-yielding dairy goats. In Western Europe outside the Mediterranean, however, goat milk is a specialty product. Fresh goat's milk is important for those allergic to cow's milk. In the United States, for example, it has been estimated that about 1 person in 1,000 has a medical need for goat milk (Haenlein 1996). Differences in the protein makeup of goat's and cow's milk make that of the former a nutritious substitute.

The American dairy-goat population of 1.5 million females is divided among six breeds. The Nubian is numerically the leading one but is surpassed in actual milk production by the three long-established Swiss breeds. California is the leading producer of goat's milk in the United States. Total production in the country is estimated at 600,000 tons, and about 300 farms and businesses sell goat's milk or goat-milk products. However, production, processing, and marketing of goat's milk is much less regulated by the states than is cow's milk. "Natural-food" stores often sell goat-milk products, including butter, ice cream, yoghurt, cosmetics, and soaps. In addition, goat milk is used to feed calves for veal production and to nurse zoo animals and pets.

Much of the world's goat milk is converted into yoghurt, butter, and cheese. Middle Eastern countries produce goat cheeses largely unknown outside their borders. Making cheeses has become the main use of goat's milk in Europe, where the relatively high price has encouraged their development as specialties for cheese lovers who enjoy their tangy flavors. When overripe, however, goat cheese can be brittle in texture, acid in smell, and ammoniacal in flavor. France still produces about 20 different kinds of goat cheese. Distinctively shaped and packaged, these cheeses are often sprinkled with a condiment like paprika or black pepper. Other European countries, especially Italy, make some goat cheese, but none of them are recognized for their quality as much as those of France. Until the late 1970s, no goat cheese was made in the United States, but by the 1990s, about 50 percent of American-produced goat milk was used to make cheese. Such cheeses – half imported and half domestic – developed a popular following and a gourmet image conveyed by use of the word "chevre" on the label.

Fleece and Skins

Goats yield other valuable products with their hair and skins. The classic Bedouin tent of southwestern Asia and northern Africa is made of goat hair. Goat fibers have also been used in pastoral societies to make carpets, brushes, and felt. High-quality goat fleece, traded internationally, derives from two specific breeds. One of these is the Angora – almost always white – which came originally from Turkey and has been known since antiquity for its lustrous fleece. Countries of western Asia export this product but do not have a monopoly. Before the Turkish Sultan decreed in 1881 that live Angora goats could not be exported, the breed had already been transported to other parts of the world. They thrive in South Africa, where they were introduced in 1838, but only much later did mohair become the main objective in raising them. At present, some 1.3 million Angora goats around Port Elizabeth in Cape Province yield 6 million kg of mohair annually.

In North America, Angora goats date from 1849 and have become highly concentrated on the Edwards Plateau of southern central Texas. More than 2 million animals are herded there on the open range, primarily to produce mohair for textile, upholstery, and wig-making industries. Mohair is more notable for its strength and luster than for its fineness of fiber. Angora goats in the United States, larger than their Turkish ancestors, are more numerous than those of any other breed.

The cashmere goat's undercoat yields a fine fiber, known in the luxury-fabric trade as cashmere. Cashmere goats live at high elevations in northern India, Tibet, western China, Kirghistan, and parts of Iran. Selection for a cold environment was a factor in evolving the quality of fleece associated with this breed.

Goatskins are a by-product of slaughter for meat. DNA analysis has found that most of the Dead Sea scrolls were written on goatskins preserved in the dry atmosphere of the hills of Palestine. In traditional cultures, goatskins have been used as containers for liquids. Water, wine, and distilled spirits have all been transported and stored in these skins, but the availability of cheap plastic has greatly diminished such usage.

Other Uses

Goat manure is another, usually subsidiary, benefit of raising these animals. At least in one place, the Rif mountain region of northern Morocco, manure has become the raison d'être of goat raising. Large numbers of goats are needed to provide the fertilizer for cannabis production. Marijuana and hashish from this plant enter into the international drug trade, and large quantities of goat manure – without which the soil would soon become exhausted – are needed to maintain production of this profitable crop year after year.

The goat has another use of local importance as a biological control agent: Goats browse undesirable plants that are otherwise expensive and difficult to control. In the western United States, they keep in check aggressive, unwanted plants such as live oak brush, gambel oak, and leafy spurge.

Production Systems

Goats lend themselves well to a pastoral way of life. In the nomadic and seminomadic systems of Africa and Asia, they form a component of the mobile livestock capital, which is moved in constant search of fresh pasture. Goats are not the most appreciated animals in a pastoralist's inventory, but they serve as a better hedge against environmental uncertainty than do cattle or sheep. The Tuareg people of the Sahara keep almost 10 times as many goats as sheep, a rational behavior in their water-scarce environment. In East Africa, goats manifest considerable resistance to the disease trypanosomiasis, which explains part of their importance there.

Goats also fit into a mixed herding and farming economy to provide meat, milk, and other products. Small farms lend themselves to goat keeping. In the tropics, goats can breed year-round; in midlatitudes, breeding occurs seasonally. Goats may be tethered or allowed to range freely on communal grazing areas. They follow a nutrition strategy of choosing grasses of high protein content and digestibility to graze upon, but they will shift to browse if its nutritive value is greater, and unlike cattle, goats can maintain themselves on browse alone.

The Environmental Effects of Goats

Free-ranging goats have a reputation for overgrazing, which happens when their numbers surpass the capacity of the land to support them. Gully erosion results when they destroy the native vegetation and compact the soil with their sharp hooves. Several characteristics of goats favor abuse of the plant cover. A mobile upper lip permits them to graze as close to the ground as sheep at the same time that their browsing capacities exceed those of their fleecy cousins. Thorny plants with small leaves are no hindrance to goats. If browse is in short supply, they will defoliate entire bushes. Goats browse to the height they can reach when standing on their hind legs. They will also forage on leaves by climbing into low trees. With their sharp hooves, they paw away soil to obtain roots and subterranean stems. Allowed to roam, goats can occupy considerable space. On the average, they move 9.7 kilometers (km) per day, compared with 6.1 km for sheep and 5.3 km for cattle (Huston 1978).

It is true that goats have contributed to desertification, but they often get more blame than they deserve. The process begins when first cattle, and then sheep, deteriorate the range, after which the invading brush is suitable only for goats, which can survive and reproduce in such environments. Thus, goats become the last alternative on eroded lands and are often seen as totally responsible for them.

Ultimately, however, destruction of vegetation by goats is a human management failure. An arid hillside combined with excessive numbers of goats will almost always mean harm for that environment. Human unwillingness to control goat density at a desired maximum, or to restrict the animals' mobility, has determined the land-use history of many areas. Humans have frequently introduced goats to islands and then left them to their own devices. Without predators, feral goat populations have exploded and destroyed ecological balances; the histories of many islands, from San Clemente, California, to St. Helena, involve goat stories.

The Mediterranean Plan, funded by the Food and Agriculture Organization of the United Nations (FAO) in the 1950s, was the first concerted international effort to deal with such problems. Impoverishment of the Mediterranean region was attributed to the environmental degradation brought on by overgrazing. We know that some of this process was begun in ancient times because classical authors discussed the goat problem two millennia earlier (Hughes 1994). The Mediterranean localities most heavily dependent on goat products were those with the most serious erosion. In the 1940s, Cyprus, which derived one-third of its milk, two-fifths of its cheese, one-fourth of its meat, and four-fifths of its leather from goats (Thirgood 1987), was deforested because of excessive goat browsing. Vegetation flourishes in the Mediterranean region where goats and sheep are restricted. In northern Morocco, the barren slopes that are grazed by goats contrast with ungrazed enclosures that maintain a luxuriant tree cover.

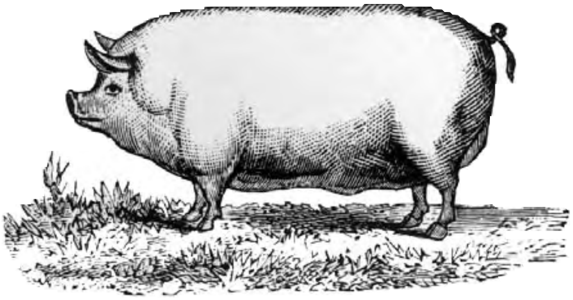
II.G.13 ~ Hogs (Pigs)

"Pig" is a term used synonymously with "hog" and "swine" for the one domesticated suid species, *Sus scrofa domesticus.* In livestock circles, a pig becomes a hog when it passes the weight threshold of 50 kilograms. The word "swine" transcends age and sex but to many has a pejorative ring. A "gilt" is any immature version of a sow, whereas a "barrow" is a young, castrated male that can never grow up to become a boar. After a piglet has been weaned, it becomes a "shoat." Most of these terms are not used by a general public whose only encounter with this animal is in the supermarket. The meat of this often maligned beast yields some of the world's best-tasting flesh and provides good-quality protein in large amounts.

Domestication

All domesticated pigs originated from the wild boar *(Sus scrofa)* (Epstein 1984). Within that one wild species, more than 20 subspecies are known in different parts of its natural range, which has extended from the British Isles and Morocco in the West to Japan and New Guinea in the East. But where in this vast stretch of territory the first domestication occurred is still uncertain, although the earliest archaeological records (c. 7000–5000 B.C.) have been concentrated in the Middle East and eastern Mediterranean.



Pig

Indeed, the recovery of bones of domesticated pigs has been done at Jericho (Palestine), Jarmo (Iraq), Catal Huyuk (Turkey), and Argissa-Margula (Greece), as well as other sites. But bones older than any of those from these sites were uncovered in 1994 at Hallan Cemi in southeastern Turkey. There, in the foothills of the Taurus Mountains, the pig was apparently kept as early as 8000 B.C., making it the oldest known domesticated creature besides the dog. Moreover, pig keeping at this site was found to predate the cultivation of wheat or barley. Both findings contradict the long-held twin assertions that sheep and goats were the world's earliest domesticated herd animals and that crop growing preceded the raising of herd animals.

An alternative view places the beginning of swine domestication in Southeast Asia. Carl O. Sauer (1952) suggested that the pig under human control diffused from there northward to China. However, Seung Og Kim (1994) has suggested that political elites in northern China established their authority by controlling intensive pig production as early as 4300 B.C. Certainly, archaeology and cultural hubris have combined to convince many Chinese that it was their ancestors who first domesticated the pig. The Chinese ideograph for "home" consists of a character for "swine" beneath another character for "roof" (Simoons 1991).

Certain innate traits of the wild boar make it plausible that multiple domestications have occurred at different times and places in the Old World. This inquisitive, opportunistic artiodactyl may, in part, have domesticated itself by choosing to freely come into association with humans. Garbage at settlement sites provided a regular food supply, and human presence offered protection from large carnivores. Reproduction in captivity could have been initiated when captured wild piglets were tamed. Human control would have been easily accomplished, for it has been observed that the striped piglets of the wild boar behave just like the unstriped piglets of the domesticated species. The next step, unconscious selection, began the long process of evolving regional distinctions in the animal's conformation. However, the emergence of distinctive breeds, as we know them today, dates mostly from the late eighteenth and nineteenth centuries, when artificial selection was implemented on a large scale.

Religion probably lay behind the transformation of the pig from a semidomesticated status to one of greater mutual dependency with humans. In ancient Egypt, followers of Seth sacrificed pigs to that god. On the Iberian Peninsula, the granite sculptures called *verracos,* carved by Celts between the sixth century B.C. and the first century A.D., suggest that pigs might have had a religious role. In ancient Greek and Roman times, pigs were sacrificed to deities. In China, the Manchus believed that a sacrificial pig drove away bad spirits and assured good fortune. In all these groups, the incentive of supplying live animals for cultic purposes could easily have resulted in breeding pigs toward greater dependency on humans.

Advantages of the Pig

From a contemporary utilitarian perspective, the pig is one of the glories of animal domestication. It is prolific. After a gestation period of only 4 months, a sow gives birth to an average of 10 piglets, though litter size may, on occasion, be as large as 30. Growth is rapid. In a 6-month period, piglets of 1.2 kilograms can potentially increase in weight by 5,000 percent. This growth translates into a higher return for energy invested than for other domesticated animals. Another advantage is the omnivory of pigs, which permits a wide range of food options; items that are plentiful and cheap can dominate the intake. For example, surplus crops, such as sweet potatoes in New Guinea, coconuts in Polynesia, maize in the midwestern United States, and barley in Denmark, are frequently enhanced in value because they can be fed to swine. A major disadvantage of pigs is their low ability to digest fibrous plant matter, so that, unlike ruminants, they cannot do well on cellulose alone.

The Range Pig

For most of their domesticated history, swine were kept in one of two ways: free-ranging in forests or sedentary in settlements. In neither case did they compete with humans for food, although pigs have the capacity to eat and thrive on the same nutrients. For the range pig, both plant and animal matter, on and beneath the forest floor, was sought. In Western Europe, where domesticated swine have been known since before 4000 B.C., they ate acorns, chestnuts, beechnuts, hazelnuts, and wild fruits such as berries, apples, pears, and hawthorns. Their powerful mobile snouts and sharp teeth were able to dig mushrooms, tubers, roots, worms, and grubs from the ground. Eggs, snakes, young birds, mice, rabbits, and even fawns were consumed as opportunity arose.

The use of pannage (pasturing in a forest) to feed pigs was recorded from antiquity in Europe and still has not totally disappeared. An abundant iconography suggests the role that swine played in the development of European rural society. The pig is always pictured as an animal with a long flat neck, straight back, narrow snout, small erect ears, and long legs. Nimble and resourceful, it thrived on mast (nuts from the forest floor). In the early Middle Ages, mast rights were a greater source of income from the forest than the sale of wood. But pannage required peasants to enclose their fields with wooden palisades or hedges to prevent pigs from entering and destroying their crops. As concern for forest resources grew, the pannage season was fixed by seigneurial decree. The main feeding period came in the autumn, when nuts, a highly concentrated source of nutrition, fell in large numbers. In many places, it became traditional to begin mast feeding on the feast of Saint Michael (September 29) and to conclude it on the last day of November (Laurans 1976).

Mast feeding has now disappeared from Europe except in a few places. Its best-known survival is in Spain, where the oak woodland still seasonally supports black and red Iberian swine (Parsons 1962). Although by 1990 these rustic mast-feeding breeds made up only 4 percent of the Spanish pig population, the cured pork products derived from them have been prized as especially delectable. Thus, cured hams *(jamon ibérico)* from these swine are very expensive; most famous are those from Jabugo, a meat-packing village in the Sierra Morena north of Huelva.

On his second voyage, Christopher Columbus brought the first pigs to the New World (1493). From an original stock of eight, they multiplied on the Caribbean island of Hispaniola, and many later became feral. Rounded up as needed, pigs were put on board ships bound for Mexico, Panama, Colombia, and all the islands in between. Francisco Pizarro, who had worked with swine in his youth in Extremadura, brought live pigs to the Andean highlands from Panama in 1531. The long-legged, nimble suid was well suited to move along with the expedition parties as a mobile fresh meat supply. Tropical America afforded no acorns or chestnuts, but an abundance of wild fruit, especially from palms, provided nourishment for the pigs. In semiarid zones, seed pods of leguminous trees were the common food of foraging swine.

The first pigs in what is now the United States arrived from Cuba with Hernando de Soto's expedition (1539–42) through the Southeast. Later introductions came from the British Isles, most notably to John Smith's settlement of Jamestown in 1607. A few years later, they had multiplied to several hundred head. In Virginia, and elsewhere in eastern North America, pigs fit well into the forested countryside as foragers. Abundant oak and chestnut mast in the Appalachians offered a good return in meat for almost no investment in feed or care. In late autumn, the semiferal animals were rounded up and slaughtered, and their fatty flesh was made into salt pork, which along with Indian corn was a staple of the early American diet. In the early nineteenth century, these Appalachian pigs were commercialized. The leading national and world position of Cincinnati, Ohio (often jokingly called "Porkopolis"), as a soap manufacturing center owes its origin to pigs brought there on barges for slaughter; their flesh was salted and their fat rendered into soap.

This type of hardy porker and wily beast of folk legend still survives in the Ozarks and elsewhere in the southern United States. In fact, these "razorbacks" could be descendants of those that accompanied the de Soto expedition. The explorer gave gifts of live pigs to the Indians, and when he died in 1542 near what is now Fort Smith, Arkansas, 700 pigs were counted among his property. In addition, Ossabow Island, off the coast of Georgia, still harbors a breed of swine considered to be direct descendants of those brought by the Spaniards.

In addition to the Caribbean Islands, other uninhabited islands around the world became homes of the pig. In many cases, the animals were introduced by explorers and mariners and left to reproduce on their own. Sailors on passing ships often rounded up and slaughtered some of these feral pigs to replenish shipboard larders. Nonetheless, pigs on islands often multiplied to the point where they destroyed native fauna and flora.

In Melanesia, semidomesticated pigs still forage in the forest and are slaughtered primarily for ritual purposes (Baldwin 1983). R. A. Rappaport (1967) has explained the impressive pig feasts among the Tsembaga people of New Guinea as a societal mechanism that fulfills the need to control the size, composition, and rate of growth of the pig population. Without the periodic slaughtering of large numbers, the pigs would seriously damage gardens and crops. Rappaport's effort to understand pigs and ritual as part of a homeostatic balance became one of the landmark works of the developing subfield of cultural ecology. Whether such a pig complex makes economic sense has been debated because, in this case, the animal is not a regular source of human food. But aside from their meat, pigs must be appreciated in manifold ways: as a hedge against uncertainty (e.g., crop failure); as a negotiable store of surplus; as a source of fertilizer; and as disposers of garbage and other wastes.

The Garbage Pig

The garbage pig was essentially "presented" with its food intake, either at a fixed site or within a circumscribed area. In eastern Asia, where centuries-old deforestation and high population densities did not favor mast feeding, pig raising was long ago oriented toward consuming wastes. Important in China and Korea, at one time, was the privy pig, kept to process human excrement into flesh for human consumption. Four young pigs could derive sustenance from the waste of a family of four humans, which provided the animals with approximately 2 kilograms of human excreta and 220 grams of garbage each day (Miller 1990). In Asia, food provided by humans rather than by foraging promoted sedentary habits that, in turn, led to the evolution of several breeds with a swayback and a dishlike face. But even the miniaturized types of Asian pigs have big appetites and large litters.

The garbage pig could also be found in ancient civilizations outside of eastern Asia. Robert L. Miller (1990) has brilliantly reconstructed the scavenging role of the pig in dynastic Egypt. But, thus far, similar evidence is lacking for ancient Greece and Rome. In Europe, the garbage pig goes back to the Middle Ages but seems not to have been common until the fifteenth century, when the so-called Celtic pig, with white skin and pendant ears, emerged. Families fattened their pigs primarily on food scraps, and when winter neared, the animals were butchered. Their meat was cured and their fat rendered to make lard for cooking and especially for food preservation. Thus, the human diet was diversified during the cold months.

This form of pig keeping expanded as forest clearing advanced and the scale of food processing increased. Grist and oil mills generated large quantities of waste materials that could be consumed by pigs, as could the garbage from institutions like hospitals and convents. Before proper sewage disposal was implemented, many cities had swine populations to serve as ambulatory sanitation services. In medieval Paris, so many pigs were locally available for slaughter that pork was the cheapest meat. The monks of Saint Anthony – the patron saint of swineherds – were given special rights to keep pigs within the city walls. In New York City, pigs wandered the alleyways well into the nineteenth century. Naples was the last large European city to use pigs for sanitation. Neapolitan families each had a pig tethered near their dwellings to consume garbage and excrement.

Certain peasant societies still value the garbage pig as an element of domestic economy. In much of rural Latin America, pigs consume what they can find, to be later slaughtered with minimal investment in feed (Gade 1987). Lard has been an important product of pig keeping there. Frying was a cooking innovation introduced with the European conquest, and native people learned to depend on this source of animal fat. Today, however, the meat quality of these haphazardly fed animals no longer meets the health requirements of city dwellers, most of whom get their pork products through inspected channels.

Unlike sheep, whose wool may be more valuable than their flesh, or cattle that are kept for their milk or for use as draft animals, pigs have had no primary nonmeat uses. A possible minor exception has been the truffle pig, employed in France – mainly in the Périgord region – to locate the black truffles synonymous with gourmandise. A trained sow can detect from 6 meters away the smell of the unseen truffles.

Swine Distribution

World hog distribution is strongly affected by cultural and ecological factors. More than 40 percent of the world porcine inventory is in China, where density is among the highest anywhere: For every three people in China, there is one pig. Some of this swinish appeal is cultural preference, though much can be explained by lack of alternatives. Human population pressure in China does not permit the extravagance of devoting large areas of land to grazing herbivores. Swine in China long had a niche as scavengers, scatovores, and consumers of surplus food crops.

Europe, including Russia, has about 170 million pigs, and Denmark is the only country in the world that has more pigs than people. The United States and Canada together have about 70 million of the animals, which means roughly one pig for every four people. Brazil has about 32 million head. Pigs are more important on many Pacific Islands than their total number (less than 5 million) would suggest.

The Middle East, however, is one part of the world that is largely devoid of pigs. Those that are kept generally belong to non-Muslims (such as the Coptic Christian peasants in Egypt), but some marginalized Muslims may keep pigs secretly. In humid Southeast Asia, the Islamic injunction against pigs is somewhat more nuanced, and in Indonesia, Muslims are among those who consume the products of the more than 8 million swine in that country.

In India, where the Hindu majority views all flesh foods as unacceptable elements of the diet, there are only about 10 million pigs, and in non-Islamic Africa, pigs number only around 18 million, considerably less than one might expect. But there African swine fever has periodically wiped out pig populations.

Elsewhere, the Arctic and Subarctic have historically had few pigs for quite different reasons. Very short growing seasons do not provide sufficient feed to maintain them; moreover, piglets cannot survive extremely cold winters without proper protection. Thus, in Greenland, the Norse settlements between A.D. 986 and 1400 had cattle but no pigs.

Pork

Many think that pork is the most savory of all flesh foods. The abundance and quality of fat keeps the meat from tasting dry and imparts a characteristically rich flavor. High pork consumption patterns are found in both China and Europe. In China, it is more important than all other meats combined, and use is made of all parts of the pig, including its liver, kidneys, feet, knuckles, tongue, skin, tail, and blood (Anderson 1988; Simoons 1991). Most pork cuts are also fried in lard.

In Europe, more than in China, cured pork products are favored. Germans and Slavs enjoy a range of sausages such as pork brain sausage *(Gehirnwurst),* much appreciated in Germany but unavailable commercially in the United States. In addition, Russians and Poles are especially fond of suckling pig.

Spaniards also enjoy high pork consumption and have a special fondness for cured hams and suckling pigs. *Cochonillo asado,* a strongly traditional Castilian meal, features a 1-month-old piglet fed only on its mother's milk and roasted in an earthenware dish. Spanish enthusiasm for pig meat stems in part from pork's past importance as a symbol of cultural identity. Because Moors and Jews did not eat it, Christians saw the meat as more than simple nutrition. In sixteenth-century Spain, pork eating was an acid test faced by Spanish Moriscos and Marranos who publicly claimed conversion to Christianity. Conspicuous pork avoidance could result in an appearance before the tribunals of the Inquisition.

In North America, pork lost its preeminent position to beef in the early twentieth century. Aside from the fact that cattle ranchers were much better organized to promote their product, pork had acquired negative connotations as the main food in the monotonous diet of poor people and pioneers. At one time, pork also had unhealthy associations because of the potential for human infection by the organism *Trichinella spiralis,* carried by pigs, but federal meat inspection to certify trichina-free meat has greatly reduced the incidence of trichinosis. Still, wide knowledge of that old health risk continues to motivate cooks to make sure that pork is served only when fully cooked. Pork is considered done when it reaches an average interior temperature of 75.9° C (170° F).

Spareribs are often used in southern-style barbecue, and bacon, which comes from what the meat trade calls "pork bellies," continues as an important component of the traditional American breakfast. "Chitterlings," made from intestines, are eaten as part of the ethnic cuisine known as "soul food," but they appear in few other cases. In contrast, ham, mostly cured, has wide appeal. Virginia hams, especially those from Smithfield, have had the best reputation among connoisseurs. Fattened on peanuts and corn, Virginia porkers yield a ham that is smoked and then matured for a year.

Avoidance of Pig Meat

Despite the popularity of pork in much of the world, it can also be observed that no other domestic animal has provoked such negative reactions in so many as the pig. In Western countries, swine are commonly seen as a metaphor for filthy, greedy, smelly, lazy, stubborn, and mean. Yet these presumed attributes have not prevented pork consumption. In other cultures, however, strongly negative attitudes toward the pig have historically resulted in its rejection as human food and even, in some cases, as an animal fit to look at.

About one-fifth of the world's population refrains from eating pork as a matter of principle. Muslims, 800 million strong, form the largest block of pork rejecters because the pig is specifically named in the Koran as an object of defilement. A millennium earlier, Jews had also decided that the pig was unacceptable as a source of food. In the Bible (Leviticus), the animal is rejected because it does not meet the arcane requirements of both having a split hoof (which it has) and chewing the cud (which it does not). It is quite possible that the prophet Mohammed acquired his conception of the pig as an unclean animal from the Jewish tradition.

The Jews, in turn, may have gotten their basic and negative idea about the pig from other neighboring peoples (Simoons 1994). Brian Hesse (1990), investigating Iron Age Palestine, found no evidence for a significant cultic role for pigs, which raises the intriguing question of whether Hebrew rules prohibited a food that no one ate in the first place. Although the Hittites of Anatolia kept pigs, they entertained negative notions about them. In dynastic Egypt, swineherds were a caste apart; pigs acquired a reputation for being unclean, and their flesh was not eaten by priests. Marvin Harris (1985) has asserted that because the pig does not fit into the hot and dry conditions of the Middle East, the Israelites banned it as an ecological misfit. Others, however, believe that the history of this fascinating taboo is more complicated than that (Simoons 1994).

Within the Christian tradition, adherents of the Ethiopian Orthodox Church do not consume pork, yet their religiously affiliated Coptic brothers in Egypt do eat it. Many Buddhists and the great majority of Hindus refuse pig meat, although in both cases this avoidance arises more from vegetarian conviction than from any explicit religious taboo toward the animal. The Mongols, those nomadic folk of central Asia whose way of life is ill suited to pig keeping, consider the pig to be a symbol of Chinese culture.

Historic reluctance to keep pigs and consume pork has also been noted in Scotland. Eric B. Ross (1983) has explained the rise of the Scottish aversion to the pig as a response to the ecological cost of keeping pigs after the decline of oak and beech forests. Because sheep raising best suited the subsequent moorland landscape, mutton became a cheaper and socially more acceptable source of animal protein.

Porcine Trends

In most industrialized countries since the 1960s, pig keeping has moved rapidly toward maximizing efficiency of production (Pond 1983). Animals are injected with growth hormones and spend their short lives within buildings in near darkness. Artificially inseminated sows (a technology that appeared in 1932) farrow in narrow steel cages. Piglets are removed early from their mother so that lactation ceases and her sexual receptivity is reactivated. In four months, another litter is produced. Piglets have their incisors removed, tails docked, ears notched, and in the case of males, their testes excised. Most pigs never reach their eighth month, although theoretically the animal can live about 15 years. Modern hog raising seeks to emulate the efficiency levels of the poultry industry. In that quest, its technological center in the United States has shifted from the Midwest to a belt of large corporate farms in eastern North Carolina. In 1994 alone, that latter-day "hog heaven" sent nearly 10 million animals, worth a total of about a billion dollars, to market. The next step, pork processing and trade, is normally quite lucrative, for about 75 percent of a pig's carcass can be made into salable cuts of meat. By-products, such as lard, bristles, gelatin, and cortisone, further enhance profitability.

For almost half a century, a spiced ham product high in fat has been a favorite canned food in the United States and many other countries. Spam, packaged by Geo. A. Hormel and Company of Austin, Minnesota, has a sales volume of close to 100 million cans a year. Since 1937, when it was put on the market, Hormel's Spam has served as an economical source of meat protein for millions of people. In 1991, following a major trend in the American food industry, Spam Lite was introduced; this product, however, barely meets federal requirements for fat content reduction.

Weight- and cholesterol-conscious consumers in Europe and North America have had an impact on the pork industry (Bichard and Bruce 1989). Consumer demand calls for leaner cuts, including substantial fat trimming, in supermarket meat cases. There is also a strong motivation to develop hog breeds with less fat in their muscle tissue, which normally has 5 to 7 percent fat. Pork fat is higher in unsaturated fatty acids than beef, veal, or lamb fat. On the average, one 85-gram serving of pork contains about 79 milligrams of cholesterol.

Lard, as a cooking medium, has ceded its former importance to vegetable oils. In response to this development, a shift in hog breeds toward the Landrace and the Large White has occurred. Of the 15 breeds of swine listed in the 1930 *USDA Agricultural Yearbook,* more than half have now disappeared. Less efficient breeds have also lost ground in Europe, where half of the 66 surviving breeds are now rare, and only 40 of 100 different breeds occurring in China are considered to be economically valuable (Epstein 1969).

International trade in pig meat originates overwhelmingly in Europe. In place for many decades, the single biggest flow of cured and canned pork is from Denmark to the United Kingdom. But even before that trade emerged, bacon had become an integral element of the British breakfast. The word "bacon" is derived from Francis Bacon (1561–1626), whose family crest featured a pig. Japan, although traditionally not a major consumer of pig meat, has become a significant importer of European pork products, and the well-known prosciutto (cured ham), from the Province of Parma in Italy, is now found in upscale shops around the world. Much potential movement of processed pig meat is thwarted because of the prevalence of three diseases, found mainly in underdeveloped countries: foot-and-mouth disease, hog cholera, and African swine fever. In Haiti in the early 1980s, for example, an epidemic of African swine fever killed two-thirds of the country's 1.2 million pigs. The surviving swine constituted a reservoir of the disease and were slaughtered. Then, disease-free swine were imported from the United States and distributed to some of Haiti's 800,000 former pig owners.

Conclusion

The story of the pig in space and time is one of a multifaceted mutualism with humans. Its early roles, as a feeder on garbage or as a free-ranging consumer of mast in the forest, freed the pig from competing with people for the same food. Part of this mutualism was also hygienic because of the animal's capacity for disposing of wastes. Transforming the least noble of materials into succulent protein, however, also engendered enough apparent disgust to ban the animal and its flesh in certain cultures. The pig is now found around the world under vastly different circumstances. In industrialized countries, questions of efficiency and fat control have become of paramount importance, and no other domesticated animal has undergone such major changes in the way it has been kept.

II.G.14 Horses

The horse represents one of the most successful outcomes of animal domestication, but for a variety of reasons it has not been widely used as a source of human food. Very little of the exacting attention given this creature over the past 5,000 years has been directed toward developing its latent meat or milk potential. Artificial selection of this nonruminant herbivore has focused on speed, strength, and configuration.

Domestication

Long before their domestication, wild horses roamed the Eurasian grasslands. They were a favorite subject of the Paleolithic cave art of western Europe, which suggests their status as a major prey species. Certain Upper Pleistocene kill sites, such as that at Solutré, France, have more horse bones than those of any other animal. Human intervention into their breeding came later than with other herd animals. Two wild horses, the tarpan *(Equus ferus gmelini)* and (Nikolai) Przhevalski's horse *(Equus ferus przewalski),* were the ancestors of the domesticated *Equus caballus.* Present knowledge places horse domestication in the grasslands of Ukraine around the fourth millennium before Christ. At Dereivka, a site of the early Kurgan culture, evidence of bit wear recovered archaeologically indicates that people rode horses (Anthony 1986). They also ate them, which is not surprising as the predecessors of these same people were avid consumers of the wild species.

Assuming present-day Ukraine to have been the center of horse domestication, the use of the animal spread westward during the next 500 years to eastern Europe, as well as eastward to the Transcaucasus and southward to Anatolia and the Mediterranean. Horse bones recovered at the site of Malyan (in Iran) that have been ingeniously analyzed reportedly show evidence of horse riding (Anthony and Brown 1989). By 2500 B.C. horses were well established in western Europe. Their main prehistoric role was as pullers of wheeled conveyances and as riding animals, and S. Bökönyi (1984) asserts that horses were used to pull carts before they were ridden. Horses were also eaten; in fact, the flesh of equids was an acceptable food in most societies that adopted them during the first 3,000 years of their domesticated state. Bronze Age sites in eastern Europe have yielded limb bones broken for the marrow and brain cases cracked open to extract the brain.

The Kurgan people, along with other early Indo-Europeans, also sacrificed horses to honor the dead and propitiate the gods (O'Flaherty 1987; Dexter 1990). This practice was widespread from Europe to South Asia, where the Aryans of India made a strong religious place for the horse. Its role as human food was not very important, although horseflesh was consumed in connection with the *asvamedha,* a sacrifice of horses borrowed from an ancient Indo-European fertility rite (Bhawe 1939). It is especially intriguing to consider that the horse gained ascendancy as a useful and ritually significant animal with the migration of Indo-European people. The Hittites of Anatolia, for example, introduced a higher level of horse keeping than had been there before, and Mediterranean antiquity extended the high prestige of the horse, but with much less ritual killing. The ancient Greeks offered horses in sacrifice to Poseidon, the god of horses, but did not generally consume the flesh. The only Roman horse sacrifice honored Mars.

Horsemeat Avoidance

In the modern world, most people and cultures have rejected the flesh of horses (and its equine relatives, the mule and the donkey) as unfit to eat. But the reasons for avoidance are not necessarily the same everywhere. In some places, the horse is a rare, even absent, animal, so that people have had little opportunity to find out what they were missing. Aside from Iceland, few horses have been kept in the Arctic or Subarctic, primarily because of the large effort needed to store a sufficient amount of fodder to get the animal through long winters. The tropics have not had big horse populations, either. Tropical forests neither suit the horse's food requirements nor favor its physiological well-being. Moreover, in much of Africa, the presence of trypanosomiasis has excluded horses from large areas.

In most parts of the world where the horse is found, neither its meat nor its milk is used. Part of this avoidance can be attributed to religious injunction. Jews, Muslims, Hindus, and, at one time, Christians have all proscribed horsemeat from the diet as a badge of their faith. Orthodox Jews include it as one of the forbidden items in their Levitical list of animals because horses neither chew the cud nor have cloven hooves. Muslims are enjoined in the Koran to eschew this flesh, a prohibition that, perhaps, grew out of the social context of Arab desert oases, where the horse was a luxury animal owned by sheikhs. Horsemeat is not eaten by most Hindus (except for untouchable groups) because it is a flesh food in a primarily vegetarian culture.

Marginalization of horsemeat in Europe had a religious basis. As Christianity spread through Teutonic lands, clerics regarded hippophagy (eating horseflesh) as a pagan residue that was tinged with barbarism. In prehistoric Ireland, horseflesh was eaten in ritual contexts, a practice that survived into the early Middle Ages. A chronicler in the twelfth century described such an occasion in which priestly sexual intercourse with a mare, sacrifice, and consumption of the flesh were involved (Giraldus Cambrensis 1982). Such behavior, outrageous to Christians, explains why horsemeat had such a bad reputation as the continent became more fully Christianized. Boniface, missionary to the Germans, undertook what amounted to a personal lobbying campaign to, successfully as it turned out, persuade the pope to place horseflesh into the forbidden category. Such a ban was certainly not based on health or scripture, but horsemeat, nonetheless, became the only specific food outlawed in the history of Christianity. Today, although most people in the Christian tradition still avoid the flesh of equines, its rejection no longer has much to do with a religious prohibition. Even the *Catholic Encyclopedia* makes no effort to recall this old taboo that had been part of canon law. Rejection can now be attributed mainly to fear of the unfamiliar. The status of the horse as an intelligent companion of humans has surely worked against experimentation with consuming its flesh, except in periods of severe food shortage.

Marvin Harris (1985) has argued that underlying these prohibitions was a stark ecological fact: The horse was an inefficient converter of grass to meat, and when compared to cattle, horses have a higher metabolic rate and a gestation period lasting two months longer. However, as H. B. Barclay (1989) points out, horses also have various advantages over cattle. They enjoy a longer life span and have greater stamina and endurance. In winter pastures, horses, unlike cattle, can paw beneath the snow to graze. Moreover, in central Asia, mare's milk yields are as high as those of cows.

In spite of early religious and later social reprobation, Europe did undergo a hippophagy movement that to some extent changed attitudes toward this meat and, as such, represents a notable case of how a food taboo broke down. Hippophagic experimentation in Europe was widespread around the middle of the nineteenth century, when conscious efforts were made to break with the old prejudice against selling and eating horseflesh. Denmark legalized its sale in 1841, as did the German state of Württemburg; Bavaria followed in 1842, and Prussia in 1843. Other countries (Norway, Sweden, Austria, and Switzerland) also legalized its sale. Russia, where horsemeat has had a historic culinary role, never banned the sale of horsemeat in the first place.

Horsemeat Consumption in Europe

In the European history of horsemeat consumption, France and francophone Belgium stand out. There the cultural barrier to selling and eating horsemeat was more successfully breached than in any other part of Europe. As with so many French attitudes, it began with elite exhortation, but it also occurred in a national culture charmed by culinary diversity and invention. Its beginnings can be traced to governmental decisions that French people should eat more flesh foods. By 1850, the opinion was that the French person's ability to perform industrial work was hindered by insufficient quantities of nitrates in the diet. Ireland was pointed to as a negative case of how dependence on the potato and little or no meat had led to physiological degeneration. In 1853, dietary regulations set a minimum daily intake of 100 grams of meat for a small adult and 140 grams for a large person. In 1889, a government medical commission increased these thresholds to 120 and 200 grams, respectively. In the French Army, the meat ration was increased in 1881 from 250 to 300 grams per day. Regulations about meat also affected institutions. In 1864, hospices and hospitals were directed to provide meat at meals twice a day, preferably roasted, which was judged to be the most nutritious form of preparation.

As meat consumption in France rose, provisioning became an issue. Since horseflesh was then much cheaper, it was judged by the authorities to be especially worthy of adoption among lower-income groups. A group of distinguished French intellectuals and scientists, led by Geoffrey Saint-Hilaire, made a conscious effort to integrate horsemeat into the French diet. Their aim was to show that *chevaline* (as it was called) was nutritious and that the old prejudices had no rational basis. Even the hierarchy of the French Church did not interfere in this conscious rejection of a medieval taboo, and the first specialized horsemeat shop opened in Paris in 1866. Shortly thereafter, dire food shortages associated with the siege of Paris gave many of that city's inhabitants an opportunity to eat horsemeat for the first time.

Two prime factors led to a generalized acceptance of horsemeat in France. First, until the 1920s, horsemeat cost half that of comparable cuts of beef and therefore was within reach of the working class. Second, horsemeat got much publicity as a high-energy food and as ostensibly valuable in physiologically reducing the human temptation to overindulge in alcoholic beverages. In touting horsemeat, the bourgeoisie indicated their conviction that it had an appropriate role to play in the diet of the working class, whose members were the main abusers of alcohol in France.

Two basic kinds of horseflesh later characterized its consumption in France. Red meat, preferred by many for its putative association with high iron content, comes mainly from older horses. A colt *(poulain)* yields light meat, favored for its tenderness and mild flavor approaching that of veal. Patterns of consumption have maintained a certain profile through the decades, with the typical horsemeat consumer in France tending to be young rather than old, working or middle class rather than rich, and urban rather than rural.

Hippophagy in France is highest in the northern part of the country, with southern Belgium an extension of that consumption pattern. Early in the twentieth century, large workhorses were numerous in this part of Europe where the Percheron and the Belgian breeds evolved. Consequently, Paris has had the most avid hippophagists in France, with a per capita consumption three times higher than that of western France and almost seven times higher than that of eastern France. Horsemeat was first promoted in Paris, and it was there that a specialized horse abattoir was set up from which horsemeat was wholesaled elsewhere. The Paris region has also had France's largest concentration of poor people, who became the most enthusiastic consumers of equine products. Paris, Lille, and other northern cities were major markets for red meat from aged animals, whereas hippophagists in Lyon and Grenoble preferred *viande de poulain.*

In spite of considerable commercial activity, horsemeat in France has had a marginal position among meat products. Except during the war years, its consumption has never amounted to more than 5 percent of that of beef. Close to 60 percent of French people do not consume any horsemeat, and of the minority that do, the per capita consumption amounts to only about 5 kilograms per year. One result, but also a cause, of such a pattern is availability. Most French towns have not had a clientele large enough to support a *boucherie chevaline,* and until the 1980s, butchers selling beef could not also sell horsemeat. This prohibition was in the form of a law that had been promulgated to prevent misrepresentation of one meat for another.

Organoleptic perception also affects consumption. Many people, for example, have stated they dislike the flavor of horsemeat. However, disagreement on whether it has a sweetish taste, some other taste, or is simply tasteless suggests differences in the kinds of slaughtered animals or preconceived notions of the meat's characteristics. The appeal of horsemeat may be culturally conditioned. For example, an organoleptic evaluation in the United States of several kinds of lean beef, regular beef, lamb, horse, and horse mixed with beef fat ranked the last two lowest in appearance, smell, and taste (Pintauro, Yuann, and Bergan 1984).

Matters of health and price explain at least part of the drop in per capita consumption of horsemeat from the 1960s to the 1990s. For many years, horsemeat was valued as a particularly healthful food due to an iron content higher and a fat content lower than beef. *Chevaline* reputation suffered, however, in 1967, when a highly publicized salmonella outbreak in a school cafeteria was traced to horsemeat patties. When findings emerged that fresh horsemeat deteriorated more rapidly than beef, the French government banned horsemeat for institutional use. In addition, awareness of *chevaline*'s possible health risk was paralleled by its rising cost. Horsemeat of the first half of the twentieth century was essentially a by-product of animals slaughtered after a useful life of pulling plows or wagons. For that reason, horsemeat was cheap compared to beef. But by the 1970s most horsemeat in France was imported, which influenced its retail price structure.

Thus in the 1990s, the French consumer paid normally as much, if not more, for horsemeat as for beef. This is because sources of horsemeat supply for the French and Belgian markets changed substantially after 1960, when mechanization of agriculture led to a sharp decline in the horse population. To meet the demand in the face of inadequate domestic sources of *chevaline,* live animals or chilled meat had to be imported from Spain, Portugal, and Eastern European countries. Between 1910 and 1980, imports of horses or horse products increased almost three times. European horses were supplemented with those from the Americas, and beginning in the 1970s, the United States became a major supplier for the French market, as did Australia and South America – especially Argentina, with its substantial horse population.

Horses raised specifically for meat production could, in theory, supply the needed tonnages and at the same time ensure quality. Colt meat in France is now mostly produced that way. Fed a controlled diet, horses grow very quickly, although they cannot compare with ruminants as an efficient converter of herbaceous matter. Breeding of the horse as a meat animal has another value of conserving the genetic patrimony of the famous work breeds of horses that are in danger of eventual extinction. In the long run, such activity might also lead to the emergence of a special kind of high-quality meat animal in the way that Hereford or Aberdeen Angus were developed as cattle with distinguishable phenotypes and genotypes.

Horses as Food in Other Countries

Several other European countries, notably Italy, Spain, Germany, and Switzerland, have achieved a small measure of hippophagic acceptance. Search for protein during the war and for some years after that accustomed Europeans to think of alternative possibilities. As recently as 1951, when meat was still scarce, the British consumed 53,000 horses. However, as other meats became abundant, horsemeat faded as a food for people. Moreover, animal rights activists in the United Kingdom have often shown vigilance about protecting the horse from becoming steak on the table.

In Asia, horsemeat is an important food in Mongolia, where the horse has been deeply integrated into a still traditional rural society. In addition, Mongolians consume mare's milk, usually in fermented form (kumiss). Though their religion bars it, Islamic people in Inner Asia have also been known to eat horseflesh.

In Japan, horsemeat is a favorite meat in the preparation of teriyaki, and in the 1980s Japan imported about one-fourth of the tonnage in the world trade of refrigerated or frozen horsemeat. Australia is a major supplier.

In the Western Hemisphere, no national culture has integrated hippophagy into its dietary possibilities, least of all those with a strong orientation toward carnivory. Argentines and Uruguayans, who are mostly of European origin, have rejected it, although some Indians of the pampas ate the meat of horses descended from those brought by the Spaniards. Some North American Indian groups who acquired the horse from the Europeans also ate horseflesh. In the United States, consumption of horsemeat is low; in fact, throughout North America, it is readily available (though not widely consumed) only in the Canadian province of Québec. French immigrants are reported as a major clientele of the 10 horsemeat shops in the city of Montreal in 1992.

The United States is the leading horsemeat-producing country in the world (FAO Production Yearbook 1990). In 1992, nearly 250,000 horses were slaughtered in the country. Thoroughbred race horses, including champions that once got high stud fees, usually end their days at the slaughterhouse. The $500 to $1,000 sale becomes a way to recover something of the high expense of raising them. Commercialization of this product has been both for shipment abroad as human food and for dog food.

In spite of the abundance of horses, equine flesh has never gained acceptance as a human food in the United States. Harris (1985) has concluded that horsemeat did not catch on because beef and pork could be produced more cheaply. More likely, preconceptions about the suitability of horsemeat have stemmed from an earlier bias brought by Europeans. Moreover, a small but vocal minority of Americans are actively opposed to its use as human food. One emotionally based argument is that it demeans such a noble animal to undergo slaughter as human food. Curiously, much less is said about the appropriateness of horsemeat as dog food, suggesting an ethic that requires humans to deal with horses in narrowly defined ways. Horse abuse in the United States receives much more publicity than mistreatment of cattle, sheep, or pigs.

The lack of horsemeat availability in American meat shops says much about the low demand, but proprietors are also afraid of losing business by making it available in the meat case. Episodes over the years of fraudulent labeling of horseflesh as beef have led to the (erroneous) assumption that the former is, by definition, an inferior meat, perhaps even tainted in some way. A slaughterhouse owner in South Carolina, who has long shipped horsemeat to the European market, has made several attempts to introduce horsemeat in his state with no lasting success. As was the case initially in Europe, a lower price for horsemeat would seem to be the critical mechanism in its acceptance. Yet economics dictate that good-quality horseflesh cannot be sold at a price much below that of beef. An unusually strong American concern for healthful and lowfat foods could possibly give it a niche. But up to now its best-known usage has been at the dining service of the Harvard Faculty Club in Cambridge, Massachusetts. There it has been maintained as a quirky tradition since World War II, when it was difficult to obtain beef.

II.G.15 ~ Insects

In the title of a delightful little book published in 1885, Vincent Holt asks, *Why Not Eat Insects?* The "why not" is hard to explain logically, nutritionally, or on the basis of the sheer abundance of these creatures. However, for Europeans and North Americans the eating of insects, or entomophagy, is considered a curiosity at best. And for many the idea is downright repulsive. Insects as food are found only in cartoons, or perhaps on the odd occasion when suitably disguised under a layer of chocolate. Yet for these same people, other invertebrate animals, such as oysters, snails, crayfish, and lobsters, are not only accepted as food but even viewed as delicacies.

In many other parts of the world, however, insects are considered good to eat and are appreciated for their taste as well as nutritional value. Some, like the giant queen ants (*Atta* sp.) of Colombia, are prized as delicacies and supposedly function as aphrodisiacs as well. Others, like the mompani worms of Africa, are frequently included in the diet and much enjoyed. Still others, like the cock chafer grubs of Ireland, although not much esteemed, have been used when more desirable foods were not available.

The purpose of this chapter is to present an overview of the role of insects in the diet in different parts of the world and in different time periods. We first review the use of insects as food within major geographical areas, in the present as well as in the historic and prehistoric past when information is available (a comprehensive list of insect species used as food is provided in Table II.G.15.1). We then summarize general patterns of insect use and provide information on the nutritional value of some commonly consumed insects.

Insects Around the World

The Americas

North America. The use of insects as food is generally frowned upon in North America, notwithstanding the repeated attempts by entomologists to make them more appealing. One of the best known of such attempts is R. L. Taylor's 1975 book, *Butterflies in My Stomach,* and the accompanying recipe guide, *Entertaining with Insects* (1976). The reasons that most North Americans do not include insects in their diets have to do with food preferences rather than nutritional value. The dietary exclusion of insects is sometimes justified by the assumption that many insects carry diseases and therefore eating them is dangerous, but there is little evidence to support such a notion (Gorham 1979).

The prohibition against eating insects among many contemporary North Americans can probably be traced to Europe. European colonists who settled in North America also had strong taboos against consuming insects. In fact, they originally classified the New England lobster as an insect and refused to eat it. But that was in the 1600s. Subsequently, the lobster has, of course, passed from the status of prohibited food to delicacy.

Native Americans, however, did not have the same prejudices against insects as food, and there are a number of ethnographic and historical accounts indicating their importance in the diet. The bulk of these reports are from the western United States, where the most heavily consumed insects were the larvae of the Pandora moth, grasshoppers, and Mormon crickets – insects that occur in great abundance during certain seasons and in certain places in the region.

Pandora moth larvae *(Colorado pandora lindseyi)* are large caterpillars found on a certain pine tree species, *Pinus jeffreyii.* They were reportedly collected in large numbers by Native American peoples, either by hand or by trenching around the bottom of trees when caterpillars descended to pupate in the soil (Fowler and Walter 1985). As recently as 1981, Pandora moth larvae were still being collected (Fowler and Walter 1985).

Grasshoppers were also frequently consumed by early Americans. They occurred in large swarms or "plagues" in drier areas at densities of more than 12,000 insects per square mile in California (Brues 1946). On the beaches of the Great Salt Lake in Utah, grasshoppers washed up by the lake can pile up in long windrows as much as 20 centimeters thick, already salted and sun-dried (Madsen 1989). The return rates for collection in kilocalories (kcal) per hour are greater than for any other known collected resource (Madsen and Kirkman 1988). Grasshoppers are relatively high in some B vitamins and can be stored (dry) for long periods in the form of flour (Sutton 1988).

Crickets are another valuable food resource; they were often collected in large quantities in trenches and stored for use in the winter (Sutton 1988). One of these was the Mormon cricket *(Anabrus simplex),* so named because Mormons tried to kill these crickets off in the late 1800s and in the process caused animosity between themselves and Paiutes (Madsen and Kirkman 1988). There is some indication that insects formed an increasingly substantial part of the Native American diet as the local habitat was modified by European newcomers (Sutton 1988).

Other insects used by the first Americans were shore flies *(Hydropyrus hians),* available in great abundance in some locations, and ants that were made into flour soup (Sutton 1988). Judging by historical accounts, grasshoppers and crickets were usually roasted and ground with pine nuts, grass seeds, or berries to make cakes, which could then be sun-dried and stored. These were called "desert fruitcakes" and (interestingly) were considered a delicacy by European travelers as well as by Native Americans (Madsen 1989).

Stage of life cycle: adult (a), egg (e), immature stage (i), larval (l), nymph (n), pupal (p). Geographic regions are North America (NA), Central America and the Caribbean (CA), South America (SA), Africa (Afr), Pacific Islands (PI), Australia and New Zealand (Aust), Europe (Eur), Middle East and South Asia (ME), Southeast Asia (SEA), East Asia (EA). Each named species was counted as one, unnamed species designated simply as spp. were also counted as one species.

Central America and the Caribbean. In Mexico, J. R. E. de Conconi and collaborators (1984) have documented the consumption of a very wide variety of insects. They found 101 species of insects regularly consumed, fresh, roasted, or fried, at various stages of development. These belong to 31 families in nine orders and include dragonflies, grasshoppers, bugs, lice, treehoppers, cicadas, caddis flies, butterflies, moths, flies, ants, bees, and wasps (Conconi et al. 1984).

Entomophagy has been practiced for a long time in Mexico (Conconi and Bourges 1977), where many insect dishes are considered delicacies. A well-known example is *ahauatle,* a mixture of hemiptera eggs. It was first reported in 1649 by Francisco Hernandez and was still consumed in 1933 (Ancona 1933). The eggs, from four species of aquatic hemiptera (two species of *Krizousacoriza* and two of *Corisella*), were collected on specially prepared bundles of leaves left in the lake water for several days during the principal egg-laying season. This mixture of eggs (said to have a shrimp-like flavor) was then fried with chicken eggs. The insect eggs were also dried and used as a condiment in the preparation of a traditional Christmas Eve dish, *revoltijo.*

The adult insects of both *Krizousacoriza* and *Corisella* were also consumed, usually along with a fifth species, *Notonecta unifasciata.* The adults were gathered in baskets, sun-dried, and sold on the street, as *mosco para los pájaros.* They were also ground and made into small cakes that were grilled. Both the eggs and adults of these species of aquatic insects were sold as fish food in Europe and in the United States (Ancona 1933).

South America. The giant queen ants of the genus *Atta* are prized as a gastronomical delicacy in Colombia. *Atta* are leaf-cutting ants considered to be a major pest in some agricultural areas. The queens of the genus are very large ants that swarm in the early rainy season and can be easily collected as they leave the nest. The gathering and toasting of these ants is a prosperous cottage industry in northeastern Colombia, and they are marketed throughout the country. Ant consumption can be traced to precolonial times: Gonzalo Jimenez de Quesada, founder of the Colombian capital, Santa Fe de Bogotá, described their use by local peoples in the highlands in 1555 (*Nación* 1989).

The consumption of a wide variety of insects (representing 10 orders and more than 50 different species) has been reported among Amerindian groups in South American rain forests. The insects that appear to be most commonly consumed are ants of the genus *Atta,* palm grubs, and caterpillars of various sorts. The consumption of the queen ants occurs throughout the Amazon Basin (Wallace 1853; Bodenheimer 1951; Denevan 1971; Weber 1972; Ruddle 1973; Dufour 1987). The first description of their use was provided by the naturalist Alfred Wallace (1853: 242–3):

> The part eaten is the abdomen, which is very rich and fatty from the mass of undeveloped eggs. They are eaten alive; the insect being held by the head as we hold a strawberry by its stalk, and the abdomen being bitten off, the body, wings and legs are thrown down to the floor, where they continue to crawl along apparently unaware of the loss of their posterior extremities.

Palm grubs, or palm worms, are the large, fatty, legless larvae of wood-boring weevils (genus *Rhynchophorus*) found in the pith of felled palm trees. The weevils are ubiquitous in tropical rain forests, and the utilization of their larvae as a valued food has been widely reported (Bodenheimer 1951; Chagnon 1968; Clastres 1972; Beckerman 1977; Lizot 1977; Milton 1984; Dufour 1987). E. Bancroft, writing in the eighteenth century, claimed they were also highly esteemed by Europeans in Surinam, particularly by the French, who mixed the roasted grubs with bread crumbs, salt, and pepper (Bancroft 1769, cited in DeFoliart 1990). In northwest Amazonia they are eaten both raw and after smoke-drying over a slow fire, as components of normal meals and as snacks. Amerindians "cultivate" palm grubs in the sense that they fell palm trees with the expectation that they will be invaded by weevils and a crop of grubs will be available for harvest in two to three months (Clastres 1972; Beckerman 1977; Dufour 1987).

The consumption of other types of grubs or larvae is frequently mentioned in ethnographic reports. In the northwest Amazon, the larvae of wood-boring beetles are extracted from felled trees (Dufour 1987). One group of Amerindians in the Peruvian montaña region "cultivate," or at least protect, an unidentified grub called *poshori,* found in piles of maize cobs (Denevan 1971).

Caterpillar eating has been reported for a number of Amerindian groups (Lizot 1977; Dufour 1987), but the actual species eaten have been identified for only one group – the Yukpa (Ruddle 1973). In the northwest Amazon region, five different species of caterpillars have been collected, two of them in large amounts (Dufour 1987). Less commonly ingested are soldier ants, termites, wasp and bee brood, and other larvae (grubs) of various sorts. The consumption of adult beetles seems to be even less common, but it has been reported for the Yukpa (Ruddle 1973) and Ache (Hurtado et al. 1985).

Europe

Although entomophagy is no longer common in Europe, insects were eaten throughout the continent at one time. Cock chafer grubs were consumed by peasants and mountain inhabitants until the 1800s and were an important source of protein in Ireland during the famine of 1688 (Bodenheimer 1951). In earlier times, those who could not afford a diet rich in protein and fat relied on insect sources to supplement their predominantly carbohydrate intake (Bodenheimer 1951).

The Greeks and Romans, who heavily influenced European culture, enjoyed insects as a food source (Bequaert 1921). Ancient Greeks apparently considered grasshoppers a delicacy, and even Aristotle reported eating cicadas. He considered them tastiest just before the final instar, but females, laden with eggs, were deemed delicious as well (Bates 1959). The Greeks and Romans also ate a large Melolonthid grub thought to be *Lucanus cervus,* which, according to Pliny, was fattened before consumption (Bequaert 1921).

Africa

The consumption of insects in Africa is still quite widespread (DeFoliart 1989), with caterpillars among the most popular. A recent survey found that 69 percent of Africans interviewed had eaten one or more species of caterpillar or lived in households where at least one species of caterpillar was consumed (Ashiru 1988). The mopanie worm *(Gonimbrasia belina),* the so-called snack that crawls, is one of the best-known edible caterpillars. It is eaten fried, dried, stewed in tomato sauce, and even raw (Brandon 1987). Mompani worms appear to constitute an important source of protein for rural dwellers (Ivbijaro 1990) and were reportedly preferred to meat in some areas when they were in season (Quin 1959).

Caterpillars have become something of a trend on menus around Africa and are currently marketed by a firm in Johannesburg (Brandon 1987; Zimbawe *Herald* 1988). Because they occur in large aggregations, the collection of caterpillars is easier than that of some other insects (Chavanduka 1975). In fact, collection rates of 40 pounds per day have been reported (Brandon 1987).

Locusts also play a significant role in the diet of Africans, particularly *Schistocerca gregaria,* the desert locust (Quin 1959; DeFoliart 1989). Indeed, in the not-so-distance past, the locusts have been so popular that locust swarms were welcomed and their arrival attributed to a mighty spirit (Bequaert 1921). The female locusts loaded with eggs were most commonly eaten, and often a soup was made of the eggs (Berensberg 1907; Bequaert 1921). High in protein and fat, locusts may be an excellent supplement to local diets that consist mainly of carbohydrates (Chavanduka 1975). P. J. Quin (1959) also notes that locusts played a significant role in sustenance and were the most popular meat of all among the Pedi of the Transvaal.

Termites are also utilized as food in Africa, especially during the early rainy season when the reproductive forms fly from the nest in large swarms and can be collected (Brickey and Gorham 1989; Kumar 1990). At one time, termites were such an important addition to the diet that their mounds were fought over as property (Bequaert 1921). Local people knew when these swarms would occur and they would cover mounds for purposes of collection (Curran 1939). Termites can be eaten raw (with care taken to avoid being bitten by the termite first) (Curran 1939) and fried, and they are also roasted. Termites not only are high in fat and protein but also contain a significant amount of lysine, which is not found in maize, a main constituent of the African diet (Chavanduka 1975; Oliveira et al. 1976).

Palm grubs, such as those of the genus *Rynchophorus,* are still consumed in Cameroon, Angola, and other parts of Africa and are occasionally raised specifically for this purpose (Oliveira et al. 1976; DeFoliart 1990). They may be prepared by stewing, frying, or grilling, but one creative recipe suggests boiling them inside coconuts instead (Grimaldi and Bikic 1985, cited in DeFoliart 1990).

Although a recent study indicates that 10 percent of the animal protein in the diet of local people in Zaire comes from insect foods, the general trend in Africa is toward a reduction in entomophagy (DeFoliart 1990; Kumar 1990). This development is, perhaps, due to an increased use of pesticides as well as to exploitation of new habitats in order to accommodate growing populations, both of which have reduced the number of insects to which populations have access (Chavanduka 1975).

Asia

Middle East and South Asia. With the exception of locusts, whose consumption continued into recent times, the Middle East and South Asia have not had a strong history of entomophagy (Bodenheimer 1951). The desert locust, *S. gregaria,* was a major source of food in the Middle East, with up to 9,000 kilograms gathered per day in some areas (DeFoliart 1989). These locusts were prepared by cooking in salt water and then sun-drying, after which they were traded at the market (DeFoliart 1989). During times of famine locusts were frequently ground into flour from which fried cakes were made (Bodenheimer 1951). In 1988, Saudi Arabians were also observed eating locusts, grilled like shrimp, after the worst locust plague in 25 years descended on the west coast (San Francisco *Chronicle* 1988).

Locusts were especially prevalent in the diet of nomadic people such as the Bedouins, who welcomed the periodic swarms (Bodenheimer 1951). The best-known incident in that part of the world involving locust eating, however, concerns John the Baptist's limited fare of locusts (St. John's bread) and honey during his ordeal in the desert. He was observing the decree of Moses found in Leviticus 9:22: "These ye may eat; the locust after his kind and the bald locust after his kind, and the cricket after his kind and the grasshopper after his kind."

A recent study of three tribes in Assam, India, has revealed a surprising number of locusts eaten on a mass scale (Bhattacharjee 1990). No other contemporary insect consumption is documented for South Asia except in Nepal. The Nepalese in the Himalayan foothills are said to prepare a native dish, called *bakuti,* in which the larvae and pupae of giant honeybees are extracted from the wax comb and cooked until they resemble scrambled eggs (Burgett 1990).

Southeast Asia. Entomophagy is still relatively popular in Southeast Asia. In fact, Thailand currently exports frozen steamed ant larvae and pupae to the United States as specialty foodstuffs (Brickey and Gorham 1989). In North Thailand, bee brood is prepared for consumption by steaming entire honeycombs wrapped in banana leaves (Burgett 1990). Such grubs and pupae must be an important food among local people because, as F. S. Bodenheimer (1951) notes, the collection of combs is done at great risk of being stung.

The consumption of beetles has been especially popular throughout Southeast Asia, with 24 species in six families listed by Bodenheimer (1951) alone. He reported that Dytiscid beetles, such as *Cybister* and Hydrophilid beetles, seem to have been the most frequently eaten and those most commonly sold at market (Hoffman 1947). The larvae of longicorn beetles and weevils were also sought by the people of Laos (Bodenheimer 1951). The larvae of *Rhynchophorus schah,* which are found in coconut palms, were roasted, and other *Rhynchophorus* larvae were fattened and sold for a good price at the market.

While in Laos and Siam (now Thailand) in the 1930s, W. S. Bristowe (1932) also noted the popularity of larval as well as adult beetles in this region. Among those he cited as favorites were dung beetles (Scarabaeidae), which were served curried, and the giant water beetle *(Lethocerus indicus),* a great delicacy that was said to taste like Gorgonzola cheese. Bristowe also observed dishes of water, set out with lighted candles in the center, to attract dragonflies and termites. These insects would singe their wings on the candles and fall into the water to be subsequently collected.

Bristowe (1932) claimed that the local people's knowledge of the life history of these food insects was very thorough and that they truly enjoyed eating the insects and were not consuming them strictly out of necessity. Furthermore, he hypothesized that by eating pest insects the people were reducing the amount of damage done to their crops.

The green weaver ant *(Oecophylla smaragdina)* was used throughout South and Southeast Asia in a condiment as well as a drink; both were said to have a rather acidic flavor (Bequaert 1921).

East Asia. Insect consumption is still quite common in some parts of East Asia. Perhaps the most well-known insect eaten in this region is the pupae of the silkworm *Bombyx mori.* These pupae are exported from Korea to the United States (Brickey and Gorham 1989) and are also eaten in China, according to a recent study done by the Institute of Insect Research in Yunnan Province, China (The Research Institute 1990). W. E. Hoffman (1947) observed that the pupae were sold throughout the silk district and often cooked immediately after the silk was unraveled, so as not to waste the valuable resource that accompanied the silk.

The larvae and pupae of Hymenopterans are another food resource currently used in East Asia. Five species of immature bees and wasps utilized as food were identified by the Institute of Insect Research in Yunnan Province. B. Hocking and F. Matsumura noted in 1960 that Japan had been exporting bee pupae in soy to the United States. Interestingly, one of the favorite dishes of Japan's late Emperor Hirohito was wasp pupae and larvae over rice (Mitsuhashi 1988). Bodenheimer (1951) also documented the consumption of the larvae and pupae of *Vespa,* a wasp, in Japan.

Locusts are presently consumed in East Asia, particularly those of the genera *Oxya* and *Locusta* (The Research Institute 1990b). Bodenheimer (1951) described the sale of grasshoppers fried in sesame oil in the local markets in China earlier in this century. Other insects consumed in East Asia included *L. indicus,* the giant water beetle, and caterpillars infected with *Cordyceps,* a fungus. These caterpillars were tied in bundles by the fungus filaments and sold as a delicacy (Hoffman 1947).

Pacific Islands. According to V. B. Meyer-Rochow (1973), insect eating is still a part of the native cultures in Papua New Guinea. Most widely documented are the sago palm grub feasts in which hundreds of pounds of *Rynchophorus bilineatus* larvae are wrapped in banana leaves and roasted. In fact, three species of palm grubs are exploited regularly, along with other larvae and adults of large beetles including many of the family Scarabaeidae (Meyer-Rochow 1973).

New Guineans also consume a great number of Orthopterans, including two species of stick insects, two of mantids, and the female of a species of locust (Meyer-Rochow 1973). Meyer-Rochow hypothesized that insect consumption provided needed dietary protein and fat because the greatest variety and quantity of insects were consumed in areas with the highest population density as well as the lowest amounts of available animal protein.

Termites were also very popular in the Pacific Islands, especially the sexual winged forms, which are higher in fat content. The predominant species eaten, *Macrotermes,* were caught after they flew into fires, burning their wings. In the Philippines, natives were said to eat the locusts that consumed their potato vines – a unique form of pest control (Bodenheimer 1951).

Australia and New Zealand

Despite a general reduction in the use of insects as food worldwide, entrepreneurs in Australia have begun to introduce insects to their commercial food market (Putting Insects on the Australian menu 1990). The insects considered to have the best potential for success include black honey ants, witchetty grubs (the larvae of a Cossid moth), bardi grubs (the larvae of a Cerambycid beetle), and *Trigona* bees. All of these insects have been supplied from around Australia where they are local delicacies. Many restaurants in Australia also now include insects on their menus (Putting Insects on the Australian menu 1990).

The black honey ant *(Camponotus inflatus)* is similar to the honey ant found throughout North and Central America. A modified worker ant with an enlarged body the size of a grape and filled with nectar, the black honey ant was highly sought after by Aboriginal Australians (Bourne 1953) and even considered a totem animal by some clans (Flood 1987; Conway 1990). The digging up of these ants is considered an important traditional practice and is still taught to children (Conway 1990). Other species of ants were also important food resources for Aboriginal Australians (Bodenheimer 1951). Tasmanians had a number of words for the various ants that they identified, and traditional feasts were held during the periods that ant pupae could be obtained (Sutton 1990).

Witchetty grubs were also an important food of Australian Aborigines (Flood 1987). The name "witchetty grub" refers to several types of grubs (Campbell 1926) and probably includes the larvae of the Cossid moth *(Xyleutes leuchomochla),* the giant ghost moth (Hepialidae), and the longicorn beetle (Cerambycidae) (Bodenheimer 1951; Sutton 1990).

Among the most unique and well-documented examples of entomophagy in Australia were the annual Bugong moth feasts that occurred in the Victorian Alps until the 1890s. Moths of *Agrotis infusa* migrate from the plains of New South Wales to aestivate (the summer equivalent of hibernation) every year in the rock crevices and caves of the Bugong Mountains, from which their name was derived (Flood 1987). Enormous numbers of moths have been counted (up to 17,000 per square meter) in some of these crevices and found on the floors of caves to depths of over 1 meter (Flood 1980). Many different tribes of Aboriginal Australians traditionally gathered to feast on the moths, and evidence of these feasts has been carbon dated to about 1,000 years ago (Flood 1980). The moths were smoked out by thrusting a burning bush into the cracks of the rock, then they were thrown into hot ashes or sand to remove the wings and legs (Campbell 1926; Flood 1980). These moths are said to have a nutty flavor and are high in both protein and fat (Campbell 1926; Sutton 1990).

Insects Are Good to Eat

General Patterns of Use

The great number and diversity of insect species (over 600) that have been or are used as food are listed in Table II.G.15.1. The largest variety of species appears to be in the tropics, which probably reflects the greater faunal diversity in these areas and the larger size of individual organisms. But it may also reflect to some extent the amount of research done on the topic in such climates. Comparatively fewer species appear to have been consumed in the more temperate regions of North America, Asia, and Europe. Fewer insect species inhabit these areas, and in general, the size of individual organisms is smaller.

A closer look at the insects listed in Table II.G.15.1 reveals that many of the same types of insects (i.e., in the same orders and families) are consumed in different parts of the world. The most widely consumed are probably the locusts (Acrididae), termites (Termitidae), and palm grubs (Curculionidae) (see Table II.G.15.2). These insects share two characteristics that are significant to their use as human food: (1) Individual insects are relatively large; and (2) individuals are highly aggregated during at least part of their life cycle. Locusts, for example, are among the largest of insects. They are also gregarious and can form swarms of thousands of individuals. Termites are generally smaller in size but are ubiquitous in tropical ecosystems. The species employed as food can be found in large, easily recognized colonies (for example, *Macrotermes* spp. in Africa), and the reproductive forms of some species can be easily captured during mating flights. Palm grubs, the larvae of weevils, can be as big as sausages. Over 50 percent of the Curculionidae reported are from the genus *Rynchophorus,* a genus found in the Americas, Africa, and Asia, which includes some of the largest of all herbivorous beetles (Crowson 1981). In addition, palm grubs can be harvested in sizable quantities from the pith of felled palm trees.

About 50 percent of the insects listed in Table II.G.15.1 are consumed in immature stages of the life cycle. The advantage to human consumers is that the immature stages are soft-bodied, typically high in fat, usually the largest form of the life cycle, and often in the stage of the life cycle when individual insects can be found in the greatest aggregations. In the order Lepidoptera (butterflies and moths), for example, the larval stage is the stage of the life cycle in which the insect is largest and has the highest energy (caloric) content. Compared to the larvae in the last instar, the adult forms have a lower body mass and a hardened exoskeleton, which reduces their digestibility. The larval stage is also often the stage of the life cycle at which the organisms are the most numerous and highly aggregated, whereas the adults are more mobile and widely dispersed. Furthermore, the larval stage is often long, as opposed to the shorter adult stage (Daly 1985), and therefore offers a greater harvesting opportunity.

Table II.G.15.2. *Number of species of the insects most commonly consumed throughout the world by geographic region (percentage consumed in immature forms in parentheses).*

	Number of species[a]			
Geographic region	Loc	Ter	PG	Total
North America	10	0	1	50 (46%)
Central Amercia, Caribbean	16	0	3	117 (81%)
South America	8	5	4	61 (57%)
Europe	2	0	0	20 (54%)
Africa	10	19	6	155 (63%)
Middle East, South Asia	6	2	0	29 (33%)
Southeast Asia	4	1	3	67 (34%)
East Asia	5	0	1	60 (40%)
Pacific Islands	4	6	4	59 (27%)
Australia, New Zealand	2	2	0	46 (68%)
Total	67	35	22	664

[a] Loc = locusts, Ter = termites; PG = palm grubs.

Table II.G.15.3. *Nutritional value of some insects consumed in tropical South America compared with other animal foods; composition per 100 grams edible portion.*

Food	Moisture (%)	Energy (kcal)	Protein (g)	Fat (g)
Ants, female sexuals *(Atta sexdens)*	6.1	628	39.7	34.7
Ants, female sexuals *(Atta cephalotes)*	6.9	580	48.1	25.8
Termites, soldiers *(Syntermes sp.)*	10.3	467	58.9	4.9
Palm grubs, smoke-dried *(Rhynchophorus sp.)*	13.7	661	24.3	55.0
Caterpillars, smoke-dried (various species)	11.6	425	52.6	15.4
River fish, smoke-dried	10.5	312	43.4	7.0
Tapir, smoke-dried	10.3	516	75.4	11.9

Food Value of Insects

In terms of nutrition, insects are comparable to other animal foods. The composition of some insects consumed in tropical South America is shown in Table II.G.15.3, and values for two other common sources of animal protein – dried fish and dried meat – are provided for comparison. The energy value of the insects is high, between 425 and 661 kcal per 100 grams, with the energy values for female alate ants (*Atta* sp.) and *Rhynchophorus* larvae the highest, because both of these are rich in fat. The amount of protein in insects is also relatively high, but its quality appears to be somewhat lower than that of vertebrates (Conconi and Bourges 1977). In relation to more familiar foods, the composition of ants, palm grubs, and caterpillars is comparable to goose liver, pork sausage, and beef liver, respectively. The composition of termite soldiers is roughly comparable to that of non-oily fish, although the latter contain more protein.

Unfortunately, the actual nutritional importance of insects in human diets is not well understood because there is little information on quantities actually consumed.

Summary and Conclusions

Insects are ubiquitous and have been included in human diets in most areas of the world at some time. They are still a component of many current diets. The inclusion of insects in these diets should not be regarded as a mere curiosity, nor should their nutritional importance be overlooked because of their small size. Insects are not only a food prized by many peoples but also a good source of energy, animal protein, and fat. Their dietary importance varies from region to region and group to group, but the widespread practice of entomophagy deserves attention in any description or evaluation of human diets.

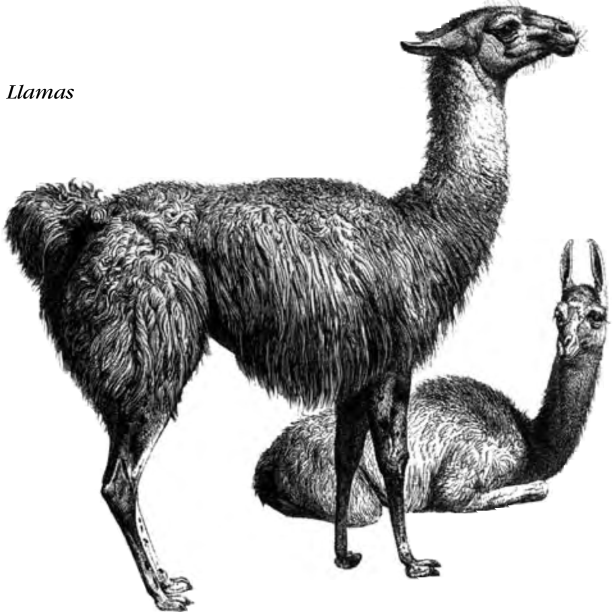
II.G.16 Llamas and Alpacas

The llama *(Lama glama)* and alpaca *(Lama pacos)* are among the few domesticated ungulates whose most important function has not been that of providing food for the people who control them. The llama has been kept primarily as a beast of burden, whereas the more petite alpaca is most valued as a source of an extraordinarily fine fleece. These South American members of the camel family may share a common biological ancestry from the guanaco *(Lama guanicoe),* for although they have long been designated as separate species, the closeness of the relationship is reflected in fertile offspring when they crossbreed. An alternative point of view now gaining in popularity is that the alpaca descended from the vicuña *(Lama vicugna),* since both animals are about the same size (44 to 65 kilograms [kg]) and both have the capacity to regenerate their incisor teeth. The distribution of both the llama and the alpaca has been traditionally centered in the Andean Highlands of Peru and Bolivia, with peripheral populations of the former in Chile, Argentina, and Ecuador. In the past three decades growing interest has increased their population on other continents, especially in North America.

Camelid Meat as Human Food

Both animals have been an important source of food in the part of the central Andes where husbandry has been most intensive. In neither case, however, are they raised primarily for their flesh, which is consumed after their most valued functions diminish with age. However, llamas possibly had a more important meat function in the pre-Pizarro Andes before the introduction of European barnyard creatures. The movement of herds from the highlands to the coast could have been a way both to transport goods and to move protein-on-the-hoof to the more densely populated coast, where at the time, meat was much rarer than in the highlands (Cobo 1956). David Browman (1989) suggested that when camelid utilization in the highlands expanded northward, starting around 1000 B.C., and long before the Inca civilization was established, meat production appeared to have been the most important use of these animals. But whether of primary or secondary importance, the protein and fat supplied by this meat have contributed to the health of the animals' Andean keepers, whose diet consists mainly of starch.



Llamas

Some fresh meat is consumed soon after an animal has been butchered. Recently butchered muscle meat is normally whitish or pinkish. Travelers' reactions to llama flesh have been mixed, although it is not always clear that the opinion is based on actual consumption. J. J. Von Tschudi (1848), for example, described it as "spongy in texture and not agreeable in flavor." It is reportedly as high in protein (more than 20 percent) as other kinds of meat but lower in fat than mutton, pork, or beef (Bustinza Choque 1984). Sausages and a kind of Andean haggis are made from the blood and intestines (Flannery, Marcus, and Reynolds 1989). The soft parts of the animals may also be fried *(chicharrones).*

Most llama and alpaca meat is dried, which in this region of the world has been the only feasible way to preserve and market it outside the local community. Chunks of the carcass are separated from the bone and cut into thin slices less than 1 centimeter thick. These are usually salted by soaking in a brine solution for several days. Then the meat is exposed for two or three weeks in May and June when night temperatures fall to minus 15° Celsius (C). The alternation of freezing cold at night and intense sunlight in the day dries the meat. Called *charqui* in Spanish (from *ch'arki* in Quechua), the dried meat keeps indefinitely. The term *charqui* has given rise to the English word "jerky," which means strips of dried meat, usually beef. In addition to its transportability, *charqui* is reportedly free of a sarcoporidian parasite that is commonly found in fresh meat (Calle Escobar 1984: 167).

The main consumers of *charqui* are Indians, who barter for it if they do not produce it themselves. *Charqui* continues to be carried in llama trains to lower ecological zones where it is exchanged for maize, fruit, and coca. It is also seen in the periodic markets on the Altiplano of southern Peru and Bolivia and is a staple food in several mining towns. Its main competitor is dried mutton. After sheep were introduced to the Andes in the sixteenth century and Indians subsequently adopted them as their own, the process for making *charqui* was applied to mutton to make *chalona.* Whether fresh or dried, the meat of llamas or alpacas is stigmatized as Indian food, and many mestizos avoid it simply for that reason. Because these animals are not inspected in certified slaughterhouses, questions have arisen about the wholesomeness of the meat.

Llamas and alpacas are led to slaughter typically when their primary functions are deteriorating. However, some other criteria are considered depending on the place or situation. George Miller (1977) pointed out that the most disobedient llamas of the herd are sometimes the ones chosen to be slaughtered. If carried out as a general practice, this kind of culling acts as a selection mechanism for docility. Llamas may also be culled for slaughter if they are unusually small or weak, qualities that inhibit their function as pack animals. Moreover, alpacas may be culled for slaughter if their fleece is multicolored; the international wool trade much prefers white or light fawn-colored fleece and pays higher prices for it. Hybrids (wari or huarizo) between an alpaca and llama have neither of the advantages of the parents and may be preferentially kept as a meat source.

Butchering may also be the result of a need or desire for ritual products from the animal. Bezoar stones, for example, which sometimes occur in the stomach and intestines of llamas and alpacas, were used in native ritual. They were also valued by the Spaniards, who believed them to be an antidote for poison. Fat *(pichuwira),* especially of llamas, has uses in rites that combine a number of items, including coca leaves, cigarettes, and wine or spirits. Fetuses of pregnant llamas and alpacas are also prized as a ritual item, especially as a substitute for sacrificing live animals in towns and cities. In La Paz, Bolivia, the native herb market sells dried fetuses; typically they are buried under the doorway of a private home to ensure fertility. Formerly, the hides of llamas were used for making sandals, but since the 1950s, Indian footwear in the Central Andes is made with rubber from worn-out truck tires.

No reliable production figures for camelid meat are available; however, the yearly slaughter in Peru and Bolivia may reach 10 percent of the combined llama and alpaca population of more than 6 million animals, which is more or less divided equally between the two (Sumar 1988: 26). Almost 89 percent of alpacas in the world are in Peru; Bolivia has 57 percent of the world's llamas (Bustinza Choque 1984). On a household basis, a poor family may butcher 4 animals a year, whereas a more affluent herder may process up to 12 head a year (Flores Ochoa 1968). Aside from slaughter, llamas may be eaten after they have died of other causes (a newborn killed by diarrhea, for example) (Novoa and Wheeler 1984: 124).

The zone of intensive husbandry today is confined to elevated areas above 3,900 meters (m), all within a 300-kilometer (km) radius of Lake Titicaca. Not surprisingly, Puno produces much more camelid meat than does any other Peruvian department. The *paramos* (flatlands) of northern Peru, Ecuador, and southern Colombia have rarely contained llamas or alpacas in any sizable numbers, and in much of Colombia and Venezuela there are none at all. In the llama heartland, the colonial period's native beast of burden was displaced to some degree when the llamas' *trochas* (trails) were widened and mule driving was introduced. When vehicle roads were built in the twentieth century, the displacement was accelerated and the llama population dropped sharply. But that same decline in numbers has not happened with alpacas, which in fact are seen by non-Indians as much more valuable animals.

The Nonmilking Enigma

The nutriments that llamas and alpacas provide do not include milk, and the failure of humans to milk these domesticated herd animals raises some important questions. Unfortunately, written sources have rather frequently contained misinformation, sometimes based on an Old World conceit about the cultural history of the Americas. Examples include assertions that llamas were used as mounts and to pull plows, and that alpacas have been beasts of burden. Encyclopedias, several geography textbooks, articles in *Nature* and *National Geographic,* and even a dictionary of zoology contain this error (Gade 1969).

Similarly, milk has been claimed as one of the useful products of the llama and alpaca, yet scholars who have studied Andean camelid domestication, ecology, and economy are silent on the subject.[1] Analyses of the archaeological context by C. Novoa and Jane Wheeler (1984) as well as Elizabeth Wing (1975) and David Browman (1974) contain no hints that Andean people kept any of the camelids for their milk. The Spanish chroniclers who wrote of the Inca say nothing about the native people using milk in any form from either species. Quechua, the language of the Inca and their descendants, differentiates human milk *(ñujñu)* and animal milk *(wilali),* but that lexical specificity by itself says nothing about any possible human use pattern of the latter.

If domestication is viewed as a process rather than a sudden occurrence, one might suppose that llamas and alpacas were developed for their milk. If we accept the reports of archaeologists who specialize in camelid bones, then it appears that domestication of the llama and alpaca had occurred by 4000 B.C. (Browman 1989). Thus, one or both of these camelids have been manipulated by humans for some 6,000 years, which (if time were of the essence in domestication) should have turned the animals into abundant milk producers.

If, however, a high level of civilization is critical in explaining the milking phenomenon, then one might expect that the civilization of the Inca (A.D. 1100–1532) would have developed this area of subsistence activity. The Inca knew enough about heredity to breed white llamas for state sacrifice and to have produced a plethora of food surpluses that testified to their skills as sedentary agriculturists and herders. The Inca and the various cultures that preceded them by a millennium were all sufficiently talented to have understood the enormous nutritional benefits of milk from their two camelids.

Milking would also have enabled a more intensive use of the grassy puna (highlands) and *paramo* above the altitudes permitting agriculture. As with cattle in the Old World, the milking (and bloodletting) of llamas might have heightened the value of pastoralism and thus encouraged a nomadic way of life. Indeed, the availability of milk would have given the Indians a sort of nutritional freedom to roam the high country above 4,000 m (3,500 m in Ecuador) at will, in search of good pasture for large herds. Certainly such activity would have been more facultative than the obligate relationship with agriculturalists that evolved in the Andes.

Llamas and alpacas have some habits in common that would theoretically predispose them to being milked by their human keepers. Both have a natural tendency to group in corrals at night. Their parturition occurs during the rainy period from January to March when abundant grass is available and the creamy surpluses of lactating females could have been removed with little deprivation for their nursing young. Finally, their general docility resembles that of sheep much more than cattle.

Why the Milking Void?

The aboriginal absence of milking in the Andes elucidates certain cultural–historical questions about domestication as a process. Least persuasive is the argument that the quantities of milk were too small to make milking a worthwhile effort. The old saying "there is no excess" (e.g., insufficient liquid left over for humans once the young have suckled) could have been originally said of cattle, sheep, goats, or water buffalo. Early in her domestication some 7,000 years ago, a cow must have yielded only small amounts of milk to the person willing to extract it. The large milk volume associated with purebred dairy cows today does not predate the nineteenth century.

Indeed, in the face of a minuscule output, the key question is why peoples in the Old World started to milk in the first place. A German cultural geographer, Eduard Hahn (1896), had perhaps the most compelling insight about the prehistoric origins of milking. He believed that milking originally had a religious, not an economic, motive. Bowls of milk were offered to the lunar mother goddess, a cult that regulated spiritual life in ancient Mesopotamia where cattle were first domesticated. The frothy white substance that sustains early life had considerable symbolic power and thus ritualistic value. The quantity of milk extracted was incidental because it had not yet spread from a ritual use among the priestly castes to become nourishment for common people. Nonetheless, expansion of milk supplies to meet the cultic requirements gave an impetus to select those cows found to have large udder capacity and tractability to human interlopers. Slowly, over many generations of selective breeding, milk quantities increased; one result of this was that the original religious motivation for milking was forgotten, and milk became a common nutriment. In other words, the nutritional benefits of milk became recognized as a sufficient reason to carry on the custom.

Such a process was probably "invented" in one place – the Fertile Crescent of southwestern Asia some 6,000 years ago – and then diffused elsewhere. As this diffusion occurred, milking spread to other domesticated mammals. For example, camels, which replaced cattle in desert environments, were first milked by using the model of bovine milking that had begun two millennia earlier. In fact, Carl Sauer (1952) reasoned that because all the Old World herd animals have been milked, milking may well have been the general motive for domesticating them in the first place.

Quantity of milk aside, another reason put forward for not milking llamas and alpacas has to do with behavioral peculiarities of the species. This line of reasoning posits that a lactating female would not allow people to manipulate the vulnerable underpart of her body, as a defense mechanism to ensure sustenance to the offspring. A related assertion is that llamas and alpacas simply cannot be milked because certain pituitary hormones inhibit the lactating female of these species from releasing her colostrum or milk to any but her own offspring. Although these two characteristics may exist, they nevertheless do not explain the phenomenon of nonmilking, again because of the vast behavioral changes that all dairy mammals have undergone to eliminate their natural refusal strategies. At some point in their domestication, individual animals that did not respond to human intervention were likely to have been culled from the breeding pool. Subsequent generations of the selected species gradually evolved in directions more conducive to human manipulation.

The physiological intolerance of Andean people to milk (lactose intolerance) is still another explanation proposed for the historic nonmilking of llamas and alpacas. As in much of Asia and Africa, most of the native folk of the Americas cannot properly digest fresh milk after they have been weaned due to insufficient amounts of the lactase enzyme in the intestine to break down milk sugars (lactose) (Simoons 1973). When pressed to drink milk, Amerindians often suffer nausea and diarrhea. In Peru, for example, nutritional studies have reported that highland children experience an adverse reaction to milk (Calderón-Viacava, Cazorla-Talleri, and León-Barua 1971; Figueroa et al. 1971).

Yet, as with the arguments already examined, lactose intolerance is still not a convincing explanation for the absence of milking in the Andes. After the Spaniards brought cows, goats, and sheep to them, the Andean peoples followed the European example and began to milk these animals. They used the milk for infant feeding and cheese making. Nursing Indian babies can be fed fresh animal milk with impunity because they still have a high level of the lactase enzyme, whereas cheese is a low-lactose dairy product that many lactose malabsorbers can consume without ill effects. Cheese has another advantage over liquid milk: It is preservable without refrigeration and thus can be transported long distances. Cows' milk predominates in making cheese, but in dry areas goats' milk is also used. Cheese making from ewes' milk has been an activity in the Altiplano of Bolivia south of Oruro since the colonial period.

In summary, then, the failure to have milked llamas or alpacas was probably not due to their low milk production, nor to the innate behavior of this camelid genus, nor can it be attributed to the lactose intolerance of the people who have kept them. This leaves a disarmingly simple reason for not milking llamas and alpacas. It never occurred to the indigenes to do so. For those who appreciate milk, yoghurt, ice cream, butter, and cheese in their diet, this failure to grasp the possibility of milking may seem illogical. Yet the pre-Columbian civilizations of the New World did not employ several other basic traits of material and nonmaterial culture either, including the concept of the wheel, the arch, and any form of real writing. To this lack of invention must be added the failure of diffusion. Isolated by oceans, the Andean people, prior to conquest, had no opportunity to learn about the idea of milking from European, African, or Asian peoples.

Moreover, the use of llama or alpaca milk for ritual purposes never emerged in the Andes as it did in the Fertile Crescent, although Inca state religion manifested many associations with flocks in its spiritual rhetoric and sacrificial practices (Brotherston 1989). The elaborate rituals concerned with fertility, curing, and divination that persist today in the high Andes do not involve milk in any way. It was camelid fat – easier to transport and less perishable than milk – that acquired the symbolic role in human needs to communicate with the supernatural forces.

As noted, Andean peoples first learned about milking cows and ewes from the Spaniards. It is puzzling, however, that after the introduction of milking, the practice was not subsequently extended to llamas and alpacas, particularly in zones above 4,200 m where they had no competition and where a kind of transhumance has prevailed. It is the case that the transfer of the idea of milking from one mammalian species to another has occurred within historic times. In northern Scandinavia, for example, after observing Swedish settlers milk their cows, the Lapps started to milk the domesticated mammal under their control, the reindeer. But although milking a lactating llama or alpaca might well have been tried on occasion over the past half millennium, it was not a practice that emerged as a use pattern or one that disseminated elsewhere. If milking these animals had been anything more than episodic, it would have been recorded in some travelers' accounts and eventually in the ethnographic record.

Llamas and Alpacas as Future Dairy Animals

The milk of the Andean camelids has received little research attention. One study in Peru, which derived 256 milk samples from 71 different lactating alpacas, found that yields in a 12-hour period varied widely from only 15 to 20 cubic centimeters (cc) of milk in some to as much as 500 cc in others, with 300 cc as a rough average (Moro 1954). Butterfat content was found to be between 3 and 4 percent and the pH ranged from 6.4 to 6.8. Porcelain white in color and with no distinctive odor, the alpaca milk examined in this study was somewhat sweeter and more viscous than cows' milk. These organoleptic characteristics contrast with the unusual flavor and salty taste reported for the milk of an Old World camelid, the dromedary, whose milk is nevertheless much appreciated in parts of the Middle East. More detailed biochemical data on camelid milk puts lipid content at 4.716 plus or minus 1.307 percent (Fernandez and Oliver 1988: 301). Development of either the llama or alpaca as a dairy animal would first entail the considerable work of selecting and breeding animals for higher milk yields.

Wider commercialization of the llama or alpaca as a source of food deserves consideration. They have potential as meat animals because their growth is fast: 9 kg at birth, they can weigh 29 kg at 9 months and 54 kg at 3 years (Bustinza Choque 1984). Carcass yield is reportedly higher than that of sheep or cattle. Although they can thrive on forage that extends well beyond the native Andean puna grasses, any serious herd investment would require better data on feeding requirements. Moreover, the prejudice against both meat and milk from these animals would need to be addressed in order to find profitable ways to market them to the public. North America, which had an estimated 23,000 llamas and alpacas in 1990, is now the center for stock improvement and creative thinking on the considerable potential of these animals. However, both Peru and Bolivia, where the diversity of the llama and alpaca gene pool is greatest, have banned the export of live animals beyond their borders.

Daniel W. Gade

Note

1. One dissenter to the otherwise solid generalization that Andean people do not milk camelids was William E. Carter, a trained anthropologist who died in 1983. Carter (1975) affirmed that llamas were milked, which prompted me to correspond with him about it. In his response dated February 28, 1975, Carter wrote, "I have on numerous occasion seen people making cheese out of llama milk and even eaten it. . . . Not much milk is obtained, of course, nor does the milking occur on a regular basis, but milking of the animal is done." Carter, however, did not state the place or places where he purportedly saw this llama cheese, or if he actually watched those llamas being milked. Could these have been accidental cases of

milk fortuitously salvaged from a lactating female that had just lost her young? None of the scholars who has intensively studied llamas or alpacas in their contemporary Andean setting alluded to them as even occasional sources of milk to their human owners (Flores Ochoa 1968; Webster 1973; Orlove 1977; Flannery et al. 1989).

William Walton (1811: 36), one of the earliest serious non-Spanish observers of llamas, stated that "her milk is scanty, and is never used by the Indians for any purpose, they prefer leaving it to the 'llamitos' which are not weaned before the age of six months."

II.G.17 Muscovy Ducks

Of the two species of domesticated anatines, the Muscovy duck *(Cairina moschata)* is larger, less vocal, and characterized by a fleshy protuberance on the head of the male. It is a duck of tropical American origin, whose wild ancestors nested in trees, whereas the common duck *(Anas platyrhynchos)* was domesticated in the Old World from the ground-dwelling mallard. The two species can mate and produce offspring, but such offspring cannot reproduce.

The Muscovy duck is misnamed, for it never had any special association with Moscow. Most likely the name is the result of a garbled corruption of *canard musqué* ("musk duck"); however, this French term is not an accurate descriptor either. Depending on area, various Spanish names are used for the duck in Latin America. Among these are *pato criollo* ("native duck"), *pato real* ("royal duck"), *pato almisclado* ("musk duck"), *pato machacón* ("insistent duck"), and *pato perulero* ("Peru duck"). In Brazilian Portuguese, it is most commonly called *pato do mato* ("forest duck"). Indigenous names for this bird indicate its New World origin, including *ñuñuma* in Quechua, *sumne* in Chibcha, and *tlalalacatl* in the Nahuatl language of Mexico.

Before the European conquest of the Americas, the bird's apparent distribution extended from north central Mexico to the Rio de la Plata in Argentina (Donkin 1989). It was and still is kept in a wide range of environments, which include the islands of the Caribbean, deserts, humid tropics, temperate plains, and the high elevations of the Andes. Although several colonial chronicles refer to *C. moschata,* such sources do not indicate that these domesticated birds were particularly important to household economies. In Mexico, the turkey has had greater importance in the houseyard. In South America, the Muscovy had no poultry competitors until the Spaniards and Portuguese brought chickens, which – because of their greater egg-laying capacity – were widely adopted.

Precisely how, where, and why the Muscovy duck was domesticated is impossible to say. Two scenarios can be constructed from knowledge of the wild species. One is that the wild duck was trapped – captured alive in fields of crops that it was feeding on. After this it was tamed and began to reproduce in captivity. Alternatively, humans removed fertilized eggs from the nesting holes of wild birds and incubated them until they hatched. The ducklings, which emerge from the egg in 30 days, then imprinted on humans as their surrogate parents. Because the behavioral characteristics of wild Muscovies draw them into ready association with people, their taming and eventual domestication could have been quite common (Nogueira-Neto 1973).

The habitat preference of wild Muscovies, which roost in trees and nest in tree holes, is near rivers and swamps backed by forests. The Caribbean lowlands of Colombia and Panama offer such habitats and today contain wild Muscovies. Yet the just mentioned behavioral characteristics that draw them into association with people make plausible the suggestion that they were domesticated from the wild in several different South and Central American locales as well as the Caribbean lowlands (Nogueira-Neto 1973).

Archaeological evidence charting the past of the Muscovy duck has been derived from bones and from artistic renderings. Osteological material dated as early as 500 B.C. comes from the coastal region of Ecuador. Close by, in northern Peru, potters of the Mochica culture (A.D. 200–700) modeled the Muscovy duck in clay. Abundant zoomorphic evidence of the Muscovy is also found on pottery vessels, gold objects, and stylized masks from pre-Columbian Mexico (Whitley 1973). In view of the latter, a religious role for the bird might be postulated.

Although the domesticated duck has the same species binomial as its wary wild cousin, certain features distinguish *Cairina moschata domestica* from the wild *C. moschata.* Many domesticated Muscovies, for example, have predominantly white plumage – a partial albinism resulting from artificial selection of a sort found in many other domesticated animals. However, feather colors and plumage patterns can vary widely and often resemble those of the wild bird. Truly domesticated birds are unable to fly; artificial selection has reduced their wings to weak appendages. Moreover, the domesticated duck can survive without access to water for swimming or feeding.

Three characteristics of the domesticated drake are his size (more than twice as large as the female), his hisslike vocalization, and his polygamous appetite for constant copulation. In the sixteenth and seventeenth centuries, the odor of musk was also said to characterize this bird, but it is still not clear if such an opinion derived from a distinctive smell of the species, a secondary sexual characteristic of the adult drake, or a dietary element that imparted a peculiar odor to the birds.

In tropical America, Muscovy ducks have been kept for their meat, their fat, and – to a much lesser degree – their eggs. However, they are slaughtered mainly for special occasions, and except where they are kept in large numbers, their role as a food source is peripheral. Indeed, in most parts of tropical America, they do not seem to have a well-defined place in regional cooking, although live birds and their eggs may be sold in some peasant markets. In times of food surpluses, they can be fed and kept alive as a kind of "bank" to be cashed in when they are sold or traded at peasant markets. Normally, it is at lower elevations that farmers raise Muscovies in sizable flocks; in the high Andes, small farmers may keep only two or three.

Raymond Gilmore (1963: 462) has referred to the production of an aromatic powder made from dried duck meat, which counts as another use, as does the large number of insects that Muscovies eat, which extends their usefulness beyond that of a food source. But most of the food Muscovies eat is from plant sources, and thus they are also employed to help keep irrigation ditches clean. On the desert coast of Peru, they are often seen in such ditches – a niche that may have made them initially useful to pre-Columbian irrigation farmers.

In the sixteenth century, the bird was taken to Europe, where its historic pathway of diffusion became confused in the written record, which often did not make the necessary distinction between the imported Muscovy and the common duck already present. In German-speaking Europe, the Muscovy became known as the *Türkische Ente* ("Turkish duck") and, in French, as *canard de Barbarie* (i.e., from the Barbary coast of North Africa). Both these names obviously suggest that the New World origin of the bird was not well understood in Europe at the time. The eighteenth century seems to have marked the high point of popularity of the Muscovy, which, in many cases, was raised by the rural gentry mainly as a curiosity and as an ornament, just as they did with peacocks.

In France, where a restless revision of the culinary imagination has a glorious history, the bird became a meat animal, and it was the French who crossed the Muscovy with the common duck to produce the *mulard* duck. This vigorous duck hybrid has been force-fed grain to produce hypertrophied livers used in making pâté de foie gras. Especially in southwestern France, farms specializing in the production of this delicacy keep both geese and *mulard* ducks.

Elsewhere in the world where they were eventually introduced, Muscovies never acquired much importance in domestic economy. Possible exceptions to this generalization are parts of West Africa, because the tropical origins of Muscovy ducks made them better adapted to hot conditions than other poultry. In Asia, where duck husbandry is important in furnishing sources of animal protein, this relative from the New World has found no real acceptance. Muscovies are an uncommon species in China, which has more ducks than any other country. Failure of the Muscovy to compete is tied in part to its lower productivity, in terms both of egg laying and body size. In addition, it does not fare as well in cold climates as the common duck. In fact, these are the reasons that commercial duck raisers in North America do not use this species. Placed on a world scale, *C. moschata domestica* has been among the less successful domesticated birds.

II.G.18 ⁂ Pigeons

Because humans seem to have had omnivorous ancestors, birds were probably a significant item in the human diet well before historic time. Many kinds of birds can be caught readily, and young adults are generally considered to be superior fare (Cott 1946). Additionally, the eggs of many kinds of birds are highly prized (Cott 1954). In the case of pigeons, the rock pigeon *(Columba livia)* is known to have frequented regions inhabited by our ancestors more than 300,000 years ago (Tchernov 1968).

At present, the domestic chicken *(Gallus domesticus)* and their eggs are extremely important in diets across the globe. Indeed, the husbandry of chickens is economically unequaled by that of any other bird. But the economic and dietary importance of domestic fowl is a relatively recent development and in large part reflects changes brought about by twentieth-century biology.

The domestic fowl, derived from Asian species of the genus *Gallus,* was introduced to the West and became known to people of the Mediterranean Near East only a little more than 2,500 years ago (Wood-Gush 1985). This was perhaps 3,000 years after rock pigeons were domesticated in southwestern Asia (Sossinka 1982) and long after they had become important in human diets. However, because pigeons also figured in early religions of the eastern Mediterranean region, the fact that they were domesticated birds does not explicitly address their use as food. Thus, the dual role pigeons have played in human affairs needs to be distinguished whenever possible.

The family Columbidae is widely distributed (Goodwin 1983). There are some 300 kinds of pigeons known to biologists, and many have been and still are used for food by humans worldwide. The record of dietary use is, however, without detail for most such species, as for example, doves. But it is likely that the flesh of most (although not necessarily their eggs) is suitable for human consumption (Cott 1946, 1954).

Rock Pigeons

The rock pigeon has a history in part coincident with that of humans for at least the past 12,000 years. The earliest information is of two kinds – the organic, subfossil, bony remains of pigeons in midden heaps in caves and the slightly later cultural record of human–pigeon interactions.

Bones from midden heaps, which constitute reasonably direct evidence that humans caught and ate rock pigeons, are present in eastern Mediterranean sites – caves in Israel that were used as dwellings by humans around 11,000 to 12,000 years ago. Because the bones are indistinguishable from those of wild rock pigeons currently living in the Near East (Bar-Yosef and Tchernov 1966), it is possible that immediate post-Pleistocene pigeons might have nested in caves used by humans. And it is also possible that their bones were incorporated into the midden heaps as a result of death by other than human agents. It is considerably more likely, however, that bones in these refuse piles indicate that the pigeons in question served as food for human hunters.

But so long as humans relied on catching wild pigeons – probably squabs from nests – pigeon would have been merely an occasional item of diet. Only after pigeons were domesticated and relegated to a life of confinement in cages did they make a regular appearance on the table. The first such attempts are not recorded, but rock pigeons are readily domesticated (Darwin 1868), and as the following discussion shows, this practice doubtless occurred relatively early.

The earliest evidence of domestication has been found in Sumerian statuary and cuneiform lists; in the remains at a funerary feast in a tomb at Saqqara, Egypt; in Sumerian culture, which includes a version of the Mesopotamian Flood Myth featuring a pigeon; and in small clay religious shrines as well as on sculptures depicting fertility goddesses, Astarte or Ishtar. Slightly later, there are Egyptian bird sacrifices on record and a Babylonian scribal list of bird names in cuneiform. We will briefly explore this evidence, beginning with that which dates from earliest times.

The Sumerian Flood Myth can be dated from a massive flood that occurred about 6,000 years ago (Langdon 1931). In the myth, a "dove" was the first bird released from the still floating Ark, and it returned for the night, signifying no available dry land.

The early Egyptian material includes traces of pigeon bones from a funeral dinner apparently held some 6,000 years ago (Hansell and Hansell 1992). This is the first, and very dim, indication of what may have been domestic pigeons playing a role in human diets.

Sumerian clay shrines, dating from some 4,500 years ago, depict pigeons that were evidently of religious importance. There are also fertility figures from the same period that have pigeons perched on their uplifted arms (Langdon 1931). Quite possibly, the significance of the pigeons in this instance has to do with their unusual reproductive capabilities (the ability of captives to lay eggs and rear young in midwinter).

Around 4,000 years ago it was recorded that the Egyptian King Rameses II offered 58,810 pigeons to the god Ammon, at Thebes (Hansell and Hansell 1992). The large number of birds involved can only mean that Egyptians were practicing pigeon husbandry at that time, for there is no way in which wild rock pigeons could have been rounded up in such numbers.

An Old Babylonian cuneiform tablet dated from 3,830 to 3,813 years ago contains 70 Akkadian bird names in more or less taxonomic groups (Black and Al-Rawi 1987), and no fewer than 3 of the names refer to pigeons, one of which almost certainly applied to the rock pigeon.

A considerable summary of such ancient records treating pigeons as sacred or at least of religious importance may be found in the opening pages of W. Levi (1974). Unfortunately, little of the archaic information provides a positive identity for the early species of domesticated pigeon. Most likely, however, rock pigeons and at least one other species, probably a kind of turtledove, were involved. In addition, of the species of pigeons (and doves) still present in the Near East, the rock pigeon, wood pigeon *(Columba palumbus),* stock dove *(Columba oenas),* and turtledove *(Streptopelia turtur)* were surely used as food and may be among the birds represented on the clay shrines and in the lists just discussed.

Rock pigeons have been common, year-round residents in the Near East. They have extremely long breeding seasons, nesting semicolonially in caves and on ledges of coastal and montane cliffs, and are thought to have sometimes become synanthropic in early Near Eastern cities (Glutz and Bauer 1980). Their reproductive capabilities of persistent, serial breeding, beginning early and ending late in the year, when no other kinds of birds are active, would have been readily observed and, thus, part of the knowledge of the time. Such knowledge would have been of considerable importance in fostering efforts aimed at holding pigeons as captives.

Fragmentary evidence as well as outright speculation about human behavior suggests that the domestication of rock pigeons took place between 6,000 and 10,000 years ago. This must have occurred after the development of grain farming (around 10,000 years ago), which was the major human cultural acquisition that permitted animal domestication in the Near East (Harlan and Zohary 1966). But although cereal agriculture and early animal domestication originated in the Near East, the wild rock pigeon has a large geographic distribution (Cramp 1985) overlapping early human agriculture in many regions of Europe and Asia (Piggott 1965; Ammermann and Cavalli-Sforza 1971).

Consequently, rock pigeons could easily have been domesticated at many different places and times in southeastern Europe, North Africa, the Near East, and southwestern and southern Asia. Doubtless, another cultural factor that assisted in the domestication of pigeons was the experience gained by humans in domesticating other creatures. Wolves, for example, were domesticated in the Near East at least 9,000 years ago and even earlier elsewhere (Reed 1969).

Pigeon chicks taken at about 2 weeks of age would have been somewhat less wild than their parents and more likely to have accepted captivity. Wild adult pigeons are nervous captives, do not accept cages, and thus sometimes injure themselves; they also spend less time in reproduction than birds accustomed to confinement. In light of this, one suspects that domestication could have occurred in one of two, somewhat different, ways.

The first would have been for hunters to have captured rock pigeon squabs in nesting caves, with the idea of holding them and feeding them in cages until they grew larger. Gradually, however, humans would have learned to continue such captivity until the birds matured and were able to reproduce. A second scenario would have humans erecting nesting platforms in dove caves. This would have turned them into primordial dovecotes, where the birds could have been harvested and where much could have been learned about their reproductive behavior and ecology.

Concurrent with these scenarios, early cities of the Near East may have been voluntarily colonized by wild rock pigeons. The mud and stone walls of such settlements would have made quite suitable nest sites, with nearby fields of wheat and barley providing nutrition. These synanthropic birds could subsequently have been taken into confinement by either of the two ways just mentioned.

Selection of Pigeons for Food

Captive pigeons probably were unconsciously selected by humans for tameness and reproductive vigor, but they would have been consciously selected for characteristics that increased their utility as high-quality food. The major one of these traits to be modified was size. Wild rock pigeons in the Near East are relatively small and average about 300 grams in undressed weight (Cramp 1985). But today, males of large domestic strains are known to reach more than seven times that size (Levi 1974). Thus, the mating of large individuals would readily have repaid any early pigeon keeper.

We have no documentation for such a selection process, but it is clear that it was practiced. By Roman times, for example, a large-bodied domestic strain (usually identified with today's "runt") was already developed (Levi 1974). The runt is preserved in a variety of substrains by pigeon fanciers and commercial squab producers.

At the time that pigeons were developed for the table, smaller dovecote pigeons were probably also being selected. Dovecote pigeons are domestics that are, for the most part, allowed to fly freely in order to obtain their own food; they are also highly site-specific and return daily to the pigeon house or dovecote in which they were reared. Dovecotes are small buildings, usually raised above the ground and providing quarters for roosting and nesting pigeons as well as access for pigeon keepers to harvest the squabs.

Prior to the time that larger mammals were kept overwinter, pigeons were a reliable source of winter protein for rural people (Murton and Westwood 1966). Indeed, well-fed pigeons with a characteristically high fat content in muscle would have been important to such diets (Barton and Houston 1993). Pigeons have continued to be used for food up to the present time, although recent practice emphasizes the gourmet table rather than the farm kitchen (Levi 1974). As already mentioned, the current dominance of domestic fowl in human diets is a reflection not of its superior quality as a source of animal protein but of its greater adaptability to human poultry husbandry, which guarantees producers large returns on their work or investment.

Pigeon Husbandry in Europe and America

In earlier times, once a pigeon house was constructed, pigeons were easy to keep, at least at low to mid latitudes. The birds of a columbarium fed themselves on wild seeds and waste agricultural grains, and if their food was supplemented in winter, a large number – thousands of pairs – could be maintained throughout the year.

It is not clear at what time pigeon husbandry on such a large scale was found in Europe, but substantial columbariums were in operation in medieval times. Of the ones that are documented, some, such as those set up by thirteenth-century emperor Frederick II, were reasonably elaborate. The emperor's holdings covered southern Italy and eastern Sicily, which were dotted with more than a dozen of his castles.

Frederick moved from one to another of these castles in the course of a year, because the large size of his court regularly required a fresh supply of food. Frequent moves also provided time at any one castle for the satisfactory recycling of wastes in between visits. Each castle had a large dovecote, built within and sharing some of the castle walls, which the court relied on for a significant fraction of its fresh meat (Frederick II 1942). We know these details of the emperor's life because he was an ornithologist as well as a builder of castles. He left behind his writings on birds and the remains of his buildings, which clearly show that the columbarium was an integral part of the castles he designed.

While in Syria, where he was otherwise engaged on a Crusade, Frederick was able to secure novel domestic strains of pigeons. Birds from the Near East may not have been bred for table use, owing to religious practices of the Syrians, but the record is important to us because it suggests widespread pigeon husbandry at that time.

In post-Renaissance Europe, pigeon keeping was, to some extent, restricted to the privileged classes of society – to manor house lords and members of the clergy (Cooke 1920). Many large flocks were maintained, and recent estimates of numbers of dovecote pigeons in England and France in the sixteenth century run to the millions (Cooke 1920; Murton and Westwood 1966). As noted earlier, dovecote birds generally foraged for themselves in the agricultural countryside, going distances of perhaps 20 to 30 kilometers (Ragionieri, Mongini, and Baldaccini 1991).

As a consequence, peasant farmers on the estates and beyond sometimes had serious problems in getting their grains and pulses to sprout because of pigeon depredations. Maturing and ripe grain was also at risk, as was stored grain, for pigeons entered storage sheds if these were not secure. To compound the problem, farmers were prohibited from killing the birds. Indeed, some political historians have suggested that the victimization of farmers by the operation of aristocratic dovecotes contributed to the rebellion against social privilege culminating in the French Revolution of 1789 (Cooke 1920).

Whether true or not, such a sequestering of rights to rear pigeons by the privileged classes of medieval and post-Renaissance Europe speaks loudly of the significance of pigeons in the diet of people of preindustrial Europe and Asia. The birds were especially important in adding fresh protein to wintertime diets for those living at high latitudes or away from seacoasts, or anywhere that cattle could not regularly be overwintered. It is likely that chickens also provided such protein in the cold months (as well as at other times of the year), but chicken reproduction dropped off considerably in winter. Thus, wintertime diets that featured chicken depended on mature birds, in contrast to the use of pigeon squabs, which appeared regularly throughout the year.

Current Pigeon Husbandry

The current architecture of pigeon houses in the Middle East, Mediterranean Europe, and North Africa may be little changed from earlier times, and rural Egyptians still build tall, earthen dovecotes – towers of mud into which clay pots have been placed for pigeons to nest in (Hollander 1959; Hafner 1993). By contrast, rural or small-town Italians use metal screening and planks of wood, usually keeping the birds in a flypen arrangement. But however pigeons are kept, adult birds of less than 7 years of age are employed as breeders, and their squabs are taken for the table at about 30 days of age (Levi 1974). The adults tend to overlap their broods, so that when well fed and fully confined, they may produce 12 to 18 squabs per year (Burley 1980; Johnson and Johnston 1989). Thus, even a small colony of 10 pairs could provide a family with squabs for the table each week.

Dovecote pigeonry in the Americas was introduced by settlers from England, France, and Germany to early seventeenth-century Nova Scotia and Virginia (Schorger 1952). Pigeons for the table (as distinct from racing or show purposes) are kept in much the same fashion today as in earlier times. The major difference is that the pigeon house in America is generally a single-story building that is spread out over a very large area relative to those of historic Europe and Asia, which tended to be columnar (Cooke 1920; Hansell and Hansell 1992).

Because a dovecote or columbarium consists of a large number of boxes, cells, or breeding enclosures in which a pair of birds can build a nest and rear young, a western European columnar columbarium facilitates the work of cleaning up by concentrating the birds' droppings. In contrast, a ranch-style unit of pigeon houses, such as in North America, allows increased time intervals in such housekeeping. The houses are usually of wooden frame construction on a concrete pad; a center aisle allows entry by keepers to the nest boxes for feeding and housekeeping, as well as for keeping track of nests and eggs, marking squabs, and, ultimately, collecting them.

The birds may be confined, which means they live partly in a roofed nest-box enclosure and partly in a screened flypen, open to the elements. The classical dovecote operation was employed until relatively recently, even in commercial establishments (Levi 1974), but it is now found chiefly on single-family farms.

Use as Food

Squabs prepared for the table are about as large as small chickens, but their distribution of edible flesh is different. In contrast to chickens, pigeons are strong-flying birds, and perhaps 30 percent of a squab's overall weight, and 70 percent of the muscular weight, will be in the paired pectorales or flight muscles. Pigeons, although also adept at running and walking, have leg muscles that are proportionally smaller than those of chickens.

Pigeons appear in the world's first cookbook, which is attributed to Apicius, a first-century Roman, but is thought to have originally been a collection of Greek monographs on cookery by several authors (Vehling 1936). If we judge only by the frequency of its pigeon recipes, which number 2 against 18 for chicken, then it would seem that the ascendancy of the latter in human diets was already marked in Mediterranean Europe by the first century. However, since all the chicken recipes could be as readily done with pigeon, it may be that the authors were offering us their own preferences (an author's prerogative) rather than indicating the relative availability of the two sorts of birds. The recipes for pigeon are ones dominated by raisins, honey, and dates, suggesting that perhaps the more pronounced flavor of pigeon is better able than chicken to emerge from such sugary dishes.

In any event, today pigeons are regularly prepared for the table in the same manner as domestic fowls, but because of the more assertive flavor of pigeons, stronger spicing may be used if desired. Pigeon breast muscles are "dark meat," so that a significant fraction of current recipes employ plenty of garlic, and those using wines specify full-bodied reds, or sherries and other fortified wines.

Pigeons Other Than Rock Pigeons

Domesticated rock pigeons are the most important food species of the 300 kinds of pigeons in the world. Only one other, the ringed turtledove *(Streptopelia risoria),* has been domesticated, but it is smaller than the rock pigeon and not of general significance for human diets. A large number of other kinds of pigeons of variable sizes are also used on occasion for food by humans. Many of these are secured by hunters using guns or nets, such as the North American mourning dove *(Zenaida macroura),* the European wood pigeon *(C. palumbus),* and many other Asiatic, African, South American, and Australian species.

Such hunting may be regulated by government restrictions, so that a yearly harvest occurs each autumn when the birds are in fairly dense migratory flocks. But hunting may also be restricted to autumn for economic reasons, as this is frequently the only time in which it is profitable to secure the birds. A notable example is the famous netting operations in the valleys of the Pyrenees between France and Spain – valleys used by a large fraction of European wood pigeons in migration.

Unfortunately, the passenger pigeons *(Ectopistes migratorius)* of North America were hunted at any time of year and became extinct around 1900, although it should be noted that the cutting of the North American hardwood forest, which destroyed a significant food source and was the chief habitat of the birds, was an equally important factor (Bucher 1992). Nonetheless, it is fair to say that pigeons and their relatives comprise a group inordinately disposed toward extinction at the hands of human hunters. No fewer than 15 species have been exterminated in historic time, including such remarkable birds as the dodo *(Raphus cucullatus)* and the solitaire *(Pezophaps solitaria),* as well as the passenger pigeon. In all instances it is clear that the birds were used for food by humans, but it is a fact that habitat destruction and the introduction of cats, dogs, and rats also contributed to such extinctions, most of which occurred on islands.

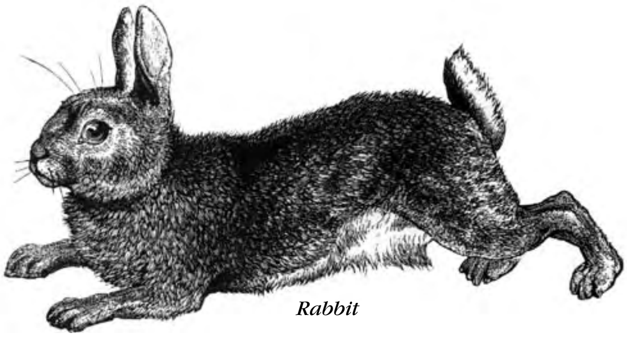
II.G.19 Rabbits

Rabbit production is significant in several countries, especially France, Italy, Malta, and Spain, where there is a long tradition of consuming rabbit meat. In the past, great numbers of rabbits were raised by subsistence farmers, who fed them locally collected forages such as weeds, grasses, and vegetable by-products. But with the intensification of agriculture, particularly in the twentieth century, and the decline in "peasant farmers," rabbit production as a cottage industry declined. However, because the tradition of eating rabbit meat endured in western European countries, an intensive, commercial, industrial-scale production of rabbits has developed to meet continuing demand.

Both the origins and the evolution of the domestic rabbit are difficult to trace. Rabbits are in the order Lagomorpha, which dates back about 45 million years in the fossil record to the late Eocene period. Modern lagomorphs (rabbits and hares) belong to two families (Leporidae and Ochotonidae) consisting of 12 genera. They range from the highly successful hares and rabbits of the *Lepus, Oryctolagus,* and *Sylvilagus* genera to several endangered genera and species. Although rabbits and hares appear to have originated in Asia, all breeds of domestic rabbits are descendants of the European wild rabbit *(Oryctolagus cuniculus)* and are Mediterranean in origin. There are more than 100 breeds of domestic rabbits, ranging in size from dwarf breeds with an adult weight of less than 1 kilogram (kg) to giant breeds weighing in excess of 10 kg.

The first recorded rabbit husbandry has been dated to early Roman times, when rabbits were kept in *leporia,* or walled rabbit gardens. They reproduced in these enclosures and were periodically captured and butchered. During the Middle Ages, rabbits were similarly kept in rock enclosures in Britain and western Europe. True domestication, which is believed to have



Rabbit

taken place in the Iberian Peninsula, probably began in the sixteenth century in monasteries. By 1700, several distinct colors had been selected. There are now many different coat colors (for example, agouti, tan, brown, white, blue, black, and red) and coat types (such as angora, normal, rex, satin, and waved), which provide for great diversity in the color and texture of the fur. (The coat-color genetics of rabbits have been reviewed comprehensively by McNitt et al. 1996.)

Domestic rabbits are now raised in virtually all countries, although, in some notable instances, feral rabbits have become major pests. Beginning in the Middle Ages, sailors introduced these animals into islands along various sea lanes – to be used as a source of food – and wherever rabbits were released, they increased greatly in number at the expense of indigenous plants and animals. In 1859, a single pair of European wild rabbits was taken to Australia, and within 30 years, these had given rise to an estimated 20 million rabbits. Feral rabbits also became a serious problem in New Zealand, which (like Australia) offered a favorable environment, abundant feed, and an absence of predators.

Periods of peak interest in rabbit production have coincided with times of economic hardship or food scarcity, both of which have encouraged people to produce some of their own food. In the United States and Europe, such periods during the twentieth century have included the Great Depression of the 1930s and World War II. A few rabbits kept in the backyard and fed weeds, grass, and other vegetation can provide a family with much inexpensive meat, and keeping them is practically trouble-free. Not only do they eat homegrown feeds, rabbits do not make noise and are easily housed in small hutches. When economic times improve, however, the interest in home production of food wanes, and those who ate rabbit meat under conditions of deprivation tend during better times to regard it as a "poor people's food."

Rabbits have a number of biological advantages when raised for meat production (Cheeke 1986, 1987). They experience rapid growth, reaching market weight at 8 to 10 weeks following birth. Their rate of reproduction is high: Theoretically, with immediate postpartum breeding, females (called does) can produce as many as 11 litters per year. And, as already noted, rabbits can be raised on fibrous feedstuffs, forages, and grain-milling by-products (such as wheat bran) and thus do not require high-quality feed grains.

Rabbit meat is a wholesome, tasty product. Compared to other common meats, it is high in protein and low in fat calories, cholesterol, and sodium (Table II.G.19.1) – properties that are related to the animals' low-energy, high-fiber diets. Because they are not fed much in the way of grain, rabbits do not have excess energy (calories) to store as body fat.

Table II.G.19.1. *Nutrient composition of rabbit meat*

Nutrient	Amount of nutrient
Crude protein (%)	18.5[a]
Fat (%)	7.4[a]
Water (%)	71[a]
Ash (%)	0.64[a]
Unsaturated fatty acids (% of total fatty acids)	63
Cholesterol (mg/100 g)	136[b]
Minerals[b]	
Zinc (mg/kg)	54
Sodium (mg/kg)	393
Potassium (g/kg)	2
Calcium (mg/kg)	130
Magnesium (mg/kg)	145
Iron (mg/kg)	29
Vitamins[b]	
Thiamine (mg/100 g)	0.11
Riboflavin (mg/100 g)	0.37
Niacin (mg/kg)	21.2
Pyridoxine (mg/kg)	0.27
Pantothenic acid (mg/kg)	0.10
Vitamin B_{12} (µg/kg)	14.9
Folic acid (µg/kg)	40.6
Biotin (µg/kg)	2.8
Amino acids[c]	
Leucine	8.6
Lysine	8.7

Source: Adapted from McNitt et al. (1996).

Total world production of rabbit meat is estimated to be about 1 million tonnes per annum (Lukefahr and Cheeke 1991). On a per capita basis, the major rabbit-consuming nations are those already mentioned as leading producing countries – Malta, France, Italy, and Spain – where rabbit has traditionally been an important meat. But in spite of many attempts to develop rabbit production and consumption in other areas, such efforts have largely been unsuccessful, which is especially unfortunate in developing countries, where consumption of good-quality protein is generally low. Moreover, the diet that rabbits consume in no way places them in competition with humans for food. They can be raised in simple structures, and the carcass size is small, so that meat storage with refrigeration is unnecessary.

Nonetheless, despite numerous rabbit development programs in Africa, Asia, and Latin America, there are few if any examples of permanent success following their introduction into local farming systems, with a number of factors accounting for this lack of success. Rabbits are quite susceptible to heat stress, so their performance in tropical countries is poor. Their Mediterranean origin has best suited them for hot, arid climates (for example, northern Africa) rather than hot, humid areas (such as equatorial Africa). In addition, because of the tremendous problems with rabbits following their introduction into Australia, many countries are reluctant to promote rabbit production out of fear that they will encounter similar problems. Concern is also often expressed about zoonoses – diseases that might be transmitted from animals to humans. In the case of rabbits, this fear is especially acute because of the disease tularemia, which humans can acquire when handling wild rabbits. In fact, however, tularemia is not a significant hazard with domestic rabbits. Finally, there is the usual cultural resistance to a new source of meat. Although there are no religious taboos against eating rabbit meat, there is the common perception that the animals are "cute" or "warm and fuzzy," which initiates an aversion in many people to rabbit consumption.

Another problem with disease has to do with myxomatosis. In Britain as well as in Australia, the hunting of wild rabbits and their sale in butcher shops was formerly widespread. But then, in both countries, the need to control the animals led to the introduction of myxomatosis, which is a devastating viral disease causing grotesque facial lesions and swelling, oral bleeding, and a generally distressing appearance. The sight of large numbers of wild rabbits dying with these symptoms hardly whets the appetite for rabbit meat, and needless to say, the traditional marketing and consumption of this meat in countries where myxomatosis was introduced has fallen drastically.

The principal U.S. market for rabbit meat is gourmet restaurants, where it is served as a traditional French specialty. In addition, ethnic markets patronized by European immigrants of French and Italian origin also are significant in large metropolitan areas, especially on the East and West coasts.

By way of conclusion, rabbit production is significant in several Mediterranean countries, where the domestic rabbit originated and was particularly well suited for small-scale production on subsistence or peasant farms. Even in these countries, however, with the introduction of fast-food restaurants and more American-style eating, there is a definite trend of decreasing rabbit consumption, especially among young people, suggesting that the importance of the rabbit as a meat animal will continue to decline. In the United States, strong interest in animal rights and vegetarianism among young people probably means that backyard rabbit production, with home slaughter of the animals, is unlikely to have much appeal. A small rabbit industry, with the production of meat for specialty or gourmet restaurants, is likely the main future of rabbit production in most countries.

II.G.20 Sea Turtles and Their Eggs

From earliest times the seashore, with its rich and diverse marine fauna, has been a uniquely attractive environment for humans, providing them with accessible, palatable, and protein-rich sustenance (Sauer 1962). Among other foods – at least in warmer seas of tropical latitudes – were giant marine turtles. These could be harvested with relative ease, either on the beaches while nesting or netted or harpooned offshore. Their soft-shell and Ping-Pong-Ball-like eggs, deposited in clutches of 100 or more in the warm sand of favored beaches, provided further nutritious fare.

Among the six or seven species of giant marine reptiles that are recognized, it is the green turtle, the *Chelonia mydas* of turtle-soup fame, that has contributed most to the human diet. Unlike other sea turtles, the greens are exclusively herbivores, thus accounting for the savory quality of their veal-like flesh. Their name derives not from the color of their shell or skin but from the soft, greenish gelatinous material known as calipee, found beneath the plastron (lower shell) and scraped from slaughtered turtles to prepare the thick green soup renowned among gastronomes.

The flesh of other sea turtles, although eaten by some coastal peoples, is generally reputed to have a somewhat uninviting fishy taste. If the animal has ingested toxic algae or crustaceans, it may even be poisonous. The hawksbill *(Eretmochelys imbricata)*, prized from antiquity as the source of the beautifully mottled tortoiseshell of commerce, is valued for jewelry and ornamentation, whereas the olive ridley *(Lepidochelys olivacea)* has recently been much sought after for its skin, used to make leather goods. This use has been stimulated by changing styles and a scarcity of crocodile skins. The smaller Kemp's ridley *(Lepidochelys kempii)*, the loggerhead *(Caretta caretta)*, and the giant leatherback *(Dermochelys coriacea)* have not traditionally been utilized. The eggs of all species are eaten. Egg collection is either an open or a clandestine business on numerous strands throughout the tropical world.

The countless "turtle islands" (such as Islas Tortugas, Iles Tortues, and Schilpad Eilanden) of tropical seas bear witness to the preference of green and other sea turtles for uninhabited offshore islands for nesting as well as to their remarkable fidelity to specific, and sometimes quite small, beaches. They unerringly return to these sites after migrations to feeding areas that may be a thousand or more miles away. Such nesting habits, especially pronounced among the greens and the two ridleys, have made sea turtles particularly vulnerable to human exploitation and lie at the base of their endangered status.

The males spend their entire lives at sea, but the females, once gravid, may make several nocturnal visits to their ancestral beaches during each nesting cycle. These cycles usually come at intervals of four or more years. Scooping out a pit in the sand with their flippers, they bury their one hundred or so eggs before lumbering back to the surf and waiting mates. Two months later, the frenzied hatchlings, not much larger than a silver dollar, emerge to scamper quickly toward the water through a gauntlet of waiting predators. For those that survive, this is the beginning of a long and mysterious migration. As mature adults they will return several years later to the same beach on which they were born. Their imprinting, and the guidance mechanism that allows them, without visible landmarks, to travel the great distances between feeding areas and nesting beaches, remains among nature's grandest enigmas.

Atlantic and Pacific populations, long separated, carry distinctive DNA markers. Moreover, size helps to distinguish the Atlantic turtles from their counterparts on the West Coast of America. The latter constitute the subspecies *Chelonia mydas agassiz,* known locally as *caguama prieta* (black turtle), whose adult members weigh from 65 to 125 kilograms. By contrast, their Atlantic and Indian Ocean counterparts are substantially larger (100 to 200 kilograms), with some from Ascension Island in the past weighing a reported 600 kilograms.

Today, sea turtles are disastrously overexploited by a rapidly expanding world population and are victimized by pollution, coastal development, and new fishing technologies. Worldwide concern for their future has led to the recent imposition of tight controls on sea turtle exploitation by all but traditional fishing folk. In the last few years, all marine turtles save the Australian flatback *(Natator depressus)* have been classified as either "threatened" or "endangered," and traffic in them and products made from them have been largely eliminated through the Convention on International Trade in Endangered Species (CITES), subscribed to by most of the world's nations. With the newly sharpened sensitivity toward conservation, and with trade in turtle products curbed or banned, the days of turtle soup and turtle steaks in the gourmet restaurants of the world's great cities have effectively come to an end.

Old World Cultural Attitudes

Cultural attitudes toward foods, particularly the consumption of animal flesh, may be decisively influenced by religion. Avoidance of sea turtle meat, as with that of the freshwater or land tortoises with which they are often confused, is widespread in South and Southeast Asia (Simoons 1994; Charles Tambiah, personal communication). The eggs are at the same time, much sought after, prized for their presumed health-giving and aphrodisiac properties. Hinduism holds turtles in veneration. Lord Vishnu is said to have taken the form of a sea turtle during one of his reincarnations, raising the world from chaos and conflict. Turtles are thus depicted as bearers of the world and, as such, command respect. Among the devout the meat is not consumed.

In theory, the Islamic faith prohibits eating the meat of reptiles. However, although this is a restriction affecting vast numbers of shore people around the Indian Ocean, it is apparently not operative in North Africa. But, although the Muslim Malay may not eat turtle, the many Chinese living in Singapore and elsewhere in the area have no aversion to it. Turtles offered in urban markets may be taken in nets or harpooned, but turning them over on the beaches is prohibited.

Buddhists, too, avoid turtle flesh, and to gain favor with the deity, they set free turtles that become entangled in their fishing nets. The Burmese are said to consider turtles divine and keep them in tanks on pagoda grounds where they are fed special foods, but this practice may more often involve river turtles. Early Chinese sources refer to freshwater or land tortoises as symbolic of the good and the long life. Only with the conquest of the south in the Han period (206 B.C. to A.D. 220) did sea turtles become generally available. In T'ang times (A.D. 618–907) the green sea turtle and its calipee are recorded as having been a tribute to the royal court paid by the city of Canton (Simoons 1991). In contemporary China, turtles apparently continue to occupy a special niche in folk belief and the apothecary trade. The recent world-record-shattering performances of several female Chinese track-and-field athletes have been attributed to their drinking of turtle blood (*Sports Illustrated,* October 24, 1994).

If there are many cases of abstinence, there are exceptions that test the rule. On Hindu Bali, as among Polynesian and Micronesian groups and converted Christians generally, turtle flesh is especially consumed at festivals and on ceremonial occasions. Pliny long ago wrote of a cave-dwelling people at the entrance to the Red Sea who worshiped the turtle as sacred yet ate its flesh. Among subsistence shore-dwelling communities of the Indian subcontinent and those throughout Southeast Asia on whom religions often rest easily, turtle is still likely to provide a significant and palatable dietary supplement as well as a source of occasional cash income. Pagan coastal peoples in Southeast Asia have generally held sea turtle eggs and flesh in high esteem. Among Australian Aborigines who live close to the sea, the green turtle remains a principal totem.

At the same time, many, and perhaps most, of the turtle beaches of these southern seas support intensive egg-collecting operations under licensing systems controlled by local authorities. These systems are often designed to assure that sufficient quantities of eggs are left to support reproduction of the turtle populations. There were, for example, more than 30 such licensed areas for egg collecting not long ago on the east coast of Malaya. The three Turtle Islands off Sarawak until 1950 consistently yielded harvests of from 1 to 2 million eggs a year, the product of a population of perhaps 10,000 females (Hendrickson 1958). Watchers on each island marked new nests each night with flags, returning in the morning to dig and box the eggs for shipment to Kuching, the Sarawak capital. The proceeds went to charities or the mosques. The killing of sea turtles is prohibited in Sarawak, as in most Southeast Asian countries, but poaching is widespread.

The American Experience

Among Native Americans encountered by the first Europeans in the turtle-rich Caribbean, attention appears to have been focused on the giant reptiles as a source of meat, whereas their eggs were of secondary interest. The green turtle was and still is at the base of the diet of such coastal people as the Miskito of Nicaragua and Honduras, the Baja California tribes, and the Seri of Sonora, all living close to major turtle pasturing grounds. In the West Indies, unfortunately, the large populations of nesting and grazing turtles described by the early chroniclers at Grand Cayman, the Dry Tortugas, and Bermuda were quickly exterminated (Carr 1954). Only at Tortuguero in Costa Rica and on tiny Aves Island off Venezuela do the greens continue to congregate in numbers in the Caribbean.

At least one Carib group in the Lesser Antilles was said not to have eaten sea turtle "for being fearful of taking on the characteristics of that reptile" (Rochefort 1606, 2: 202). Yet eggs were relished. A similar preoccupation with turtle eggs, rather than turtle flesh, was evident for early Indian peoples on the west coast of Mexico and in Brazil. Turtle eggs are smaller than those of poultry but have more fatty yolk. They are often consumed raw. One might speculate, in terms of conservation, whether it is better to take the turtles or their eggs. Had both been subject to unrestrained exploitation, the prospects for the survival of the species would have been bleak much earlier.

The Europeans who first came into contact with the green and hawksbill populations of the Caribbean were not of one accord in their judgment of this fortuitously accessible new resource. The Spanish and Portuguese seemed for the most part uninterested in turtle. Alvise da Cadamosto, the first Portuguese to mention what must have been the green turtle, fed it to his crew in the Cape Verde Islands in 1456 and found it "a good and healthy" food. Fernandez de Oviedo y Valdez, in his *Historia Natural* of 1526, agreed. But most Spanish and Portuguese chroniclers of the early period ignored the animal or suspected it of being poisonous; it was the later-arriving English who were most outspoken in their praise of the green turtle's virtues (Parsons 1962). Its health-giving qualities were much commented upon by observers of the seventeenth and eighteenth centuries. To John Fryer (1909: 306), writing of East India and Persia in the late seventeenth century, it was "neither fish nor fowl nor good red herring, restoring vigor to the body and giving it a grace and luster as elegant as viper wine does to consumptive persons and worn out prostitutes."

Many an ill-disposed Englishman on Jamaica went to the Cayman Islands during the turtling season to recover his health by feasting on turtle. As a cure for scurvy and relief from the monotony of a hardtack and salt-beef diet, the meat was much prized by explorers, merchantmen, and buccaneers. The great clumsy creatures were abundant, easy to catch, and most important in the tropical heat, able to be kept alive on the decks of ships for weeks. The late Archie Carr (1973) suggested that the green turtle more than any other dietary factor supported the opening up of the Caribbean. It seems to have played a similar role in the Indian Ocean. William Dampier, that rough seaman who, Oliver Goldsmith observed, added more to natural history than half the philosophers who went before him, made repeated and extensive references to sea turtles as a shipboard meat reserve in his *Voyages,* written between 1681 and 1688 (Dampier 1906). In his eyes, the eggs were for natives.

Learning from the Miskito

The coastal Miskito are the world's foremost sea turtle people (Carr 1973; Nietschmann 1973, 1979). The coral cays and shelf off their Nicaraguan home coast are the principal feeding ground for green turtles from the renowned Tortuguero rookery, some 200 miles to the south in Costa Rica. Under subsistence exploitation regulated by local Miskito communities with strong cultural, religious, and economic ties to the species, the population remained stable. But with commercialization, first by Cayman Islanders who had seen the turtles of their own island decimated, and then by other foreign interests, extraction rates became excessive. Yet this coast, between Cape Gracias a Dios and Bluefields, still supports the largest remaining population of greens, and also hawksbills, in the Caribbean. With the recent establishment of the Miskito Coast Protected Area, there is prospect for a return to culturally regulated exploitation after a long period of overuse (Nietschmann 1991).

The Miskito may have taught the English to appreciate turtle. As early as 1633, a trading station had been established among the Miskitos at Cape Gracias a Dios by English adventurers from the Puritan colony at Old Providence Island. From the beginning, relations between natives and traders were amicable, encouraging a sort of symbiotic relationship that was nurtured in part by mutual antagonism toward the Spaniard. The Indians, superb boatmen, had an "eye" for turtles that never ceased to amaze the Europeans. Many an English and Dutch pirate vessel carried at least one Miskito man as a "striker" to harpoon turtle for the mess table. "Their chief employment in their own country," wrote Dampier,

> is to strike fish, turtle, and manatee. . . . for this they are esteemed by all privateers, for one or two of them in a ship will maintain 100 men, so that when we careen our ships we choose commonly places where there is plenty of turtle or manatee for these Miskito men to strike; it is very rare to find privateers without one or more of them. (Dampier 1906, 1:39)

Caymanian turtlers were working the Miskito shore by at least 1837. From Grand Cayman, turtle boats could reach the cays in three or four days. The turtlers assembled their catch at temporary camps in the cays, carrying them north at the end of the season to be kept in "crawls" until marketed. From 2,000 to 4,000 turtles were taken annually. (A turtle-soup cannery was established in Grand Cayman in 1952 by the Colonial Development Corporation, but it closed after one year.) When, in 1967, this traditional arrangement with the Caymanian turtlers was terminated by the Somoza government and turtling rights were granted to higher bidders, the extraction rate soared to an insupportable 10,000 a year. By 1979, international conservation pressure had forced the Nicaraguan government to shut down the turtle companies and to ban further commercial exploitation (Nietschmann 1993).

Turtle was in as great demand as a slave food in the West Indian colonies in the seventeenth and eighteenth centuries as was salt cod from Newfoundland. But the reptile was also enjoyed by the West Indian white aristocracy. It was considered a special delicacy when eaten fresh. "To eat this animal is the highest perfection," wrote Goldsmith (1825: 164), "instead of bringing the turtle to the epicure, he ought to be transported to the turtle." Janet Schaw, describing her visit to Antigua in the 1770s, wrote:

> I have now seen turtle almost every day, and though I never could eat it at home, am vastly fond of it here, where it is indeed a very different thing. You get nothing but old ones there [London], the "chickens" being unable to stand the voyage; and even these are starved, or at best fed on coarse and improper food. Here they are young, tender, fresh from the water, where they feed as delicately and are as great epicures as those who feed on them. (Schaw 1939: 95)

The special quality of turtle soup was said to be that it did not "cloy." In other words, one could eat almost any quantity without ill effects. Its easily assimilated proteins, without carbohydrate or fat, were proclaimed to prepare the stomach in superb fashion for what was to come. When banquets started with this soup, the diner was considered best able to enjoy the numerous rich dishes to follow. Goldsmith wrote that turtle "has become a favorite food of those who are desirous of eating a great deal without surfeiting. . . . by the importation of it alone among us, gluttony is freed from one of its greatest restraints" (1825: 674). The soup, flavored with sherry, capsicums, ginger, cloves, and nutmeg, and served piping hot, was considered at its fiery best "when, after having eaten, one is obliged to rest with his mouth wide open, and cool the fevered palate with Madeira or Port" (Simmonds 1883: 366). In 20 years in the West Indies, one doctor professed, he had never heard of an "accident" arising from eating it! It was also held to be an ideal food for convalescents, especially when served in jellied form.

The Dutch, although they partook of it, seem to have been rather indifferent to turtle in the East, perhaps because of their close association with the Malays, who avoided the meat. In the West, the French, while interested, found but a limited supply of green turtle available to them, most of the best turtling grounds being under English control. From the seventeenth-century account of Père Labat, a Dominican monk, it is evident that the animal's merits were not unrecognized. Yet it did not rate so much as a mention in Brillat-Savarin's exhaustive *Physiologie du gout,* written in 1825. For the French, turtle was clearly an English dish.

Spanish Disdain for Turtle

As rivalry between Spain and England intensified, Spanish disdain for what the English considered among the finest of foods heightened. Dampier (1906, 2: 399), describing the turtles found on the Brazilian coast, wrote in 1699:

> neither the Spaniards nor Portuguese lov(e) them; Nay they have a great antipathy against them, and would rather eat a porpoise, tho' our English count the green turtle very extraordinary food. The reason that is commonly given in the West Indies for the Spaniards not caring to eat them is the fear they have lest, being usually foul-bodied, and many of them pox'd (lying as they do so promiscuously with their Negrines and other She-slaves), they should break out loathsomely like lepers; which this sort of food, 'tis said, does much incline men to do, searching the body and driving out any such gross humours.

Richard Walter, writing in 1748 while with Lord George Anson on his voyage around the world, thought it strange, considering the scarcity of provisions on the Pacific coast of Central America,

> that a species of food so very palatable and salubrious as turtle should be proscribed by the Spaniards as unwholesome and little less than

> poisonous. Perhaps the strange appearance of this animal may have been the foundation of this ridiculous and superstitious aversion, which is strongly rooted in all of the inhabitants of this coast. (Walter 1928: 208)

Of the Indians and Negroes (slaves of the Spaniards) who had been taken as prizes in Peru, Walter noted:

> These poor people, being possessed with the prejudices of the country they came from, were astonished at our feeding on turtle and seemed fully persuaded that it would soon destroy us. . . . it was with great reluctance and very sparingly that they first began to eat it; but the relish improving upon them by degrees, they at last grew extremely fond of it, and preferred it to every other kind of food. . . . a food more luxurious to the palate than any their haughty Lords and Masters could indulge in. (Walter 1928: 288)

The Spaniards' apparent lack of interest in turtle appears in part a reaction to the close identification of it with the rival and hated English. In his study of Old World food prejudices, Frederick Simoons (1994) has shown the frequency with which particular animals or foods have become identified with particular ethnic, religious, or other groups through the course of history. The tendency to identify peoples with distinctive food habits is only a step from the rejection of foods simply because they are associated with a rival group. Pastoralists' rejection of the pig, an animal closely associated with and symbolic of the settled farmer, is an extreme, but by no means isolated, example of this sort of attitude.

The London Turtle Trade

Although the virtues of turtle had long been familiar to West Indian planters and to men of the sea, its introduction to the tables of London came only in the mid-eighteenth century. The *Gentleman's Magazine* in 1753 and 1754 carried several notices of large sea turtles, brought from Ascension Island and the West Indies, being dressed at public houses in London. One of the turtles was brought by Lord Anson. At the Kings Arms tavern in Pall Mall, the door of the oven had to be taken down to admit the plastron of a 350-pound specimen. "It may be noted," it was observed, "that what is common in the West Indies is a luxury here" (Anon. 1753: 489).

Although these were certainly not the first live green turtles seen in England, they were of sufficient rarity to gain newspaper comment. "Of all the improvements in the modern kitchen," said the *World* in an account of a London banquet at about this time, "there are none that can bear a comparison with the introduction of the turtle" (quoted in *Notes and Queries,* 1884 [6th ser., 9: 114–15]). But Dr. Samuel Johnson, in his *Dictionary* (1775), tersely defined "turtle" as a term "used among sailors and gluttons for a tortoise."

As English demand increased, vessels in the West Indian trade were provided with flat wooden tanks in which live turtles could be deck-loaded. Although they were fed grass and banana leaves on the journey, after arrival at the Leadenhall Street turtle tanks they still had to be fattened before reaching the tables of the well-to-do. The largest, which were not necessarily the best, were often destined for the royal palace. For the less affluent there already were substitutes. As early as 1808, Mrs. Elizabeth Raffald's *The Experienced English Housekeeper* was offering a recipe for "artificial" or mock turtle soup made from a calf's head.

Steamships greatly facilitated the movement of live turtles across the Atlantic. Imports of "preserved turtle" from Jamaica were initiated in 1841. The turtles had been taken by Cayman Islanders and, thus, by British subjects. By 1880 imports of "prepared turtle" were listed as 10,800 pounds. This was apparently the designation applied to the sun-dried meat and calipee that in late years had begun to place turtle soup, by one account, "within the reach of the general consumer." But it was to remain preeminently a prestige food. Mrs. Isabella Beeton called turtle soup "the most expensive soup brought to the table," with 1 guinea the standard price for a quart of it. Her widely read *Mrs. Beeton's Book of Household Management* states:

> The price of live turtle ranges from 8d. to 2s. per pound, according to supply and demand. When live turtle is dear, many cooks use the tinned turtle, which is killed when caught, preserved by being put into hermetically sealed canisters, and so sent over to England. (Beeton 1861: 178–80)

The Queen of Soups

"Turtle soup from Painter's Ship & Turtle on Leadenhall Street," wrote one observer at the end of the nineteenth century, "is decidedly the best thing in the shape of soup that can be had in this, or perhaps any other country." Located there, he asserted, was the only "turtle artist" in Europe (Hayward 1899: 24–5). A French visitor described the establishment in 1904. A large pool of water contained upwards of 50 turtles awaiting "sacrifice." Alongside was the slaughter room and next to it the kitchen, where 10 to 12 men were occupied in making this national soup, which was sent out each day to the city, to the provinces, and even to foreign markets. It brought the exorbitant price of 1 guinea per liter for the regular soup and 25 shillings for the clear soup. A bowl of turtle soup served in the restaurant cost 3 shillings, the price including the glass of punch that followed it (Suzanne 1904: 15).

Blending and seasoning were of the greatest importance in soup making and called for much experience and "know-how." Some cooks insisted that the fins and steak or inside red muscle meat of the turtle were chiefly responsible for the flavor, and that genuine "real turtle soup" (the sort that jelled of its own accord on cooling) was properly made only from a broth of turtle meat. To this, diced calipee was added as a relish. Others, especially in London, regarded beef stock as an essential basis of the soup, holding that without it turtle soup tended to lack character. In this they claimed the support of the famous *Maître Chef* Auguste Escoffier.

Tinned turtle products entered midlatitude markets about the middle of the nineteenth century. Some of the first canneries were located within the tropics, close to sources of supply such as one at Pearl Lagoon, Nicaragua. Another in Key West, Florida, employing 10 vessels and 60 men for turtle gathering, was reported in 1880 to be turning out 200,000 cases a year. The "green fat," or calipee, was often tinned separately from the meat and soup. It was once customary to serve it as a side dish, a spoonful being added to the soup if desired. The largest shipments of tinned turtle products were to London, but New York was a substantial secondary market. Although turtle canneries operated from time to time in Jamaica, Nicaragua, Grand Cayman, Mexico, Australia, North Borneo, and Kenya, they were short-lived ventures. In later years, until forced cessation of the trade, the larger share of the green-turtle soup and red meat that went into cans was processed either in the New York area or in London.

The leading London soup maker, John Lusty, Ltd., "By Appointment Purveyors of Real Turtle Soup to the Royal Household since the Reign of Edward VII," had been in business near the London docks and Greenwich Naval Base since at least 1851 (long before the reign of Edward VII). Captains of Royal Navy ships returning from the West Indies or Ascension Island often brought back live green turtles and desired that they be made into soup for presentation to "My Lords of the Admiralty," who prized it as a great delicacy. The West Indies was the principal source of Lusty's supply.

After World War II, however, few live turtles were imported, the animals being slaughtered and refrigerated at the port of shipment. In its last years in business Lusty's supplies (mostly frozen) came from Kenya and the Seychelles. For Bender & Cassel, Ltd., the other major London producer, the Cayman Islands provided the supplies. It was at this time that a substantial demand for green turtle soup developed on the Continent. It became a standard feature on the menus of luxury restaurants, particularly in the larger cities and tourist centers of Germany, the Low Countries, and, to a lesser extent, France. There were canning operations in West Germany, France, Denmark, and Switzerland. For most of these concerns the Indian Ocean seems to have been the principal source of supply.

In the United States, the dominant company in the green-turtle and turtle-soup business was Moore & Company Soups, Inc., of Newark, New Jersey ("Ancora" brand), formerly located in Manhattan. It had begun making turtle soup in 1883. Initially, the turtles arrived at the port of New York deck-loaded on banana boats; later they were trucked, turned on their backs, from Tampa or Key West. In the early 1960s, an average of two truckloads a week arrived at the Newark plant, where they were held in a pond until slaughtered. If frozen, the carcasses were placed in refrigerators.

The End of an Era

In 1962 I hazarded the guess that between 15,000 and 20,000 green turtles a year were finding their way, in one form or another, to the commercial markets of North America and Europe. The guess included those animals slaughtered on the Indian Ocean islands and elsewhere exclusively for their calipee. Although the aristocracy was consuming less turtle soup than in times past, the market had been immensely broadened. What was once reserved for the epicures of London and New York had become available on the shelves of quality grocery stores throughout Europe and America. The implications of such an expanding demand in the midlatitudes, coupled with the growing population of the tropical world, seemed ominous.

But today, with most nations of the world signatory parties to CITES, international commerce in turtles and turtle products has all but ceased, although the animals continue to be exploited on a limited scale by traditional coastal populations, and turtle meat or eggs may be marketed clandestinely. Egg collecting may be permitted under restraining community rules, as at the important olive ridley nesting beach at Ostional on the Pacific coast of Costa Rica or at the Sarawak Turtle Islands. But in Mexico, perhaps most conspicuously in sparsely settled Baja California, illegal poaching for commercial purposes remains widespread. In that country turtle eggs, as well as the penis of the reptile, are prized for their presumed aphrodisiac qualities.

At Mexico's Rancho Nuevo beach (on the Tamaulipas coast), famed for the massive synchronous nesting emergences *(arribadas)* of the rare Kemp's ridleys, eggs for a time were removed to a protected hatchery within hours of being laid to avoid depredation by coyotes, shore birds, and humans. Under a U.S.–Mexico cooperative "head start" program, hatchlings were transferred in large numbers to Texas beaches in the hope of imprinting them and establishing new rookeries (Rancho Nuevo is the lone known Kemp's ridley beach in the world). But the project did not produce the hoped-for results and was finally abandoned as futile (*Marine Turtle Newsletter* 1993: October, 63).

A film made in 1950 of the Tamaulipas *arribada* showed some 40,000 females storming the beach in daylight hours, but the same beach today supports fewer than 1,000 nesters in a season. Apparently the entire world stock of Kemp's ridleys has been severely depleted in the interim, many trapped and damaged in the trawls of commercial shrimpers (Cornelius 1990). Presently large *arribadas* of the vastly more abundant olive ridley turtle occur at one remaining Mexican West Coast beach and at others in Costa Rica and India. The phenomenon, one of the most spectacular examples of mass activity in the animal kingdom, is especially characteristic of the two ridleys. At least three Mexican *arribada* sites had been eliminated by commercial fishermen before government restrictions began to be enforced. An estimated 2 million turtles were slaughtered on the West Coast of Mexico, more to meet demands for leather than for meat, in the five years leading up to 1969, before efforts were made to rationalize the harvest with catch quotas (Cornelius 1990: 54; *Marine Turtle Newsletter* 1991: April, 53). The India site, in Orissa State on the Bay of Bengal, of which the scientific world has only recently become aware, is reported to support *arribadas* of up to 200,000 ridleys, presumably in a single season. Despite the fact that much of the site is within a wildlife reserve, thousands of illegal takings occur offshore annually. The extent to which eggs are collected is unclear. The excessive harvest of eggs has been identified as one of the most important factors causing the decline of sea turtle populations.

In the Caribbean area, turtle deaths have increased with the intensified activities of shrimp trawlers in recent years (National Research Council 1990). Strandings of dead loggerheads on Florida beaches from this cause (13,000 in a recent year, with a small number of greens) have been sharply reduced by the Turtle Exclusionary Devices (TEDs) now required on the U.S. trawler fleet. Extension of their use to other nations is being urged. The ingestion of plastic bags, debris, and toxic substances such as petroleum further contributes to turtle mortality. Tourism and turtles, too, are on a collision course in several places. Coastal resort development and other forms of habitat encroachment deny nesting turtles their habitual nesting localities, as does the increasing artificial lighting along coastlines, to which the greens seem especially sensitive.

Gastronomy or Ecotourism?

Captive breeding programs for the more valued greens and hawksbills have been generally unsuccessful. The Cayman Islands Turtle Farm, established in 1968 as Mariculture, Ltd., for a time raised greens in tanks for export to commercial processors. In the face of CITES restrictions, it has been converted to a successful educational and tourist attraction. Production of meat (and perhaps eggs) continues on a reduced scale for local island consumption. The U.S. market has been closed since 1978, as, increasingly, are those of other countries (Wood 1991; Fosdick and Fosdick 1994). Provision for trade in farmed turtles continues to be sought, but the pressure against any trading in species whose wild populations are endangered or threatened is substantial. Sea turtle research, including the tagging and release of hatchlings and yearlings, has been an additional feature of the farm's activities. In recent years, farms have sought to be self-sustaining, independent of wild stocks of eggs or wild breeding turtles. The animals are fed twice daily with a high-protein, pelletized Purina Turtle Chow. They are slaughtered at 4 years of age, at 20 to 30 kilograms.

If sea turtles have a future it seems likely to be in ecotourism rather than gastronomy. They are featured on the flag, seal, currency, and postage stamps of the Cayman Islands, reflecting their close association with the islands and their presumed emotional appeal to potential visitors. Elsewhere, too, as in Florida, in Costa Rica, on the Great Barrier Reef, and on some islands of the Aegean Sea, "turtle watching" is becoming a featured tourist attraction.

The groundswell of concern for the future of sea turtles that has put all but the Australian flatback on the endangered species lists has led to a surge in scientific research on the animals and on the causes and consequences of their decline (Bjorndal 1981; National Research Council 1990). Representative of this effort are the activities of the Marine Turtle Specialty Group of the International Union for the Conservation of Nature (IUCN) and the *Marine Turtle Newsletter,* a comprehensive quarterly now published in both English and Spanish by the Hubbs–Sea World Research Institute of San Diego, California. So are the symposia on Sea Turtle Biology and Conservation, which are annual workshops devoted to these questions.

Realization of the seriousness of the plight of sea turtles, underscored by the CITES trade restrictions, has led to the effective elimination of turtle steaks, turtle soup, and turtle eggs from the tables of all but a handful of tropical developing countries. We are losing, as a consequence, a palatable and nutritious marine food of unique cultural and historical significance. Turtle meat is remarkably lean, with 5 percent of calories in fat compared to 40 for most meats (James Stewart, M.D., personal communication). The eggs are comparable to chicken or duck eggs in protein content and are rich in vitamin A (Simoons 1991: 366–7). Both the world of gastronomy and the lives of many coastal populations of the tropics are being significantly impoverished as turtle and turtle products, a primary source of red meat and protein, are being forced from menus by the excessive pressures of commercialization as well as by the relentless increase in human numbers.

II.G.21 ~ Sheep

Probably the earliest domesticated herd animal in the Old World, the sheep *(Ovis aries)* makes an unparalleled contribution of food and fiber. The great advantage of these small ruminants is their ability to digest the cellulose of wild grasses and coarse woody shrubs in their complex stomachs and convert it into usable products.

Origin and Domestication

Sheep were domesticated on the flanks of the Taurus–Zagros Mountains, which run from southern Turkey to southern Iran. Within that arc is found the urial *(Ovis orientalis),* a wild sheep now generally regarded as the ancestor of the domesticated sheep. Early archaeological evidence of sheep under human control comes from Shanidar Cave and nearby Zaqi Chemi in Kurdistan. Sheep bones recovered in abundance at these two sites have been dated to between 8,000 and 9,000 years ago and contrast with other Neolithic sites close to the Mediterranean, where similar evidence of domesticated sheep is rare. However, accurate species identification has posed problems, for the bones of goats and sheep are often difficult to distinguish from one another. Therefore, some archaeological reports have grouped them together as "sheep/goat" or "caprine."

The domestication process that transformed *O. orientalis* into *O. aries* involved several key changes. The body size of the sheep was reduced from that of the urial. Diminution could have been accomplished over many generations by culling out larger, aggressive males as sires. Selection also occurred for hornlessness, but this process is not complete. Although many breeds of domesticated female (and some male) sheep typically have no horns, in other males the horns have only been reduced in size. Domesticated sheep also have a long tail as compared with the wild ancestor. The most significant physical transformation of the animal was the replacement of the hairy outercoat with wool fibers, which turned the sheep into much more than a food source. As early as 6,000 years ago, woolly sheep had differentiated from hairy sheep, and in ancient Mesopotamia, the raising of wool-bearing animals was a major activity in lowland areas. Selection for white-wooled animals explains the gradual dominance of that color.

Sheep

In spite of the many human uses of sheep, domestication may have been motivated by religion rather than economics. Urials were animals of ritual significance, and to ensure a ready supply for sacrifice, humans may well have sought to tame and then breed them in captivity. At Catal Hüyük in Anatolia, the remains of sanctuaries from between the seventh and sixth millenniums B.C. depict ram heads.

The early use of sheep as sacrificial offerings went hand in hand with a long selection for qualities of fecklessness, timidity, and total dependency. Long after successful domestication, sheep sacrifices continued in religious ritual. The cultic use of sheep was known in ancient Egypt, Greece, Rome, and China. The Hebrew Bible made many allusions to ovine sacrifice, and from this, Christianity developed the idea of the "Lamb of God," a metaphor for Jesus as a sacrificial vessel for the sins of mankind. Unlike Christianity, Islam incorporated sacrifice as a literal requirement of the faith. Each year, during the festival of *Id al-Adha,* every male Muslim is enjoined to slaughter a domesticated animal, in most cases a sheep, as a sign of his submission to the will of God. Sheep accompanied the spread of Islam from its Arabian core, not only because of religious associations but also because the Arabs were, above all, pastoralists.

Ovine Diversity

Through isolation and/or mutation, sheep differentiated into almost 1,000 breeds, most with regional distributions. Some of these have now disappeared as more productive breeds have taken their places. The selection of sheep breeds in Western Europe has been influenced largely by the strong Western bias toward high productivity. During the eighteenth and nineteenth centuries, the breeds of Cheviot, Cotswold, Dorset, Hampshire, Leicester, Oxford, Romney, Shropshire, Suffolk, and Southdown all emerged in the British Isles, bred in some cases for their wool and in others primarily for their meat. The Rambouillet, a smooth-bodied wool breed, originated in France. In the United States, the breeds of Columbia, Debouillet, Montalde, Panama, and Targhee were developed (mostly in the twentieth century) through crossing of different breeds to adapt them to North American environmental conditions.

About 10 percent of classified breeds produce fine wool. Merino sheep are the outstanding source of high-quality wool and, as such, are the most important of all sheep breeds. The long fibers of Merino wool are turned into yarn used for worsted apparel. The history of Merino sheep in Spain is well documented after about A.D. 1500, but their origin is not. It seems most plausible, however, that this breed was brought from North Africa during the Moorish occupation of the Iberian Peninsula.

Genotypic and phenotypic diversity of sheep is greatest in the Near East, where these animals have been part of human livelihoods longer than anywhere else in the world. Breeds of indigenous origin, well adapted to the local environmental conditions, still dominate there. Some breeds, such as the Awassi and Karaman, have fat tails – fat tails being a much-appreciated delicacy in places such as the Middle East; others have semifat tails (e.g., Chios sheep); still others have thin tails, for example, the Karayaka of Turkey. Fat-rumped breeds form yet another category. Near Eastern breeds have several kinds of fleece, or none at all. The good-quality carpet wool yielded by some breeds makes possible the manufacture of Oriental rugs, one of the world's magnificent art forms. Fur-sheep are another category; most famous are lamb pelts from Karakul sheep produced in the Middle East and central Asia, especially in Bokhara, where this breed originated. Many sheep of western Asia also have their variants in Africa (Epstein 1971).

In places where sheep are raised more for their subsistence value, numerous breeds may be represented in a single flock. For example, in northeastern Brazil, an owner may keep hair sheep and those with wool; polled sheep and those carrying horns; sheep with colors ranging from red-brown to white to black-pied; sheep with horizontal ears, but also those with lop ears; sheep with thin tails, but also those with semifat tails. These heterogeneous mixtures are the result of several introductions and free crossings over time. The first sheep were exported to Brazil in the sixteenth century from Portugal and included both the coarse-wooled Churro and the fine-wooled Merino. The Crioulo breed, coarse-wooled and horned, emerged from the Churro. Hair sheep were imported from the Caribbean and elsewhere, and in the twentieth century, sheep were brought from Italy to Brazil.

Keeping of Sheep

Sheep have been kept either as part of pastoral livelihoods or as an element of mixed agropastoralism. In the former, they consume grass and woody shrubs that are part of the natural vegetation. Sheep grazing on the coastal meadows *(prés salés)* of western France has established a standard for high-quality lamb production known throughout the culinary world. When integrated with a farming economy, sheep consume stubble in the fields and, in turn, contribute manure to renew the soil. Sheep are almost never kept in stalls or feedlots as cattle are. Intensive sheep production has lagged far behind that of cattle and pigs.

Where aridity has made agriculture too uncertain or impossible, sheep can survive on sparse wild grasses and woody shrubs. Sheep raising has traditionally been most profitable when natural vegetation on land owned by the community or the state reduced the cost of production. Often, however, the need of such vegetation has involved seasonal movement to find proper forage at all times of the year. In much of the subhumid world, transhumance is the solution to providing livestock with what they need to survive. In the Iberian Peninsula, sheep raising became the most valuable avenue of land use after the introduction of the Merino. The powerful sheepowners' organization, the *Mesta,* obtained priority in deploying their sheep over the countryside. Always in search of more and better pastures, sheep were driven north and south on the Spanish plateau along designated pathways called *cañadas.* The migration of millions of sharp-hoofed animals etched miniature canyons into the land that can still be seen as relict features in the landscape.

Traditional patterns of seasonal sheep movement continue to prevail in the Middle East, North Africa, and central Asia. In Europe, transhumance between high and low pastures is still practiced, but now sheep may be transported by rail and truck rather than on foot. Transhumance is also found in western North America and southern South America, but more in the form of commercial livestock strategy than cultural adaptation. In all forms of sheepherding, shepherds and dogs remain indispensable, for they protect their defenseless charges not only from predators but also from the sheep's own mimetic behavior and innate stupidity.

Sheep Products

Wool

Wool is the main product of commercial sheep raising such as is practiced in Australia, New Zealand, South Africa, Argentina, Uruguay, and North America. Most wool involved in world trade comes from these areas. Wool is also a major product for small farmers throughout the world. Sheep's wool has many advantages: It is resilient, which imparts to fabrics the ability to retain shape and resist wrinkling. Wool traps and retains heat-insulating air, but at the same time its low density permits the manufacture of lightweight fabrics. In addition, wool fiber takes dyestuffs well.

Meat

If all the world's sheep are taken into consideration, meat has been the primary objective of raising them. Fat (tallow) from sheep was once tremendously important for making candles until paraffin replaced it; in the Middle East and Africa, tallow continues to have considerable value as a substitute for cooking oils. Selection for fat tails is ancient. Herodotus mentioned sheep in which the tail constituted one-sixth of the total weight of the butchered animal. In some sheep, the tail is so large and heavy that it is an obstruction to the animal's mobility. Cases are known in which owners have constructed a little wheeled cart to relieve the weight of the tail and keep it from dragging on the ground.

Sheep meat is divided into mutton and lamb, with the latter deriving from an animal of up to 1 year of age and without permanent teeth. Mutton – the meat of a sheep older than 1 year – is the favorite meat of the Middle East and North Africa. Indeed, more than 50 percent of those regions' total meat requirements are satisfied by mutton. The sheep is the prestige animal of Islam, which ecology has encouraged, because the quality and quantity of forage in this part of the world favor it over cattle, which have much larger appetites and more stringent feed requirements in order to thrive. Goats are an alternative to sheep. Pigs are taboo.

Mutton is also culturally important in central Asia as a food, more so than in China, even though that country is the world's leading mutton producer. Australia, with its population of less than 20 million people, nevertheless produces four times as much sheep meat as the United States with 265 million people. Australians eat most of it but also export considerable quantities. The island peoples of Mauritius and Papua New Guinea, for example, derive a major part of their commercial meat supply from imported Australian mutton.

In Europe, sheep meat consumption is only one-eighth that of beef and veal and one-sixteenth that of pork. Among Europeans, the British have been especially fond of mutton, but their consumption of it has declined in recent decades in response to the availability of cheaper sources of protein such as poultry. Nonetheless, the United Kingdom still produces three times more sheep meat than the United States and also relies on mutton imports from Argentina.

The preferred sheep meat in many Western countries is lamb, which is more tender and subtle in flavor than mutton. A century ago, however, lambs were rarely marketed as a source of meat. One specialized variant of lamb is a milk-fed baby, which yields a succulent white flesh. In Mediterranean countries, suckling lamb is a much appreciated Easter delicacy. It is an old specialty *(abbaccho)* of the Roman Campagna, a favorite residential area of Rome in ancient times, and in Greece, milk-fed lamb is considered the height of gourmandise.

As already hinted, Americans eat little sheep meat of any kind. In 1985, less than 1 percent of the red meat consumed in the United States was lamb or mutton (USDA 1987). One explanation for this small amount is that sheep flesh was historically of poor quality because the only sheep slaughtered were those whose wool-bearing days were over. The nineteenth-century rise of the beef-centered meatpacking industry may also have played a role in marginalizing sheep meat. But most persuasive in explaining the weak pattern of sheep meat consumption are protein alternatives. Since 1963, the use of lamb and mutton in the United States has decreased more than 60 percent; during this time, pork, beef, and especially poultry have become relatively cheaper to purchase.

Another contributing factor is meat cuts: Mutton and lamb have a higher ratio of fat and bone than do beef or pork.

Today, what little sheep meat is consumed in the United States is as lamb. Part of that market is composed of immigrant populations, which reduces even more its consumption among mainstream American meat-eaters. The latter group may eat it mainly in restaurants specializing in Greek, Middle Eastern, and French cuisines. However, in some regions of the country, particularly the South and the Midwest, lamb is not even readily available in many supermarkets. Where found, in the meat counters of larger cities, lamb is typically at least as expensive as beef or pork, and usually more so.

Consumers who reject lamb for reasons other than price often state that they do not like its strong taste. The main factors controlling flavor in lamb meat are breed (Rambouillet lambs have a more intense flavor than Columbia lambs); sex (rams have a more intense flavor than wethers or ewes); and age and weight (flavor intensity varies inversely with these) (Crouse 1983).

Milk and Cheese

Milk has been a subsidiary product from sheep for millennia. Today, it is most important in the Middle East, where it is occasionally drunk fresh but is more commonly turned into yoghurt and cheese. Turkey, Iran, and Syria are major producers of dairy products from ewes, but most of these products are not commercialized beyond the local area. In Europe, the human use of sheep's milk is said to have increased when the Hundred Years' War killed off many cattle. Today, however, fresh sheep's milk is no longer consumed by most Europeans. The relative inefficiency of milking sheep, and their low productivity (150 pounds per lactation compared to 20,000 pounds for a cow), has encouraged the conversion of sheep milk into higher-value dairy products. In the Balkans, sheep's milk is made into yoghurt, but elsewhere in Europe, it is almost entirely made into cheese.

Europe's most famous sheep's-milk cheese is Roquefort – made distinctive by its veins of blue-green mold which develops on curd placed to cure in cool limestone caves. "Roquefort" is a controlled appellation *(appellation contrôlée),* which means that cheeses with this name can come only from a designated territory in the Cévennes region of France with the town of Roquefort as its center. However, the sheep's milk from which the curd is made comes from a much wider area that extends from the Massif Central to the Pyrenees and the island of Corsica. Almost all French sheep's milk produced is now devoted to making Roquefort cheese.

The manufacture of Roquefort is a holdout of tradition; other French cheeses once made with sheep's milk are now made from cow's milk. In Italy, sheep's-milk cheese is called pecorino (*pecora* is the Italian for ewe); it can be either soft and fresh (ricotta pecorino) or hard (pecorino romano, or simply Romano, used in grated form on pasta). *Queijo da serra* ("mountain cheese") is a notable cheese from the mountainous interior of Portugal, a country that well into the twentieth century made most of its cheese from sheep's milk. Greece produces large amounts of feta, a sheep's-milk cheese salted and then preserved in a brine of milk, water, and salt.

The lands of the New World produce very little sheep's-milk cheese. About 90 percent of Latin American production comes from the Bolivian Altiplano near Oruro. The native cheese makers of *queso de Paria* are indigenous people whose ancestors were taught the art of making a soft, unripened cheese by the Spanish conquerors of the Andes. In the United States, sheep's-milk cheese is manufactured on a small scale in the upper Midwest and in California and Vermont. It is considered a gourmet item because sheep's milk commands four to five times the price of cow's milk. One advantage of sheep's milk is that it can be successfully frozen and stored. Hinkley, Minnesota, has a cheese-processing plant that derives its sheep's milk from a wide area.

Environmental Effects of Sheep

Sheepherding has an ecological downside when considered historically over long periods. These ungulates have frequently overgrazed the land and brought about serious erosion, especially in areas where vegetation regenerates slowly. Sheep graze plants much closer to the ground than do cattle, and if uncontrolled, they can even, by consuming tree seedlings, denude an area to the point of preventing regeneration. Sheep contributed to the early formation of eroded landscapes in the Middle East and the Mediterranean region. Even a recently settled land such as Australia shows strong evidence of the sort of damage that intensive sheep raising can do. By 1854, New South Wales had a sheep population of over 12 million. It was an "ungulate irruption" that changed species composition of the vegetation, encouraged the introduction of noxious weeds, and degraded the soil. Sheep introduced into the New World have caused deterioration in the ranges of the western United States, Argentine Patagonia, and the Andean highlands. In Mexico, a case study of the Valle del Mezquital north of Mexico City has documented environmental changes wrought largely by intensive sheep grazing during the colonial period (Melville 1994).

World Production and Trade

More than 1 billion sheep are found in the world today, and they occur on all inhabited continents. Ovines are found in the hottest countries, such as

Somalia and Sudan, but there are also large herds in cold, windswept lands near Antarctica, such as Patagonia in southern Argentina and the Falklands (Malvinas), and on the fringes of the Arctic, as in the Faroe Islands and Iceland. Depending on the area, plains, plateaus, and mountains can all support sheep populations. Tolerance for hot, cold, dry, and wet conditions, along with an absence of any cultural prejudice against the animal and its multifaceted uses, account for its wide distribution.

Asia has about a third of the world's sheep, with especially large populations in China (mainly west and north), Iran, India, Kazakhstan, and Pakistan. Africa's sheep are found in all countries of that continent and, in the northern, western, and eastern parts, are often associated with nomadic, seminomadic, or transhumant groups. As a country (though not as a continent), Australia has, without question, the largest sheep population. Sheep are also the kingpin of agropastoralism in New Zealand, where the sheep–human ratio is among the highest in the world.

Europe (west and east combined) has about as many sheep as Australia. The superhumid United Kingdom and subhumid Spain have the largest ovine populations in the European Union. South America has more than five times as many sheep as North and Middle America taken together. Sheep are the most important domesticated animal in the high Andes of Peru, Bolivia, and Ecuador, where the cold climate and a homespun tradition make wool an especially valuable product. But 5 million sheep are also found in hot northeastern Brazil, where wool has little value. Much farther south, commercial wool production is important in temperate southern Brazil, Uruguay, Argentina, and Chile. The pastoralists of tiny Uruguay, which has about the same number of sheep as the United States, have long grazed sheep and cattle together.

Multispecies grazing in Uruguay contrasts with the conflictive tradition in western North America, where sheepmen and cattlemen pitted themselves against one another in a struggle for domination of the range. Since 1942, the rise of synthetic fibers, a shortage of skilled labor, and the increased cost of land have together forced a decline in the sheep industry in the United States. Nevertheless, entrepreneurial sheep raising on federally owned expanses still constitutes an important use of land in parts of the arid West.

Live sheep also find their way into world trade. Nigeria, Senegal, Kuwait, and especially Saudi Arabia import large numbers of them to be slaughtered in prescribed Islamic fashion. Movements of live sheep from Australia to Saudi Arabia are particularly large, enabling the faithful to satisfy their obligation of dispatching a sacrificial animal during the pilgrimage to Mecca. Normally, more than 1 million sheep are sacrificed each year for this purpose. Much of this slaughter, which wastes the meat, occurs in five abattoirs in Mina, near Mecca (Brooke 1987).

The long-term future of sheep raising in the world appears bright. Ruminant animals possess a keen advantage in being able to make use of arid or steep lands that cannot be cultivated. Sheep are productive, adaptable, and largely noncompetitive with humans. More than any other domesticate, their dual contributions of food and fiber give sheep an economic edge that spreads the risk of keeping them. And, finally, there are no cultural barriers to constrain their use.

II.G.22 Turkeys

The process of capture, taming, and eventual domestication of most animals is a difficult and lengthy process, often consisting of a trial-and-error approach. One notable exception was the domestication of the North American wild turkey, *Meleagris gallopavo.* The U.S. National Park Service archaeologist Jean Pinkley, while stationed at Mesa Verde National Park, put forth a logical scenario outlining the unique process of taming and domesticating the prehistoric pueblo turkeys of that area. Pinkley (1965) has pointed out that some domesticated animals apparently first exploited humans before becoming another of their agricultural conquests. The turkey is such an example.

The pueblo turkeys had become extinct in the Mesa Verde area by historic times, and the Park Service reintroduced breeding stock in 1944 (Pinkley 1965). This permitted observation of the wild turkeys and their relationship with the employees of the park. The

Turkey

turkeys were timid at first, but as they learned where food could be found – in this case, feeding stations that the government set out for small birds – they took over these sources. They also moved into warm roosting places available in the park's residential areas, and despite efforts to chase them away by tossing Fourth of July cherry bombs and firing guns into the air, the birds continued to congregate in and around park dwellings.

There is little reason to believe that prehistoric humans in Mesa Verde were not tormented by turkeys in much the same manner, and sooner or later, when it dawned on them that the birds could not be driven off or frightened away, the Pueblo Indians would out of despair have begun to corral them to protect crops and foodstores. At this point, recognition of the turkey as a source of food and materials for bone tools would presumably have been a logical next step.

That the turkeys were utilized over a wide area is evidenced by their numerous bones recovered from many archaeological excavations throughout the southwestern United States. All growth and age stages of the turkey – from eggs and poults on through old adults – are represented in these findings. Also of considerable interest are the pens that were constructed long ago in the pueblo region to keep the birds from straying from areas of confinement.

A number of turkey pens have been found associated with early pueblos. I recall walking down the sandy bottom of White Canyon in Utah in 1950 during the uranium boom and spotting a small two-room ruin high on the canyon wall overhead. After a tedious but not particularly dangerous climb, I reached the ledge to find the ruin virtually undisturbed. There were black-on-white bowl fragments lying about, along with stone grinding tools. On one end of the overhanging rock, where it joined with the smooth main cliff face, was a wedge-shaped turkey pen. It was constructed of cottonwood twigs, about the size of a finger in diameter, held together by plant fibers. The gate had hinges made of leather thongs and had been secured with a tied leather loop. On the floor of the small pen was a thick layer of turkey droppings. As I untied the gate and heard the squeak of the leather thongs as it opened, I thought about the last person who had secured the empty cage, perhaps intending to return with more wild birds.

The determination of whether a turkey was domestic or wild on the basis of skeletal evidence alone is – unlike with many other domesticates – nearly impossible, and when such determinations are advanced they are "shaky" at best. But poultry experts at the Cooperative Extension Service at Clemson University in York, South Carolina, have arrived at an interesting conclusion regarding the color of turkey feathers that may help separate domestic from wild birds.

Color change in feathers is brought about, in part, by the presence of lysine, a biologically important basic amino acid (C6H14 N2°2) and one of the building blocks of protein. In the case of turkeys, if lysine is not present in the diet in adequate amounts, their feathers lose some of their pigment. Turkeys generally obtain the needed amino acid from natural foods of whole protein, including insects, worms, and grubs. But many vegetable foods are low in lysine, and one of the poorest is corn. Because evidence indicates that corn was one of the major foods given to the Pueblo turkeys, and because confinement would have prevented the birds from foraging for other supplements, this diet may have contributed to the increase in white-tipped feathers that are found with domestic birds.

Two turkeys were and are present in the Americas. These are the ocellated turkey *(Meleagris "Agriocharis" ocellata)* of Central America and southern Mexico, and the turkey that is regarded as the Thanksgiving bird in the United States *(M. gallopavo),* which is found throughout much of North America.

The genus *Meleagris* and, perhaps, the species *gallopavo* are reported from the Pleistocene of North America. The birds are known from a Basketmaker site (see Table II.G.22.1) at Tseahaliso Cave, Canyon Del Muerto, Arizona, having an associated date of 3700 B.C. Turkeys were definitely domesticated by Pueblo I times (A.D. 750–900).

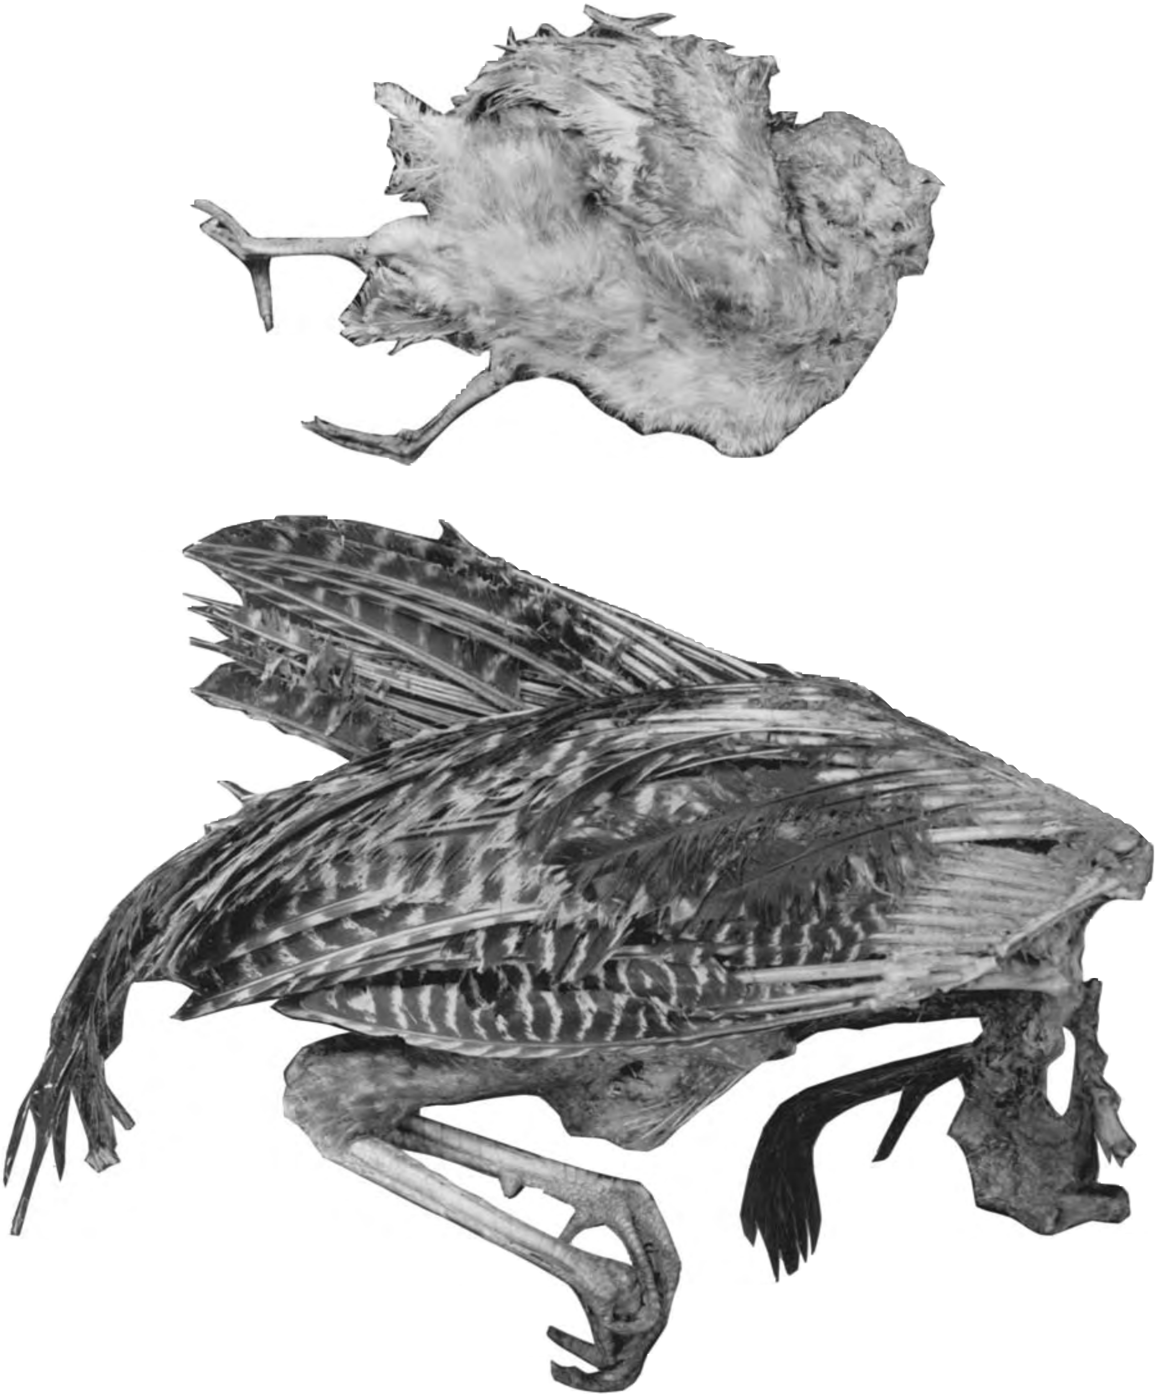

Figure II.G.22.1. Early pueblo domestic turkeys: top, a domestic turkey poult from a pueblo trash slope in Mesa Verde National Park, Colorado; bottom, natural mummy from an archaeological site in Canyon de Chelly National Monument, Arizona. (Photograph by John W. Olsen.)

Most historians agree that Christopher Columbus and his men were probably the first Europeans to see the turkey. During the fourth voyage of Columbus in 1502, his party landed at present-day Honduras, where friendly natives brought them food that included native birds the Spaniards called *gallinas de la tierra,* or "land chickens." Subsequent Spanish visitors to the Mexican mainland also reported the turkey, such as Hernando Cortés, who saw them in the markets of the City of Mexico in 1519.

The ocellated turkey was long familiar to the Maya, and its bones are rather common discoveries in Maya sites in Yucatan and Guatemala. Indeed, the Maya referred to their part of the world as the land of the turkey and the deer. Yet there is little evidence indicating that the ocellated turkey was ever domesticated. Rather, it was probably a captive and not easily induced to breed in captivity.

The first European country to receive the turkey from the New World was Spain; Pedro Alonso Niño took some birds to that country in the early 1500s. The birds were established on Spanish poultry farms by 1530, were in Rome by 1525, were in France by 1538, and then spread rapidly to other parts of the Old World.

Ironically, the travels of the turkey came full circle when English settlers in Virginia brought the bird back to its home continent in 1584. The first turkeys to be brought from Europe to Massachusetts arrived in 1629. But contemporary accounts indicate that the turkey did not achieve its prominent place in the Thanksgiving festival in New England until the late eighteenth century.

This is not, however, to imply that turkeys were scarce in North America. Spanish explorers in the present-day southwestern United States, particularly those with Francisco Vásquez de Coronado from 1540 to 1542, supplemented their food supply with local animals encountered both in the wild and in Indian villages. Indeed, they frequently mentioned foods they encountered in the pueblos of Cibola and Cibuique, and Antonio Castañeda,[1] in his record of the Coronado expedition, noted that at the fortified village of Acoma (atop a large mesa in present-day New Mexico), the villagers gave the Spaniards presents of turkeys.

Coronado himself wrote of seeing domesticated turkeys in the southwestern pueblos. The Indians informed him, however, that the turkeys were not used as food but instead for their feathers that went to make robes (Winship 1896). Coronado, who did not take this statement seriously, claimed that the birds were an excellent source of food. Yet he also wrote that the Hopi pueblos kept both eagles and turkeys for their feathers. Feather-string robes similar to those reported in New Mexico have also been recovered from pre-Columbian Indian burials at several sites in Arizona.

Reports such as this one help explain why for many years archaeologists believed that turkeys were not eaten by the early Basketmakers and Pueblo Indians. But this theory also developed because of a number of complete natural turkey mummies – some buried with offerings of corn – that had been found (Figure II.G.22.1). This discovery was, however, before the thirteenth-century Mug House Ruin at Mesa Verde National Park was excavated (Rohn 1971) and over 1,074 turkey bones were recovered, representing from 183 to 815 individual birds (depending on the method of determining the minimum number of individuals).

Many bones at this site showed signs of butchering, and some were scorched or burned. In fact, turkeys appear to have been the most important source of meat for the Mug House occupants. The turkeys were housed mainly in the ruin's "Room 46," where numerous droppings found in most dry deposits, as well as remains of young birds or poults and some eggshell fragments, indicate that the birds were domesticated to a point at which they were reproducing. However, the limited number of eggshell fragments suggests that eggs were not an important food item (if, indeed, they were used for food at all). Grooved stones at the site may have been used as "anchors" to tether the birds and limit their wandering around the crowded pueblo (Rohn 1971).

Many of the turkey bones from Mug House, and other Pueblo sites, were made into awls, needles, and tubular beads. The bones selected to be "worked" were the humeri, femora, tarsometatarsi, and tibiotarsi. Even though turkey (and eagle) bones appear to be weaker in structure when compared with those of mammals, they are generally quite strong; thus, they could be worked and polished into implements.

A number of turkey humeri indicate that they were intentionally broken, or "captured," and then allowed to grow back, leaving the birds unable to fly again. This method of "wing clipping" is also employed with macaws and is still used by bird collectors in Central America.

Depictions of turkeys are rather common in works of native art. The Hopi kivas at Awatovi Pueblo have identifiable turkeys on the walls. The Mimbres vessels of the Southwest have quite accurate portrayals of turkeys, as well as some other depictions with accurate turkey heads and beards but in combination with anatomical characteristics of reptiles and mammals, such as jackrabbit ears and deer limbs.

One of the more unusual artistic depictions of turkeys found in the southwestern United States is a rather large mural that was painted on the back wall of a cliff dwelling. The dwelling (Classic Pueblo, A.D. 1100–1300), in Arizona's Navajo Tribal Park, is located some 60 to 70 feet above the floor of Little Canyon de Chelly. It is a site that is difficult to reach and, thus, was little known and virtually unvisited until the

1960s. The well-executed mural features three large turkeys roosting in a line.

Assemblages of turkey bones are preserved in many museum collections. Mug House Ruin, already mentioned, and Big Juniper House, also at Mesa Verde, have rather large collections of worked turkey bones. Seventeen bone awls representing the turkey, and one made from a golden eagle, were identified at Big Juniper House.

Worked turkey bones were also encountered in the following sites in prehistoric Arizona: Poncho House (4), Betatakin Pueblo (1), Kiet Siel Pueblo (77), Turkey Cave (3), Awatovi (1), and Wupaki Pueblo (1). Most of these turkey bones are from areas where, historically, the wild turkey is not known. Moreover, Lyndon Hargrave (1939), who did much of the identification of the bones, has pointed out that identifying single bones, particularly incomplete elements, can be less than accurate if turkeys, golden eagles, and sandhill cranes are all represented. Alden Miller (1932) has also reported on bird (including turkey) bones from archaeological sites in Arizona. These bones were from a dwelling site 35 miles north of Flagstaff. They were dated between A.D. 1000 and 1100, their age attested to by pottery types found with the turkey bones.

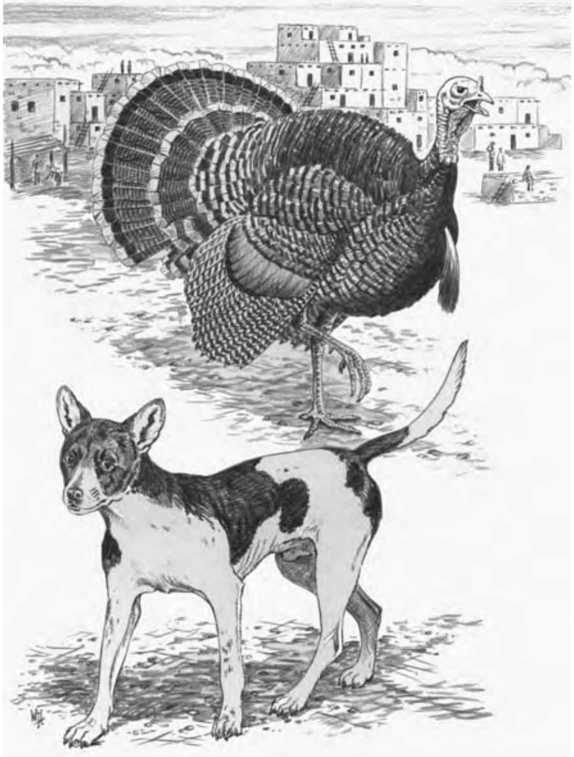

Figure II.G.22.2. Only two domestic animals greeted the first Europeans to visit the southwestern pueblos. They were the dog and the turkey. (Drawing by Wallace Hughes.)

Clearly, the turkey was prized for much more than just meat, and regardless of the degree to which *M. gallopavo* was considered as a food source in the Southwest, the evidence indicates that it was among the most sought-after animals over a wide area and a considerable span of time.

It is difficult to obtain reliable information on why turkeys were not fully accepted in many areas of the world where they were introduced. A. W. Schorger, in his book *The Wild Turkey; Its History and Domestication* (1966), devoted 36 pages to a discussion of the travels of the North American turkey to England, Norway, Germany, India, Portugal, and Africa, and throughout much of the Western Hemisphere, including Peru and Colombia. Nonetheless, North America seems to be the region where turkeys are most accepted, although no reason has ever been offered for such popularity.

The dog, *Canis familiaris,* and the turkey, *M. gallopavo,* were the only domestic animals present in North America during pre-Columbian times (Figure II.G.22.2). It is true that some workers credit the pre-Columbian Maya with domesticating the Muscovy duck, although my studies of the Maya fauna do not substantiate this hypothesis. In the Caribbean, Columbus observed the Carib Indians with penned (domesticated or merely captive?) muscovies. Obviously we still have much to learn about domesticated fowl in the early Americas.

Stanley J. Olsen

Notes

1. George Parker Winship (1896) presents the narrative of Castañeda in the original Spanish as well as an English translation. He also has compiled a most useful list of original Spanish works on the early Spanish explorers in the New World for the use of scholars who may wish to pursue this subject in greater detail.

II.G.23 ☙ Water Buffalo

> When the first created man saw the animals that God had made, it is said that he presumptuously, over-rating his powers, asked that he too might be given the creative power to fashion others like them. God granted his request and man tried his prentice hand. But the result was the buffalo, and man seeing that it was not good, asked in disgust that the creative power might be taken back again from him for ever. The buffalo, however, remained as the only living handiwork of man. (Bradley-Birt 1910: 115)

Although of limited value as a clue to the origins of the domesticated water buffalo *(Bubalus bubalis),* this tale from India does reflect the rather low opinion of this bovine held by many, including, it seems, scientists who have shown relatively little interest in it. Considering the large size of its population, its widespread distribution, and its essential role in the economic lives of millions of people, especially in southern and eastern Asia, it is remarkable that so little is known about the water buffalo. Bovine admiration and scholarly attention have been reserved for those more highly regarded distant relatives of the buffalo, the taurine and zebu cattle.

Admittedly, some admirable efforts have been made within the last few decades to remedy this situation. Most of the work that has been done has focused on the present-day conditions and future potential of buffalo husbandry, with breeding, management, and productivity being of central concern.[1] Research on the cultural and historical aspects of the buffalo, however, has been very limited.[2] Certainly, in the discussion of animal domestication, the buffalo has been largely ignored.[3]

This chapter presents the results of a preliminary investigation of the original domestication and history of the water buffalo. A perusal of the available literature reveals a frustrating scarcity of information and very sketchy evidence. Consequently, interpretations must be highly speculative. At this stage in the research definitive answers are well beyond reach, and the best conclusions we can now offer are merely those that might guide future research.

Nomenclature

Although there is general agreement that the domesticated water buffalo represents a single species, its relationship to other bovines[4] has been the subject of much disagreement. It received the name *Bos bubalis* from those naturalists who, beginning with Linnaeus in 1758, believed that bovines were all sufficiently similar to warrant classification under the same genus *(Bos).* Later taxonomists, using elaborate anatomical criteria, argued that bovine differences should be recognized by subgenera or genera status. In the many multiple genera and subgenera schemes that were proposed, a *Bubalus* genus or subgenus was always included for the classification of the water buffalo (and usually the other related "buffalo" – the *anoa, tamarau,* and African buffalo[5]).

The origin of the Latin appellation *bubalus* (or *bubalis*) is unknown. The learned ancients of Greece and Rome used the term, but seemingly in reference to an African antelope, most likely the bubal hartebeest *(Alcelaphus buselaphus).* From Roman through medieval times it was also applied to the European wild bison and the wild auroch (Buffon 1812: 304–8, 316–18; Pliny 1855: 262–3). When a Benedictine monk, Paul the Deacon, recorded the introduction of the domesticated Asian buffalo into Italy during the late sixth century A.D., he used the term *bubali* (Paul the Deacon 1907: 158–9; White 1974: 203–4). Thereafter, the accepted usage for *bubalus* was in reference to the Asian water buffalo.

The word "buffalo" was undoubtedly derived from the Latin *bubalus.* The Old English forms, *buffle* and *buff,* probably evolved through the French form *buffle,* but the present form seems to have entered English from the Portuguese *bufalo.* After some early European travelers in India erroneously used the word "buffalo" to refer to the zebu, the term "water buffalo" came into use to differentiate the true buffalo (Yule and Burnell 1903: 122; Murray et al. 1933: 1157). The confusion continued – as part of what Lynn White, Jr. (1974: 204), has called "the colonial transmission of antique and medieval perversity to North America" – when English speakers mistakenly used the word "buffalo" for the American bison. Use of the term "water buffalo" has been perpetuated as a means of avoiding this further confusion.

Biological and Ecological Characteristics

Appearance

The buffalo has a broad and massive body with short muscular legs ending in large splayed hoofs. Its shoulder height averages about 5 feet, and its length from nose to tail averages about 10 feet. The weight for adult buffalo varies from about 600 to 2,000 pounds. Although their massive bodies do not appear particularly graceful, they do reflect the animals' great strength (Figures II.G.23.1 and II.G.23.2).

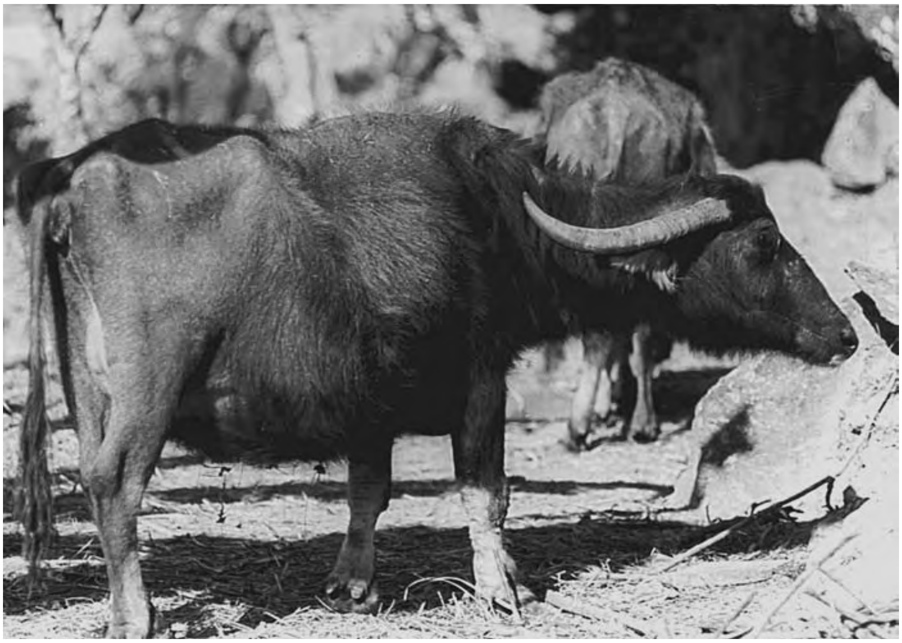

Figure II.G.23.1 The domesticated water buffalo. (Photograph by the author.)

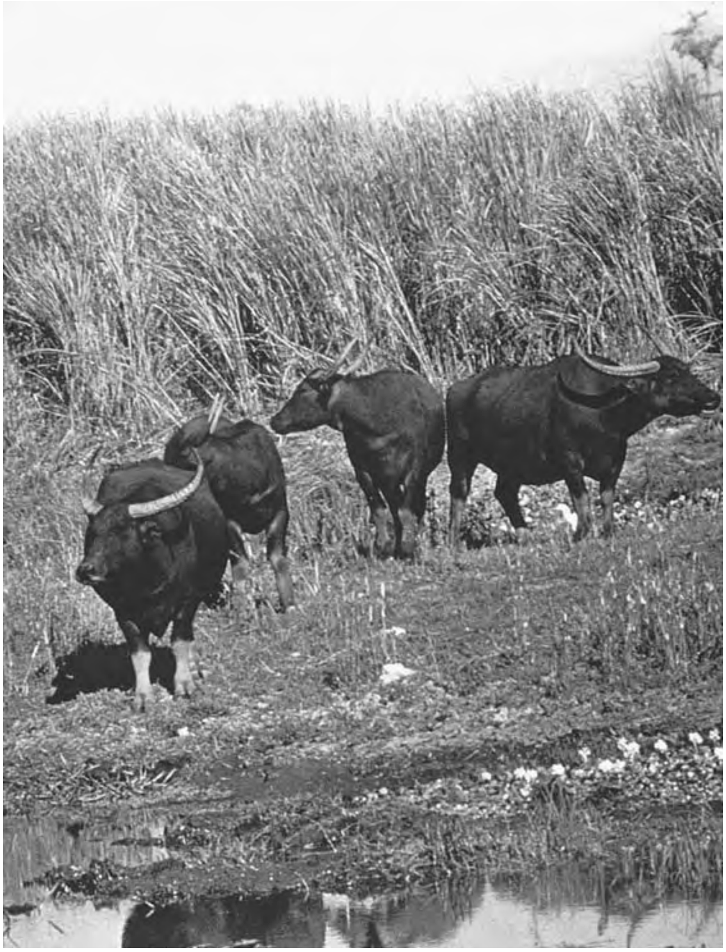

Figure II.G.23.2. Wild buffalo in Assam, with typical riparian and tall-grass habitat depicted. (Photo by Philippa Scott, from Pfeffer 1968: 156; courtesy of Chanticleer Press.)

Both sexes carry very distinctive transversely grooved and triangular cross-sectioned horns. These horns normally are crescent-shaped and incline upward, outward, and slightly backward following a single plane extending above and in the same plane as that of the forehead. Many variations in size and shape are found, from the short and tightly curled horns of the Murrah breed of northwestern India to the very long and nearly straight horns of the wild buffalo in Assam.

Shades of slate gray to black are the most common colors for the buffalo's skin and hair. Frequently the animal has light-colored chevrons under the jaw and on the chest and white or gray stockings. Although buffalo are born with a thick coat of long coarse hair, this hair generally becomes sparse as they age. In temperate or high-altitude locations, however, where cold weather is encountered, a heavy coat of hair is retained in the adult stage. Hair whorls are found in all breeds, and their individual distinctiveness has caused them to be used in some countries as a criterion for legal recognition and registration (Cockrill 1974a).

Adaptation and Habitat

Usually described as a denizen of the tropics, the buffalo is not capable of high heat tolerance. Its heat-regulating mechanisms are less efficient than those of European and Asian cattle, and under conditions of exposure to direct solar radiation, the buffalo exhibits a greater rise in body temperature, pulse, and respiration rates, and general discomfort. The buffalo is quicker, however, to show signs of comfort with a lowering of body temperature as a result of shade, artificial showers, or natural rain. As a means of cooling themselves and ridding themselves of insect pests, buffalo, unlike cattle, show a natural inclination to wallow.

The animal's preference for shade and semiaquatic conditions is at least partially explained by the color and structure of its skin. Like most tropical animals, the buffalo has black skin that absorbs ultraviolet light, thus preventing inflammation and damage to the deeper skin layers. But unlike most tropical mammals that have a coat of light-colored hair that reflects infrared waves, the buffalo has only a sparse coat of dark hair on its dark skin. Although this black surface facilitates the absorption of heat in direct sun, it is also advantageous in shade because of its high heat-radiating powers. The buffalo also suffers from the absence of an efficient perspiring mechanism. The number of sweat glands per unit area of buffalo skin is less than one-sixth that of Western cattle and an even lesser proportion of that of zebu.[6]

Thus, the buffalo is well adapted to a tropical environment provided that environment includes sufficient cooling systems in the form of shade and water. In the wild state these conditions are met with an environment of high rainfall, heavy vegetation cover, and streams, lakes, swamps, or marshes for wallowing. Husbandry practices attempt to duplicate the conditions of the animal's natural habitat as much as possible by providing artificial shade, nearby water bodies for wallowing, and frequent splashing when needed.

The nature of the buffalo's feet, and its dietary habits, further indicates a semiaquatic, humid/tropical adaptation. The exceptional flexibility of its fetlock and pastern joints and its large splayed hoofs enable the animal to move easily in mud and water (Cockrill 1967: 124). Buffalo also reveal the remarkable ability to subsist entirely on those crude fibrous plants that form so much of tropical vegetation (especially around water courses), which other livestock will not touch. Experimentation has shown that compared to the zebu (its major economic rival in South Asia), the buffalo will consume more low-quality roughage, digest it more efficiently, and thereby maintain itself in better condition with greater strength and productivity (Whyte 1968: 218; Whyte and Mathur 1974: 555–6).

The "Swamp" and "River" Buffalo Types

Roderick MacGregor (1941) was probably the first to recognize a significant subdivision within the *B. bubalis* species. Based initially on his observations of differences in bathing habitat preferences, he distinguished the "Swamp buffalo," which was the native domesticated buffalo of East and Southeast Asia, from the "River buffalo," which was the type generally found in India and farther west.

A number of differences separate these two types. Swamp buffalo prefer mud-bottomed swamps and marshlands in contrast to the River buffalos' preference for rivers with firm bottoms and clear water. Swamp buffalo throughout their range seem to be morphologically very similar, with little specialization having occurred. They appear to be much closer to the wild buffalo than are the River buffalo. The latter, in contrast, show a great deal of regional variation, with many specialized breeds having been developed, especially for improved milk yield. The Swamp buffalo tends to have a shorter body, larger girth, shorter and thinner legs, and a shorter face than the River buffalo. Swamp buffalo horns are fairly uniform in size with the common widespread crescent shape; River buffalo manifest great variety in horn shapes, often with a spiraling curve close to the head.

Population, Distribution, and Uses

Before we venture into the distant past in search of clues to the buffalo's original domestication, it is valuable to view the present-day consequences of that domestication.[7] As the result of many millennia of human–buffalo interaction, the buffalo currently has an extensive geographical range and is involved in a great variety of husbandry contexts. Recent estimates place the total world population of domesticated buffalo at about 142 million (Table II.G.23.1). Although these animals are reported from 31 countries (Map II.G.23.1), a high degree of concentration characterizes this distribution: Ninety-six percent reside in the countries of South, Southeast, and East Asia, with 80 percent in just the three countries of India, Pakistan, and China. India leads all other countries with 54 percent of the world total (about 77 million buffalo). Relatively small numbers are found in Southwest Asia, southern and Eastern Europe, and South America. The only countries within this peripheral zone that possess fairly significant numbers (over 1 million) are Egypt and Brazil.

East and Southeast Asia

In the area east of India, the Swamp buffalo dominates and is essentially a single-purpose animal, contributing primarily to the traction needs of the agricultural system. It is in the wet rice fields of southern China and Southeast Asia that the buffalo distinguishes itself as the preferred draft animal. The humid climate, the mud, and the water suit the animal's constitution and habits. No other domesticated animal can equal the buffalo's ability to carry out the plowing, harrowing, and puddling tasks of wet rice cultivation. Its considerable weight causes it to sink deep in the mud; the flexibility of its fetlock and pastern joints, its large splayed hoofs, coarse limbs, and bulky body allow it to maintain a balanced traction in mud and water; its enormous strength enables it to pull the plow deep into the soil.

In China, the cattle to buffalo ratio is about 4:1, with the buffalo distribution limited almost entirely to the rice-growing area in the southeast. Cattle are preferred in the drier and more temperate northern and western regions (Phillips, Johnson, and Moyer 1945: 62–6; Epstein 1969: 26–32; Cockrill 1976). But in mainland and island Southeast Asia, where wet rice cultivation dominates the agricultural economies, the buffalo becomes more important. The average cattle to buffalo ratio throughout Southeast Asia is about 2:1. Three countries – Laos, Brunei Darus, and the Philippines – actually possess more buffalo than cattle.

Eastern and southeastern Asia is located beyond the traditional limits of milking and milk use in Asia (Simoons 1970). The peoples in this area generally do not include milk or milk products in their diet and exhibit high incidences of primary adult lactose intolerance.[8] A limited market for buffalo milk, however, has been found in some cities and in the small Indian and European communities scattered throughout the region.

Buffalo are rarely raised specifically for meat production or for any other purpose. Retired work animals, after having provided 10 to 20 years of service, are either slaughtered or allowed to die a natural death, at which time they contribute meat, horns, and hides to the local economy. While alive, the buffalo produces a very important by-product for the farmer – manure, a valuable alternative or addition to scarce and expensive chemical fertilizers.

Table II.G.23.1. *Population of water buffalo (based on national livestock censuses and FAO estimates for 1991)*

Region/Country	Population	Buffalo per 1,000 people
South Asia		
Bangladesh	810,000[a]	6.8
Bhutan	4,000[a]	2.6
India	77,000,000	88.4
Nepal	3,101,000[a]	158.2
Pakistan	15,031,000	118.7
Sri Lanka	981,000[a]	56.3
Southeast Asia		
Brunei Darus	10,000[a]	36.5
Indonesia	3,500,000[a]	18.6
Kampuchia	760,000[a]	18.7
Laos	1,100,000[a]	257.9
Malaysia	190,000[a]	10.4
Myanmar	2,080,000[a]	48.9
Philippines	2,710,000	42.4
Thailand	4,743,000	84.0
Vietnam	371,000	43.0
East Asia		
China (incl. Taiwan)	21,635,000	18.7
Southwest Asia and Africa		
Egypt	2,550,000[a]	47.6
Iran	300,000	5.4
Iraq	110,000[a]	5.6
Syria	1,000[a]	0.1
Turkey	371,000	6.5
Europe and the former Soviet Union		
Albania	2,000[a]	0.6
Bulgaria	26,000	2.9
Greece	1,000[a]	0.1
Italy	112,000	1.9
Romania	180,000[a]	7.8
Yugoslavia (former)	20,000[a]	0.8
Former Soviet Union	434,000[a]	1.5
South America and the Caribbean		
Brazil	1,490,000	9.7
Trinidad and Tobago	9,000[a]	6.9
Suriname	1,000[a]	2.3
World Total	142,189,000	26.4

Map II.G.23.1. World distribution of water buffalo.

South Asia

The buffalo is found in its greatest concentration in South Asia and there exhibits its greatest biological diversity and attains its greatest utility as a dairy animal. The distributions of the River and Swamp buffalo meet, and in some places overlap, in South Asia, and, although River buffalo predominate, Swamp buffalo are found in the Assam and Tamil Nadu states of India, and in Bangladesh, Sri Lanka, and Nepal (Porter 1991: 290–1). Selective breeding of River buffalo, primarily in India and Pakistan, has resulted in the formation of several distinct dairy breeds and even a few draft breeds. Probably between 15 and 20 percent of the buffalo in this region can be identified as representatives of defined breeds; the rest are nondescript local varieties (Hoffpauir 1974: 141–51).

As in eastern Asia, the buffalo in South Asia performs an important service as a work animal, especially in the wet rice fields, but this role is subordinate to that of milk production. In India, for example, only about 15 percent of all buffalo are classified as work animals, and they account for only about 10 percent of the total bovine workforce. The more versatile zebu bullock is the generally preferred work animal.

Even though the zebu outnumbers the buffalo in India by about 2.6 to 1, and buffalo account for only about one-third of the bovine population that is milked, over 60 percent of the milk produced comes from buffalo (Hoffpauir 1982: 223). In Pakistan and Nepal, fully two-thirds of the milk produced comes from buffalo (Cockrill 1974b: 605; Khan 1974: 612). Nature (presumably aided by selective breeding) has provided the buffalo with certain milk-producing abilities that are distinctly superior to those of the zebu – namely, the ability to yield more milk (usually between two and three times more), the ability to produce milk with higher butterfat content (between 6.5 and 8.5 percent, compared with 3.0 to 5.0 percent in zebu milk), and the ability to produce this milk while subsisting on poor-quality fodder (Hoffpauir 1977).

In Hindu India the slaughtering of the buffalo and the eating of its flesh is not generally practiced. This is probably explained by the general *ahimsa* (the Hindu/Jain/Buddhist principle of noninjury to living things) and vegetarian proclivities of the Indian culture, rather than by any special status similar to that of the sacred zebu. The Moslems in Pakistan and Bangladesh have no prohibition on the slaughtering of buffalo, but buffalo meat is unpopular because of the poor quality that is marketed. Most Pakistanis and Bangladeshis prefer beef (Cockrill 1974b: 535; Khan 1974: 611).

The population of buffalo in Bangladesh is far less than might be expected, given the predominance of wet rice cultivation throughout this Ganges–Brahmaputra delta area. In fact, it appears that the disasters this country has suffered in recent decades (typhoons, floods, earthquakes, and warfare) have decimated the buffalo population. Most of the buffalo still there are of the Swamp type and are used mainly for work. Small numbers of dairy buffalo have been imported, but milk production remains low (Cockrill 1974b: 533–5).

The adaptability of the buffalo to high altitudes is clearly demonstrated in Nepal, where this tropical animal is maintained in village settings as high as 9,000 feet and is taken for summer pasturage as high as 15,000 feet. In Nepal, the buffalo is truly a multipurpose animal: It provides work power, milk, manure, and meat. In the tropical lowlands of the *terai* (the northern extension of the Indo-Gangetic plain in southern Nepal), it is the preferred draft animal for wet rice cultivation; it is seldom used for work elsewhere. In the lower and middle altitudes, the buffalo is the primary source of milk. Buffalo have been introduced into Nepal from India for the purpose of improving milk production. Whether the native Nepalese buffalo are of the Swamp or River type has yet to be determined. In many mountainous locations, the buffalo is used exclusively for the production of manure, an extremely valuable resource given the low fertility of the mountain soils. Nepalese law permits the killing of male buffalo, and considerable numbers are slaughtered for ritual sacrifice and for the urban meat market (Rouse 1970, 2: 905–6; Cockrill 1974b: 603–9; Epstein 1977: 38–46; Hoffpauir 1978: 238–41).

In many ways Sri Lanka follows the typical Southeast Asian pattern of buffalo use. Its indigenous buffalo is of the Swamp type and serves primarily as a work animal in the rice-growing areas. Some buffalo milk is produced and sold in the form of curd, but generally buffalo owners are not interested in milk production. Frederick Simoons (1970: 561–3) has commented on the survival of a nonmilking attitude among the Sinhalese, the dominant group in Sri Lanka. With a population that is predominantly Buddhist and Hindu, Sri Lanka has a limited demand for meat. Only old, sick, or infertile buffalo are allowed by law to be slaughtered; so the buffalo meat that reaches the markets tends to be tough and without taste (Cockrill 1974b: 629–35; Porter 1991: 291).

Southwest Asia and Egypt

There are few environments in the dry southwestern end of Asia and northern Africa that are suitable for the buffalo. Consequently, those in Iran, Iraq, Syria, Turkey, and Egypt account for only about 2.4 percent of the world's total. The only country in this region where buffalo make a significant economic contribution is Egypt. For the Southwest Asian countries, the cattle to buffalo ratio is 26:1; for Egypt it is 1.4:1.

All of the buffalo in this region appear to be of River buffalo ancestry, having been introduced from South Asia during the first millennium A.D. According to historical records, Sassanians brought domesticated buffalo and their herders from Sind in Pakistan to the marshes of the lower Tigris and Euphrates Delta during the fifth century A.D. Buffalo were established in the Jordan Valley by the eighth century and in Anatolia by the ninth century (White 1974: 204–5). They were not known in ancient Egypt and do not seem to have appeared in the Nile Valley until about the ninth century A.D. (Epstein 1971: 567–8; Cockrill 1984: 57).

The 2.5 million buffalo in the Nile Valley of Egypt today are fully utilized for milk, work, and meat. Egyptians have thoroughly researched their productivity and have developed an efficient husbandry system. Buffalo are highly valued as milk animals and produce far more milk than cattle. Although cattle are more important than buffalo for draft purposes, the latter are used for plowing and harrowing in rice fields, for raising water from wells for irrigation, and for threshing. John E. Rouse (1970: 621–2) reported that only buffalo cows are used for work. The common practice is for male calves to be slaughtered at a very young age for veal, which brings a high market price. Female buffalo are also slaughtered for their meat, but only if they are old, infertile, or injured (Epstein I: 1971: 564; El-Itriby 1974; Porter 1991: 299–300).[9]

Not surprisingly, given the water needs of this bovine, the major concentrations of buffalo in Southwest Asia are in swampy areas and along coasts. The buffalo in Southwest Asia is esteemed only by small numbers of peasant farmers and herders who recognize the animal's unique adaptability to environments that are unable to support other livestock. Throughout this area the buffalo is valued primarily as a milk animal[10] and used very little for work, except in Turkey, where in some areas buffalo are employed in plowing and road haulage. Buffalo meat is merely a by-product from old retired animals (Rouse 1970, 2: 794, 804, 854; Cockrill 1974b: 510–32; Porter 1991: 297, 298).

Europe and Transcaucasia

The existence of the buffalo in the temperate latitudes of Italy, Greece, the Balkan peninsula, and Transcaucasia in the former Soviet Union attests to the animal's ability to tolerate cold winter temperatures. But their numbers are small – the total population being only about 775,000 – and care must be taken to keep these animals warm during the winter; cold winds and sudden drops in temperature can cause fatal illnesses, including pneumonia (National Research Council 1981: 45–6).

All European and Transcaucasian buffalo are of the River type. Historical accounts are sketchy but indicate that domesticated buffalo may have entered Europe by a route north of the Black Sea, from Persia to southern Russia to the Danube Valley and, finally, to Italy by the end of the sixth century A.D. Another likely route could have been from Turkey to Greece, the Balkans, and Italy. They were established in Transylvania by the eleventh century and were numerous in the area around Rome by the twelfth century (Bökönyi 1974: 151; White 1974: 203–6).

The discontinuous and spotty distribution pattern that characterizes the buffalo's existence in Southwest Asia is also found in Europe. In Greece, for example, 90 percent of the buffalo are found in Macedonia and Thrace. In Romania there are two concentrations, one in the central regions near Cluj and Fagaras, and another in the Danube Valley of the south. The Italian buffalo are found mainly in the southern part of the country. The only buffalo in the former Soviet Union are in the Transcaucasus region, where they are most numerous in the Kura Valley and along the Caspian coast in Azerbaijan.

Throughout most of its European and Transcaucasian distribution, the buffalo has served as a triple-purpose animal. Its use as a work animal, originally of primary importance, has declined in recent times with the mechanization of agriculture, especially in Italy, Greece, and Bulgaria. Meat production is growing in importance, although buffalo meat still comes mostly from old animals whose usefulness for work and milk production has been exhausted. The buffalo is highly valued for its rich milk, which is often made into yoghurt and cheese. In Italy, where probably the best buffalo in Europe are found, the emphasis has long been on milk production, with the highly popular mozzarella cheese the major product (Cockrill 1974b: 708, 731–5, 748–54; Polikhronov 1974; Salerno 1974; Porter 1991: 297–9).

Tropical America

Introductions of buffalo into various Caribbean and South American countries during the past 100 years have met with mixed results. Those into Bolivia, Colombia, French Guiana, Guyana, Peru, and Venezuela were apparently unsuccessful, and either the animals have entirely disappeared or their numbers have become too insignificant to be reported in recent censuses. Possibly a thousand buffalo can still be found in Surinam, derived from an 1895 introduction of Swamp buffalo from Southeast Asia, via French Guiana, to work on the sugar plantations. They are used today in logging operations and for meat production. Indian River buffalo were brought into Trinidad and Tobago during the early 1900s, also for the sugar plantations. A sizable population of about 9,000 animals has developed, and they are highly valued for their work power and meat (Cockrill 1974b: 676, 692–7, 705–7; Mahadevan 1974; Porter 1991: 300–2).

The most successful establishment of buffalo husbandry in the Western Hemisphere has been in Brazil. Numerous introductions of both Swamp buffalo (from eastern and southern Asia) and River buffalo (from India and Italy) have occurred over the last century. The nearly 2.5 million Brazilian buffalo today are concentrated in two areas, with about 75 percent in the Amazon Basin and the rest in and around the states of São Paulo and Minas Gerais. The buffalo are used primarily for milk in the latter areas, with meat production secondary although growing in importance. In the Amazon area the buffalo has found a paradise, with ideal environmental conditions. On Marajó Island, large herds of free-ranging buffalo thrive on the tropical grasses and aquatic plants. Buffalo meat and milk command a ready market in the towns of Amazonia, and the animal is also used for road haulage and riding (Gade 1970; Cockrill 1974b: 677–91; Porter 1991: 301).

The Wild Ancestor

Unlike the progenitors of many other domesticated animals, the wild form from which the domesticated buffalo originated is not only known but still survives in a few locations. Wild buffalo differ from the domesticated form chiefly in their greater size, larger horns, and generally more robust and sleek appearance.

The Plio-Pleistocene Buffalo

The evolutionary history of the wild buffalo appears to have begun about 3.5 million years ago in the northwestern corner of the Indian subcontinent. The earliest fossil to show uniquely *Bubalus* characteristics is *Proamphibos* from the upper Dhokpathan Formation (Middle Pliocene) of the Siwalik Hills (Groves 1981: 270, 276).

Within South Asia, when the conditions in the northwest became unfavorable on account of Pleistocene glaciation, the Siwalik fauna, including the buffalo, apparently migrated southward and eastward. The Middle Pleistocene form *Bubalus palaeindicus* has been discovered in the Potwar Plain of northern Pakistan as well as in the Narbada Valley of peninsular India. By the Upper Pleistocene the buffalo was found as far south as Tamil Nadu and as far east as Bihar. As revealed by bone finds and cave paintings[11] over a wide range of the Indian subcontinent, the buffalo was undoubtedly hunted by Paleolithic and Mesolithic peoples throughout the Pleistocene and into the Holocene (Map II.G.23.2 and Table II.G.23.2).

The buffalo appeared in China as early as the Middle Pleistocene (possibly between 1 million and 500,000 years ago), and its remains are often found associated with early hominids/humans in Paleolithic sites. Although most *Bubalus* finds from Chinese sites are reported as being of indeterminate species, some distinct species have been identified. A dozen Pleistocene sites in South China (south of the Qin Ling Mountains) have yielded buffalo remains.

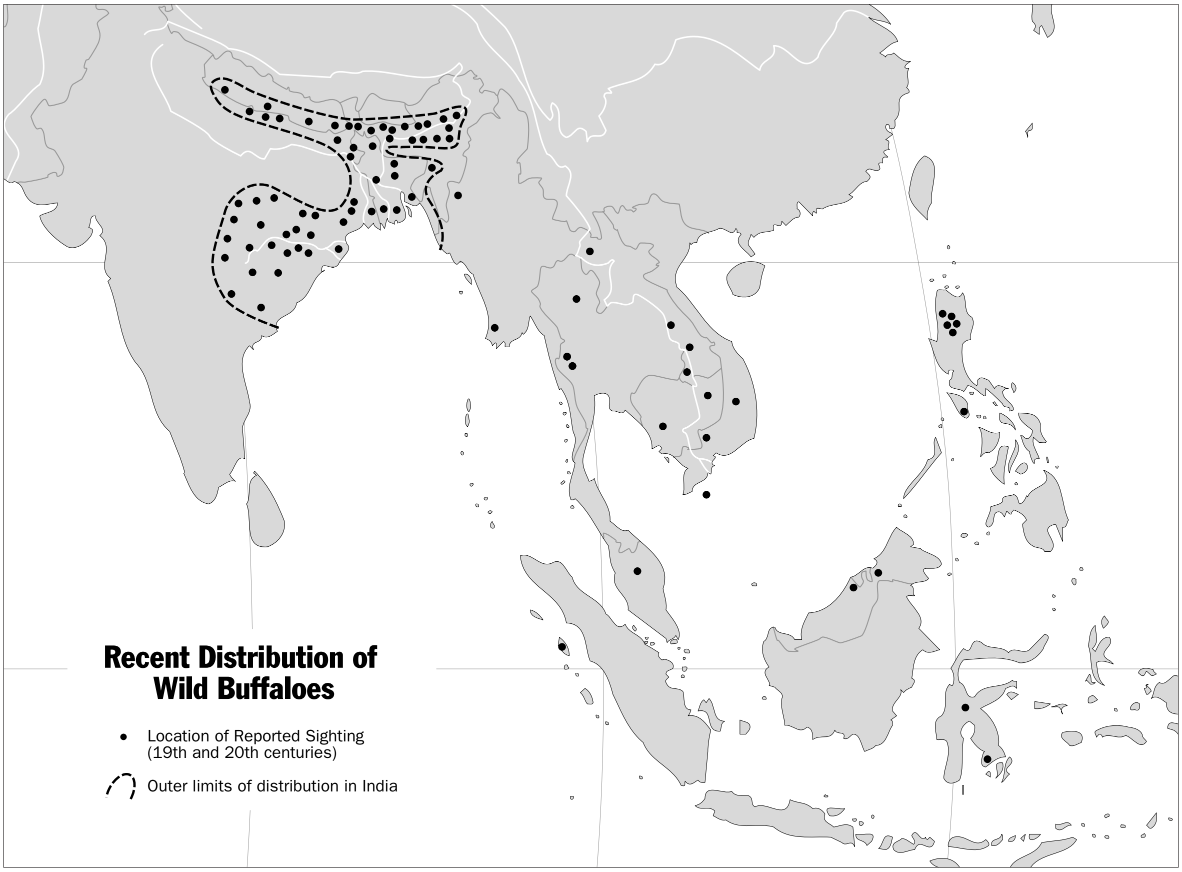
The Pleistocene buffalo that appear in North China are interpreted as immigrants from the south, and their existence as far north as 40° north latitude attests to their adaptability to cooler and drier environments. The buffalo apparently extended its range eastward from North China into Korea during the Middle Pleistocene. *Bubalus* has been uncovered at two cave sites, Sangwon Komunmoru and Tokchon. As in North China, this presence appears to represent a remarkable adaptation to what must have been a rather harsh Pleistocene environment.

Buffalo ventured out onto the land masses of the Sunda shelf probably as early as they reached China. Although no Pleistocene buffalo have been firmly identified as yet from mainland Southeast Asia, they must have existed there, or at least passed through on their way to Sundaland. A very large form of a now extinct buffalo *Bubalus paleo kerabau* inhabited Java from the early Middle Pleistocene to the early Holocene. The only other indication of the buffalo in island Southeast Asia[12] comes from the discovery of *Bubalus* in association with the Liwanian Flake Tool Tradition in the Cagayan Valley on the Philippine island of Luzon. Robert Fox (1978: 82, 1979: 229–30) has suggested that Paleolithic hunters, along with the buffalo and other typical Middle Pleistocene mammals, migrated from South China into the Philippines across the then-existing land connections via Taiwan.

A long-distance westward migration of Pleistocene buffalo is evidenced by the finding of *Bubalus* at three sites in Europe (not shown on Map II.G.23.2).[13] A form called *Bubalus murrensis* is known from the two sites at Steinheim and Schönebeck in Germany, both dated from the Mindel-Riss interglacial, about 250,000 years ago, and Riss-Würm interglacial site of possibly 100,000 years ago in the Peneios Valley of Greece. The buffalo seem to have been able to exist in Europe only during the interglacial periods and had disappeared by the beginning of the last (Würm) glaciation (Zeuner 1963: 246; Kurtén 1968: 187; Bökönyi 1974: 149–50).

Holocene Survivals

The wild buffalo probably maintained a broad range throughout southern, eastern, and southeastern Asia well into the Holocene. Evidence of *B. bubalis* has been reported from many archaeological sites in this area, dating from between 10,000 and 2,000 years ago. But whether these findings reflect locations before or



Recent Distribution of Wild Buffaloes
● Location of Reported Sighting (19th and 20th centuries)
Outer limits of distribution in India

Map II.G.23.3. Recent distribution of wild buffaloes.

after domestication is, in many cases, difficult to say because of the morphological similarity between wild and domesticated buffalo. (The significance of these Neolithic and early Metal Age findings to the question of earliest domestication is discussed later in this chapter.) Consequently, we do not have a clear picture of the distribution of the wild buffalo several thousand years ago when it probably was first domesticated.

Reported sightings during the last two centuries indicate that the wild buffalo's range has generally retreated to east of the 80° meridian in southern and southeastern Asia (Map II.G.23.3). In South Asia, the wild buffalo are known in the *terai* of Nepal, the plains of Bengal and Assam, and lowland areas in Orissa, Madhya Pradesh, and Andhra Pradesh. They are described as generally inhabiting moist lowland riverine tracts where dense and high vegetation cover, usually tall grass jungles, and nearby swamps are available.

The distribution of the wild form of a domesticated species has often proved a valuable indicator of that animal's original place of domestication. This, unfortunately, is not the case with the buffalo. All that can be concluded from the available evidence is that the wild buffalo's distribution has responded to changing environmental circumstances that have occurred during and since the Pleistocene. As conditions under which the buffalo can exist have appeared and disappeared, its range has changed accordingly. Generally, the animal's extremely broad range during the Pleistocene, especially during the interglacial stages, has been shrinking throughout the Holocene. Its recent limited distribution is best seen as merely its last remaining refuge area and not necessarily as indicative of an ancestral hearth of domestication.

Domestication

Archaeological Evidence

The most convincing and satisfying evidence for the place and time of domestication of an animal species would be well-preserved fossilized bones that can be clearly identified as to species and domesticated status. Unfortunately, such evidence is relatively rare for the buffalo because the warm and moist environments in which buffalo usually exist make the chances of good skeletal preservation poor. Even when *B. bubalis* bones can be identified, as they have in many Neolithic and Metal Age sites (Map II.G.23.4 and Table II.G.23.3), the ability to distinguish between wild and domesticated forms is hindered by the absence of clear morphological differences. Consequently, fossil evidence must be very cautiously interpreted.[14]

South Asia. The earliest indication of a possibly domesticated buffalo in South Asia comes from the Indus Valley civilization (about 2300–1750 B.C.). The evidence, collected from the two sites of Mohenjo-daro and Harappa, consists of only a few fossils (teeth, horn cores, and bones[15]), depictions on a small number of seal-amulets (Figure II.G.23.3), and two small figurines.[16] Many authorities have accepted the notion that the Indus Valley buffalo was domesticated, and some have even suggested that these finds represent the original domestication.[17] Such a conclusion, however, seems to be based solely on the fossils' structural resemblance to the domesticated form and on the fact that a few seals show the buffalo standing in front of an object that has been interpreted as a feeding trough (Figure II.G.23.3).

Evidence that the buffalo existed in the Indus Valley only in the wild state is far more convincing. There are four scenes from seals and prism-amulets that seem to depict the buffalo being hunted. In three scenes (Figure II.G.23.3) a man is shown with a foot on the animal's head, one hand grasping a horn and the other hand holding a spear about to be thrust into the beast. In another scene the buffalo appears to have attacked a number of people who are sprawled around the ground.

When the sex of the animal can be detected, it is always male. As with the depictions of all other bovines, the Indus Valley seals seem to emphasize the power and strength of the bulls rather than the services derived from them or the cows. There are no scenes of the buffalo being milked or pulling a plow or cart, and the so-called food trough also appears on other seals in front of tigers and rhinoceroses. In fact, the troughs are not shown with those animals that were most likely domesticated, such as sheep, goats, elephants, and zebu.[18] Sir John Marshall (1931, 1: 70), the original excavator of Mohenjo-daro, suggested that the troughs represent offerings of food to worshiped animals, both in the wild and in captivity. Others have interpreted the troughs as cult objects or symbols connected to sacrificial ritual (Hiltebeitel 1978: 779).

Interpreting religious content from artifactual remains is, at best, a dangerous endeavor. With the Indus Valley culture in mind, Sir Mortimer Wheeler (1968: 108) has reminded us of "the notorious incapacity of material symbols to represent the true content and affinity of a religion or belief" and of "the indivisibility of religious and secular concepts in ancient times." Much of the attempt to decipher the religion of the Indus Valley people has focused on the interpretation of one particular seal scene, called the "Proto-Siva" scene, in which the buffalo plays a prominent role (Figure II.G.23.3). The significance of the buffalo and other animals shown around the seated godlike figure and the meaning of the buffalo-horn headdress worn by the seated figure are but two of the many concerns scholars have had about this picture. Some writers have assigned an important role to the buffalo in the religious symbolism and ritual life of these people (Sastri 1957: 6–13; Sullivan 1964; Srinivasan 1975–6; Hiltebeitel 1978). If true, the implications could be profound for the question of domestication, suggesting, for example, a ceremonial motivation.

Within the riparian environment of the Indus River and its tributaries, the wild buffalo could have found

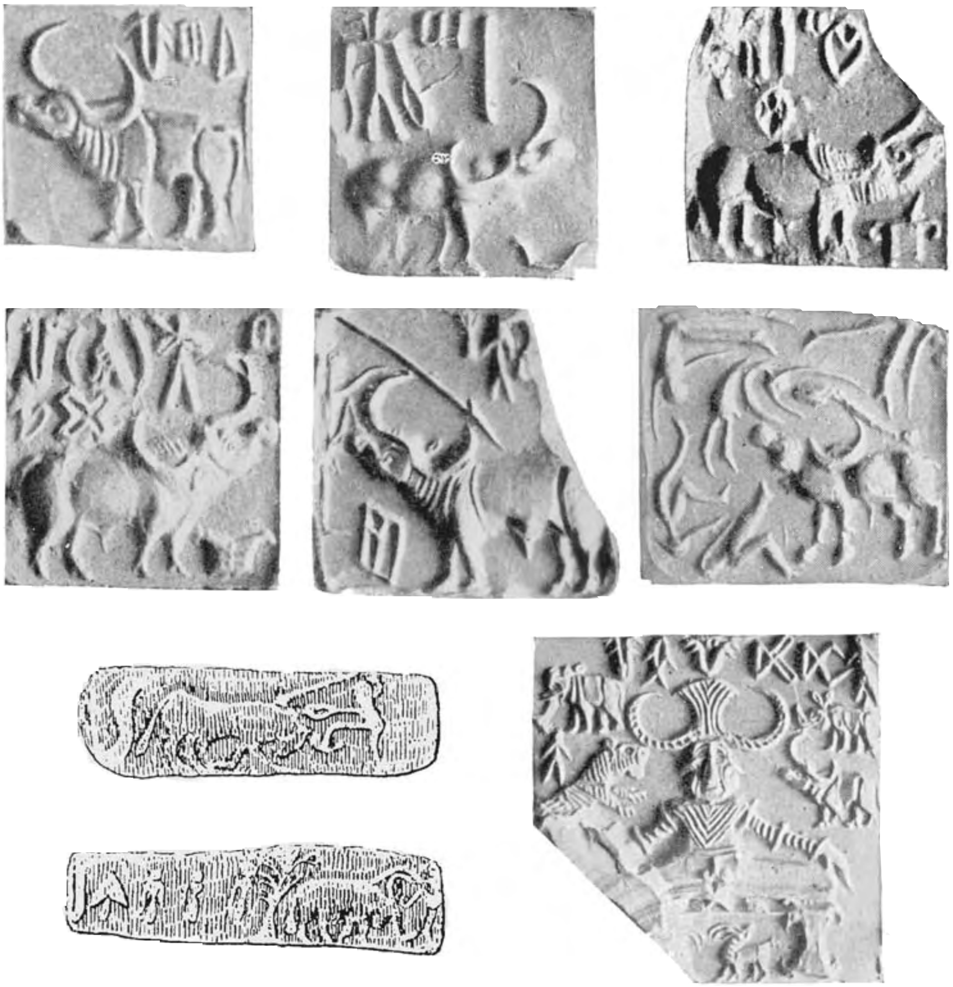


Figure II.G.23.3. Depictions of water buffalo on seal-amulets from Mohenjo-daro. (From Mackay 1937–38.)

the marshy and grassy habitats that it prefers. The safest conclusion that can be reached at this point is that the wild buffalo existed in the Indus Valley during the third millennium B.C.; it was possibly hunted for its meat and may even have played some role in the religious life of the people. But the case for the existence of the domesticated buffalo is weak and unconvincing.[19]

The buffalo appears in later archaeological sites in India (see Map II.G.23.4 and Table II.G.23.3), but the domesticated status continues to be indeterminable. Small numbers of buffalo bones have been uncovered in Neolithic and Copper Age sites, dated from the second and first millennia B.C., south and east of the Indus Valley. But the majority of the bones at these sites belong to the domesticated zebu *(Bos indicus),* and the number of buffalo bones is very small, sometimes no more than a single bone at a site. Some of the bones are charred and have cut marks on them, a clear indication that the animals were cooked and eaten. An occasional successful hunt of the wild buffalo could easily explain these remains.

The north Indian site of Hastinapura (1100 B.C. to A.D. 300) is said to reflect the expansion of the Indo-Aryan peoples from their original homeland in the Punjab region into the Ganges Valley of Uttar Pradesh. Although the fossil evidence (12 buffalo bones, some charred and with cut marks) is no more convincing than at other sites, it is probably safe to say that these were domesticated buffalo.

We can draw this conclusion because, although archaeological evidence fails us, literary evidence, at least for early historic northern India, throws some light on the question. The oldest literary work, the *Rig Veda,* which is believed to reflect Indo-Aryan culture as early as 1500 B.C., makes reference to "buffaloes yoked in fours," the eating of buffalo flesh by the gods, and the slaughtering of from 100 to 300 buffalo at a time as sacrificial offerings to the god Indra (Griffith 1963, 1: 489, 575, 2: 123, 133, 226).

The *Yajur Veda,* dating from the early part of the first millennium B.C., mentions buffalo "reared for purposes of cultivation" (Chand 1959: 234). Although no earlier references exist, it appears that at least by the time of the writing of the Sutras (about 800–300 B.C.), the use of the buffalo for milk was well established (Bühler 1882: 73, 1896: 63; Jolly 1900: 166, 167).

This record probably represents the earliest use of the buffalo as a dairy animal anywhere. Although literal interpretations of this ancient literature are not always possible, it would seem safe at this point to conclude that the buffalo was a domesticated animal in northern India at least 3,000 years ago. For the wetter eastern parts of India, where environmental conditions suit the buffalo particularly well, archaeological and literary evidence is notably scarce. Consequently, the antiquity of the domesticated buffalo in eastern India cannot, as yet, be clearly shown.

Southwest Asia. Mesopotamia presents us with a situation very similar to that of the Indus Valley. The buffalo was undoubtedly well known in ancient Mesopotamia, but its domesticated status is disputed. One site in northern Iraq (Grai Resh), dating from the Uruk culture period (about 3500 B.C.), has yielded a horn core of a buffalo. Most of the remaining evidence is representational, coming from depictions on cylinder seals from the third millennium B.C. Arguments in favor of the buffalo's domesticated status rely mainly on scenes showing the animal in the company of humans (or possibly gods or mythical heroes), in some cases being watered and fed by the human figures (Figure II.G.23.4). Some supporters of this argument propose that the buffalo was actually domesticated by the Sumerians or Akkadians, and others suggest that the animal was imported from the Indus Valley already in a domesticated state.[20] These seal scenes might well reflect, as suggested by Henri Frankfort (1939: 85–94), religious and mythical symbolism, or maybe just artistic imagination or descriptive design. Wild buffalo probably existed at that time in the swamps of the Tigris and Euphrates Delta and could easily have inspired the seal depictions (Duerst 1908: 360–2; Ward 1910: 414–5; Bodenheimer 1960: 50, 102; White 1974: 202).

Whether wild or domesticated, buffalo seem to have disappeared from Mesopotamia possibly by the end of the first millennium B.C., although they may have survived longer in other parts of Southwest Asia. Frederick Bliss (1894) reported that fossil water buffalo teeth, dated between 1700 and 500 B.C., were found at Tell el Hesy, near Gaza in ancient Palestine. Buffalo bones were also found in post-Hittite layers of Boghazköy in north central Turkey, dated between the twelfth and seventh centuries B.C. (Bökönyi 1974: 151). A Sassanian seal depiction of a buffalo (illustrated in Bivar 1969: 83, plate 15 EM1) indicates that the buffalo still existed (or at least was still remembered by artists) in northern Iraq or Iran during the first half of the first millennium A.D.

China. Because of the close association of the domesticated buffalo with wet rice cultivation throughout southern and eastern Asia, some authors have suggested the possibility that the buffalo was originally domesticated as a work animal in the rice-growing area. They usually point to southern China or the

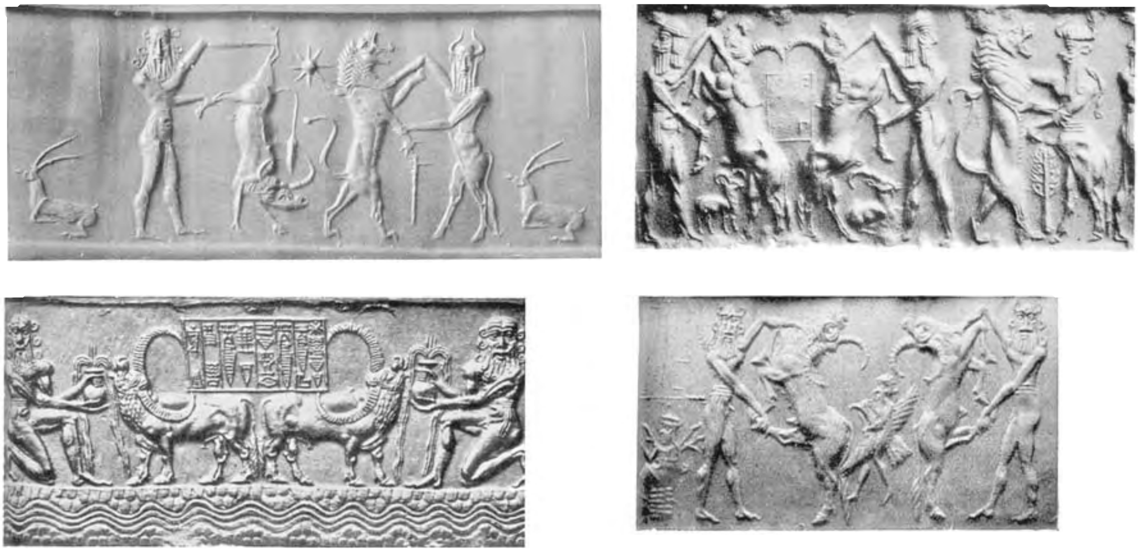

Figure II.G.23.4. Depictions of water buffalo on cylinder seals from Mesopotamia (Akkadian dynasty, about 2300–2100 B.C.). (From Frankfort 1939.)

mainland of southeastern Asia (Zeuner 1963: 251; Bökönyi 1974: 150–1; Clutton-Brock 1981: 140). Until recently there was no archaeological evidence to support this contention. But that has all changed with the astonishing archaeological finds in China during and since the 1970s.

Between about 6,500 and 4,500 years ago, two closely related Neolithic cultures coexisted near the mouth of the Yangtze River; the Ma-chia-pang culture was located north of Hang-chou Bay, and the Ho-mu-tu culture was located to its south. This was a "subtropical, fresh-water wetlands environment of the coastal plain" that was "crisscrossed by rivers and streams and dotted with large and small lakes, ponds, and freshwater marshes" (Smith 1995: 124).

Large quantities of refuse reveal that these people were rice cultivators who probably kept domesticated pigs, dogs, and buffalo. Although the buffalo bones found there are no easier to distinguish as domesticated than at other sites, the unusually large number of bones does indicate a heavily exploited resource. Buffalo shoulder blades were lashed to wooden handles and used as spades, which were the main cultivation tools; no plows were used. Since these people evidently were skilled hunters and fishermen, it could be reasoned that large numbers of wild buffalo existed in the area and were intensively hunted.

If, however, the buffalo was domesticated, which seems to be the unanimous opinion of the excavators and analysts, it undoubtedly was kept for its meat (and shoulder blades); other uses are impossible to determine at this time. It is possible that even without the plow the buffalo might have been used to prepare the rice fields. As is practiced by many rice farmers in South China and Southeast Asia today, the soil can be thoroughly puddled merely by driving one or more buffalo around in the flooded field (Ho 1975: 72).[21] However, the finding of buffalo in association with cultivated rice does not necessarily imply that the animals were actually used in the cultivation process.

Radiocarbon dates place these buffalo in the fifth millennium B.C. Thus, if domesticated, they are the earliest ones known anywhere in the world (Pearson 1983; Chang 1986: 196–201, 208–11; Zhao and Wu 1986–7; Smith 1995: 124–7).[22] Domesticated rice and buffalo have also been found as part of the Liang-chu culture (4000–2000 B.C.), which, although known since the 1930s, is now considered an outgrowth of the Ma-chia-pang culture in the same Yangtze Delta area.

The next appearance of the buffalo in a Neolithic context is in northern China at sites dated from the third millennium B.C. The earlier Neolithic cultures of North China (between 5500 and 2500 B.C.) appear to have been based on the hoe cultivation of millets and the keeping of domesticated pigs, dogs, and chickens. Although a few bovine bones have been found, their identity and domesticated status are uncertain (Ho 1975: 91–5; Smith 1995: 133–40). Bovine remains, claimed as domesticated, are more frequently encountered at later sites, with most identified as *Bos* sp. and only a few as *Bubalus* sp. (from Shaanxi Province).

By early historic times in northern China (second millennium B.C.), the domesticated buffalo seems to have been well established, as the remains from the Shang Dynasty sites near An-yang suggest. Bones identified as belonging to the species *Bubalus mephistopheles* were found in great abundance. Authorities believe that buffalo were able to exist this far north because the climate, as surmised from paleontological and palynological evidence and oracle bone inscriptions, was warmer and wetter than it is today. There seems to be little doubt that these buffalo were fully domesticated, along with cattle, pigs, dogs, sheep, and goats.

Southeast Asia. Archaeology has not been able to offer much support for the rather popular assertion that peninsular Southeast Asia was the place of origin for the domestication of rice and, by association, the buffalo. The oldest presumably domesticated rice in Southeast Asia (from the Non Nok Tha and Ban Chiang sites in Thailand) dates only from the fourth millennium B.C., which makes it at least 1,000 (and possibly 3,000) years younger than the earliest Chinese rice. Demonstration of a great antiquity for the domesticated buffalo has also eluded archaeologists.

One early site in northern Vietnam has yielded buffalo remains dating from about 8000 B.C. Vietnamese archaeologists have suggested that this site, Bo-lum, and the many others belonging to the Bacsonian culture could be associated with the beginnings of agriculture (fruit trees, tubers, leguminous plants, and hill rice) and animal husbandry (dog and buffalo). But this claim appears to be based solely on the assumption that polished stone tools and pottery, which are found at the Bacsonian sites, imply an early Neolithic agricultural society. It is with greater confidence that we can approach the assertion that wet rice cultivation with buffalo-drawn plows existed in northern Vietnam by the time the Bronze/Iron Age Dong Son culture appears (600–400 B.C.). This claim is based on the finding of rice remains and bronze plowshares (Bellwood 1985: 273–5).

The most significant Southeast Asian evidence relating to the buffalo comes from the site of Ban Chiang in the Sakon Nakhon Basin of northeastern Thailand. An analysis of the faunal remains by Charles Higham and Amphan Kijngam (1979, 1985) has shown that the buffalo made its appearance here about 1600 B.C., coinciding with the first appearance of iron metallurgy. Remains of rice have been found throughout the site's occupation period, going back to about 3500 B.C.

Based on the size of the buffalo bones, which are considerably smaller than those of wild buffalo, and on the fact that the buffalo phalanges showed stress areas (indicative of plowing) similar to those found on modern work buffalo, the authors concluded not only that the Ban Chiang buffalo was domesticated but that it was used for plowing. No prehistoric plows have been found at this or any other site in Thailand. Higham and Kijngam reasoned that before 1600 B.C. the people of Ban Chiang were probably collecting wild rice and practicing swidden rice cultivation. With the introduction of the buffalo and iron, the agricultural system changed to an inundation system of wet rice farming. Two other sites in the Sakon Nakhon Basin show similar patterns, with buffalo absent from the earlier levels and appearing only in the later periods, apparently about the same time (during the second millennium B.C.) as they do in Ban Chiang.

Ethnographic Evidence

When archaeological findings are unsatisfyingly fragmentary, as is certainly the case with the buffalo, we search for any other possible indicators of the prehistoric past. The use of ethnographic evidence is based on the shaky assumption that primitive people living today or in the recent past can provide us with a glimpse, via extrapolation, of ways of life that may have existed long ago.[23] Drawing conclusions from such evidence must be done with great caution. Sometimes several different, yet equally reasonable, scenarios can be postulated.

A cursory investigation of the position of the buffalo among the primitive tribal societies of southern and eastern Asia reveals a surprisingly widespread pattern of use that might suggest an early motive for keeping and domesticating the buffalo. Most of these tribes inhabit hilly regions, practice the plowless shifting cultivation of dry rice, and do not drink milk.[24] Consequently, they usually do not keep domesticated animals for milk production, plowing, or other work.

Yet in spite of the absence of any of these economic uses, many groups do keep domesticated bovines. These animals are slaughtered and their meat eaten, but the motive is not simply the secular dietary desire for meat, which is met by the hunting of wildlife in the nearby forests. The major purpose for keeping these animals is for sacrifice, and their meat is eaten only at ceremonial feasts. Within the southern and eastern Asian realm, the buffalo is the bovine most frequently used for this purpose. Only a few tribal groups prefer other domesticated bovines as sacrificial victims, such as the zebu among a few tribes in India and the mithan among the groups inhabiting the eastern Himalayas and the India–Burma border region. Tribes practicing buffalo sacrifice are scattered throughout the Indian subcontinent, across mainland Southeast Asia, in parts of southern China, and in the hilly interiors of the islands of the Philippines (Map II.G.23.5 and Table II.G.23.4). All of the occasions for buffalo sacrifices are broadly related, in one way or another, to the desire to enhance or maintain the well-being of an individual or community – fertility in its broadest sense.

Economic or Religious Motivation

Given the obviously useful contributions of domesticated bovines to the economic life of humans, it is not surprising that most attempts to explain their origin seek rational and practical motives. Eduard Hahn (1896) was one of the earliest scholars to propose a thesis on cattle domestication that did not conform to the principles of materialistic rationalism. He was the first in a line of speculators who argued that cattle were originally domesticated not for milk, meat, or traction, but to provide sacrificial victims for the worshiped deities.

Those who followed with sympathetic support, similar premises, and further research included, most notably, Carl Sauer (1952: 88–94), Erich Isaac (1962), and Frederick and Elizabeth Simoons (1968: 234–58). These scholars have pointed out the widespread Eurasian distribution and antiquity of a complex of traits that link bovines, sacrificial practices, and fertility rites. Simoons and Simoons (1968: 261–2) postulated that taurine cattle were the first to be domesticated in this ceremonial context, followed by the buffalo in imitation of cattle, and then by the mithan in imitation of the buffalo.

In the case of the domestication of the water buffalo, we have very little concrete evidence and can offer only speculations that seem to accommodate the fragmented information we have. Nature has provided a massively built and formidable bovine that is ideally suited to tropical and swampy lowland environments. Paleontological evidence places the ancestor of this creature in southern and eastern Asia. Wild buffalo have seemingly adapted to a wide range of habitats as their distribution has expanded and contracted throughout the course of the Pleistocene and Holocene. Until the next discovery, currently available archaeological evidence points to southern China during the fifth millennium B.C. as the most probable place and time for the earliest domestication of the buffalo.

With the invention of the plow, the buffalo's contribution to the wet rice cultivation process was fully realized. Thus far, the earliest indication of the buffalo–plow–wet rice complex comes from northern Thailand about 3,600 years ago at the Ban Chiang site. It is postulated that this complex diffused into the Indo-Malaysian archipelago roughly 1,000 years later (Bellwood 1985: 205, 241–4). This line of thinking, which focuses on the evolving economic benefits accrued from the domesticated buffalo, would fulfill the requirements of materialistic rationalism. If ethnography can be transposed to the Neolithic, an alternative scenario can also be envisioned. Buffalo might have been initially tended for their religious and social value, rather than their economic value. A belief that the sacrificing of buffalo would be repaid with fertility and well-being could have motivated people to begin domestication. To conform with the archaeological evidence, it could be hypothesized that this buffalo sacrificing fertility cult initially developed in South China. Buffalo sacrificing has been reported among the early Thai (Eberhard 1968: 183–93, 216) and the traditional Miao peoples (Mickey 1947: 78–80; Beauclair 1956: 29–31) of that area. This sacrificial complex could have diffused southward into mainland Southeast Asia and from there westward into India.

By historic times, both buffalo systems – the primitive hill farming system with the sacrificial buffalo and the sophisticated lowland rice paddy system with the plow buffalo – were well established and widely distributed in southern and eastern Asia. Archaeology has not, as yet, been able to sort out the chronological relationships between the two systems. The suggestion that the sacrificial buffalo system is antecedent to the plow buffalo system is based primarily on ethnohistorical traditions that commonly identify the hill peoples of southern and eastern Asia as being the indigenous inhabitants and indicate that settlement and cultivation of the lowland plains came later. Without evidence to the contrary, we further assume that the recent cultural practices of these tribal peoples represent survivals from a much earlier time that have been preserved by the groups' relative isolation. Obviously, caution must accompany our speculation.

The popular archetypal image that many Westerners have of the water buffalo is as the lumbering beast of burden patiently pulling a plow and a frail Asian farmer through a flooded rice paddy. Although this may be an accurate depiction of the animal's economic value to humans, it may not reflect the original value conferred upon the water buffalo when it was first brought under domestication. We must consider an additional image of the buffalo as a powerful, virile symbol of fertility that is tied to a sacrificial post and about to be ceremonially slaughtered as an offering to the supernatural.

Biological, archaeological, and ethnographic evidence provides us with only a few fragments with which to construct images. As we try to fit the pieces together, we hope that the images that emerge, as preliminary and speculative as they may be, will be the result of objective, multidimensional analysis that has considered economic, religious, and all other relevant factors.

Robert Hoffpauir

Notes

1. Compilations of available knowledge of the buffalo have appeared from time to time, including Roderick MacGregor (1941), Bradford Knapp (1957), D. C. Rife (1959), W. Ross Cockrill (1967, 1974b, 1976), M. R. de Guzman and A. V. Allo (1975), and National Research Council (1981).
2. The present author's past work on the buffalo has included some cultural and historical considerations in an attempt to understand the current buffalo situation in South Asia (Hoffpauir 1968, 1974, 1977, 1982). Whereas several studies could be cited as examples of the cultural–historical approach to the analysis of domesticated animals, Frederick and Elizabeth Simoons's (1968) masterful study of the mithan *(Bos frontalis)* stands as the model of this approach.
3. Two earlier attempts to address specifically the domestication of the buffalo have revealed how little we know. Frederick Zeuner's often-cited survey, *A History of Domesticated Animals,* devoted only an 8-page portion of one chapter to the buffalo (1963: 245–52), and more recently, Cockrill (1984) contributed a short chapter on the buffalo to Ian L. Mason's anthology, *Evolution of Domesticated Animals.*
4. The term "bovine" refers to those animals that have been classified in the order Artiodactyla, suborder Ruminantia, family Bovidae, subfamily Bovidae. This includes European

domestic cattle,* zebu cattle,* gaur, mithan,* banteng, Bali cattle,* *kouprey,* domestic yak,* wild yak, American bison, European bison, wild Asian buffalo, domesticated water buffalo,* *anoa, tamarau,* and African buffalo. (Asterisks [*] indicate the domesticated forms.)

5. The *anoa* (confined to the island of Sulawesi in Indonesia) and *tamarau* (confined to the island of Mindoro in the Philippines) are still usually classified under the *Bubalus* genus (*Bubalus depressicornis* and *Bubalus mindorensis,* respectively). The mountain *anoa* is sometimes given separate species status under the name *Bubalus quarlesi.* The African buffalo is now regarded as a more distantly related animal requiring a separate genus designation, *Syncerus caffer.*
6. The literature on the environmental physiology of the buffalo is reviewed by Knapp (1957: 37–42) and Mason (1974).
7. This section of the chapter focuses only on the present-day economic contributions of the buffalo. The importance of the buffalo in the socioreligious realm is of great cultural–historical significance, at least in this author's opinion, and is discussed later in the chapter.
8. For comments on those rare situations of milking and milk consumption in this region, the reader is referred to Simoons (1970: 570–7) and Paul Wheatley (1965).
9. Recent experimental introductions of very small numbers of buffalo have occurred in other parts of Africa – specifically in Mozambique, Tunisia, Madagascar, Uganda, Tanzania, Nigeria, Zaire, and Congo – but their current status is unknown (Porter 1991: 300).
10. Esteem for the milk buffalo as an economic resource probably reaches its highest cultural expression in Southwest Asia among the Marsh Arabs (the Ma'dan) of southern Iraq. These "buffalo people" have developed an elaborate cultural system focused on the husbandry of buffalo. The reader is referred to the ethnographic descriptions by Wilfred Thesiger (1954, 1964).
11. For a discussion of the prominent role played by wild buffalo in the cave art of Mesolithic India, see Yashodhar Mathpal (1984, 1985) and V. N. Misra (1985: 119–20).
12. The often-cited identification of two teeth of Upper Pleistocene or early Holocene date found at Niah Cave in northern Borneo as belonging to *Bubalus* (Koenigswald 1958: 624–5) has been disputed by Lord Medway (1965: 162), who believes the teeth could just as well belong to *Bos javanicus,* the Banteng.
13. It was once commonly thought that buffalo named *Bubalus antiquus* roamed over North Africa from the late Pleistocene to the Holocene, as revealed by bone finds and rock paintings and engravings created by Paleolithic and Neolithic hunters (Wulsin 1941). Current opinion, however, identifies these animals as members of the *Syncerus* genus (Zeuner 1963: 245–6). More than 100 years ago, Richard Lydekker (1898: 116) suggested that these buffalo might better be regarded as ancestral to the African buffalo.
14. Unless otherwise mentioned, the sources used for the following discussion of archaeological sites are listed in Table II.G.23.3.
15. For a description of the buffalo remains found at Harappa, see Baini Prashad (1936: 43–6).
16. From Mohenjo-daro, Sir John Marshall (1931, 2: 386) listed only three seals showing buffalo, and E. J. H. Mackay (1937–8, 1: 298, 311, 330, 358–9) recorded one pottery figurine, one bronze figure, eight seals, and two prism-amulets. From Harappa, Madho Sarup Vats (1940: 323) published only two fragmented seals.
17. See, for example, Marshall (1931, 1: v), Prashad (1936: 8–9), M. S. Randhawa (1946: 10), Stuart Piggott (1950: 155–6), V. Gordon Childe (1957: 176), Kaj Birket-Smith (1965: 151), C. D. Darlington (1970: 55), Henry Hodges (1970: 252), and Cockrill (1984: 55).
18. H. F. Friedrichs (as cited in Mackay 1937–8, 1: 670–1) argued that the presence of the trough before the buffalo, tiger, and rhinoceros indicates that these animals were kept under restraint, that is, that they were not as yet fully domesticated. The symbol was not needed in front of the zebu, sheep, goat, and elephant because these animals were more domesticated and possibly kept in pastures where a feeding trough would be unnecessary.
19. A few authors have indicated their uncertainty about the buffalo's domesticated status in the Indus Valley (Zeuner 1963: 249; Bökönyi 1974: 151; Clason 1977: 268). One writer, D. D. Kosambi (1965: 60), has even expressed the opinion that the buffalo was probably not domesticated in the Indus Valley.
20. Those who have supported the idea of a domesticated buffalo in ancient Mesopotamia include Seton Lloyd (1947: 7), Berthold Klatt (1948: 34), Samuel Noah Kramer (1967: 88), H. Epstein (1971: 569), S. Bökönyi (1974: 151), and Cockrill (1974b: 516, 1984: 56). Zeuner (1963: 249–50), although finding the evidence strongly suggestive of "tame, if not domesticated" buffalo, does admit that the question "remains to be settled." At least one author (Kingdon 1990: 136) has expressed the opinion that Mesopotamia is the place of earliest domestication of the buffalo. Presumably, these authors believe that the buffalo was kept primarily as a meat source, as no evidence has been presented for the buffalo being used for milk or work. Dominique Collon (1987: 187) says that buffalo – she does not specify wild or domesticated – may have been imported from the Indus Valley for the royal zoos during the time of Sargon of Akkad. Epstein (1971: 569) bolsters his argument for the existence of the domesticated buffalo with an ancient Assyrian clay tablet (from about 2000 B.C.) showing the head of a buffalo with "horns curved in a manner that is occasionally encountered in domestic buffaloes but never in the wild beast." Lynn White, Jr. (1974: 202) counters this argument by pointing out that wild African buffalo *(Syncerus)* have such horns.
21. For a long time, the thought has been that the animal-drawn plow was not part of the original technique of wet rice cultivation but was added later (Pelzer 1945: 14). It has been hypothesized that the original form of rice cultivation involved broadcasting the seed onto naturally swampy or seasonally flooded lowland areas. The archaeological findings in the Yangtze Delta appear to be consistent with this hypothesis. The swidden cultivation of dry rice and the irrigation cultivation of wet rice, it is suggested, developed later (Harris 1974: 142; Gorman 1977: 338–40). Initially, no animals may have been used. Buffalo involvement in rice cultivation might have started with the use of the animal for puddling; perhaps only later was it attached to a plow. Wolfram Eberhard (1968: 215) contends that among the Thai of southern China, the practice of plowing, which was adopted very late, was anteceded by letting buffalo trample the fields. R. D. Hill (1977: 85, 98, 133, 161, 177) documents this practice during the nineteenth century in Malaya and Siam. It seems to have been widespread among many different groups, such as the Rhadé (LeBar, Hickey, and Musgrave 1964: 252) and Maà' Huang (Condominas 1980: 246) in Vietnam and Cambodia, the Savunese in the Savu Islands of Indonesia (LeBar 1972: 77), the Lampong in south Sumatra (Loeb 1935: 266), the Kalabits in north Borneo (Hose and McDougall 1912: 97–8), and the Kalingas of northern Luzon (Lawless 1975: 82–3).
22. The only evidence of rice cultivation earlier than the Yangtze Delta finds is from the eastern end of the Yangtze

Valley at the site of Peng-tou-shan in the Hupei Basin, dated at between 6400 and 5800 B.C. No evidence of domesticated animals has been uncovered from this site as yet (Smith 1995: 130–1). Rice cultivation cannot be documented before 3600 B.C. in Southeast Asia or before 2500 B.C. in India (Bellwood et al. 1992). Thus far, the oldest evidence of both rice and buffalo domestication comes from the Yangtze Valley of China.

23. The value of this ethnographic approach, when carefully executed, is demonstrated by Simoons and Simoons's (1968) study of the mithan. In the absence of archaeological evidence, a skillful use of ethnographic evidence allowed Simoons and Simoons to develop a very convincing hypothesis for the domestication of this bovine.
24. For the purposes of this discussion, I employ the convention of speaking in the "ethnographic present." Some of the sources used describe conditions as they existed during the late nineteenth and early twentieth centuries. Subsequent acculturation has undoubtedly obliterated many of the (presumably) traditional practices originally observed and described.

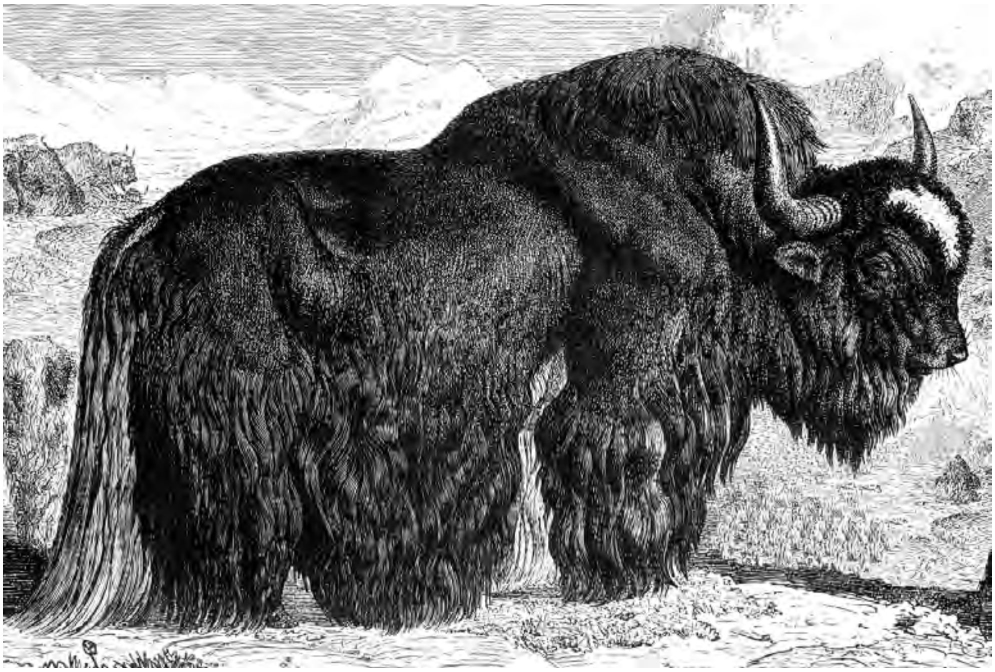
II.G.24 ~ Yak

Despite recent interest in domesticated animals in general and bovines in particular, there has been little systematic study of yak.[1] Nevertheless, enough is known to warrant a closer consideration of the role these cattle play in the culture, diet, and ecology of the several peoples who exploit them in some of the harshest and most difficult environments of Asia.

Taxonomy, Description, and Habitat

Yak are members of the subfamily of cattle Bovinae.[2] Although the genetic relationships among its members are not precisely understood, Herwart Bohlken (1958: 167–8, 1958–60: 113–202) argues that yak belong to the genus *Bos* and subgenus *Poëphagus.* Moreover, Bohlken draws a further distinction between wild yak, *Bos [Poëphagus] mutus* Przhelval'skii (1883), and domesticated yak, *Bos [Poëphagus] grunniens* Linnaeus (1766). Although wild and domesticated yak are interfertile, domesticated yak can be crossed with a variety of other cattle, including common cattle *(Bos taurus),* and zebu *(Bos indicus)* to produce hybrids of various types.[3]



Yak

Both wild and domesticated yak are massively built, with barrel-shaped bodies carried on legs that are quite short but solid (see Figure II.G.24.1). Although yak have no humps (as zebus do), they do have a dorsal ridgelike prominence that adds to their massive appearance. From this prominence, a short heavy neck slopes downward, ending in a large head with a broad, flat forehead, large eyes, and small ears.

Probably the most conspicuous features of the yak, however, are its horns and hair. The horns are large, dark, and double-curved. That is, they emerge horizontally from either side of the head, curve and extend first upward, then backward. The hair is coarse and shaggy and covers the animal's body almost entirely. The hair is abundant and is generally 4 or more inches in length. Fringing the chest, lower shoulders, sides, flanks, and thighs of the yak is even longer hair, which almost reaches the ground. The tail, too, is entirely covered by long hair, giving it a pronounced bushy appearance.

Wild yak are characteristically black or dark brown, occasionally with lighter colors on the forehead and along the back. Domesticated yak, in contrast, are much more variable in color. They range from black to white, and even piebalds are common.

Large numbers of wild yak once roamed over much of Tibet and the high Himalayas, though they have decreased in numbers and range. Today, only small herds occur, and only in certain restricted and inhospitable places, including small portions of the great mountain ranges of Inner Asia (the Tien Shan, Kunlun Shan, Pamirs, Karakorum) and the most remote areas of the Greater Himalayas. They are also found in small numbers in the dry Changtang, a vast, virtually uninhabited plateau that sweeps across northern Tibet in a great arc, extending from the Tibet–India border in the west to the Koko Nor region in the east.

In the better watered areas of the Changtang, small herds of wild yak give way to the large herds of domesticated yak managed by pastoralists. Domesticated yak also thrive in the more moist regions of Mongolia and central Asia and in the deep river valleys and small plains of southern and eastern Tibet, as well as along the high, south-facing flank of the Himalayas. Here, temperatures are higher, rainfall is much greater and more predictable, and vegetation is more abundant. These are regions occupied by farming folk, who are far more numerous than the pastoral nomads of the plateaus.

Yak in Culture and Diet

Wherever yak are kept, they are a central element in human ecology and adaptation. Farmers, for example, use these animals for a variety of agricultural purposes, including plowing and threshing. Among pastoral nomads, yak are a source of hair for tentcloth and may be employed in caravan work. For transhumant populations in mountainous regions, who combine certain aspects of pastoral and agricultural economies, yak are employed in these and other ways to wrest a living from often fragile environments. But most important, perhaps, to those who keep yak is the role the animal plays in the direct provision of food for human consumption and nutrition. In this regard, any detailed consideration of the wide variety of useful dietary products supplied by yak must focus on meat, milk, milk products, and blood.

Meat

Although most yak-keeping folk profess Buddhism, a religion that encourages a vegetarian diet by forbidding the slaughter of animals, few abstain from meat eating. Quite the opposite seems to be the case. Flesh foods are relished by most of these people, and every attempt is made to include at least some meat in the main meal each day. This is not always possible, however, because in most regions meat is a seasonal commodity and, in any case, is expensive.

The Buddhist prohibition of slaughter stems from a central concept in Buddha's teachings: *ahimsa.* Slaughter and meat eating compromise Buddhist yakherders and are a source of guilt, for they contribute to the suffering and death of yak. To escape guilt, people slaughter yak in ways that rationalize and minimize responsibility. For example, calves may be denied the milk of their mothers. Since such animals starve and blood is not shed, death is considered a matter of fate and not the result of human action.

When slaughter by starvation is not practical, other methods are employed. Adult yak, for example, can be suffocated with a cord tied tightly around the animal's mouth and nose. And according to Marion H. Duncan (personal communication), Tibetans of Kham in eastern Tibet fit a leather sack tightly around the animal's muzzle, thereby cutting off air.

Perhaps the most common method of minimizing guilt is to give yak over to a hereditary group of professional butchers for slaughter. Such butchers absolve others of moral responsibility in the affair and are considered damned for their transgressions. Many butchers form a distinct caste in Buddhist societies. Others, such as those of Lhasa, are Moslems, originally from Ladakh or Kansu, who do not adhere to the *ahimsa* concept.

Although the slaughter of yak by butchers takes place throughout the year, especially in larger settlements, slaughtering by farmers and nomads is a seasonal affair. Most are killed in late autumn or early winter when the animals are well fleshed from spring and summer grazing. This is the time of year when winter temperatures facilitate preservation and storage of meat; the timing of the slaughter also reflects an attempt, in regions of limited pasturing opportunities, to minimize overgrazing and herd losses by careful control of herd size.

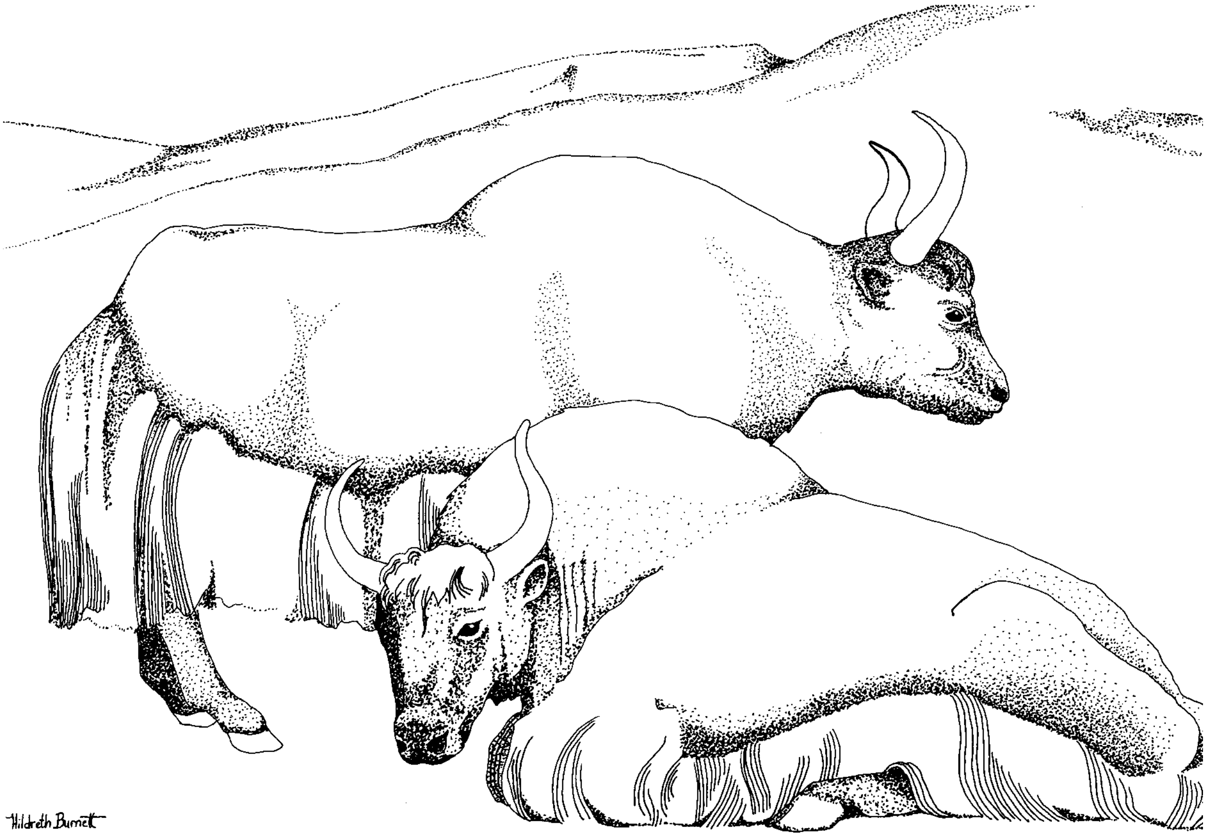


Figure II.G.24.1. Domesticated yak. (Drawing by Hildreth Burnett.)

Selection of yak to be slaughtered in late autumn or early winter is not random. Rather, each animal is carefully considered, and those deemed least able to survive the harsh winter months are culled out first. To these are added others that are considered poor economic investments. Such yak are usually the male cattle, often yak bulls too old, too sick, or too weak for traction or burden. Female yak are selected if they are dry or past the age of breeding. Selective slaughter, thus, not only provides an abundance of meat but also enhances the ability of the remaining cattle to survive the deprivations of winter. In addition, it results in a more efficient allocation of pasturing and other resources and a more efficient and economical herd.

Meat not eaten immediately after slaughter must be preserved or traded. If fresh meat is traded, distances involved are very limited – within a village, for example, to folk who have little access to meat and who pay cash, barter goods, or provide services in exchange. If properly preserved, however, such meat can be kept for months, even years, and traded over great distances.

Yak meat is preserved in a variety of ways. The lower temperatures of the slaughtering season may be used to freeze it. The meat is also salted and smoked, but drying is by far the most common method of preservation. Carcasses of slaughtered yak may be simply cut into joints, which are hung outdoors. The joints slowly dry, often shrinking to half their original size.

More commonly, the beef is cut into thin strips, which are set out in the sun to dry, sometimes on cloths spread over the ground, more often on racks erected for this purpose. Beef jerked in this way is very popular in Tibet and the high Nepal Himalaya.

Not only does drying preserve meat, it also reduces its weight, allowing more to be carried on long journeys. In wintertime, dried meat is an important item of barter and sale. This is especially true for pastoral nomads, who use meat and other animal products to trade for the carbohydrate-rich plant foods of farmers and transhumant folk.

Meat also plays a prominent role in the diet of most yak-keeping peoples as a ceremonial or feast food. Among more prosperous families, meat of some kind is eaten nearly every day, but because of the expense involved, poorer families eat meat only occasionally. Whenever possible, however, even the poorest will try to offer a meat dish to visitors and guests. When unable to do so, apologies are given or excuses made.

Not everyone eats yak meat, however, and even those who do often abstain from certain kinds of flesh or from flesh prepared in proscribed ways. Some Tibetans, for example, consume the flesh of yak and female hybrids eagerly but refuse to eat the flesh of male hybrids. When asked why, they reply that male hybrids are sinful animals and their flesh is polluting.

Yak meat that has been roasted, broiled, or fried is considered polluting and impure by virtually all Tibetans and Himalayan Buddhists.[4] Some Tibetan nomads believe that consumption of flesh prepared in these ways will result in sickness or bad luck – the punishment of gods angered by the odor of scorched flesh. Although many farmers and transhumant peoples agree with this pastoral nomadic belief, perhaps in an attempt to emulate this more prestigious group, others strike a compromise. According to them, the indoor roasting, broiling, and frying of meat produces odors that house gods find offensive. If, however, meat is prepared in these ways outside the home, it can be eaten with no harmful effects. In any case, the most common method of cooking yak and hybrid meat is boiling, a method acceptable to all. But flesh is also eaten uncooked, whether fresh or preserved.

In a few areas of Tibet bordering on India, Tibetans have been affected by Hindu views of the sacredness of common cattle. In some cases, Hindus themselves have transferred their views concerning common cattle to yak and hybrids, and in areas under their political influence such flesh has been (at one time or another), difficult or impossible to get. In other cases, Tibetans have taken over Hindu views. Some Tibetans of western Tibet, for example, were reported to view yak as sacred and avoided eating its flesh at all costs. Other Tibetans of the same region, however, who were less affected by Hindu ways, ate yak meat freely (Sherring 1906).

Some inhabitants of the Nepal Himalaya have been similarly influenced by Hindu ideas. The Gurung and Thakali are two such groups. The legends of the Gurungs, a tribal people of west central Nepal, indicate that they once consumed yak flesh freely, but according to Donald Messerschmidt (personal communication), present-day Hinduized Gurung consider this practice abhorrent because they have transferred Hindu ideas concerning common cattle to yak.

The Thakali of the Kali Gandaki Valley gave up eating the flesh of yak in the nineteenth century in an attempt to elevate the social status of their caste and to facilitate establishment of social relations with dominant members of Nepal's Hindu ruling class. Tradition maintains that Harkaman Subba Sherchan (1860–1905), a customs contractor, initiated the banning of yak flesh (Fürer-Haimendorf 1966: 144–5).

Milk

Because of the feelings of guilt associated with the consumption of yak flesh, meat is included in a category of "black" foods, considered unceremonious, harmful, or improper. Milk and milk products, however, are classed as "white" foods, suitable for all occasions and persons. Most yak herders consider milk, in both its fresh and processed states, a tasty food to be consumed eagerly by all ages. But while these views are associated with milk in general, distinctions are made among a variety of milk types, each the product of different mammals. Furthermore, each type of milk occupies a position in a hierarchy of milk preference that varies little, if at all, from place to place.

Among Tibetans and Himalayan folk, for example, there exists a strikingly consistent pattern or hierarchy of milk preference from place to place and group to group. Above all others, milk of yak is preferred, not only for its flavor and richness but also because it is considered especially healthful. Milk of hybrid cows is thought to be less tasty than yak milk but is preferred over that of common cattle (the other component of hybrid parentage).

Distinctions, however, are made by those more familiar with hybrids. The Sherpa of Nepal, for example, distinguish between milk of the two major hybrid types and prefer milk of hybrids (dimdzo) sired by common bulls to that of hybrids (urangdzo) sired by yak bulls. In any case, milk of common cows is not especially liked but is considered superior to the milk of backcross cows and ewes and is consumed when more highly prized milk is not available. Milk of female goats is least preferred and is seldom consumed by Tibetans and Himalayan folk, even the poorest.

This pattern of preference is generally explained in terms of the varying quality of milk types. Quality is defined as "thickness" or "richness." Such terms refer to the fat content of the various milks, for analyses of these milks do indeed show substantial differences in fat content. This content may range widely, however, depending on such factors as the season when the milk was obtained, grazing conditions at the time of milking, and availability and utilization of supplementary feed. Thus, the fat content by volume of yak milk has been assayed by some to be between 4.8 percent and 16 percent (Mittaine 1962: 693; Schley 1967: 45–6, 78). But a study by Peter Schley of experiments on yak, hybrids, and common cattle in the Soviet Union has demonstrated that at any given time, fat content of yak milk is 18 percent to 28 percent greater than that of hybrid cow milk and 39 percent to 97 percent greater than the milk of common cows. Furthermore, the fat content of hybrid cow milk is, according to Schley's figures, 13 percent to 65 percent greater than that of common cows (Schley 1967: 78).

With respect to fat content, the obvious superiority of yak milk to that of hybrids and common cows is somewhat offset by the inability of yak to produce as great a volume of milk as hybrid and common cows. But, as with the fat content of milk, production figures for yak, hybrids, and common cows vary from place to place and season to season. Grazing conditions account for a goodly part of these variations, but milk production also varies with age of milch cows. Yak and hybrid cows, for example, begin lactating at 2 or 3 years of age. As they grow older, and until they reach the age of 10, the lactation period lengthens from approximately 230 days to 300 days. Naturally, this lengthening is reflected in higher production of milk. After this maximum is reached, milk production declines.

Whatever the actual milk production figures are for yak and for hybrids and common cows kept under similar conditions, field observations in the Nepal Himalaya reveal several constants that should be noted. First, hybrid cows produce twice as much milk as yak and 50 percent more than common cows. The latter, however, consistently produce more than yak by about 30 percent.

The second constant reflects the season of milk production. Milk yields for yak, hybrids, and common cows increase as summer waxes and grazing improves, then begin to decline in late summer. In midwinter, lactation nearly ceases, though hybrids tend to be able to lactate during this period somewhat better than yak or common cows. Percentage of fat by volume, however, does not decline with the seasonal decline in milk quantity. Rather, it continues to climb, reaching its maximum when milk yields are lowest. These data confirm the findings of Schley and others but conflict with certain other sources.[5]

Tibetans and others do make some efforts to increase the milk production of their cattle. For example, they use stud that derive from lineages renowned for their milking characteristics. Another technique involves supplemental feeding of lactating yak and hybrids. A number of fodders are used for this purpose, including grasses and leaves collected in pasture and transported to the agricultural village or nomadic camp, where the feed is given to animals in the evening or stored for future use. Also used are fodder crops such as radishes and the straw of harvested grains. And some Tibetan nomads occasionally cultivate fields of planted and volunteer fodder crops for just such use.

Among the more interesting Tibetan customs employed to maximize milk yields is the feeding of salt to lactating cows; more frequent milking, especially as the grazing season progresses; restricting nursing by calves; and stimulating the milk let-down response in stubborn females.[6] In this last, several methods are employed, among them use of calf substitutes, calf dolls, and vaginal insufflation.[7]

Milking of yak and hybrids is done almost exclusively by women and girls; only occasionally will men and boys involve themselves in this work. Whoever does it, the milking procedure seldom varies. The milker always squats beside the cow with her head pressed against the animal's side for balance. The milk pail is set on the ground or held against the milker's thigh by a hook attached to her belt and fitted into a notch in the pail. Robert B. Ekvall, who had extensive experience among the Tibetans of northeastern Tibet, has described the hook as a prized item of female attire that, when wealth permits, is covered in silver, coral, and turquoise. According to Ekvall, the milking hook has come to symbolize, in nomadic society at least, the female's role in foodgetting (Ekvall 1968: 50).

No distinction is made between milk taken in the morning and that collected in the evening; both are considered equal in all respects. For children, especially, milk is considered a very healthy and nutritious food and may be made more appetizing by the addition of sugar, butter, or some other ingredient. The Mewu Fantzu, a pastoral group of Kansu, are said to consider yak milk better for children than even mother's milk, which they say makes children stupid (Stübel 1958: 8). Although this is probably a radical position, it nonetheless serves as an indicator of the esteem in which yak milk is held.

While some Tibetans allow small children to drink fresh milk, it does not seem to be the practice among adults or children over 4 or 5 years of age. For them, milk must be boiled before it is consumed. When asked to explain why they boil milk before drinking it, many Tibetans insist it is necessary to avoid the diarrhea, flatulence, vomiting, and stomach cramps that would surely follow the drinking of fresh milk. Some, however, maintain that milk is boiled simply to improve its taste and that no medical considerations are involved. Whatever the reason, milk is not boiled very long but rather is heated just until it boils, after which it is quickly removed from the fire.

Milk Products: Butter and Cheese

Most milk is converted into milk products as quickly as possible. There are two reasons for this practice. First, milk processing results in products much less perishable than liquid milk. Second, such products can be transported more easily than liquid milk, even over short distances. Because a great deal of milk is produced and collected in pastures distant from established villages and milk yields vary from season to season, transportability and perishability are important factors that must be dealt with by pastoralists.

Butter is, perhaps, the most important product derived from milk both in amount produced and quantity consumed. Butter derived from the milk of yak has the highest prestige value and is preferred over all others for its taste, richness, and color, which varies from season to season from a golden hue in summer to pale yellow in late winter. No distinction seems to be drawn among butters of various hybrids.

The major instrument of butter making is the churn, and a variety of types are employed, with some made of wood, some of leather, and others of pottery.[8]

Butter making, like milking, is principally a female occupation. However, no universal rule exists on this point. As with milking, the process of butter making varies little. After milk is collected from animals, it is warmed over a fire and stored for about a day perhaps in a churn, or in vessels assigned for that use. In either case, the warmed milk is allowed to curdle. Sometimes, a small amount of starter is added to hasten curdling. Once curd is formed, the mass is transferred to a churn and agitated. As soon as butter begins to form, a quantity of warm water is added a little at a time, to encourage the process. As larger clots of butter float to the surface of the buttermilk, they are picked out and squeezed by hand to remove any remaining liquid.

Those who maintain large herds of milch cows produce more butter than is necessary for the normal needs of their families; thus, they store excess butter in a variety of ways for future use, sale, and trade. A common method of storing butter in the Nepal Himalayas nowadays is simply to pack it solidly in 5-gallon kerosene tins. Before tins were commonly available, however, butter was packed in sheep stomachs or wrapped in wet rawhide bags, which, sewn shut and dried, are said to have kept butter from a few months to a year or more. Butter is also stored in wooden boxes and barrels and, according to some Tibetans, pottery containers as well.

Butter, a valuable low-bulk manufacture, is traded widely and is sold by weight. Demand for butter is the result of various factors, not least of which is its prominent role in the diet. Seldom is butter eaten in its raw state. More often it is melted and used in frying or mixed with other foodstuffs. The largest percentage of butter is consumed in the form of *tsocha,* the ubiquitous butter-tea of Tibet and the Himalayan region. *Tsocha* is souplike in consistency and nourishment. And, although the ingredients do not vary at all from place to place, the taste of *tsocha* varies from family to family, perhaps because of the quality or quantity of ingredients used.

Only three ingredients are necessary to make *tsocha:* tea, butter, and salt. Tea, even among the poorest, must be Chinese, imported at great expense in brick or cone form. A quantity of tea is broken off and boiled in water that is then strained and poured into a tea churn. After hot tea is poured into the churn, butter and salt are added. The best *tsocha* is said to be made with yak butter; when this is unavailable, butter of hybrids is used, followed, in order of preference, by the butters of common cows, sheep, and goats. Salt is almost always of Tibetan origin; Indian salt is seldom used because it is thought to cause illness. After being thoroughly churned, the *tsocha* is poured into a kettle for reheating; when hot, it is served in handleless cups or in glasses. *Tsocha* is a dietary staple drunk many times a day by persons of all ages.

Two other factors help explain the high value of butter and the constant demand for this commodity in the marketplaces of Tibet and Nepal. First is the role of butter in discharging social obligations, and second is the multifarious ceremonial role of butter.

With respect to social obligations, in many instances payment in the form of butter is a desirable method of settling accounts. Turning briefly to religious and ceremonial requirements, we find an almost insatiable demand for butter. In lamaseries, for example, large quantities are required for making the *tsocha* served to lamas, and enormous amounts are consumed in the many votive lamps kept burning on altars. One scholar has suggested that the larger lamaseries of Tibet required tons of butter each year for just these two purposes (Tucci 1967: 94).

Unlike butter, however, there is no great market for or monetary value attached to the soft and hard cheeses made from yak milk. Nonetheless, cheese, made from buttermilk, is appreciated as a nourishing and tasty addition to meals; as an easily carried, sustaining food for long journeys; and as a treat on festive occasions.

Women, who are solely responsible for cheese making, do not hesitate to mix the buttermilk of yak, hybrids, and common cows in order to produce cheese. The principal concern seems to be the availability of enough buttermilk to warrant the long, tedious process of cheese making and not the composition of the buttermilk.

In any case, after the butter is removed from a churn, the remaining buttermilk is poured into kettles which are set over a fire. The buttermilk is brought to a rolling boil, after which it is removed from the fire to cool. As it cools, the buttermilk separates, forming a thick, spongy, white mass that floats to the surface of a clear liquid.

Solids are skimmed off with a shallow strainer, something like a dipper, and are placed in a cloth bag to allow whey to drain off. What remains in the cloth constitutes soft cheese, which is eaten immediately. On special occasions, sugar is added to make a sweet, tasty mixture. Soft cheese is also fried before eating, mixed with barley flour to form a doughlike food, or boiled with butter, salt, and other spices and served as a soup. More commonly, however, soft cheese is dried to form the second, hard type of cheese.

Hard cheese is produced by drying soft cheese in the sun or by the fire. Sun-drying is much preferred over fire-drying, for the latter darkens the cheese and makes it less tasty. If weather permits, soft cheese is scattered on cloths spread on the ground close to the house. If this is not possible, soft cheese is arranged before an indoor fire, on mats woven of vegetable material. In either case, soft cheese shrinks to about a fourth of its original size, forming a very hard cheese that is said to keep indefinitely.

Hard cheese most commonly is eaten by slowly dissolving pieces in the mouth. But this kind of cheese is also added to stews and soups or dropped into cups of *tsocha.* As an easily carried food, cubes of hard cheese are often taken on journeys to supplement meals purchased on the trail, or they may be the sole sustenance of the traveler.

Blood

Bleeding of live cattle is a widespread and common practice among the peoples of Tibet and Nepal. Bleeding is done for a variety of purposes, principal among them to obtain blood for human consumption.

Unlike milk, butter, and cheese (which are available and eaten throughout the year), blood is a seasonal food. Bleeding of yak for food takes place in late spring and early summer; only if there should be a famine are cattle bled for food in other seasons.

Not all yak are bled for food, however. Yak oxen are the animals most often bled, but occasionally yak cows, if they are not lactating, are bled as well. Hybrid cows seem never to be bled for food, and only persons who have no yak, or insufficient numbers of them, bleed male hybrids. There seems to be no evidence of bleeding common cattle for the sole purpose of procuring blood for food, though they are bled for other reasons. Moreover, no consistent and uniform explanation exists for not bleeding yak dams, female hybrids, and common cattle, but the strong impression is that although bleeding males for food is not quite proper, bleeding females for food is quite offensive.

Perhaps because bleeding cattle for food offends Buddhist sensibilities, Tibetans and Himalayans derive most blood food as a by-product of bleeding for other purposes. One is to prevent disease in cattle and ensure the cattle's survival by encouraging them to gain weight quickly.[9] Such operations, like bloodletting for food, generally take place in late spring and early summer when cattle, after surviving the winter, begin feeding on new grass.

Any animal considered lean or prone to disease is a candidate for bleeding, though more time and consideration is given to the selection of milch cows and dams lest bloodletting cause lactation to cease. Even calves are bled to improve their health and chances for survival. Cattle that are sick or so weak that they are in immediate danger of dying are also bled. But blood drawn from such animals is not considered fit for human consumption.

As previously noted, lactating yak dams and hybrid cows are seldom, if ever, bled to supply their owners with food. And a great deal more care is shown in the selection of females for prophylactic bloodletting operations than is extended to males. Perhaps this more sympathetic treatment of cows is, as some Tibetans suggest, an attempt to reconcile human food needs with the Buddhist view that bloodletting is an improper activity because it involves use of a knife and the spilling of blood.

Or perhaps the explanation of more secular Tibetans is correct. According to them, milch cows and dams are rarely bled because there is always a possibility that the operation will prove fatal or result in cessation of lactation. This thinking suggests that decisions are based purely on selfish and economic grounds and not on higher concerns. In any case, no such consideration is shown to dry cows and to those that have difficulty being impregnated. These animals are bled in spring to improve their chances of pregnancy.[10]

Whatever the purposes of bleeding, the method varies little from place to place and from group to group. Essentially, bleeding begins with the application of a tourniquet, simply a length of rope, around the animal's neck. Often, but not always, a similar tourniquet is tied around the animal's belly or buttocks to force (it is maintained) blood to the neck. Once in place, the neck tourniquet is tightened. If accompanied by another tourniquet, both are tightened. This action causes the blood vessels of the neck to stand out. One of these vessels is chosen, and using a small awl-like instrument or a special handleless chisel-edged tool called a *tsakpu,* the bloodletter makes an incision (not a puncture) of about 1/4-inch to 1/2-inch in length. The blood that spurts from the wound is caught in a container if it is to be prepared as food, or it is allowed to fall directly to the ground if considered inedible.

Varying quantities of blood are taken from cattle, depending primarily upon the sex, size, and condition of the animal. If the animal is male and in good condition, a half gallon of blood may be taken; if it is female and in poor condition, only a pint or so may be removed. If the operation is performed correctly, bleeding stops as soon as the tourniquet is loosened.

Bleeding of cattle is strictly a male task; women never perform the operation under any circumstances. Among nomads, each adult male is an accomplished bloodletter, having learned from his elders during childhood. Among settled folk, some perform the operation on their own cattle, but others, not as skilled, often prefer to have more experienced men bleed their cattle.

If bleeding of cattle is a task assigned to men, preparation of blood for eating is strictly a female occupation. Blood food must undergo some kind of processing because nobody would consume fresh blood. There are a number of methods of preparing blood drawn from live cattle; the particular one employed by a family depends entirely upon personal preference. One of the most common ways of preparing blood food involves simply allowing the blood to coagulate (a process that sometimes is hastened by the addition of salt), after which it is either boiled in water or fried in butter.

Another method of preparation requires that the blood be mixed with water; after a period of time, a thick mass forms that is eaten plain or mixed with salt and/or barley flour. Or barley flour may be mixed with fresh blood to form a dough that is then cooked. Some prefer to put fresh blood into metal containers that are set over a fire to warm. When the blood coagulates into a jellylike substance, it is seasoned with salt and cut into cubes to be eaten plain, fried, or boiled.

Finally, there is a blood food that seems to be peculiar to the Sherpa of Solukhumbu in Nepal. Blood drawn from cattle is allowed to dry out thoroughly and is rubbed between the hands to form a powder. This powder, or "blood flour," is added to various dishes as a seasoning.

However it is prepared, blood is not considered entirely proper as a food. Some Tibetans and Himalayans, more committed to the Buddhist concept of nonviolence, believe that the consumption of blood food is sinful even though the process of bloodletting may benefit cattle. Nevertheless, virtually everyone eats blood food with relish, finding it tasty and nourishing. This religious-dietary dilemma is, perhaps, understandable when it is remembered that blood food is a seasonal commodity, available in large quantities during late spring and early summer. This timing coincides with the period of meat shortage for most Tibetan and Himalayan folk. Meat derived from stocks put up the previous autumn is near depletion at this time, and blood is a welcome addition to the diet, too tempting to forgo.

Richard P. Palmieri

The author is grateful to the National Geographic Society for two research grants that supported fieldwork in the Nepal Himalayas in 1972 and 1973, and to Mary Washington College for financial support that enabled preparation of this manuscript.

Notes

1. Works that focus on yak or at least deal with this animal in a more than cursory fashion include the recent studies of the Sherpa of Khumbu in Nepal by Barbara A. Brower (1991) and Stanley F. Stevens (1993), the collection of essays in the volume edited by Joseph Bonnemaire and Corneille Jest (1976), the several articles by Richard P. Palmieri (1972, 1974, 1980, 1982, and 1987), and three books on Tibetan pastoral nomadism: one by Matthias Hermanns (1948), another by Robert B. Ekvall (1968), and the third by Melvyn C. Goldstein and Cynthia M. Beall (1990).
2. It is, perhaps, useful to clarify the term "yak." It is Tibetan in origin (Tib. *gyag*) and refers specifically to the domesticated male. Females are correctly known as *di* or *dri;* in some regions of the Himalaya, however, females are also called *nak,* although this term more precisely refers to cattle in general.
3. The question of yak hybridization is the focus of several papers, many of them referred to in my study (Palmieri 1987), which deals with the complex nomenclature, animal husbandry practices, and ecology of hybrids among the Sherpa of Nepal.
4. A detailed discussion of the concept of pollution among the Sherpa, for example, can be found in Ortner (1973).
5. The literature on this topic includes a wide range of conflicting figures that are difficult to reconcile. This variability may simply represent data collected in different environments, the contrasting characteristics of dissimilar herds, or the various seasons during which the figures were developed. In any case, the following sources may be consulted: Das (1904: 96-7); King (1926: 75); Kislovsky (1938: 32); Phillips, Johnson, and Moyer (1945: 70); Phillips, Tolstoy, and Johnson (1946: 170); White, Phillips, and Elting (1946: 357); Hermanns (1948: 128); Stübel (1958: 19); Fürer-Haimendorf (1964: 12); and Field and Pandey (1969: 50-2).
6. A discussion of the biological and behavioral bases for the milk let-down reflex can be found in Amoroso and Jewell (1963).
7. In this last, it should be noted that African and European parallels do exist. See, for example, Lagercrantz (1950: 44-50) and Bühler-Oppenheim (1948: 4275-6). With respect to insufflation of yak, see Edgar (1924: 39); Combe (1926: 105-6); Bühler-Oppenheim (1948: 4276); Duncan (1964: 240); and Ekvall (1968: 50).
8. The principal difference between various wooden churns is the apparatus employed to agitate the milk: Some are equipped with dashers, others with paddle-like arrangements. Both the pottery and leather churns are rocked or shaken to produce butter.
9. Some Africans bleed their cattle for similar reasons. See, for example, Kroll (1928: 244) and Lagercrantz (1950: 51-4).
10. Interestingly, farmers in the Bavarian and Austrian Alps also bleed their barren cows just before rutting season in an attempt to increase their chances of becoming gravid. For this information, I am most grateful to Professor Ludwig Erhard of the Tierzucht Forschung e. F. München Institut für Blutgruppenforschung (Munich).

PART III

Dietary Liquids

Drinks, many of which were also globalized in the events following 1492, seem to have produced even more ill effects than foods. Unfortunately, more often than not, they did indigenous peoples unaccustomed to them no good. Along with wine and distilled beverages, beer – which had been brewed since the early stages of the Neolithic – entered all newly discovered corners of the earth as quickly as the Europeans reached them. Superficially more healthful was the spread of tea from China, coffee from Ethiopia, and cocoa from the Americas. But consumers of these beverages also demanded the addition of sugar and the processing of this Asian plant soon became an American enterprise fueled by unwilling African labor, which was also applied to coffee production.

Water that fostered disease was a problem from the very beginning of the Neolithic, and one that grew steadily worse as more and more people crowded together to pollute local sources. Alcoholic beverages were humankind's first line of defense against pathogen-packed water, and later, the procedure of boiling water to make tea, coffee, or cocoa had the same purifying effect. But it was only in the twentieth century that public water supplies were rendered safe to drink in the world's developed countries, and unsafe water remains a problem throughout the developing world.

This means, among other things, that formula feeding of the young continues to cause infant deaths in that world when local water is used, making breast milk by far the best alternative (save of course in the presence of AIDS). Bovine milk, by contrast, is not an especially good food for infants and is positively dangerous for some. In the past, bovine milk imparted bovine tuberculosis (scrofula) to the lactose *tolerant,* and, of course, milk drinking did not even catch on among the bulk of the planet's people (who are lactose *intolerant*), although it is the case that many reduced-lactose products of milk, such as yoghurt and cheeses, have become welcome dietary additions.

Caffeine-carrying kola nuts from Africa helped to launch the soft-drink industry, which became a giant all across the globe during the course of the twentieth century and provided even more stimulation for the sugar industry, not to mention the dental profession.

Khat and kava are among the few beverages of the world that have not been globalized. Khat (more often chewed these days than made into a beverage) remains confined to northeastern Africa, whereas kava is a drink of the Pacific. In the past confined to ceremonial affairs, kava, with its narcoticlike properties, has become a local alternative to alcohol.

III.1 Beer and Ale

Beer and ale are mildly alcoholic beverages made from the action of yeast fermenting a usually grain-based mixture. Throughout their history, they have constituted both a refreshing social drink and an important energy-rich food. The basic ingredients of most beers and ales have included grain, water, yeast, and (more recently) hops, and despite many regional variations, the process of fermenting the grain has changed little over time. To be completely accurate, it must be noted that ale is defined as unhopped beer; in this chapter, however, the terms "beer" and "ale" are employed interchangeably for the period before hops were used.

The Chemical Basis of Fermentation

Before fermentation can take place, yeast, a single-cell fungus occurring naturally in several varieties, must be allowed to act on the sugar present in grain. This releases two crucial by-products, alcohol and carbon dioxide. A grain often used for this purpose is barley – even though, in its natural state, it contains only a trace amount of free sugar – because of its high content of starch, a complex polymer of sugar. Barley also contains substances known collectively as diastases, which convert the barley starches into sugar to be used as food for the growing plant. When barley is crushed and dried carefully, the essential starches and diastases are released and preserved, rendering a substance called "malt."

Until sometime around the ninth century, "beer" was actually "ale," made by a process known as mashing, whereby the barley malt was mixed with hot – but not boiling – water. The effect of the hot water was to induce the diastases to act immediately in breaking down the complex starches into sugar. This process is referred to as conversion and results in "wort," one of its most essential products. The mashing procedure not only produced the brown, sugary wort but also permitted inert elements of the barley, such as the husks, to be drawn off. In the production of pure ale (such as the first human brewers would have made), all that remained was for yeast to act upon the wort so that the sugars could be converted into alcohol and carbon dioxide.

Beginning in approximately the ninth century in central Europe (authorities vary widely and wildly regarding the date but not the place), the procedure began to be modified, and beer came into being with the addition of blossoms from the hop plant. Numerous modern beers are labeled as ale, but as mentioned, technically "ale" means unhopped beer. In order to convert ale into beer, dried hop blossoms are added to the boiling wort mix after the mashing but before the yeast is allowed to act. This releases two resins, lupulon and humulon, that act as excellent natural preservatives, preventing the growth of certain types of bacteria which, although harmless to humans, are detrimental to beer. Before the use of hops, pure ale had a very limited "shelf life" and often spoiled, much as milk does. The diastases in barley also acted against the bacteria in question, but not nearly so effectively as hops. In fact, it can be argued that it was the harnessing of the preservative power of hops that permitted the production, storage, and distribution of beer in large quantities. Moreover, in addition to its antibacterial properties, the hop plant adds flavorful oils that mask the otherwise sweet taste of pure ale (Kloss 1959: 31–2).

Varieties

Today, the use of hops is standard, and very little pure ale has been mass-produced in the twentieth century. Thus, the words *ale* and *beer* have become largely (if wrongly) synonymous. Modern technology and advanced techniques have modified and refined the brewing process considerably. The most commonly mass-produced type of beer is known as a "lager" or a "Pilsner" and is lighter in color and generally milder in taste than other beers. The vast majority of North and South American beers, most European beers, the beers of Australia, and those of nearly all major Asian nations are crafted in the Pilsner style.

Darker beers that are dryer and richer in taste are referred to as porters and stouts, with the latter merely a stronger, drier porter. Several popular German beers make use of large quantities of wheat rather than barley to make *Weizenbier* (wheat beer). Belgium is famous for fruity ales, typically known as "lambic" beers, the production of which involves a complex process of spontaneous fermentation. In addition to the use of fruits to add flavor, as in the case of the lambic beers, one method of increasing taste is "dry-hopping," a process whereby additional hops are added at the end of the process to replace the residue lost when the wort and hop blossoms are first boiled together. Like hops, yeast and sugar are occasionally added to the bottle when it is sealed to further enhance the beer's strength. This is not so much the production of yet another style of beer as it is a method of setting up a secondary fermentation process within the bottle to make stout, porter, and "bitter."

Earliest Origins

No one has yet managed to date the origins of beer with any precision, and it is probably an impossible task. Indeed, there are scholars who have theorized that a taste for ale prompted the beginning of agriculture, in which case humans have been brewing for some 10,000 years (Katz and Voigt 1986). Most archaeological evidence, however, suggests that fermentation was being used in one manner or another by around 4000 to 3500 B.C. Some of this evidence – from an ancient Mesopotamian trading outpost called

Godin Tepe in present-day Iran – indicates that barley was being fermented at that location around 3500 B.C. Additional evidence recovered at Hacinebi Tepe (a similar site in southern Turkey) also suggests that ancient Mesopotamians were fermenting barley at a very early date (Smith 1995).

At present, however, the evidence from both sites is sufficiently sparse to preclude any definitive assertion that the ancient Mesopotamians were the first people to make beer. On the other hand, one can speculate: There is no question that fermentation takes place accidentally (as it must have done countless times before humans learned something about controlling the process), and most investigators believe that barley was first cultivated in the Fertile Crescent region of lower Mesopotamia between the Tigris and Euphrates rivers. Grain is heavy to transport relative to the beer made from it, so it is not surprising that there may be evidence of ale in these outposts and not unreasonable to suspect that accidental fermentation did occur at some point in the ancient Mesopotamian region, leading to beer making (Corran 1975: 15–16).

In any event, we know that not much later the Sumerians were, in fact, making beer. The clay tablets (unearthed from the ancient city of Uruk in Lower Mesopotamia – now Iraq – and dating from the second half of the fourth millennium) that tell the story of Gilgamesh, the fifth king of the second Sumerian dynasty, make it clear that ale was in widespread use (Toussaint-Samat 1992), and Reay Tannahill (1988: 48) has written that "a staggering amount of the Sumerian grain yield went into ale; something like 40 percent of the total."

At approximately the same time, people of the ancient Nubian culture to the south of Egypt were also fermenting a crude, ale-like beverage known as *bousa,* which is still brewed by African farmers and peasants to this day (Smith 1995). Indeed, although many scholars maintain that the Mesopotamian culture was the first to brew beer, others argue that it was the ancient people of East Africa who first produced and consumed a fermented product (Dirar 1993: 20).

In much the same fashion as with grain, the fermentation of fruit and fruit juices probably also occurred by accident at around this same time, leading to the earliest forms of wine. What is more difficult to ascertain, however, is how much knowledge ancient people had of the process. It is also difficult to know with any reasonable certainty how extensive their use of fermented barley was and exactly how much their ale might have resembled what the world now recognizes as beer.

The Importance of Ale in Early Societies

From the beginning of its production, ale (even in its crudest forms) would have been an important addition to an otherwise frequently limited diet. Resembling the chemical makeup of bread in several ways, ale was a convenient package of starches, sugars, and other grain by-products that provided nutritional supplementation. Similarly, for people with few means of storing foods for any length of time and who depended on the vagaries of nature for subsistence, ale could be an excellent (and doubtless at times vital) source of calories.

Moreover, ale (and later beer) afforded an escape from the feces-fouled drinking water that plagued peoples for millennia. Although humans, until very recently, had no knowledge of pathogenic infection, water (and milk) was understood to provoke dangerous illnesses, even death, whereas fermented beverages were considered safe. And because of sterilization by boiling and by the action of yeast, this was generally the case.

Ale was also important because the earliest cultures, particularly those of the Sumerians and Egyptians, attached religious significance to its consumption. And throughout the ages, savants frequently maintained that ale had curative properties. But probably the most important reason for drinking ale and other alcoholic beverages was to achieve a desired level of intoxication. Because invectives against drunkenness can be found in both the Bible and the Koran, we know that people, beset by life's hardships or just seeking relaxation, were reaching that goal a long time ago. Indeed, the ancient Egyptians are credited with celebrating ale consumption by composing some of the world's earliest-known drinking songs.

Brewing in Antiquity

Although the fermenting of barley probably developed independently in several cultures, knowledge of brewing technology doubtless was spread throughout the Middle East by various nomadic peoples. One aspect of brewing technology common to the Egyptians, Sumerians, and Babylonians alike was the use of baked loaves of malted barley and grain that resembled baked bread. There were several variations of this technique, but basically the loaves of barley and wheat, once baked, were covered with water to form a mash, which was then placed in an earthen vessel for a time. In some cases, fermentation probably occurred spontaneously. In others, it was doubtless generated by the presence of yeast cells in the cracks and linings of the earthen vessels that were used over and over again. But in addition, skillful brewers had most likely learned to keep the remains of a previous mix to use as a starter (Smith 1995: 12–13).

The Greeks probably gained most of their understanding of brewing from the Egyptians, although the Babylonians may also have passed along what they knew. The Roman Empire, at its height, had the advantage of being able to borrow brewing techniques eclectically from several cultures. Roman historians, for example, did not credit Rome with spreading information on ale making to the Germanic tribes of Europe. Rather, Tacitus recorded that these peoples were already fermenting a beverage from barley or wheat when they came into contact with Rome. Pliny also wrote of the barbarians and their beer, and it seems likely that the tribes of central and northern Europe gained brewing knowledge not from the Romans but from the Babylonians and other Asian civilizations. Or it could have been a situation such as that of the Celts of the British Isles, who are said to have developed a crude process of fermentation independently, but refined their ale-making skills with technology from other cultures (Corran 1975: 23–4).

Brewing in the Islamic World

By the time of the collapse of the Roman empire in the fifth century, the production of alcoholic beverages had been expanded, and beer was only one of many alcoholic beverages produced in the Arabian peninsula – a list which included a honey-based mead and fermented camel's milk. Their consumption – and especially that of ale – was widespread before the advent of Islam, despite a number of localized religions that had instituted prohibitions against it. Along the caravan and trading routes, houses, taverns, and inns were prosperous businesses that supplied beer and mead to travelers and, in some locations, to townspeople as well (Ghalioungui 1979: 13–15).

The spread of the Islamic religion did not, at first, bring restriction of alcoholic beverages; indeed, the Koran, like the Bible, celebrated the drinking of wine. Rather quickly, however, Islamic teaching began to forbid drinking alcohol, although the degree to which the rule was observed varied from place to place (Ghalioungui 1979: 15).

Egypt was one area in which alcohol continued to be used, although in the years following the entrance of Islam into Egypt, various rulers periodically enforced the Muslim prohibition. But the consumption of fermented beverages was never entirely eradicated (Ghalioungui 1979: 15), and, among the peasant population, *bousa* continued to be produced and consumed as it had been for centuries.

Despite such exceptions, however, Islam had an enormous impact on beer brewing in the Middle East and elsewhere in the Muslim world, with the result that it never was the mass-produced, socially accepted beverage that it became in Europe during the Middle Ages. Europeans, especially monks in the monasteries of the Catholic Church, not only kept the knowledge of brewing alive but also began its refinement into a modern science.

Brewing in Europe

Over the course of the Middle Ages, beer brewing flourished in northern Europe (where foods laden with carbohydrates and fats required much liquid to wash them down) and evolved into a distinct industry (Tannahill 1988). As such, by the end of the Middle Ages, beer had become subject to taxation and also to government regulation (especially in Britain and the German states) aimed at standardizing the brewing process.

In the early Middle Ages, however, monasteries and churches were the principal ale makers in Europe. Because the church was at the center of the lives of the people, monasteries and churches commonly provided the settings for festivals, weddings, and other social gatherings that were lubricated with ale. Indeed, such was the control of the church over access to ale that it became a device for ensuring the participation of parishioners in church rituals. Later, as guilds developed, the church influenced – even controlled – many of their activities with the promise of ale.

In addition, monasteries were much more than just monastic retreats. The growing of food was one of the monks' primary occupations, and as a rule, the land owned by their orders was sufficient enough for the rotation of crops in such a way as to ensure a constant supply of cereals. Much of the cereal produced – including spelt, wheat, oat, and rye, as well as barley – went into ale, the quality as well as quantity of which the monks improved upon, just as they did with their wines and cheeses (Toussaint-Samat 1992). Many monasteries also served as inns that provided room and board for travelers, and some became famous for their ales, their praise carried by church pilgrims, merchants, and others on the move. There is no question that monastery-produced ales, made on a near-industrial scale, brought in a very good income for the various orders.

Later, however, as the Middle Ages progressed, ale production in the towns and countryside began to rival that of the church. And as the craft passed into private hands, it mirrored other early trades with its guilds and specialization. Because of its limited shelf life (prior to the use of hops), ale was usually brewed and distributed on the same site, and consequently, the first brewers outside of the church were generally boardinghouse owners and tavern keepers who provided ale to travelers and guests. Local inns and taverns came to be regarded by townspeople and villagers alike as social gathering places (Corran 1975: 36–7).

Because water is vital to the brewing process, the breweries of taverns and inns had to be located near an abundant water supply. But the type of water was important. If it was hard water with lime, the fermentation process might not work well; if it had iron in it, the beer would always be cloudy.

Women frequently oversaw the breweries while their husbands ran the inns. In fact, women were much involved in the ale business, sometimes owning boardinghouses as well as breweries and holding special licenses to distribute their product.

By the end of the Middle Ages, breweries and drinking establishments of one sort or another had multiplied to the point where they overshadowed the monasteries, both in England and on the Continent. As the church ceased to dominate the brewing industry, states began to take an interest in both taxing and (because of increasing adulteration) regulating it. An example of the former is the 1551 licensing of English and Welsh alehouses for the first time (Trager 1995), although the classic example of regulation had come earlier, in 1516, when William VI, Duke of Bavaria, instituted a *Reinheitsgebot* – an "Edict of Purity" – which decreed that the only ingredients permitted in beer were water, barley, malt, yeast, and hops. The edict is still in effect, now for all of Germany, but it is said that only Bavaria holds to it for exported beers.

Hops, which converted ale into modern beer, were coming into widespread use at about this time. Hop blossoms are derived from the hop plant (a relative of *Cannabis*), and as their use became common, a hop garden was an essential component of a brewery. As noted, the aromatic hop greatly enhanced the taste of ale, as did the addition of other herbs and flavorings. More importantly, however, hops greatly extended the life of ale, which in turn removed the necessity for locating breweries and taverns close to one another. The use of hops was eventually so universal that the brewing of pure ale became nearly extinct, until the modern, twentieth-century "Campaign for Real Ale" movement in Britain sought to revive what was perceived as a dying art.

The revolution that hops worked in the brewing industry, however, was a long time in coming. Since Neolithic times, hops were believed good for one's health and sometimes carried the burden of a reputation as an aphrodisiac. It has been suggested that the utilization of hops in beer can be traced back as far as the ancient Egyptians. But we hear nothing of hops in beer in the Roman world. Pliny tells us only that the Romans ate hop shoots much like asparagus. During the early Middle Ages, hops were grown for medicinal purposes in gardens throughout the central European region from the North Sea and the Baltic to western Austria and northern Italy, but people apparently began putting them in ale only around the eighth or ninth century (Toussaint-Samat 1992).

The hop was only one of many herbs added to ales, but brewers sooner or later noticed that this herb improved the appearance of ale, that it acted as a diuretic, and most importantly, that it was a preservative. Nonetheless, the church successfully fought the widespread adoption of hops for centuries – apparently in part because of the aphrodisiac reputation of the plant, but also because the church, with its virtual monopoly on ale, did not welcome change. Moreover, hops were long viewed as an adulterant added to mask the taste of spoiled beer. Yet, somewhat ironically, it was probably the monks, with their considerable knowledge of medicinal herbs, who had added hops to ale in the first place (Toussaint-Samat 1992).

By the beginning of the sixteenth century, hops had become an essential ingredient for beers made on the Continent, and late in the reign of Henry VIII (died 1547), they were introduced to England. At first, the idea of adding hops to ale was a distressing one for the English, who continued to view them as adulterants and passed laws to prohibit their use. In 1554, however, Flemish hop growers emigrated to England to begin their production in Kent for a wary British brewing industry. Afterward, the use of hops was generally accepted, although many clung to their unhopped ales. Not until around 1700 was ale in England regularly hopped and the terms "ale" and "beer" accepted there as more or less identical (McGee 1984; Trager 1995).

The preservative powers of the hop plant contributed to the development of larger breweries producing beer in ever greater quantities – a trend in both England and Europe throughout the sixteenth and into the seventeenth centuries, especially in Flanders, northern and eastern France, and Bavaria, where the climate best suited the growing of hops. Because hops endowed beer with a greatly extended shelf life, brewers could now locate at a distance from the towns and, consequently, close to less-polluted stretches of streams and rivers, whose waters contributed to better-quality beers. Such moves were also necessitated by the regulatory measures of crowded cities, which sought to minimize the fire hazards arising from kilns burning in brewery buildings constructed of wood. Converting brewhouses into stone or brick structures or, alternatively, moving them out of the cities were both expensive options, and as a result, the sixteenth and seventeenth centuries in Europe also saw a trend toward fewer breweries – but much larger ones that, in many cases, were the forerunners of modern breweries still in operation at the end of the twentieth century.

With the mass production of high-quality beers, brewers cast an eye on the export market, and as exporting beer became a widespread endeavor, states enacted laws to regulate trade. One example of this trend comes from sixteenth-century England, where because of concern that the volume exportation of beer in wood casks and barrels would accelerate the dwindling of the island's supply of timber, brewers were compelled to bring as much wood into the country as they sent away.

Brewing in the New World

Traditional interpretations hold that beer and brewing technology came to the Americas from Europe via the Jamestown settlers and the Pilgrims. However, several indigenous American cultures (outside of North America) had developed fermented products long before the Europeans arrived. In the Andean society of the

Incan empire, the fermentation of beverages was well established – the term *chicha* referring collectively to the numerous indigenous fermented beverages of South America.

The *chicha* of the Incas was elaborated primarily from maize, although there were variants, including beverages made from manioc roots and peanuts, to name just two. It is interesting to note that in the absence of hops, diastases (by-products important for flavoring and increasing alcohol content) were introduced to maize beer from human saliva, as moistened maize powder was rolled into balls and placed in the mouth (Morris 1979: 22).

Evidence from Spanish colonial sources and archaeological finds suggests that the production and consumption of maize beer was fairly widespread in the Andes area. Like the ales of Europe, *chicha* was not only a significant component of religious and economic life but served nutritional needs as well. Its importance was apparent in its large-scale, state-controlled production – revealed by archaeological excavations that have indicated the existence of state-run breweries and distribution centers (Morris 1979: 26–7).

The mass production of *chicha* in the Incan empire was abolished by the Spaniards, but the making of maize beer on a smaller scale remained widespread and continues today in the Andes and elsewhere. The relatively high price of modern beer makes *chicha* an attractive alternative in the rural areas of Central and South America.

Another indigenous American beverage that is still produced is a Brazilian beer known as *kaschiri,* which is fermented from manioc roots. Its manufacture is similar to the Incan maize beer in that the tubers are chewed and moistened by salivation. Maize is also used by Indians in Mexico to make a crude beer called *tesguino.* Far more pervasive, however, was *pulque,* the fermented juice of the *agave,* a plant which later was employed to make tequila. Like other local beverages among impoverished peoples, both *pulque* and *tesguino* still deliver important nutrients to their Mexican Indian consumers.

Since the Spanish conquest in Mexico and South America and the English settlement of North America, none of the indigenous American beverages have been produced on a large scale except for *pulque,* which remained a common drink of poor Mexicans until well into the 1940s. The mass-produced, twentieth-century beers of Central and South America are almost universally hopped Pilsners and employ techniques brought to the New World by Europeans.

Brewing in Early North America

Beer and ale were present from the beginning in the English settlements of North America. Records of both the London Company and the Jamestown colony indicate that beer reached the latter in 1607, its very first year of existence. But in those early years, beer was too bulky (and thus too expensive) to transport efficiently; it also spoiled in the summer heat, and so the colonists soon began brewing their own (Rorabaugh 1979: 108–9). Although barley and hops were not at hand, other basic materials that would ferment, such as persimmons, pumpkins, maize, Jerusalem artichokes, and maple sugar, were abundant in eastern America, and by 1609, the governor of Virginia was advertising for brewers to come to the colony (Baron 1962: 4).

A bit later, in Massachusetts, the Puritans – like other Europeans of the age who justifiably viewed water consumption with intense suspicion – had followed suit and were brewing their own beer. The Puritans also pioneered some of America's first regulatory statutes for the production, distribution, and consumption of the beverage. By 1637, taverns and inns had to be licensed by the General Court, and it was forbidden for them to brew their own product. Rather, beer was to be obtained from a commercial brewer, also licensed by the court, who was enjoined to sell at court-specified prices. By 1629, similar regulations had also been adopted in Virginia (which now had two large brewhouses).

Not that there were all that many taverns in early America, and beer was more often than not brewed and consumed in the home. Those who had access to barley or could afford to import malt from England produced something a European might recognize; other beers continued to be made from local ingredients and from West Indies molasses. In addition, beer was imported on a fairly large scale from England, or from the Netherlands in the case of New Amsterdam, where the Dutch had established beer as a prominent drink back in the 1620s.

Beer production kept pace with the growing population throughout the remainder of the seventeenth century and into the eighteenth, with Philadelphia and Boston becoming major brewing towns. As was the case in Europe, the vast majority of colonial towns had taverns that not only provided places of lodging for travelers but also served as local social centers. These dispensed some beer, but rum and (to a lesser extent) corn whiskey and cider increasingly enjoyed more appeal, and even tea, made available in quantity by British mercantilism, cut into beer consumption. Nonetheless, that consumption grew anyway in the eighteenth century because the population was growing (Baron 1962: 56–8).

Innovations

The eighteenth century also saw numerous innovations in beer production, although as a rule, these were slow to reach America. One illustration has to do with what is typically called porter. During the period, working men in England would often order ale and a few other beers mixed together in a tankard, and tavern keepers came to dread the extra time and effort required to satisfy such a request. Eventually, however, several of these brews were being mixed together in a single cask with extra hops. The resulting dark, strong, beverage was called porter, after the London laborers ("porters") who popularized it. It was during this period as well that many of the familiar English beers, such as Courage, Whitbread, and Guinness, were born.

Another significant technological innovation in beer brewing was glass bottling, which came into widespread use in the eighteenth century. Glass bottles made beer easier to transport and store and, after the advent of sealed bottles, extended its shelf life. But because the Industrial Revolution was first an English and European phenomenon (and because of British mercantile restrictions), glass bottling in America began in earnest only after the Revolution. Glass bottles enabled people to store and consume beer at home with greater ease and, perhaps coupled with the growth of alternative beverages, diminished the role of the tavern in the social life of towns.

By about 1750, coke and coal were providing maltsters with greater control over the roasting of malt, which made possible the brewing of pale and amber beers, and a classification system to differentiate these from the dark stout and porter brews became an important issue. Later in the century, thermometers and hydrometers added more control to the different stages of the brewing process, and in 1817, a "patent malt" was developed that made stout and porter brews lighter than they had previously been – beginning a trend toward less-alcoholic beer that continues to this day (McGee 1984).

Brewing in the Modern World

In the nineteenth century, beer brewing was revolutionized by a process that had originally been discovered back when hops were just beginning to find their way into ale on a regular basis. Until about 1400, "top" fermentation had been the procedure used. However, at about that time in Bavaria, the process of "bottom" fermentation was developed – "top" and "bottom" indicating where yeast collects in the vat. Bottom fermentation permits the manufacture of a lighter beer, but it was not until the 1840s that the technique spread from Bavaria first to Pilsen, Czechoslovakia, and Copenhagen, Denmark, and then to the wider world. "Pilsner lager" became the prototype of modern beers, with only England and Belgium persisting in the use of top fermentation.

Yet even before the spread of the new lager beer, the nineteenth century had begun to witness the rise of large-scale commercial breweries. These were encouraged by the growth of cities, which provided mass markets and rising wages for an ever-growing urban working class. By 1800, brewers in England, such as Whitbread and Barclay Perkins, were producing 100,000 to 200,000 barrels of beer per year. The largest brewer, Arthur Guinness, held a virtual monopoly in Ireland (Hawkins 1979: 14).

At about midcentury, German immigrants set about completely transforming the brewing industry in the United States. It was in 1844 that Frederick Lauer – a second-generation brewer in Reading, Pennsylvania – introduced the new lagering process, and the business of beer exploded. During the 1850s and 1860s, under the direction of other German immigrants, both Milwaukee and St. Louis became the major centers of the lager industry, with Pabst, Schlitz, Miller, and Blatz becoming giants in the former and Anheuser and Busch in the latter. Companies that came into being outside of these centers around this time were Hamm in St. Paul, Heileman in La Crosse, and Stroh in Detroit. Almost overnight, the Pilsner-style beers edged out the darker and richer beers that had first reached America with the English colonists.

More innovations came along to improve them. The development by Copenhagen's Carlsberg brewery of an absolutely pure brewer's yeast – which would end brewing failures – occurred in 1883. With the turn-of-the-century development of airtight kegs and carbonation, America's beers became bubbly, Pilsner-style beers, and in 1935, the Krueger company of New Jersey introduced the first canned beer (Trager 1995).

The Anheuser-Busch company may be said to embody the story of American beer. Formed by German immigrants Eberhard Anheuser and Adolphus Busch in the mid–nineteenth century, it capitalized on improved transportation and aggressive marketing techniques to the extent that, by 1901, the company was producing more than 1 million barrels of beer annually and had become the first to mass-market bottled beer. To provide the freshest beer available, Anheuser-Busch formed its own refrigerated railcar company and was one of the first brewers to employ pasteurization techniques (Smith 1995: 114–15). The company survived Prohibition by producing "nearbeer" and malt for home brewers, maintained and even updated its brewing equipment, and emerged aggressively from those difficult times to become the giant it is today.

One reason for the popularity of lager beer in the United States is that hot summer days seem to call for ice-cold beverages, and the heavier beers did (and do) not lend themselves well to chilling. Presumably this explains why the British and many other Europeans drink beer that is at room temperature or perhaps cool but not cold. Another reason, however, is taste. Many believe that chilling removes taste, and in fact, most non-Americans do not particularly care for American beer, which they find to be uniformly bland in taste and lacking in character. European Pilsners contain less in the way of chemicals and generally more in the way of alcohol than American beers. On the other hand, Americans in general – and not just those in the United States – enjoy cold lagers; in fact, Mexico and Brazil are among the world's top beer-producing countries. Mexican breweries in particular make a wide selection of light-tasting lagers, with perhaps Corona, along with Dos Equis (a dark Pilsner), among the best known (Pepper 1996).

It was Americans who introduced Foster's beer to Australia in 1888 and did it "American style" with refrigeration, bottom fermentation, and bottling – in the process creating a product that became Australia's national drink. In Jamaica, by contrast, the famous Red Stripe continued under English influence to be a dark, alelike brew until 1934, after which it finally was transformed into a light-tasting lager (Trager 1995).

Beer was brought to East Africa by the British in 1922 and is brewed there today mainly by East Africa Breweries in both Kenya and Uganda. Kenya Breweries, a subsidiary of East Africa Breweries, produces the Tusker lagers, some of the best-known beers in Africa (Pepper 1996: 135). Nigeria and South Africa, however, are the major beer producers on the African continent. Most of Nigeria's beer is brewed by Guinness and Heineken (both of which have major stakes in Nigeria), along with several indigenous breweries. South Africa's beer is produced by South African Breweries and is almost entirely in the lager style (Pepper 1996: 135).

Lager beer reached Asia in 1904, when German and British entrepreneurs established a Western-style brewery along the coast of northern China, producing a brand known as Tsingtao. The Dai Nippon Beer Company of Japan acquired the Tsingtao Brewery in 1916 and retained it until after World War II. In 1932, Japan continued the spread of lager in East Asia by constructing another brewery in Manchuria and introduced breweries into Korea as well. The Dai Nippon Beer Company, along with Kirin, dominated the Japanese beer market until broken up by American occupation authorities in the aftermath of World War II (Laker 1986: 60, 1987: 25–8).

Throughout the twentieth century, the trend has been toward ever larger commercial brewers. In the United States, for example, the number of large breweries has decreased from more than 200 to less than 50. Today, it is mostly lager beers that are consumed globally, and these are produced by big corporations for large markets – often international ones. Although European and American lagers tend to dominate the world market, one exception to this trend is Singha, a lager from Thailand, which is one of the few Asian beers that enjoy a wide degree of export to the West, especially as Thai restaurants continue to grow in popularity (Pepper 1996: 130).

The exceptions to the dominance of mass-produced, globally marketed beers are the products of some "microbreweries" (but not those connected with the giant brewing companies) that found a ready market in the 1980s and 1990s, when entrepreneurs began distributing innumerable beers that were produced either in a "brew pub" or in a small brewery. Microbrewers offer a uniqueness not found in mass-produced beers, crafting their microbrews in a fashion reminiscent of earlier days, when beer production was confined to monasteries, village breweries, or to the home itself. Generally priced higher than their mass-produced counterparts but with a more refined appeal, microbrews have established a niche among the more affluent consumers in America and Europe.

III.2 Breast Milk and Artificial Infant Feeding

The importance of maternal breast feeding is considerable for infant survival until weaning and beyond. In addition to nutrition, it also provides many of the mother's immunological defenses to a baby whose own defenses are weak at birth. In the past, however, the protective (as well as the nutritive) qualities of maternal milk were unknown, and wet-nursing practices were common for social, cultural, and economic reasons. In the West, maternal breast feeding in the first year of life was most common in rural areas. But animal milks and solid food were given to babies everywhere when breast feeding was not possible, practical, or convenient, or when it was considered insufficient.

Maternal Breast Feeding

During the first year of life, mortality should be independent of the purely nutritional factor. It has been demonstrated that even undernourished mothers, subsisting on around 1,500 calories a day, are able to nourish their babies adequately through breast feeding (Livi-Bacci 1991). Nonetheless, in the past, infant mortality figures (which were usually high) varied enormously with maternal feeding practices. Babies not breast-fed are easily prone to gastrointestinal infections in summer and to respiratory infections in winter. Thus, environmental circumstances and child care were secondary factors of survival when compared with the manner in which infants were nourished.

Mother's milk is in itself complete nourishment for a new infant. However, compared to the milk of a new mother (which comes in response to the direct demand of the suckling child), the milk of a wet nurse has neither the "age" nor the exact composition required for neonates, because usually the nurse has given birth to a child of her own some months earlier. Nevertheless, female milk is preferable to animal milk. Our ancestors were perfectly aware of the age of the milk – its color and consistency – when choosing a wet nurse. Yet before the 1750s, they did not fully appreciate the qualities of human milk and the superiority of a mother's milk for her own child.

The Qualities of Human Milk

The constituents of human milk – water, protein, fat, carbohydrates, minerals, vitamins, lactose, casein, and so forth – have all been examined, and comparisons made with cow's milk and other animal milks (Paul and Palmer 1972; Davidson et al. 1975; Souci, Fachmann, and Kraut 1981). Such studies have demonstrated the advantages of human milk, and they show why cow's milk cannot safely be given to very young children unless it has been processed. This procedure involves dilution with water, to reduce the excessive protein concentration, and also the addition of sugar. Moreover, before pasteurization, cow's milk presented other dangers. Since the milk was not boiled, and bottles and other instruments were not sterilized, artificial feeding could easily produce fatal infections. With direct sucking, however, such consequences were avoided.

The Wasted Colostrum

In European societies, there was a common and widespread belief that a mother's first milk, the colostrum, was not good for the newborn baby, who had to get rid of his or her meconium. Thus, another lactating woman frequently suckled the child for the first four or five days. Unfortunately, delayed lactation for new mothers could result in milk fever, painful milk retention, and unprepared nipples that could discourage her from ever breast-feeding (Fauve-Chamoux 1983).

Nor was such a procedure good for the baby. Although people of many cultures – from ancient Greeks to Mexican Indians (Soranus of Ephesus 1956; Kay 1981) – have shared the belief that the colostrum may be dangerous (indigestible, heavy, and corrupt), it is, although lightly purgative, actually well assimilated and very protective in the antibodies it delivers.

Yet until the middle of the eighteenth century, or even later, medical literature condemned the colostrum. Samuel Tissot, for example, in his best-selling handbook, *Avis au peuple sur sa santé* (1782: 379), wrote:

> The stomach and bowels of the child, when he comes to the world, are full of a thick and sticky substance called *meconium*. This substance must be evacuated before the child is fed with milk, otherwise it would corrupt the milk; it would turn very bitter and produce two kinds of severe problems the child would not survive.
>
> This excrement may be evacuated (1) if no milk is given during the first 24 hours. (2) If water is given during this time, with a little sugar or honey in it; resulting in a dilution of the meconium, a better natural evacuation and perhaps vomiting. (3) To ascertain that all the substance has gone, it is recommended to give, every four or five hours, an ounce of syrup made of *composite chicory*, added with a little water. This diet is of great advantage; it should be common practice, as it is now here [in Switzerland] since the last years; this syrup is better than any others, particularly better than almond's oil.
>
> If the baby is very weak, and if some food is requested during the first day of life, some biscuit, soaked in water, is usually given, or a light *panade* [bread soup].

Most children of preindustrial rural families were fortunate enough to have this treatment succeeded by maternal breast feeding. But for many less-fortunate urban children, it was followed by a regimen of wet nursing and complementary foods.

Control of the Milk Supply

According to the Greek physician Soranus, active in Rome and Alexandria about A.D. 100, a nurse's milk should be regularly tested for consistency and quantity. In order to maintain a good milk supply, any nursing woman had to follow a regimen of diet, rest, and some exercise. Earlier, around A.D. 60, Pliny the Elder in his *Naturalis Historia,* had indicated that some foods helped increase one's milk supply. These included cabbages, fennel, *Agnus castus* seeds, anemone, and the boiled stalk of sow thistle (Pliny 1601; Soranus 1956; Knibiehler and Fouquet 1980).

In late-nineteenth-century literature, it was often recommended that a lactating woman eat good meals, with cereals, lentils, and chocolate. In addition, it was believed that drinking beer, cider, or even coffee would help maintain a "humectant" diet (Delahaye 1990). However, it is interesting to note that, before the 1830s, such literature was astonishingly silent about beverages. From antiquity on, treatises recommending maternal breast feeding seem oblivious to the importance of drinking liquids. Yet 87 percent of human milk is water (Table III.2.1), and so a lactating mother should drink extra liquid to feed the child (Table III.2.2).

Indeed, this may be one of the reasons that so many urban women of the past complained about not being able to produce sufficient milk: They simply did not drink enough liquids. In European urban areas, water pollution was so general that water might have been used for cooking soup but not for drinking, and unboiled water was dangerous to health.

In rural areas, by contrast, peasants knew the respective qualities of various water sources and frequently had easier access to fresh spring water than urban dwellers, although it is true that even in the country, unusual pollution occasionally resulted in serious epidemics. The generally greater access to clean water supplies, however, helped ensure that breast feeding not only remained a predominantly rural practice but was also a paying occupation of peasant women, because they were regarded as fit to produce human milk on demand for several years at a time. In addition to earning money, country nurses probably also knew that lengthy lactation might help them avoid another pregnancy.

Table III.2.1. *Typical analyses of milk from various species*

	Human	Cow	Goat	Ass
Water (g/100ml)	87	87.5	86.5	91
Protein (g/100ml)	1.5	3.5	3.7	1.9
Fat (g/100ml)	4.0	3.5	4.8	1
Carbohydrates (g/100ml)	6.8	5.0	4.5	6.0
Minerals (g/100ml)	0.2	0.7	0.8	0.4
Lactose (g/100ml)	7	4.5	4.1	6.1
Energy (kcal)	68	66	76	41

Delaying Conception: Milk Versus Blood

Acting through a complex hormonal mechanism, lactation can inhibit ovulation under optimal circumstances. However, both ethnographic and demographic data indicate that the relationship between breast feeding and anovulation is not perfect (Corsini 1979). In addition, other data help to disguise the importance of sexual abstinence during the postpartum period. In fact, many historical and/or demographic studies are difficult to interpret because they are mute about breast-feeding habits. When a mother is the sole source of infant nourishment, anovulation is frequent, and many populations have depended on the contraceptive effect of breast feeding for the spacing of births. Yet despite many recent historical studies using family reconstitution methods, the exact role of breast feeding in causing postpartum amenorrhea in past Western societies has eluded quantitative elucidation.

The age of the nurse, her nutrition, body weight, and fatness are all unknown parameters to which sexual behavior should be added (Knodel and Van de Walle 1967; Chamoux 1973b; Corsini 1974; Fauve-Chamoux 1983). Hippocrates and Soranus shared the idea that pregnancy could not occur without menstruation, the resumption of which, they thought, was encouraged by sexual intercourse, with the result that this specific blood altered the milk. Thus, many authorities insisted on the necessity of sexual abstinence during breast feeding (Van de Walle and Van de Walle 1972), but it seems that the great majority of European couples never accepted this taboo.

Soon after birth, part of the mother's blood was said to be transferred to the breasts as milk. "After helping a new life in the maternal uterus, blood goes up to breasts, following an admirable, natural and economic way, and becomes a sweet and familiar food" (Verdier-Heurtin 1804: 30). Before conception, the female's extra blood was thought to be evacuated every month. Thus, after birth, if the mother did not lactate, her milk might be dangerously "driven back" and could make her sick. If menstruation or pregnancy occurred while wet-nursing, the milk was considered "spoiled" (Chamoux 1973b; Sussman 1982; Fauve-Chamoux 1985; Fildes 1988); in consequence, the milk of a pregnant nurse had a very bad reputation (Kay 1981; Fildes 1988).

Medical literature of the eighteenth century, which is replete with discussions of maternal breast feeding versus mercenary nursing, defended the Hippocratic principle of respect for nature: The free circulation of "humors" should be encouraged, and any impediment to this natural principle might create severe physical and moral troubles. Also common in the literature were references to the dangers of physical and moral contamination: "A child would have been honest if he had suckled his own mother's milk; instead he was a villain, a libertine, a vicious man with a bad temper; from suckling a bad wet-nurse he got all her vices and defaults" (Dionis 1721: 57).

A lascivious or hysterical nurse was believed to transmit her character through her milk, along with various eventual diseases – especially those of a venereal nature. Despite this, however, menstruating wet nurses were numerous, and those who were employed did their best to hide their monthly visitations (as well as any pregnancies) so as to continue nursing.

The Length of the Nursing Period

According to Soranus, the nursing period in his era ranged from 18 to 24 months – until the child could chew. Russian children of the eighteenth century were weaned after some 10 to 15 months of nursing (Chamoux 1973b; Ransel 1988). In Brittany at the beginning of the twentieth century, the weaning limit was 18 months, and "[t]hen my mother definitely closed her shirt and corselet," related Pierre Jakez Hélias (1975). "Then I had to eat my bouillie alone." Another tradition indicated that a child could be weaned when he had grown twenty teeth. In France, children of the rich could be suckled by their wet nurses until age 20 or 22 months.

By contrast, at the end of the ancien régime, the great majority of foundlings who survived were officially weaned when 12 months old. In the Rheims region, however, 54 percent of illegitimate babies were weaned when 12 months old, and 31 percent when 13 months old, for a very simple administrative reason: Wet nurses had a monthly salary, and thus the change took place on the first day of the month. But unfortunately, weaning concerned only the 30 percent of children who survived to secure access to a nurse's breast in the first place. Legitimate city children sent to wet nurses in the country were not returned to Paris before 19 or 20 months of age, although they had been weaned some months before. Because treatises of the Enlightenment period did not recommend breast feeding exclusively (Hecquet 1708; Lerebourg 1767; L'Epinoy 1785), semisolid food was also a part of the infant's diet. Thus, some children could be weaned as early as 6 months or even less. The weaning schedule depended on a question of money: A dry nurse was cheaper than a wet nurse, and peasant women could officially sell their milk as soon as their own child reached 7 months (*Code des nourrices de Paris* [1715] cited in Delahaye 1990). It seems, however, that cheating was the norm in Paris as far as this regulation was concerned, and the age of the nurse's milk could be only a guess.

Mercenary Breast Feeding in Europe

Until the middle of the seventeenth century in Europe, the practice of putting a child out to nurse was reserved for the aristocracy. It was standard behavior to hand over an aristocrat's newborn child to a paid nurse, although the nurse was usually strictly supervised by the family. Much later, in the nineteenth century, bourgeois families utilized the system of an "on-the-spot" wet nurse who was given board and lodging and was, like her earlier counterpart, closely supervised. But in between these two periods – during the seventeenth and eighteenth centuries – newborn babies of those who could afford it were often sent to the country, and thus placed out of range of their mothers' control. We do not know how extensive this phenomenon was throughout Europe. In France, it was limited primarily to residents of the main towns (Chamoux 1973a), and in Renaissance Florence, there was a long tradition of urban parents sending infants out to nurse *(a balia)* soon after birth (Klapisch-Zuber 1985).

In preindustrial England, such a practice was never so widespread as in some other parts of Europe, but well-to-do urban families of merchants, lawyers, physicians, and clergymen – especially those residing in London – tended to employ country women a few miles away from the city (Fildes 1988). Similar situations existed in Warsaw, Hamburg, Stockholm, Vienna, and Madrid.

Parental Behavior and Social Norms

In the past, paternal feelings for children who had not yet reached the age of reason were frequently negative. Michel de Montaigne, for example, wrote in his *Essays* (1580), without mentioning his wife's opinion: "I cannot feel that passion necessary to kiss a barely-born child, with neither movement of his soul, nor a recognizable shape to its body, by which it might make itself pleasing to me. Nor have I been inclined to have them fed close by me." He continued that it was "a good school to send them [the small children] to the country, to bring them up in the lowest and commonest way to live under popular and natural law."

Basically, Montaigne's "natural" educational model did not differ very much from that of Jean-Jacques Rousseau. Following the fame he had acquired from the articulation of his philosophy of child care in *Émile* (1762), in 1789 Rousseau wrote in his *Confessions* (1959): "I have neglected my duties as a father, but the desire to do them harm did not enter my heart, and my fatherly entrails could hardly cry out for children who have never been seen." The latter remark was a reference to a wet-nursing arrangement that distanced the mother from her infant. As an earlier observer had lamented:

> I am quite at a loss to account for the general practice of sending infants out of doors, to be suckled, or dry-nursed by another woman, who has not so much understanding, nor can have so much affection for it, as the parents; and how it comes to pass, that the people of good sense and easy circumstances will not give themselves the pains to watch over the health and welfare of their children (Cadogan 1748: 24).

Clearly, a bond between nurse and child frequently replaced that between mother and child, and many medical writers followed Soranus of Ephesus – the most famous gynecological and obstretrical writer of antiquity – who thought that a good wet nurse helped in protecting the mother's health and youth. In the time of Soranus, however, the nurse was present in the family, and her behavior was under strict supervision. In the eighteenth century, this was not the case, and even a mother's quest for elegance and parental desires for tranquillity cannot fully account for putting children out to nurse. Nonetheless, this was a widespread social phenomenon, which resulted in half the babies in Paris being sent outside the capital, no matter what their sex or birth order. The explanation seems to be that it had become common middle-class behavior.

Urban Females and Breast Feeding

Refusing the maternal duty of breast feeding, however, also extended to the lower classes, especially in preindustrial European towns. A French writer in Lyon in the 1860s explained:

> Shopkeepers' wives have, in general, as much importance in their business as their husbands, they cannot nurse for themselves; and besides, they usually live far from their shops, so they have to resort to the wet nursing bureaux. It is the same with female silk workers, who earn almost as much as their husbands and have an interest in putting their children out to nurse in the country (Sussman 1982: 104).

A century before, when women were working hard for the *manufactures,* a police officer in Lyon observed that "[t]heir situation, work, condition do not allow the women any time, any freedom, to feed their own children" (Prost de Royer 1778).

There may, however, have been other reasons, not related to the work of the mothers, for sending children away. To send the newborn child to fresh air, in the belief that the bad urban air spoiled maternal milk, was doubtless one reason. Another may have been the perception that the diet of urban females did not contain enough in the way of appropriate beverages and good-quality proteins. Indeed, in France, consumption of meat in urban areas was very low at the end of the ancien régime (Livi-Bacci 1991). Thus, poor women of the countryside may even have had a better diet than their urban counterparts. Nonetheless, we are forced to wonder again what meaning "motherhood" held for those couples who put their children out to unsupervised country nurses, or what it meant for those mothers, often alone, who abandoned their babies to charity.

Love and Premodern Motherhood

It is doubtful that people of the past did not realize that putting a child out to nurse was risky, and that abandoning a child was to condemn it to death. This makes it difficult to explain how, in those days of enlightened philosophers, the widespread practice of abandonment of newborns (which in pre-Pasteur times usually amounted to infanticide) could coexist with a clear renewal of interest in children (Aries 1962; Shorter 1975; Badinter 1981; Bardet, Corsini, Perez Moreda, et al. 1991).

Indeed, it is morbidly fascinating that Rousseau, the herald of individual morality, seems to have had no difficulty adopting the behavior of contemporary Parisians with regard to bastard children: He abandoned his own children to the Paris foundling hospital. His reasons for this choice are very clear (Rousseau 1959), but the mentality that inspired them remains incomprehensible to us. Rousseau did not belong to any of the social groups regularly acquainted with child abandonment, such as domestic servants, urban workers, or impoverished day laborers, but his children were all bastards, and raising them was apparently not among his priorities.The same held for Thérèse Levasseur, his companion, who seemingly did not fight to keep her children, nor did she try to suckle her succession of babies, boys or girls. In Europe, as many boys were abandoned as girls (Bardet et al. 1991).

An abundant eighteenth-century literature encouraging maternal breast feeding stirred little interest in French, Italian, Russian, Polish, or English urban societies (Hecquet 1708; Lerebourg 1767; L'Epinoy 1785). It was the case that some grand ladies (who could afford to) breast-fed their children and then boasted about it as a way of returning to nature. Similarly, it was fashionable to have one's portrait painted when breast-feeding, like a Madonna (Fauve-Chamoux 1985). All of this was a way to affirm one's modernity and to symbolize an advanced feminism, but it was also the case that men frequently did not wish their wives to breast-feed. Thus, often, aristocratic women who breast-fed their infants only did so during the day; at night, maids or nurses took care of the babies. The day for the child, the night for the husband; the sum was a compromise with God.

Serving the Husband before the Child

Since polygamy is not tolerated in most Christian societies, theologians and confessors have had great difficulty in establishing a hierarchy of sins: A woman was supposed to do everything possible to avoid a too-ardent husband, and, of course, also to avoid adultery. Yet neither could she refuse her wifely duty for too long, even if her aim was to preserve her milk, which helps to explain why confessors finally justified the practice of putting children out to nurse as being the lesser of two evils: "If the husband is in danger of lacking restraint, the woman must, if she is able, put her child out to nurse in order to tend to her husband's infirmity," said the *Abrégé du dictionnaire des cas de conscience* by M. Pontas (1764).

Certainly such a practice preserved the peace of the household by ensuring the father permanent access to his wife's bed. This aristocratic habit was popularized in France and reveals the importance placed by the Catholic Church on conjugal relations. The Church favored the relationship between the parents and relegated the child's interest to second place (Aries 1962; Noonan 1966; Flandrin 1973).

Religious attachment also influenced attitudes with respect to childbearing and nursing. Protestant women generally bore fewer children than their Catholic counterparts and nursed them more often themselves. Infant mortality was, thus, much higher in Catholic than in Protestant families during the seventeenth century (Knodel and Van de Walle 1967). But despite dechristianization and an enormous literature in favor of maternal care, there was no widespread return to maternal feeding at the end of the eighteenth century, and France remained a cornerstone of the nursing industry. Families characteristically had fewer children, but the practices of wet nursing and artificial feeding continued, and until World War I, the custom of putting infants out to nurse remained widespread and infant mortality remained high (Rollet-Echalier 1990). In short, the status of infants did not improve greatly in France (or in western Europe, for that matter) before the first decades of the twentieth century.

Differential Infant Mortality

The consequences of this apparent unconcern for the welfare of the young were of considerable importance. Putting babies out to nurse raised the infant mortality level and, in the absence of contraceptive practice, accelerated the rate of successive pregnancies. France's infant mortality, much higher than that of England, Sweden, or Denmark, was clearly a function of less breast feeding and poor child care (Table III.2.4).

Table III.2.3. *Number of babies, aged less than 1, abandoned in Paris Foundling Hospital, 1773–7, with infant mortality for each group, according to their origin*

	From Hôtel-Dieu	From Paris and the suburbs	From the provinces	Total
Babies abandoned	6,523	14,552	9,039	30,114
Died under 31 days	5,395	10,650	5,854	21,899
Died within 12 months	5,892	12,185	7,180	25,257
Died under 31 days	82.7%	73.1%	64.7%	72.7%
Died within 12 months	90.3%	83.7%	79.4%	83.8%

Sources: Dr. Tenon, Bibliothèque Nationale, Paris, NAF 22746, cited in Chamoux (1973b).

Among Parisian craftsmen who kept their children in the eighteenth century, one baby out of every four died before his or her first birthday. But in Lyon in the 1780s, the "Society for Helping Poor Mothers" paid women 9 pounds a month if they breast-fed their own children during the first year of life. The infant mortality level soon fell to 1 out of 6 babies; the drop was considered a large success. By contrast, however, when infants were systematically put out to nurse, the infant mortality rate at least doubled. Thus, 40 percent of legitimate babies in Rouen died if they were put out to a wet nurse. But when their mothers nursed them, infant mortality dropped to 20 percent, showing the vital importance of maternal breast feeding (Bardet 1973). In Lyon, only one-third came back alive from wet nursing, and in Paris, only between one-half and one-third of legitimate children survived mercenary nursing (Prost de Royer 1778).

From the Refusal of Breast Feeding to Contraception

Rejection of the newborn was accompanied in France by a progressive diminution of family size. In Rheims, at the end of the seventeenth century, women who married before age 20 bore an average of 11 or 12 children. But in the late eighteenth century, on the eve of the French Revolution, women were having only 6 children (Fauve-Chamoux 1985). The conjugal practices of urban elite groups had undoubtedly shown the way with regard to contraception. As early as the 1670s, the leading families of large cities like Rheims or Rouen (Bardet 1973; Fauve-Chamoux 1985) were successfully limiting the number of their children, and social differences in this regard were strongly marked.

During the eighteenth century, behavior that would later be called "Malthusian" took root in the middle class. This was a "family-planning" outlook that implied deep changes in attitude toward the Christian religion, and toward love and procreation. But, for the lower classes, little had changed. Poor mothers, frequently without husbands, often considered that they had no choice but to abandon their children, whether legitimate or not. And this custom continued to confront societies with moral as well as practical questions concerning the care and feeding of the young.

Artificial Infant Feeding

Feeding Foundlings

About one-third of the children abandoned in Paris during the eighteenth century came from the provinces and, thus, were at least a few days old and already sick and underfed. Many of these babies died before reaching the ancient hospital, the Hôtel-Dieu, which also served as a foundling home. Among other things, these deaths tended to skew mortality data and make it appear that, at the Hôtel-Dieu, the mortality of children from the provinces was lower than that of children born and abandoned in Paris (Table III.2.5). In 1772, the king prohibited this transfer of infants to Paris, but the flow continued. The ban was renewed in 1779 but with no better results, and at the end of the *ancien régime,* between 6,000 and 7,000 newborn babies were being abandoned in the capital each year (Table III.2.5).

The mortality of these children was horrifying. More than 80 percent died, with 7 out of 10 deaths occurring during the first month of life and resulting from lack of appropriate food and nursing (Table III.2.3). Three-quarters of those who died were estimated by the authorities to be of illegitimate birth. European urban hospitals of the time, like the Hôtel Dieu, were transformed into depositories for abandoned children. Paradoxically, however, such institutional efforts may have encouraged the phenomenon of infant abandonment all over Europe (Bardet et al. 1991).

Table III.2.4. *General infant and child mortality in four European countries during the second half of the eighteenth century*

France 1750–99	England 1750–99	Sweden 1750–99	Denmark 1780–1800
273	165	200	191
215	104	155	156

Source: Livi-Bacci (1991), p. 74.

The scarcity of wet nurses for such children was general throughout Europe: Institutions paid low wages and the women they employed were poor, often unfit for proper breast feeding, and frequently without enough maternal milk. Therefore, French hospitals experimented with different methods of nourishing abandoned young children, trying cow's, goat's, and donkey's milk, and often combining the animal milks with water and barley or with "rice water." At the Hôtel-Dieu in Paris, and at similar institutions in Rheims and Milan (where abandoned children were numerous), feeding with animal milks led to the use of feeding bottles and special feeding horns, called *cornets.* These became part of a baby's equipment when leaving the foundling hospital for the wet nurse's home, and they provided a ready means of dry nursing and early weaning.

In Paris at the end of the eighteenth century, there were 208 cradles for foundlings that were permanently occupied. Each saw an ultra-rapid turnover, and each had a personal crystal bottle attached (Chamoux 1973b).

Animal Milk and Baby Food

Cow's milk, mixed with "barley water" in the Paris foundling hospital during the eighteenth century, probably contributed to the death of many children during the first weeks of life. "Wheat water" was also given as a separate drink. A common milk lightener was "lentil water," with a dilution as high as 50 percent for "healthy babies," according to the French physician Dr. J. Tenon,[1] who explained that this liquid was made available "in a porc bladder equipped with a teat or in a feeding-bottle when the children were crying" (Tenon manuscripts, Bibliothèque Nationale, Paris).

Milk from goats was widely known to be lighter, and therefore better, for infants than that of cows. A sixteenth-century observer near Bordeaux, for example, wrote of country women whose breasts did not contain enough milk to feed their infants and consequently called upon goats "to help them" (Montaigne 1580). In 1634, goats were employed by Paris's Hôtel Dieu to feed the foundlings, as had been done successfully in Italy in the previous century (Lallemand 1885).

Table III.2.5. *Number of children abandoned in Paris Foundling Hospital, 1773–7, according to their age and origin*

From Hôtel-Dieu	From Paris and the suburbs		From the provinces		
Newborn	Age less than 1	Age +1	Age less than 1	Age +1	Total
6,523	14,552	462	9,039	1,375	31,951

Such nourishment was certainly good when the babies were directly suckling the animals. But unfortunately, bottles, with all their attendant germs, were often used as intermediaries, and if another liquid was added – for example, herb tea of *chiendent* ("couch grass") – it made for a dangerous diet. Goats were easier to maintain in an urban institution than donkeys, whose milk had enjoyed a good reputation for its digestibility since Roman times (Table III.2.1). In Paris in the 1880s, donkeys were used for direct suckling at the stable of the *Hospice des Enfants Malades.* But they were troublesome because lactation could not be prolonged unless the animals fed their own foals, and the experiment did not last long. Direct animal suckling, however, was usually a practice in hospitals for syphilitic children, who, because of fear of contagion, were never breast-fed.

Wine was said to be a "tonic" when given in dilution and in small quantity. It was often employed when no milk was available, particularly when the child was being transported without any nurse. For example, it had the effect of keeping abandoned children quiet when they were taken by slow carriage to the Parisian foundling hospital from far away. But alcohol was also believed good for infants when they suffered from gastrointestinal complaints (Fildes 1988). Calvados, champagne, or other spirits may, on occasion, have been ritually added to feeding bottles to celebrate baptisms or like events.

European Bouillies

Solid food for infants consisted of a kind of porridge, called *bouillie* in French. This was a food usually reserved for a weaning diet and for older children. In much of France, wheat was preferred for the porridge (oats were considered a food for animals), but the use of corn was common in southern France after the end of the ancien régime. There, a porridge called *millias,* cooked in a pan, served as a main course for both adults and children. This dish was similar to Romanian *mamaliga* or Italian and Iberian *polenta* (Livi-Bacci 1991).

It is fortunate that such complementary foods were not strictly reserved for weaning or for mercenary nursing but rather were given, along with milk, to very young children in both European and colonial societies. This explains why *marasmus* – the result of a grossly deficient intake of both proteins and calories (Gift, Washbon, and Harrison 1972; Livi-Bacci 1991) – was not a common type of malnutrition in past Western societies. By contrast, many Occidental babies died of too much unaccustomed solid food and too little of their own mothers' milk. One example of such an imbalance was a "biscuit soup" prepared every day in a London foundling hospital. The apothecary complained in 1759 that milk was often forgotten in the mixture: "The biscuit is directed to be boiled in water to a proper consistence and afterward mixed with a proper proportion of milk, but it is now and has been given to the children without any milk at all" (Fildes 1988: 169).

During the 1770s, Tenon collected information from all over France and Europe about artificial baby food. He understood that any artificial food was usually a killer when the very young baby was not or was no longer breast-fed. "Those foods," he wrote, "given as supplements to breast milk, as thick *bouillies* made of ordinary milk, flour, yolk, and wine, sweetened with sugar, destroy the positive effects from the very little milk they happen to suckle; those foods are too thick and too heavy for a delicate baby's stomach" (Chamoux 1973b: 415).

When mother's milk was lacking, Alsatian and German women gave their own children a cream made from rice or bread. In seventeenth-century Brittany, rural mothers often fed their children with a finger, after first warming the bread soup in their own mouths (Lemieux 1985). Certainly, in the past, the easiest food to give a baby, other than milk, was wet and mashed bread.

Such a *panade* figured prominently in the weaning process, which came about when the mother could not, or no longer wanted to, breast-feed her own child. This was often the case when a woman was wet-nursing another child. In Salpêtrière Hospital in 1755, for example, children of employed wet nurses were served a portion of *bouillie* in the morning and another in the evening, and given soup at lunch time. A "portion" was half of a big spoonful, and 17 portions were prepared twice a day in a cooking pot called a *bonet.* Most of those children, who rarely received mother's milk, also consumed a daily supplement of a pint of animal milk.

Tenon, who commented so extensively on eighteenth-century baby food, was, for his time, a rare defender of cow's milk, apparently because he was influenced by positive reports of Russian customs. Muscovite children, he wrote, were treated roughly but seemed to become accustomed very early to animal milk and solid food. Indeed, from the very first day of life, Russian babies were fed with salted, mashed bread and cow's milk. "The woman in charge puts the milk in her own mouth to get it warm and spits it in a feeding horn for the baby. When aged ten months, the child is given *cacha,* a sort of gruel from *sarrazin* (buckwheat) – cooked with milk, a much better *bouillie* than the one made in our countries." Three other kinds of traditional Russian baby foods and pastes are mentioned by Tenon. One was made of mashed bread, butter, and beer, another of mashed bread with honey, and still another of mashed bread with premasticated meat. And when the babies cried, they were given, as early as one month of age, a light narcotic made from poppy seeds, commonly used for making traditional pastries (Tenon Manuscripts, Bibliothèque Nationale, Paris).

This diet, Tenon noted with admiration, "never results in *edema,*" which is a well-known symptom of malnutrition still observed in twentieth-century developing countries. Sometimes it is called *kwashiorkor* and is the result of a deficiency of protein even when caloric intake is relatively adequate (Gift et al. 1972). In light of Tenon's observation, it seems that Russian children may have enjoyed more good-quality protein in their diet than any dry-nursed babies in western Europe, who were never given meat or fish but only cereals, and who often suffered from edema.

It turns out, however, that Tenon was misled by the French edition of a book concerning the new foundling hospitals of Russia established by Catherine the Great; he believed that Russian women did not usually breast-feed their children (Betzy 1775). Today we know that at the end of the eighteenth century, the feeding of foundlings was as much a problem in Moscow and St. Petersburg as it was elsewhere in Europe. Fully 14,000 babies were registered annually by the Moscow Foundling Hospital (Ransel 1988), and their mortality was estimated to be at least 60 percent, which was roughly comparable to French figures.

During the 1880s, wet nursing became a common female profession in Russia: "The majority of new mothers from our area," wrote a Russian physician, "do not think merely of how it would be best to nurse their baby but how they might best draw advantage from their breast milk; this unfortunate phenomenon is expressed in two forms – either becoming a [private] wet nurse or by taking a foundling, and sometimes not one but several" (Ransel 1988). Such a situation had long been common in most of Europe, but it was one that was in the process of change for the better.

The Swan Song of the Wet Nurse

Many significant changes in baby care occurred during the nineteenth century. Among the middle classes in Europe, in Paris and Lyon as well as in London, Madrid, Vienna, and Moscow, it became expected that the wet nurse would reside in the home of the infant (Fay-Sallois 1980; Sussman 1982; Fildes 1988). In England, however, during early Victorian times, when an unmarried wet nurse left her own baby of six weeks to sell her milk in a London bourgeois family, she condemned him or her to death. Infants of the poor still rarely survived artificial feeding, and the absence of human milk and early weaning sacrificed most illegitimate, as well as many legitimate, children.

In Britain, the Infant Life Protection Bill was passed in 1872, but this failed to stop baby farming and wet nursing. In France, the Roussel Law (1874) had no more immediate effect, but it did oblige families to register all children who were nursed outside the home, to provide the name and address of the wet nurse, and to indicate the fate of the children. This permitted the calculation of regional and national statistics on infant survival and the impact of feeding methods. In Marseille, during 1875, 50 percent of parents employed wet nurses. From the data available, it would seem that 20 percent of wet nurses lived in the homes of the infants and 10 percent lived close to the baby's city. But 70 percent lived far away from the baby's home, sometimes more than 100 miles.

In the 1890s, the importance of pasteurization was understood, and artificial feeding at last became less dangerous. Nevertheless, some baby bottles were impossible to clean properly, especially those with a long tube attached to them.

Conclusion

Information from the World Fertility Survey (*Population Reports* 1986), as well as from recent studies conducted in developing countries where diarrheal diseases are a major problem for infants, shows how important breast feeding can be to infant survival (Carballo and Marin-Lira 1984). In most of western Europe, North America, and Japan, the potential impact of low breast-feeding rates has been attenuated by improved water supply and sanitary systems. But such major changes occurred less than a century ago with the advent of pasteurization techniques in conjunction with cultural, economic, and social changes. In fact, the so-called 3 Ps (Pasteur, Politics, and Progress) worked together to make artificial feeding safer. Therefore, little effort was exerted from the 1940s to the early 1970s to promote breast feeding, and by 1973, the prevalence of maternal breast feeding had fallen to 25 percent in the United States, with a mean duration of three months or less.

However, in the 1980s and 1990s, a return to breast feeding was noticeable in many industrialized countries, and especially among the better-educated mothers (La Leche International 1981). They became aware both of the immunological and antimicrobial properties of their maternal milk and of the "bifidus factor" concerning the intestinal flora of their babies. In addition, mothers understood that breast feeding benefits their infants with less exposure to contaminants, and finally, they realized that their own milk has superior nutritional properties to animal milks.

In the past, mothers had no such knowledge, however, and if babies died in innocence and purity they were supposedly blessed in heaven. Thus, putting children out to nurse remained a common practice during the nineteenth century throughout the Western world and particularly in France. In addition, before the systematic pasteurization of milk and the provision of sterilized bottles, artificial feeding frequently sent babies, especially those abandoned in European institutions, to their graves. Maternal breast feeding remains, as it was in the past, a matter of culture, family norms, and religion.

Note

1. Dr. J. Tenon's manuscripts, from which I quote, may be found in the collections of the Bibliothèque Nationale, Paris. His project during the 1770s was to reform the French hospital system. His most important opinions about artificial infant feeding habits in late eighteenth-century Europe have been discussed by Chamoux (1973b).

III.3 ~ Cacao

Origins, Varieties, and Cultivation

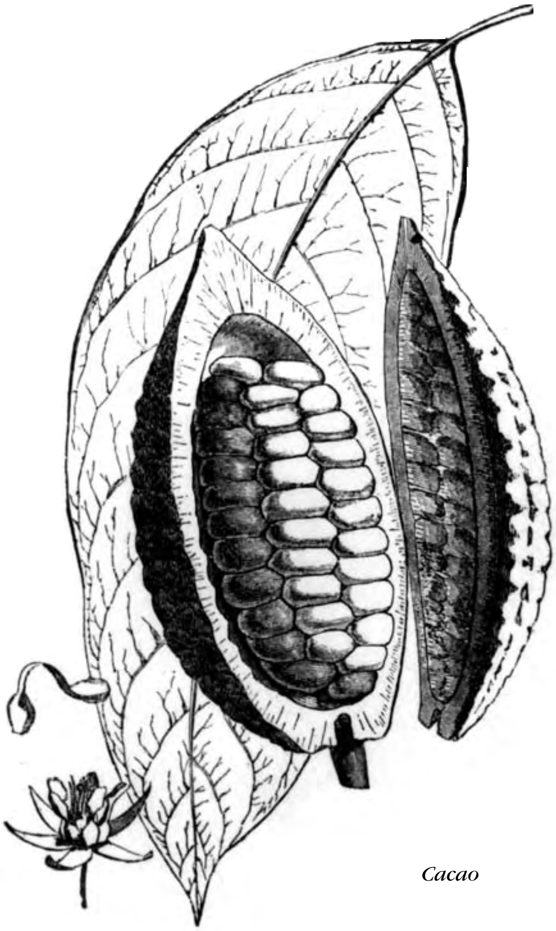
Cacao *(Theobroma cacao),* "the drink of the gods," and its main by-product, chocolate, are derived from the seeds of a fleshy pod, the fruit of the cacao tree. This tree is a tropical plant, certainly American and probably Amazonian in origin. In the Amazon region it is sometimes still found in its wild state, an understory plant usually well shaded by taller trees with dense foliage.

Today, cacao trees are sometimes grown in direct sunlight, thanks to modern fertilizers and hormonal treatments that help the trees produce a dense upper foliage. Most cacao trees, however, still require shade, and this is often provided by the simultaneous planting of shade trees and cacao saplings. Lemon trees, tall palms, and banana plants are employed, but more common is the aptly named *madre de cacao,* or "mother of the cacao" *(Gliricidia sepium),* another American native now found in all tropical areas. Various acacias and the coral tree have also been used to shade cacao plantations.

There is another species related to cacao, *Theobroma bicolor,* which is now a garden crop, although its pods were collected in the forest from ancient times until late in the Spanish-American colonial period. It does not produce true cacao and is known in Mesoamerica as *pataxte* or *patlaxtli.* Spaniards at first thought *patlaxtli* was harmful, but later they used the pods as a minor food and, in a few places, the tree to shade cacao trees.

There is some disagreement among experts as to cacao types. Many identify two varieties, others three, whereas a few claim that such distinctions evolved within historical times and were brought about by human selection and cultivation. For what it may be worth, most students of the subject agree that there are three types.

The *criollo* or "native" cacaos – that seem to have been grown only in Mesoamerica prior to the arrival of the Europeans – are considered to be the finest. All cacao trees demand considerable care, but *criollos* are the most difficult to cultivate. They are fragile, plagued by many pests, and relatively low in yield, and their cultivation today is limited to Mexico, Central America, Venezuela, and the Caribbean islands. *Criollo* cacao is often used to upgrade the quality of chocolate or chocolate drinks, and connoisseurs place great stock in the percentage of *criollo* cacao in such confections.



Cacao

Since the Spanish colonial period in America, *forastero* cacaos have been considered hardier and more prolific in yield, although of a lower quality than *criollo* cacaos. The meaning attached to the term *forastero* has varied, although it is always associated with wildness and alien origin. The plant may have spread from Brazil, but by the middle of the seventeenth century, it was thoroughly domesticated and widely cultivated in Ecuador and Venezuela. The Portuguese carried this variety from Brazil to São Tome and other offshore islands of West Africa, from whence it spread to the mainland. Today it is a leading crop in several African countries and in Southeast Asia.

The third variety of cacao, according to several authorities, is a crossbreed between the two original types, and because it was first widely grown on the island of Trinidad, it has acquired the name *trinitario.* This variety is now dispersed and can be found as far from home as Indonesia and other parts of Asia.

Indeed, it may well be that the original Amazonian wild cacaos have become so geographically scattered and modified by human agency that they now appear to be highly distinctive varieties. Experts tend to identify cacaos and their various differences and desired qualities by regions, soils, and kinds of processing, so that Guayaquil cacaos, Brazilian cacaos, and varieties from the Ivory Coast or Malaysia, for example, are all characterized according to aroma, sweetness, the shape and size of the bean, oil or "butter" content, and other attributes.

Domesticated cacao trees are seldom allowed to grow to more than 20 feet in height. They are pruned and topped frequently to keep them accessible and to protect the cacao pods from sunlight and entangled branches. The pods develop from flowers that are fertilized naturally by midges, or artificially, and have the shape and rough size of an American football, although the size can vary greatly. The pod develops on the bark of the trunk or on large branches, not at the end of branches or twigs. The inside of the pod contains the beans or "nibs" and a white pulp, which is consumed by birds, animals, and humans. Cacao trees, although delicate, have a useful life of up to 50 years, but this can vary widely according to care, soil, region, and other circumstances. The trees develop slowly, usually from seedlings, and seldom yield any harvest until the third or fourth year. They are very sensitive to cold and drought and require year-round water from rain or irrigation.

Because cacao trees are too delicate to be climbed, harvesting must be done from the ground. Long poles topped by a cutting implement reach the higher fruit. After the pods are split open, the nibs are separated from the sticky pulp (by machine on modern plantations). The discarded pods are employed as fertilizer or animal fodder. The nibs are then fermented and dried. The workers heap them up in a shaded area and turn them over frequently for several days. Once fermentation is complete – the timing of which requires considerable expertise – the nibs are spread in the sun or dried artificially for a week or more, with workers again often raking and turning them.

The cacao nibs are then graded (nowadays by machine), poured into large sacks, inspected, and shipped to the major markets and consuming countries, where they are transformed and manufactured into hard chocolate, cacao powder, cacao butter, and other products.

A History of American Cacaos

The remote history of cacao is disputed; many deny its Amazonian origin and believe that in its "wild" state, the cacao tree grew in a number of other parts of the Americas, including perhaps the Upper Orinoco flood plain. Because the nibs have a short fertile life, there was difficulty in transporting them elsewhere to plant new seedlings, especially before modern transportation. Thus, gaps between areas of cultivation and different varieties came into existence.

In any event, it is in Mesoamerica that the first recorded histories of cacao are to be found. The plant and its nibs were part of the most ancient mythologies there. The Olmecs knew cacao, possibly before 1000 B.C., and the word itself, or one like it, may belong to a proto–Mixe-Zoquean language probably spoken by the Olmecs. Cacao was also part of the material and cultural lives of the Maya and their predecessors, as well as the various other societies (including that of the so-called Aztecs) that were destroyed by the Spanish invaders of Mesoamerica.

The Maya were probably the first people to write about cacao via their now-deciphered hieroglyphics. There may have been some link between cacao as a drink and the sacrifice of human blood. Certainly, elite burials and tombs often contained elaborate vessels with cacao drinks in them. Some scholars believe, in fact, that the consumption of cacao was a privilege of the nobility, but to others this practice seems unlikely (or at least not widespread), given the extent of its cultivation in various Mesoamerican tropical lowlands. Probably cacao was drunk (there is, so far, little evidence that it was eaten as a hard substance among Mesoamericans) by people of all classes. The drink was very much a part of public ceremony and ritual.

Cacao beans were an important item in Mesoamerican trade and tribute long before the European invasions. Cacao's climatic requirements, and the sophistication of state systems of trade and tribute, led to regional specialization – perhaps even monoculture – in a few places. In such areas as Guerrero, Colima, Veracruz, Tabasco, and the Gulf of Honduras, cacao was grown in plantation-like settings for export to distant centers. On his fourth voyage in 1502, Christopher Columbus in the Gulf of Honduras came upon a very large seagoing canoe that was transporting a varied cargo that included cacao beans. The most important growing areas, as far as present knowledge goes, were Soconusco (today the Pacific coast of Chiapas, Mexico) and the Pacific coastal plains and piedmonts of present-day Guatemala and El Salvador. From these plantations, large quantities of beans found their way to the highlands as trade and tribute. Soconusco, though distant from Tenochtitlan (now Mexico City), became a prized part of the Aztec conquests and paid tribute to Montezuma. Cacao beans were stored in great warehouses in the capital.

Money, therefore, "grew on trees." Cacao nibs were used as coinage throughout Mesoamerica from ancient times, and at least as far south as Costa Rica during the colonial period, especially when there were shortages of official coinage. Our knowledge of this coinage before the arrival of Europeans, however, is sketchy. In Nicaragua, a distant periphery of Mesoamerica, beans were widely used as petty coins and may have had standard equivalencies, evidence of a formal and official coinage. Additional evidence can be found in a widely used serial system of measures that was based, not on weight, but upon the number of cacao nibs. There is also evidence of a thriving industry in counterfeit cacao beans, another sign of their monetary value. In some regions, however, the beans may have served only as substitute, specialized, or occasional coins.

Mesoamericans had many recipes for cacao drinks. Ground beans were mixed with hot or cold water and with maize, ground chillies, annatto, vanilla, and seeds, roots, and flowers of many kinds. Many of the dishes were soups, and the liquid chocolate, poured into or over many other dishes, was perhaps the ancestor of modern *mole* sauces. These peoples had a preference for chocolate drinks beaten to a froth, and to this end poured chocolate in a stream from one container to another. The upper classes and the *pochteca,* a kind of official merchant class, consumed large quantities of these soups and drinks at festivals and public banquets.

Hernán Cortés and his invading band noticed the many uses of cacao and captured stores of it in Tenochtitlan to use as money. They also saw the flourishing groves in such areas as Soconusco and Izalcos (in present-day El Salvador). In Soconusco, the harvests quickly attracted large numbers of mule trains and merchants. Some of the most lucrative *encomiendas* (grants of the labor and tribute of subject natives) in Central America were in Izalcos where cacao was generally the means of tribute-payment. But Spaniards usually did not try to seize legal ownership of cacao groves, perhaps because cultivation and care of the fragile, valuable trees was both a specialized business and hard work in a humid, tropical climate. Instead, they did their best to monopolize labor in the groves, not to mention the taxes cacao produced, and the cacao trade. Tribute to the crown and to private individuals continued to be paid in cacao long after the Spanish conquests, and large quantities were carried by sea and by land to central Mexico.

Gradually, the new colonial elites made changes in the "cacao economy" – not in the kinds of production or ownership, but rather in the intensity of cultivation and in patterns of distribution and consumption. *Encomenderos* (holders of *encomiendas*) and local royal officials forced native producers to intensify planting and harvesting, which may have been counterproductive for two reasons. First, the Native American population was already in severe decline because of the epidemiological invasion brought on by the arrival of Europeans and Africans. Overwork and other oppressions exacerbated this mortality, and replacements brought in from the highlands died just as quickly. By the late sixteenth century, many of the productive zones were suffering from severe labor shortages. Second, overplanting may also have been self-defeating. Shade trees were cut down, destroying the understory conditions needed by cacao trees. No doubt, labor shortages and changing agricultural conditions were related.

At the same time as production in Mesoamerica declined, consumption rose. If cacao had once been a food limited to the upper classes, itself a doubtful proposition, this soon changed. Shortly after the conquest, it was apparent to some of the enterprising interlopers that cacao consumption was very large indeed; impressionistic accounts describe Indians quaffing massive, almost unbelievable, quantities of chocolate. Trade – often long-distance trade – in the crop became important, and demand was such that suppliers from faraway plantations could pay expensive freight costs and still show a profit.

As Central American production declined, prices in Mexico rose, and even more distant producers entered the market. The fine Central American *criollo* cacaos retained, and still retain, a market niche because of their reputed quality, but the Guayaquil basin of Ecuador and the coastal valleys of Venezuela west of Caracas, along the Tuy River, and south of Maracaibo, replaced Central America, Tabasco, and Guerrero as the largest producing areas. We know little about the origins of this new competition. In both areas, growers used the more hardy and productive *forastero* cacaos.

At first, Venezuelan cacao dominated. From around 1670, as the native populations disappeared, plantations were worked by African slaves. Exports from La Guaira, Maracaibo, and smaller ports were carried on a fleet of small ships to Veracruz, and from there by mule to Puebla and Mexico City. The Venezuelan elite became known as the "grandes cacaos," some of whom owned as many as a quarter of a million trees. In 1728, a clique of Basque entrepreneurs obtained an export monopoly called the Royal Guipuzcoa Company, or, colloquially, the Caracas Company. Between 1730 and 1754, exports nearly doubled to 3,800 tons per year, and a large part of the crop went no longer to Mexico but to Spain. Cacao also became part of a growing contraband trade, with smuggling by the Dutch especially important because of their colony at nearby Curaçao and because of a growing market for cacao in Amsterdam. In fact, Dutch traders dared to establish semipermanent trading depots in Venezuela well upstream on some of the rivers.

Guayaquil cacao plantations came into being at about the same time as those of Venezuela, and soon were shipping to Peru, Central America, and Mexico. Hardy varieties, plentiful water, good soils, and high yields contributed to the production of inexpensive cacaos, and Guayaquil prices, despite long trade routes, were able to undercut those of Central America and even Venezuela. Unlike the plantations in Venezuela, where African slaves were employed, Guayaquil cacao was worked by local laborers, often native migrants from the *sierra.*

Central American growers complained about the flood of inexpensive Guayaquil beans, and the Spanish crown, alarmed that a growing trade between Peru and Mexico would threaten its export trade in European goods to America, prohibited all South American ports – including Guayaquil – from trading with Mexico. Again, contraband and fraud flourished. By 1700, Guayaquil's production rivaled or surpassed that of Venezuela. Later in the century, as free trade grew and faster ships became common, Guayaquil cacao began to reach Spain and other European markets, even though by the late eighteenth century, the region's plentiful exports were satisfying about three-quarters of the Mexican demand.

Amazonian cacao was slow to develop. This area of Brazil was neglected by Portugal and had few settlers. Lisbon was not a large market, and most of the trees, at least at first, were scattered in the forests. By the middle of the eighteenth century, however, Marañón cacao, worked mostly by African slaves, commanded a share of European markets.

Venezuelan cacao plantations spread to Trinidad, where the hybrid *trinitario* developed. Other parts of the circum-Caribbean, such as the coast of Costa Rica, Grenada, Martinique, and Saint-Domingue, also enjoyed ephemeral booms before production sank back, giving them only minor places in the Atlantic markets.

Changing Tastes and New Markets

The first Spaniards to encounter large stocks of cacao quickly realized (and exploited) its lucrative possibilities, especially in Mesoamerica. Their own taste for chocolate, however, developed more slowly. Native peoples sometimes added honey, but most of their recipes were bitter – even biting – to Spanish palates, especially when chilli peppers were added. English pirates, who were even less familiar with chocolate, burned or dumped the cargoes of cacao they captured. Sugar, introduced to the Americas by Spain and Portugal, helped to change minds, as did vanilla and other flavorings, although part of the story of Spanish and Portuguese acceptance of chocolate is also, no doubt, one of acculturation and acquired tastes. By the late sixteenth century, Europeans in the Americas were drinking sweet chocolate with great enthusiasm and had elaborated intricate and expensive containers, cups, and *molineros,* or beating sticks, as frothy chocolate was still favored. So pervasive was the habit of drinking hot chocolate among Creole women that at least one bishop had to forbid it during Mass. An Englishman from Jamaica was amazed at the Spaniards' craving for chocolate drinks, and claimed that they seemed unable to live without them (Hans Sloane manuscript 11.410, folio 321, British Library).

Cacao beans probably reached Europe as early as the 1520s, shortly after the conquest of Mexico, but it was late in the century before regular cargoes were shipped from Veracruz. At first, chocolate was an expensive drink, largely confined to the Spanish court and noble houses. From Spain, it soon spread to Italy and – via a royal marriage – to France, where Ana of Austria, daughter of Philip III, married the young Louis XIII. The next marriage between French and Spanish royalty was that of Louis XIV and the daughter of Philip IV of Spain, Maria Theresa, of whom it was said that her only passions were chocolate and His Majesty – probably in that order.

By the mid-seventeenth century, chocolate houses were common in Paris, although still patronized exclusively by the elite. They had also spread to London, where these establishments soon competed with coffee shops. During the life of Samuel Pepys, the English government official and well-known diarist, chocolate drinks passed from being a novelty to a regular luncheon beverage and a staple of public salons. The Dutch, who had captured Curaçao in 1634, began to send large cargoes of contraband Venezuelan cacao to Amsterdam, which became the great cacao mart of Europe. Ironically, by the late seventeenth century, even Spanish merchants had to buy there.

Chocolate, as a drink, is filling and quite nutritious, and so became popular among all classes in Catholic Europe, especially in the Mediterranean countries. But a problem arose: Was it to be considered a food or a beverage? Did the drinking of chocolate break a religious fast? In the 1660s, the Church decided that because wine – although nutritious – was considered a drink rather than a food, chocolate drinks would be treated the same way. Opinions differed as to chocolate's merits and failings, and these debates continue today. For reasons not yet understood, chocolate became a drink for women and coffee a drink for men in some parts of western Europe.

In the eighteenth century, chocolate was known throughout Europe, and further regional variations developed, as did cultural and fashionable attitudes toward it and its consumption. It was usually sold as a fairly solid paste or block, and already by the early part of the century, these commercial products contained vanilla, sugar, cloves, and other spices. About this time, some drinkers began to add milk or wine. Frothiness was still appreciated, and numerous recipes stipulated the amount of heating needed and the best way of whipping the chocolate to provide the ideal frappé.

The eating of solid chocolate, while still far behind the drink in popularity, also gained acceptance, often in the form of the so-called Spanish sticks. In France, small chocolate pastilles gained favor. Cacao butter, used since the sixteenth century as a cosmetic to improve the complexion, now became of some importance for elite cuisine.

In much of eighteenth-century Europe, chocolate remained an elite and rather expensive drink, sometimes considered a stimulant, or even an aphrodisiac (what exotic substance has not been so imagined?). In England, however, both coffee and chocolate houses lost their upper-class cachet in the second half of the century, and chocolate houses, in particular, came to be associated with raucous behavior, licentiousness, and marginal social groups. But even then, chocolate remained expensive; although American production had increased to supply the growing demand, it had not increased enough to lower the price significantly. Moreover, processing techniques had failed to adapt. In the middle years of the eighteenth century, cacao was grown, harvested, elaborated, and sold much as it had been by Native Americans before Europeans arrived in Mexico.

Some innovations did appear. For example, Joseph S. Fry, who founded a company in England in 1728 (which lasted into the late twentieth century), created factory conditions for the mass production of chocolate products for the English market. Others in England and on the continent followed, but radical transformations in many other areas of the chocolate trade had to wait until the nineteenth and twentieth centuries.

The Industrial, Commercial, and Supply Revolutions

The Dutchman Coenrad Johannes Van Houten was the first in a line of inventors and entrepreneurs who modernized the manufacture of chocolate. He sought a better method for extracting the cacao "butter" or fats from the beans. He had started a factory in Amsterdam in 1815 and was unhappy with the traditional method of boiling the chocolate and then skimming off the fats. By 1828, he had invented and patented a dry press, which left much less butter in the end product. Van Houten then treated this "cocoa" powder with alkaline salts to make it more adaptable to various kinds of mixes, and very quickly, many of the older methods of manufacturing yielded to cocoa. Some twenty years later, an early form of "instant" chocolate had become widely accepted, and about midcentury, Joseph Fry and his sons seized upon this new cocoa powder and began to market the first commercial chocolate bars.

The Van Houten innovation was, historically and gastronomically speaking, just in time. By 1800, chocolate drinks had fallen well behind competing alkaloid beverages. In the West coffee dominated almost everywhere and has remained in the lead to the present day – except in England, where coffee first defeated chocolate and was then, in turn, defeated by tea. Chocolate was to survive and flourish, however, by going its separate way and leaving the field of adult drinks to its competitors. Except in a few of the Mediterranean countries and in parts of Latin America, where chocolate drinks retained popularity, chocolate now became cocoa, heavily sugared and drunk mostly by children and invalids, or chocolate bars and wrapped candy, devoured by all ages and classes.

The early great British rivals of the Fry Company were the Cadburys and Rowntrees. It was the firm of Cadbury, which quickly became the leading British confectioner, that first emphasized the connection between boxes of chocolate and romance. Chocolates and cut flowers became tokens of romantic love and soon were the typical presents given to a woman. Sales of chocolate in boxes and specialty chocolates soared, and increase even more so today, especially on Valentine's Day, at Christmas time, and at Easter – the season for chocolate eggs.

After the breakthroughs of the Dutch and English pioneers, Swiss inventors and businessmen took over. François Louis Cailler and Phillipe Suchard opened modern factories in the 1820s. Henri Nestlé, a chemist who first elaborated powdered milk, and Daniel Peter combined their talents to produce milk-chocolate bars, and Rodolphe Lindt, yet another Swiss, invented a process by which cacao was made smoother to the palate, more homogenized, and of finer aroma. Lindt's "conching" process, which he began in 1879, radically changed the manufacture of chocolate, and his smooth chocolates soon replaced the rougher and grainier ones of the past. Swiss chocolate became the world standard for the chocolate bar, and such companies as Lindt and Nestlé are corporate giants today.

The country that was the scene for Henry Ford's genius now saw the rise of the great entrepreneur of chocolate manufacture and sale. Milton Hershey, like Ford, saw the great possibilities of economies of scale and uniformity in producing and mass marketing for the millions. A confectioner from his youth, Hershey became convinced after a journey to Europe that he should concentrate on chocolate. He built a model workers' town (named after himself) in Pennsylvania, on a much larger scale than those of Cadbury and Rowntree in England. To supply his huge chocolate factory, Hershey also transformed other landscapes: He boasted that the enormous dairy farms surrounding his town supplied 60,000 gallons of milk every working day. In Cuba, vast sugarcane estates were laid out east of Havana, complete with their own railroads and port terminals. (The Hershey empire in Cuba was later nationalized by the Castro government.) The Hershey Company was a model of modern manufacture and merchandising and soon controlled a giant share of the U.S. market.

In spite of mass manufacturers such as Cadbury and Hershey, producers of fine chocolates managed to retain a respectable and profitable share of the market, which has increased in recent years. High-quality chocolates, such as Godiva of Belgium and Valrhona of France, are known worldwide. Chocolate has entered the world of great cuisine, too. Profiteroles, chocolate cakes and pastries, mousses, and humble chocolate ice cream all have fanatical addicts.

Just as Hershey's chocolate for the masses created dairy farms and sugar plantations, it also led to the expansion of cacao production. Cacao has become a world commodity, grown in all tropical regions, and traded and speculated upon in the stock and futures markets of London, New York, Paris, and other financial hubs.

Venezuelan exports, which had seemed so well placed geographically and logistically to supply

European markets during the Spanish colonial years, began to decline around 1800. The wars of independence there were enormously destructive, and Venezuelan producers found themselves less able to hold their own against both old and new competitors. Nonetheless, although coffee replaced cacao as the country's main export after 1830, Venezuela retained a respectable place as a supplier of cacao until about 1900.

It was the Guayaquil plantations of Ecuador, however, that satisfied the largest part of the world's needs in the nineteenth century. The Panama Canal opened, and Ecuador was fortunate (or unfortunate) to have an abundant, inexpensive labor supply from the highlands, where the failure of the textile industry in the face of British competitive imports had sent waves of unemployed workers to the coast. Cacao was promoted by early leaders of the newly independent republic, including its first president, Juan José Flores (1800–64), himself an owner of large plantations. There was a plateau in production – caused by civil war and yellow fever – between 1840 and 1870, but then output again accelerated, reaching more than 20,000 tons per year by 1900. In the first decades of the twentieth century, however, Ecuador's predominance in cacao production finally yielded to two major factors. Witchbroom disease destroyed many of the plantings in the 1920s, and the 1930s saw depressed world prices. As a consequence, new areas in other parts of the world began to compete.

The first threat to Latin American producers and exporters came from islands off the west coast of Africa, where cacao had been introduced to São Tome and Principe by the Portuguese. Development of the crop's products, however, suffered considerable delay because the islands continued to concentrate on coffee growing with slave labor until that industry suffered a crisis brought on by the abolition of slavery in 1875. Chocolate then took over, although working conditions on the cacao plantations were little better than those of slavery. By 1905, the two islands were the world's leading exporters of cacao beans.

This success aroused interest in the nearby mainland British colonies, although it was often the local people, rather than the colonial government, who developed the crop. By the 1920s, the Gold Coast (now Ghana) led the world in output, and Africa had passed America in cacao exports. The growth in demand during the first 40 years of this century was astonishing. World trade in the commodity went from about 100,000 tons in 1900 to 786,000 tons in 1939, a growth of nearly 800 percent! Nigeria and the Ivory Coast were now rivals of the Gold Coast in cacao production, and other colonies, such as Gabon and the Belgian Congo, were becoming exporters. By the 1990s, the Ivory Coast was the world's leading producer.

Nonetheless, West Africa was losing its dominant position. It produced three-quarters of the world's cacao in 1960, but just over half by the 1990s. Latin American plantings began to revive somewhat, especially on new establishments around Bahia, but the latest rival areas were in Indonesia, and, above all, Malaysia, which by the early 1990s was the world's fourth leading producer of cacao, with annual exports of about 220,000 tons.

The world market in cacao remained impressive at about 2,500,000 tons per year in the 1990s, but that amount was much less than half of the total for coffee and represented just over 2 percent of the world trade in sugar. A constant problem with cacao has been a lack of price stability. Prices have fluctuated widely since World War II, and stabilization agreements have had little success. The United States is by far the leading consumer of cacao, followed by western Europe, Russia, and Japan. Per capita consumption in the United States and western Europe has doubled since 1945. The Swiss eat the most chocolate, followed by the British. The Norwegians and Austrians lead the world as drinkers of chocolate.

To what does chocolate owe its success? It is, for one thing, a well-rounded food, containing glucose, lipids, and proteins. It also provides significant quantities of important minerals, such as potassium and calcium. Of course, such additives as milk and sugar bring other qualities and calories. Cacao contains several stimulants, led by theobromine, then caffeine and serotonin.

Debates based on more impressionistic evidence have raged. Chocolate was long ago accused of being a cause of juvenile acne, but this now appears to be untrue. The argument that chocolate can elevate cholesterol levels has not yet been resolved. Is chocolate addictive? "Chocoholics" would certainly answer in the affirmative. So, we suppose, would the native peoples of sixteenth-century Mesoamerica. Recently, researchers reported that cacao consumption stimulates a mild, marijuanalike effect, reducing stress and encouraging a harmless euphoria. Debates and research continue, and meanwhile, the product's market range expands. Attempts to find substitutes enjoy little success, and the "food of the gods" continues to delight the millions.

III.4 Coffee

Coffee is a tree or bush that originated in Africa. It was first domesticated in Arabia, and massively consumed in Europe and North America. Later grown in Asia and Latin America, coffee, more than any other crop, has tied together the rich and the poor. Originally a luxury, coffee has become a necessity for consumer and producer alike and, in terms of value, is one of the leading internationally traded commodities today and probably has been the most important internationally traded agricultural product in history.

Coffee, however, has also been one of the most contradictory and controversial of crops. It has linked the religious and the secular, the archaic and the bourgeois, the proletarian and the intellectual, the enslaved and the free, the laborer and the dilettante. It has been accused of destroying societies, of perpetuating vice, and of undermining developing economies.

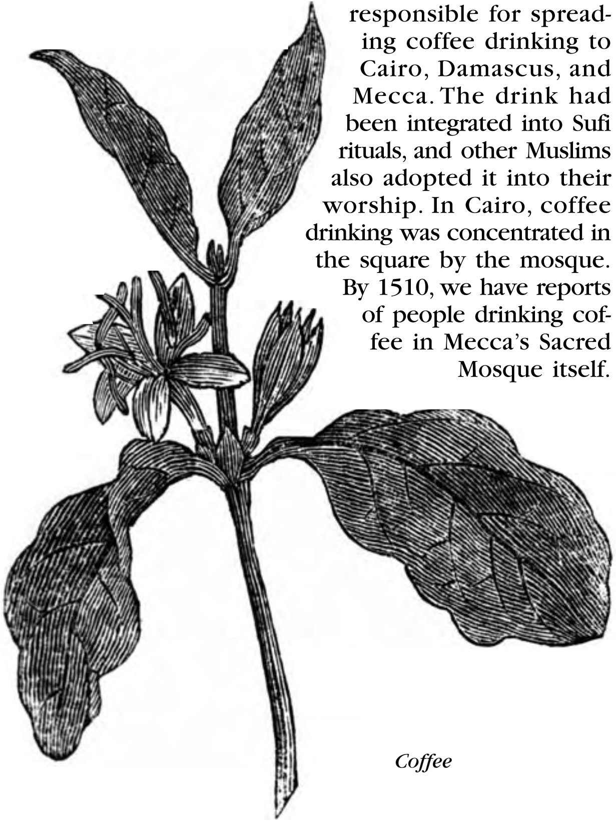
Origins

The first human consumption of coffee has been obscured by time. But legends abound, such as that of a ninth century A.D. Ethiopian goatherd who tasted the bitter berries that left his flock animated, or about Arab traders, and even Christian monks, who first recognized the virtues of coffee. *Coffea arabica* first appeared natively in Ethiopia, yet the berries went largely ignored before Arabs in Yemen used them to brew a drink. Although some Africans drank coffee made from fresh berries, others roasted it with melted butter, and in a few regions it was chewed without any preparation. However, no extensive local traditions of arabica berry usage developed (see Ukers 1948; Uribe 1954), and consequently, coffee became an exotic crop, growing far from its original home. Indeed, it was only in the twentieth century that African coffee production became substantial.

The mystical Shadhili Sufi, to the east of Ethiopia in Yemen, seem to have been among the first to embrace this wandering crop. They sought elixirs to produce visions granting access to the Godhead, and they also wished to remain awake during their long nighttime chanting rituals, in which they attempted to enter an ecstatic trance. Thus, from the beginning, coffee was employed as both a drug and a social drink. Early accounts, however, speak much more of its physical effects than its taste or efficacy in quenching thirst. A sheikh of the Sufi order who lived in the port town of Mocca in the late fourteenth or early fifteenth century may have been the first to devise a technique for roasting, grinding, and brewing coffee beans.

It was in the mountains of northern Yemen that the arabica was first domesticated, and for two and a half centuries Yemen held a virtual world monopoly on coffee production. But it is interesting to note that in Yemen, many preferred to chew the beans or brew a tea with the husk of *Coffea arabica,* rather than use the beans, and to this day Yemenis do not drink much coffee. They prefer tea or chewing a shrub, *khat,* which not only fills coffee's social role but occupies much of the land suitable for coffee cultivation.

By 1500, the beverage had become widespread on the Arabian peninsula (Hattox 1985; Wenner 1991), with the Sufi probably responsible for spreading coffee drinking to Cairo, Damascus, and Mecca. The drink had been integrated into Sufi rituals, and other Muslims also adopted it into their worship. In Cairo, coffee drinking was concentrated in the square by the mosque. By 1510, we have reports of people drinking coffee in Mecca's Sacred Mosque itself.



Coffee

The beverage became associated with Mohammed's birthday and was commonly drunk at night during the monthlong fast of Ramadan. Indeed, various legends ascribed coffee's origins to Mohammed, who, through the Archangel Gabriel, gave it to the world to replace the wine that Islam forbade. Certainly, Muslims were instrumental in spreading the beverage throughout the Islamic world as far as India and Indonesia, as the religious brought beans back from their pilgrimages to Mecca (Becker, Hoehfeld, and Kopp 1979).

Coffee was also intimately related to the growth of secular society. The Sufi were not full-time mystics, and as ordinary tradespeople during the day, they spread their taste for the drink to the business world. Its name probably comes from the Arabic *qahwah* – an epithet for "wine" – indicating a replacement of the forbidden alcoholic beverage. Indeed, although coffee grows wild in the region of Ethiopia known as Kaffa, the place is not the origin of its name, just as the coffee "bean" is not a bean but more like a cherry pit. Its name is a corruption of the Arabic for the arabica plant, *bunn.*

As already noted, the thick, dark, hot beverage became popular probably more because of its physical effects and the sociability it encouraged than because of its taste, although its reputed medicinal properties, said to cure mange, may have increased its appeal. But despite the fact that sugar had been grown in the Middle East for hundreds of years before coffee's arrival, it was not added to the brew. Neither was milk, which was blamed for causing leprosy when combined with *qahwah.* In fact, cardamom was the only spice added with any frequency, although in some disreputable quarters, opium and hashish apparently were also stirred in. The fact that coffee grounds must have boiling water poured over them to impart their flavor probably added to the drink's attractiveness. In an era before safe water supplies, boiling was the one sure method of insuring purity.

Probably the technology of coffee making – roasting and grinding the beans and boiling water – caused the beverage, more than almost any other commodity, to be associated with a site. The café was born in the Middle East, and in many cultures that subsequently adopted the beverage, the word for the site and the beverage became the same. R. Hattox (1985) suggests that early merchants, such as two Syrians who introduced coffee from Egypt to Istanbul in 1555, used the coffeehouse as a marketing device. To acquaint new consumers with the beverage, it had to be presented to them hot and correctly brewed. Consequently, these Syrian merchants and many others from the Levant who opened cafés found, in the process, an unoccupied niche in Middle Eastern society. Restaurants were almost unknown, and taverns were forbidden to Muslims. Hence, coffeehouses became one of the few secular public places in Muslim lands where men could congregate with other nonfamily members.

Cafés offered one of the only social possibilities for nightlife. They were an inexpensive place to offer friends entertainment and hospitality, playing an important role in the commodification of what previously had been largely private, domestic functions. Men read, listened to stories and music, watched puppet shows, played backgammon and chess, gambled, and sometimes solicited prostitutes. Such an ambience also led to conversations on forbidden subjects.

The cafés catered to a wide range of clients, sometimes mixing men of various classes. Although some cafés were little more than stalls in the marketplace, others were virtual pleasure palaces. Said the French traveler Philippe Dufour in 1685: "All the cafes of Damascus are beautiful – many fountains, nearby rivers, in tree-shaded spots with roses and other flowers" (Hattox 1985: 81). But because coffeehouses in Cairo, Istanbul, Damascus, and Algiers quickly became centers of political intrigue and fleshly vice (Carlier 1990), government officials soon reacted, and as early as 1511, they burned bags of coffee in the streets of Mecca.

Although some medical authorities claimed that the arabica's cold and dry humors created melancholy and, more seriously, transgressed the laws of Islam by intoxicating its users, these arguments never carried much weight. It was the politically subversive possibilities of the coffeehouse that most worried Middle Eastern rulers. Thus, the Turkish grand vizier was sufficiently concerned about the political effects of the 600 coffeehouses in Istanbul that he decreed that the punishment for operating a coffeehouse was cudgeling; for a second offense, the perpetrator was sewn into a leather bag and thrown into the Bosporus.

Even these draconian measures proved ineffectual, however, and Turkish coffee became famous as the generic name for a certain thick brew in which the grinds were mixed directly into boiling water in small increments, often 10 to 12 times. The Middle East and Southeast Asia were the world's principal coffee drinking areas until roughly the middle of the eighteenth century. But ironically, today the Turks produce and consume virtually no coffee.

European Consumption

The increasing popularity of coffee in seventeenth-century Europe paralleled the emergence of commercial capitalism. The Middle Eastern bean, fostered by the ascetic Sufi to free themselves from worldly matters, evolved into a Western capitalist commodity. Coffee reached Europe via trade, diplomacy, war, and immigration. Venetian traders, with their command of Mediterranean commerce, introduced it into southern Europe. The Dutch, who superseded them in the Orient, were even more important in spreading the arabica.

At first, coffee was regarded in Europe as a medicinal drug that could cure sore eyes, dropsy, gout, and scurvy. Its social role and prestige, however, were considerably enhanced in 1665 and 1666 by the arrival in France of emissaries of the Ottoman sultan who poured the exotic liquor for their aristocratic European guests during extravagant soirees (Leclant 1979; Heise 1987).

According to Austrian lore, coffee first became a drink Europeans found palatable when bags of it were left behind by the Ottoman Turks after their 1683 siege of Vienna failed to break the Austrians' spirit. These spoils of war not only uplifted Viennese spirits but also helped transform coffee from medicine into a leisure drink when the owner of the first Viennese coffeehouse, Georg Kolshitsky, thought to remove the sediment from Turkish coffee and add honey and milk. Elsewhere in Europe, Armenians, Greeks, Lebanese, and other Christian traders from the Levant spread knowledge of the beverage. Southern and central Europeans devised many of the most popular ways of brewing, roasting, and mixing coffee: Espresso, cappuccino, café au lait, and French and Vienna roasts are still familiar terms today.

Yet it was the northern Europeans who became the greatest consumers. In England, coffee was closely tied to the academic community from the beginning: The country's first coffeehouse seems to have been one opened in Oxford in 1637 by a Greek merchant. But soon London merchants were also imbibing the potion in coffeehouses, such as Jonathan's and Garraway's (which served for three-quarters of a century as England's main stock exchanges), the Virginia, the Baltic (which doubled as the mercantile shipping exchange), and Lloyd's Café (which became the world's largest insurance company). In addition to serving as commercial houses and office buildings, coffeehouses became "penny universities" that disseminated the latest news, reading libraries, and the first men's clubs.

Such social areas outside of the home and the court helped stimulate business but also outraged wives. They resented their husbands' addiction to the dark, noisy coffeehouses and the black and nauseous liquid that allegedly caused impotence. Their complaint, which was echoed in other corners of Europe, was in striking contrast to the mullahs' fears that coffee stimulated carnal desires. Charles II, concerned more with café patrons' political discussions than their familial responsibilities, tried unsuccessfully to close down the coffeehouses. It would take the rise of the East India Company, the Indian colonies, and high taxes on coffee to convert Britain to a tea-consuming country (Ellis 1956; Bramah 1972).

On the Continent, cafés symbolized and served the beneficiaries of capitalist prosperity who constituted the new leisure class, although debates continued to rage over the brew's medicinal properties. In the best scientific tradition, Sweden's Gustav III reputedly commuted the death sentences of twin brothers convicted of murder on the condition that one be given only tea to drink and the other coffee. The tea drinker died first – at age 83 – and Sweden became the world's most ardent coffee-consuming nation, with its citizens drinking five cups per person per day by 1975. In 1992, most of the 10 leading coffee-consuming nations on a per capita basis were still in northern Europe: The 10 were (in order) Finland, Sweden, Denmark, Norway, Netherlands, Switzerland, Austria, Germany, France, and Belgium (United States Department of Agriculture 1993).

The eighteenth-century mercantilist policies of tax-hungry kings posed another kind of threat to coffee drinkers. Frederick the Great, for example, was less open-minded than King Gustav and less concerned with his subjects' health than with their political proclivities and the balance of trade. He consequently sought to prevent commoners from drinking the brew by making it a royal monopoly. Although he failed, the high import duties in the seventeenth and eighteenth centuries restricted consumption to the relatively affluent in major cities. The same was true in France and Austria (Heise 1987) and in Switzerland, between 1756 and 1822, there were five different decrees prohibiting coffee importation.

Cafés prospered in the capitals, however. Their great popularity in Paris served to distinguish the elite from their social inferiors, who bought their coffee in the marketplace. The coffeehouse denizens constituted an elite of achievement, a bourgeois elite. Coffee's great virtue, in contradistinction to alcohol, was that it stimulated the body while clearing the mind. Intellectuals now had discussions rather than orgies, and some coffeehouses, such as the Procope in Paris, served as centers of intellectual and artistic life where such men as Voltaire skewered aristocratic foibles.

The Café Heinrichhof in Vienna inspired Johannes Brahms and other great composers, as well as merchants who preferred the sound of money. Other coffeehouses (such as this author's grandmother's Café Mozart in Vienna) hosted cards and billiards and other such less-inspired diversions. The leisure of the coffeehouse was serious business.

Coffeehouses were also intimately involved in the birth of civil society and the democratization of semifeudal aristocracies. Thus, it was in Paris's Café Foy that on July 13, 1789, Camille Desmoulins planned the assault on the Bastille that ushered in a new political age (Oliveira 1984). It is perhaps ironic that his action would also set into motion events that destroyed the coffee plantations of the world's greatest coffee producer, the French colony of St. Domingue (today Haiti).

Coffeehouses continued to be associated with subversion in the nineteenth century. Preparations for the 1848 revolutions were made in the coffeehouses of Berlin, Budapest, and Venice. In France, one of the first responses to threatened revolt was to close down the cafés (Barrows 1991). Ulla Heise (1987) argues, however, that although émigrés continued to plot in cafés after 1850, the coffeehouses lost their revolutionary association. Revolution became more proletarian, and workers tended to frequent taverns, bars, and winehouses. S. Barrows, on the other hand, credits the declining political radicalism of the coffeehouses to the rise of newspapers, music halls, and other places for association.

If coffee in Europe was a part of the middle class's struggle for democracy, coffee itself became increasingly democratized. Although taxes kept the price high, coffee became the breakfast beverage of choice for the Continent's urban working class. To compensate for the high prices, the poor often drank coffee substitutes rather than the arabica (in Germany, *Kaffee* can refer to any number of beverages; the arabica or robusta is called *Bohnenkaffee*).

United States Consumption

As clanging factories gave birth to the industrial age, coffee came to represent labor as well as leisure. North American thirst was instrumental in making coffee a mass consumer product, a drug to prop up the drooping eyelids and awaken the flagging consciousness of an army of laborers. But this could occur only after they had abandoned tea. The citizens of the original 13 British colonies were tea drinkers, in part at least because British taxation and transport policies had made the arabica inaccessible to all but the rich. There were a few coffeehouses, such as Boston's Green Dragon, which Daniel Webster called the "headquarters of the revolution," and The Merchant's Coffeehouse in New York, also associated with the independence movement. But the taverns – which doubled as courtrooms and public meeting halls – were by far the favorite drinking spots in colonial times, although even those were little frequented because of the rural (and in places puritanical) nature of settlements.

United States coffee consumption in 1783 was only one-eighteenth of a pound per capita a year. By the 1830s, however, North Americans had cast aside tea for coffee, and by midcentury they were each drinking more than five pounds a year. Although the 1765 Stamp Act and the Boston Tea Party certainly dampened enthusiasm for tea, commerce and demography were probably more responsible for transforming the United States into the world's greatest coffee market. Resistance to the British East India Company was bolstered by the proximity of the French coffee-producing colonies of St. Domingue (Haiti) and Martinique and, later, Portuguese Brazil.

After independence, Americans were free to trade with these colonies, supplying them with slaves and naval stores in exchange for coffee. Thus, New England merchants introduced coffee into North America in relatively large volume. The price of coffee fell from 18 shillings per pound in 1683 to 9 shillings in 1774 to just 1 shilling in 1783. Such lower prices naturally expanded demand, and government policy further aided the transformation as import taxes on the beans were first lowered and then abolished in 1832. Resumed during the Civil War, they were definitively abolished in 1872.

The absence of a coffeehouse culture in the United States meant that the beverage's popularity was not associated with political subversion as it was in the Middle East and Europe, and its consumption could be encouraged with no political danger. The flood of northern European immigrants from coffee-drinking countries probably also contributed to the shift from tea. Soon coffee drinking became entrenched as a social institution, and annual per capita consumption ballooned from under one pound at independence to nine pounds by 1882.

Nonetheless, it took time for the coffee trade in the United States to become institutionalized. It was originally specialized and artisanal; U.S. importers became involved only after the green beans reached New York. There, they sold them to wholesalers who, in turn, peddled them to thousands of retailers. As in Europe, there was no brand identity early on, with each grocer selling his own blends. But to a much greater extent than Europeans with their cafés, nineteenth-century North Americans bought beans in bulk at the grocers and roasted them at home.

This habit gave the housewife discretion over coffee purchases. Unlike her British sisters, who denounced coffee because of coffeehouses, the North American wife was the one who bought coffee; and brewing a good cup of coffee was often a measure of wifely abilities as a "homemaker." Consequently, in contrast to the customs in the Middle East or Europe, coffee merchandising in the United States became much more oriented to women than men. Arbuckle's 1872 advertisement, the first handbill in color for coffee, shows two women by the kitchen stove, the first complaining "Oh, I have burnt my coffee again," and the second counseling "Buy Arbuckle's Roasted, as I do, and you will have no trouble" (Ukers 1935: 451).

In fact, because so much coffee was purchased at the grocery store, where product differentiation was accentuated (rather than at the café where there was much less variety and brand was not displayed), coffee brand identification first arose in the United States. This was achieved through great efforts to create brand loyalty, although instead of market segmentation and differentiation, there was a tendency toward homogenization.

Today, to attract women to its brands, General Foods, one of the largest coffee merchandisers in the world, brings together hundreds of women in focus groups each year and sends out thousands of questionnaires. The coffee market is still female-oriented in the United States, as is demonstrated by the tendency to employ women in televised coffee advertisements.

Before brand loyalty, however, there came new technology to improve the quality and marketing of coffee. In the nineteenth century, because of fairly primitive transportation and packaging techniques, the quality of coffee once it reached a Cincinnati or an Omaha was fairly poor. Consequently, consumers in such areas had a different idea of how coffee should taste than consumers do today. Some brewed it with an egg to give the drink a rich yellow color. It was also popular to add the uncooked skin of a mild codfish to the pot. In the western states, coffee was put in a saucepan and simmered for two to three hours and reheated as necessary. Mass-consumed coffee was not necessarily good coffee, but the cowboy huddled around the campfire was not a demanding gourmet. Under these conditions, it is not surprising that importers were slow to improve the quality of the coffee they sold. Roasted coffee could not be widely marketed because it lost its taste, and ground roasted beans lost flavor much more quickly. The green bean, on the other hand, could be stored for months or years without harm.

The demand for improved and standardized coffee probably derived in large part from improved transportation, roasting, grinding, and brewing technologies. Although green beans traveled well, they were frequently damaged during long sea voyages aboard sailing ships. Merchant efforts to dye damaged beans with rust, or indigo, or beef blood, or to glaze them with eggs improved their appearance, but not their flavor. Nor did the practice of roasting impaired beans with cinnamon, cloves, cocoa, and onions help much. In addition, coffee grinders did not have sufficiently sharp blades to grind the beans finely, and using mortar and pestle was a laborious business. Consequently, grinds had to remain in contact with water longer to impart their flavor, which had the drawback of creating a bitter brew: Tannin, which causes the bitter taste, begins to be extracted from the grinds about 45 seconds after contact with hot water. And finally, coffeepots were primitive. Before the invention in 1800 of a kind of percolator with a built-in filter, most people simply threw grounds into water, much as with tea.

Many of these difficulties in brewing good coffee were resolved somewhat in the nineteenth century. Railroads sped coffee from the fields to ports where the rapid and relatively large steamships that replaced sailing ships spared the green beans ocean damage. Improved control was achieved over oven temperatures, allowing for more regular roasting by, for example, the spherical roaster invented by an Austrian, Max Bode, in 1851, and the pull-out roaster produced by a New Yorker, Jabez Burns, in 1864. Better grinders, producing finer and more even grounds, were also invented, and a welter of coffeepots were mass-produced. The first predictable pumping percolator, patented in France in 1827, became the most popular North American pot in the first half of the twentieth century. Drip pots were improved with the invention of the disposable filter in 1907 (the prototype, which was cut from an ink blotter, was a considerable improvement over the previous horsehair filters). These pots were more popular in Europe, as was the espresso pot, first designed in 1837. Such pots were true monuments to the industrial age with its drawbacks and its charms. Espresso pots sometimes exploded. But if they did not, they could do a host of other things (Bersten 1993). One pressure pot also boiled eggs. The Armstong Perc-O-Toaster toasted bread and baked waffles while it perked coffee (Panati 1987).

Improvements in technology led to standardization, and eventually, to a wholesaling oligopoly in the United States. Whereas the French concentrated on devising new pots to improve the quality of brewing for the refined palate, North Americans focused on roasting, packaging, and marketing to reach the mass market. The first packaged roasted coffee was "Osborn's Celebrated Prepared Java Coffee," which appeared in 1860. The first brand to enjoy a national market was "Arbuckle's Ariosa," beginning in 1873. Sales of packaged coffees, however, were slow to replace those of green coffee beans until 1900, when Edwin Norton invented vacuum packing, which allowed roasted, ground coffee to retain its flavor. In 1903, Hills Brothers was the first company to commercially employ the process (Ukers 1935; Uribe 1954).

The ability to preserve roasted coffee in vacuum packages allowed a few national brands to dominate the trade in the United States. (Europeans were much slower to buy canned coffee, preferring beans and cafés). North American firms began to integrate vertically, with the A & P grocery chain in the forefront, even to the extent of stationing buying agents in the interior of Brazil, as well as importing, roasting, packing, and retailing its own brand. Still, many smaller brands and wholesale grocers persisted. In 1923 there were 1,500 roasters and 4,000 wholesale coffee grocers in the United States (Ukers 1930).

The market power of a relatively small number of powerful wholesalers combined with U.S. government policy to create standardization. Since its inception, the wholesale market had been completely unregulated and subject to rampant speculation and fraud. Many traders mixed together a number of coffee qualities, adulterated the mix with chicory and grains, and then called it "Mocca" or "Java." (The name "mocca" derived from Yemen's main port and stood for authentic coffee, not a combination of chocolate and coffee as it does today.) In the 1860s, a typical 122-pound bag of "Java" coffee arrived from Jamaica with about 5 pounds of sticks and stones added to it.

The freewheeling coffee market began to change in 1874 when a submarine cable tied South America to New York and London by telegraph. Information about prices and demand and supply became internationally homogeneous. The establishment, in 1882, of the New York Coffee Exchange, which was instituted to prevent commercial corners from driving up prices (as had happened in 1880), institutionalized access to information, and Le Havre, Hamburg, and London followed with their own major coffee exchanges. Prices and grades thereby became more generalized, and coffee became more purely a commodity as well, in the sense that coffee shipments were now bought and sold on the market floor without the buyer actually seeing the lot in question.

Until the early twentieth century, professionals would judge a sample bean's quality on its color, size, shape, and shine. Later, taste tests were instituted to check aroma, body, bitterness, and richness. Coffees became commodities possessing a bundle of specific, graded attributes. Indeed, with the advent of futures, buyers purchased coffee not yet blossoming on distant trees. By 1880, merchants were already buying an idea, rather than palpable beans: In that year there were 61 million bags bought and sold on the Hamburg futures market when the entire world harvest was less than 7 million bags!

Grinding did not become standardized until 1948 when the National Bureau of Standards of the Department of Commerce issued guidelines for three categories of grind – regular, drip, and fine – which most U.S. producers still follow. Much earlier, however, the Pure Food and Drug Act had decreed in 1907 that imported coffee be marked according to its port of exit. Thus "Santos" became a specific type of coffee, as did "Java" or "Mocca." There were more than a hundred different types of coffee imported into the United States, representing the greatest variety in the world. Importers were now less able to adulterate and defraud buyers.

The buyers, in turn, became more conscious of the quality of their coffee as they were able to buy professionally and uniformly roasted beans. The almost 4 million pamphlets issued by the National Coffee Roasters' Association at the beginning of the twentieth century in a campaign to educate housewives in proper brewing techniques apparently paid dividends. North American per capita consumption almost doubled between 1880 and 1920 to 16 pounds per capita. The growth of cities and factories accelerated the trend. No longer primarily the beverage of spiritual contemplation, commerce, or leisure, coffee became the alarm clock that marked industrial time. North American coffee imports swelled almost ninetyfold in the nineteenth century.

Temperance societies in the United States and Europe began to promote coffee and coffeehouses as the antidote to the alcoholism of the saloon, which was quite an ironic shift from the Islamic mullahs' fear of the brew's intoxicating effects. A sign in one Christian café read: "Coffee-house – God's house; Brandy shop – Devil's drop" (Heise 1987: 227). But there seems to have been no close relationship between coffee and alcohol. Coffee consumption did not suddenly increase in the United States with the onset of Prohibition, nor did consumption sharply drop with the relegalization of alcohol.

In another ironic twist, at the same time that the prohibitionists were singing coffee's praises, makers of cereal-based beverages launched an expensive attack on coffee's harmful properties. Coffee producers responded with an even more expensive defense of their drink. These mass-media campaigns encouraged the oligopolization of the market, and in 1933 just two companies, Standard Brands and General Foods, accounted for half of coffee's $6 million outlay to advertise coffee on the radio.

Despite the "many bugaboos raised by the cereal sinners," coffee became increasingly linked to sociability as ever more was drunk in public places (Ukers 1935: 477). The twentieth century saw the rise of the coffee shop and the cafeteria. Workers, especially white-collar workers needing to pause from their labor and socialize with their colleagues, took coffee breaks. Indeed, the beverage became embedded in popular speech. "Let's have a cup of coffee" came to mean "let's have a conversation."

Restaurants began using coffee to attract customers by keeping the price low and offering unlimited refills. (Iced tea was the only other beverage to be given this privileged status until the recent inclusion of soft drinks). Grocery stores often employed coffee as a loss leader to bring in shoppers, and when in the middle 1970s prices rose steeply, many grocers absorbed the higher price rather than alienate their customers. Because of its strong connection with sociability, its tendency to addict consumers, the medicinal effect of its caffeine, and the small number of substitutes, coffee has come to be viewed as a necessity more than almost any other food or beverage (Lucier 1988; Oldenburg 1989).

The growth of the vast U.S. market for coffee and the beverage's privileged social function led to the expansion both vertically and horizontally of a few companies creating an oligopoly. Today three companies – General Foods, Proctor and Gamble, and Nestlé (which also dominates much of the international market) – are responsible for 80 percent of the U.S. coffee market. They spend hundreds of millions of dollars a year to promote their brands, yet paradoxically, the price and profit levels of coffee remain low, despite the drink's status as a necessity, even a drug, for which the taste is perhaps less important than the effect it produces and the price it commands.

In recent years, however, specialty coffee beans, sold mostly by small companies and cafés, have challenged the conventional wisdom that North American consumers are unwilling to pay a high price for good coffee. Gourmet coffees, offered by creators who stress their national origins, the roast employed, and sometimes the flavorings added, have collectively become the only sector of the U.S. coffee market that is growing. They tend to appeal to younger, more affluent buyers for whom gourmet coffee is more a status symbol or a declaration of one's lifestyle than it is a necessity.

Yet even before the rise in the popularity of gourmet coffee, roasters had sought ways of expanding the mass market. After many attempts, the first commercially successful dried coffee was produced in 1906 by a North American chemist residing in Guatemala. But it attracted few drinkers until World War II when it was included in soldiers' rations, and since that time the market for instant coffee has grown substantially. By the 1960s, as much as one-third of home-prepared coffee was instant soluble. Its ease of preparation helped expand consumption but undermined quality because instant coffee utilizes mostly robusta coffee, which is a faster-growing but more bitter species than the arabica. As with gourmet beans, since the 1980s there has been a trend toward adding other flavorings to soluble coffee to produce specialty drinks that resemble, to name a few, Irish coffee or cappuccino.

Another major innovation has been decaffeinated coffee. It was developed in Germany at the beginning of the twentieth century by Ludwig Roselius, a sworn enemy of caffeine, which he blamed for his father's death. In Roselius's original process, green coffee was steamed and then soaked in a chlorinated organic solvent. Other processes have subsequently been developed, some involving the breeding of coffee trees with low caffeine yields. As coffee has come under attack for contributing to cardiac problems, decaffeinated consumption has soared.

The medical community is divided on the effects of coffee drinking. There are certainly beneficial effects, and the brew is sometimes prescribed in the treatment of barbiturate poisoning, migraines, chronic asthma, and autism in children. That heart ailments may be a negative effect is strongly debated, with each side marshaling impressive evidence. It seems clear that coffee's physical effects vary greatly, depending on the consumer. One study has concluded that for about 14 percent of the population, caffeine dependence produces a physical addiction similar to an addiction to alcohol or cocaine.

Such controversy over the ill effects of coffee helped drive down per capita consumption in the United States from its peak of 3.2 cups per day in the 1960s to 1.8 cups in 1993. Still, health concerns alone cannot explain this retreat because consumption of two other beverages with caffeine – soft drinks and tea – has grown since 1970, with soft drinks more than doubling in per capita consumption to reach almost 40 percent of all beverages consumed. By contrast, milk consumption has declined and that of juices has remained flat (United States Department of Agriculture 1993). No doubt advertising and packaging have had a substantial impact, and it is the case that soft drinks and bottled water (another rapidly growing beverage) require no preparation.

Numerous coffee companies rose to the challenge to compete directly with soft drinks by creating new products, such as prebrewed coffee, bottled iced coffee, and iced cappuccino. This seemed to be the logical terminus of a century-long process in which the activities of roasting, grinding, and brewing, formerly done in the home, became industrialized.

Yet there is a countertrend as well in the growing gourmet market. The swelling army of connoisseurs who want to make American coffee "a national honor," to borrow the words of coffee expert W. Ukers written decades ago (1935; 570), rather than a "national disgrace" are buying a great variety of specialty roasted beans and grinding them at home. Specialty coffeepots and espresso makers also constitute a booming market.

Coffee Drinking in the World

In other parts of the world, the popularity of coffee is at least being sustained or is on the increase. Coffee-producing countries have increased their share of consumption from less than 10 percent of production at the end of the nineteenth century to about one-quarter by the end of the twentieth century. Among coffee growers, Costa Ricans have the greatest taste for their own beans, and Brazilians are second. But even in these nations, per capita consumption is well under one-half that of northern European countries. Africans, except for Ethiopians, consume almost none of the beans they produce. Coffee is still very much a commodity consumed in rich countries and produced by poor ones, and per capita consumption is closely correlated to the wealth of consuming nations. It is also negatively correlated to an ability to grow arabica bushes or to historic ties to the trade (United States Department of Agriculture 1993). Few of the countries earliest involved in coffee's history – Yemen, Turkey, Indonesia, Haiti, or Martinique – are significant consumers, and in Europe, those with the oldest ties to the coffee trade – Greece, Portugal, Italy, and the United Kingdom – are among the lowest consumers. On the other hand, countries in Asia with no historic connection with the arabica – Japan, Korea, and Singapore – are rapidly increasing per capita coffee drinking as incomes climb. In 1992, Japan was the fourth largest coffee importer in the world. In mainland China, the arabica is making inroads not as a proletarian beverage but as a bourgeois one.

Worldwide, the human race drank about 380 billion cups of coffee in 1991[1] or about 76 cups for each man, woman, and child on the planet. Clearly, the exotic drink that Yemenis first tasted nearly 600 years ago has assumed a position of some considerable global importance.

Production in Arabia

Despite the fact that *Coffea arabica* grew wild in Ethiopia and *Coffea robusta* appeared naturally in the Congo, Yemen had a virtual world monopoly on production for about half of coffee's 600 years of lifetime as a commodity. Stern measures were taken to prevent the smuggling out of coffee plants, and although this move was not entirely successful – there are reports of coffee growing on India's Malabar coast and perhaps Ceylon in the sixteenth century – Yemen's grip remained firm until the middle of the eighteenth century. In the early part of that century, Yemen may have been producing some 20 million pounds a year (Raymond 1973–4; Becker et al. 1979).

The beans were grown in small, irrigated mountain gardens in various small, broken areas of northern Yemen, then transported by camel either to port or across the deserts (Daum 1988). The entire crop was consumed in the Middle East and Southwest Asia until the middle of the seventeenth century, and even thereafter, the East remained the main market for another hundred years.

Europeans initially purchased Yemen's coffee through Arabian traders. The Dutch and British East India Companies eventually established factors in Mocca, but they still exercised no control over production and had to make purchases with gold and silver because the Arabs much preferred Asian trade goods to European products. Another drawback was that such wealth attracted pirates, often based in Madagascar. Not satisfied with this precarious trade in a product whose value was growing vertiginously, the Europeans smuggled out coffee plants to begin production elsewhere. This decision ultimately spread the Arabian bean to more than 100 countries on 4 continents. Yemen soon became an inconsequential coffee producer, and the thriving coffee port of Mocca, which probably had more than 30,000 inhabitants at its height, dwindled to 400 stragglers living amidst its ruins in 1901.

Production in Asia

More than any other commodity, coffee was produced in poor colonies and countries for the enjoyment of those in rich countries. But, as we have seen, the Europeans who created coffee colonies (the Dutch, British, French, and Portuguese) were not the ones who consumed the most coffee on a per capita basis. Coffee was not only an export crop but a reexport crop.

In 1690, the Dutch introduced the coffee bush to Java, where their colonial might was soon employed to force peasants to labor on coffee plantations. Others were compelled to grow trees on village lands and give over shares or to sell at fixed low prices to government agents. Although clearly a coercive system, it relied on traditional local power relations and peasant agriculture to extract profit. Technology was primitive and yields low. But costs, for the Dutch, were even lower; so profits were high. The Javanese, however, experienced little capital accumulation or economic development (Kok 1864; Geertz 1971). A different kind of labor system was employed on the tiny island of Bourbon (renamed Reunion), lying southwest of Madagascar, where French colonists forced African slaves to grow coffee. In the eighteenth century, the island became one of the world's largest coffee producers.

Throughout Asia, coffee growing was a colonial enterprise as it continues to be in Papua New Guinea (Stewart 1992). Dutch and British East Indian colonies were among the world's leading producers until the last part of the nineteenth century when a fungus devastated coffee fields. And disease has plagued coffee growers the world over because "coffee is one of the tropical plants most susceptible to diseases and insect attacks which may destroy whole plantations" (International Institute of Agriculture 1947: 22).

Many East Indian plantations turned to tea or rubber, and where coffee maintained its hold, as in Sumatra, it was mostly the robusta, rather than the disease-plagued arabica, that was grown on peasant plots. Ceylon (Sri Lanka), India, and the Philippines were also major coffee producers into the nineteenth century, but were overwhelmed by Latin American production in the twentieth century.

Production in the Caribbean

The Dutch, who brought some arabica trees to Amsterdam's botanical garden, assisted coffee in its move westward by planting it in Surinam; later some seedlings were transported to Brazil. Another early Dutch contribution to the dissemination of coffee in the Americas was even more circuitous. An arabica tree, given by the mayor of Amsterdam to Louis XIV, was cultivated in Paris's botanical garden. One of its seedlings, however, made its way to the Americas early in the eighteenth century when the Frenchman Gabriel de Clieu carried it across the Atlantic to a New World home in Martinique. From there it spread to St. Domingue (today Haiti) and later the mainland.

On St. Domingue, colonial production was perfected when slaves, already imported to grow sugar on the island, were also employed in the coffee fields. European consumption grew tenfold in the 50 years between 1739 and 1789, with French colonies supplying three-quarters of the total. In fact, relatively inexpensive Caribbean coffee was already displacing Yemeni beans even in the Cairo market, demonstrating, among other things, the competitive advantage of slave labor and plantation agriculture over the garden plots of Yemen and the peasant farms of Java. Nonetheless, the arabica remained a rather exceptional specialty product under mercantilism. In 1800, on the eve of the Industrial Revolution, Europeans consumed on average only about three-quarters of a pound per year.

By the end of that century, however, coffee had become the world's third most important traded commodity in terms of value, thanks to the Industrial Revolution and its transformation of transportation systems and markets. Perhaps fittingly, it was also during the nineteenth century that coffee was grown for the first time on an industrial scale. This occurred in the fields of Latin America where, unfortunately, coffee helped to sustain slavery – even to resurrect it.

The slave revolution in St. Domingue severed the colonial tie with France, abolished slavery, gave birth to modern Haiti, and sent the island's coffee economy into an irreversible decline. But rather than ending slavery, French and Spanish planters made Cuba the next great slave-operated coffee system. Its reign, however, was short-lived because the profitability of sugar overshadowed that of coffee. Meanwhile Brazilians, who were having difficulty competing with Cuban sugar, switched to coffee growing, and Brazil in the 1830s began a domination of world coffee production that has endured to this day. For most of the nineteenth century, Brazil owed that domination to the toil of slaves.

Brazil

The transition from slave-based sugar to coffee growing in Brazil was natural, but not inevitable. An agricultural downturn during the first four decades of the nineteenth century propelled government officials, and even some planters, to reassess the newly independent country's export orientation and reliance on human chattel. But a burst of European and North American demand for coffee redoubled reliance on the export economy and stimulated the craving for slaves; the planter elite, once again, confidently pronounced Brazil an "essentially agricultural country" and, more specifically stated, that Brazil *was* coffee, and coffee meant slaves. The rate at which Africans were landed in Rio de Janeiro and Bahia between 1800 and the abolition of the Atlantic trade in 1850 far surpassed that of any previous place or time. Brazil had been by far the largest importer of African bondsmen and was the last country of the Western world to abolish slavery when emancipation finally arrived in 1888 (Curtin 1969).

Contemporary critics complained that slavery was not only socially dangerous but was also delaying Brazil's social, economic, and political development. Later, in the 1960s, a school of analysis known as "dependency theory" extended this critique. The coffee industry was accused of reinforcing slavery, which, in turn, had impeded the development of a domestic bourgeoisie, restricted commodity and capital markets, skewed wealth distribution, created an unfavorable view of manual labor, and fashioned a liberal oligarchic state that sold national sovereignty and progress in the bags of coffee shipped abroad (Frank 1969; Santos 1974). Indeed dependency theory maintained that not only slavery but also monocultural export economies in general had led to the underdevelopment of neocolonies that were tied to the world economy.

A counter-argument, however, concedes that the *dependistas* were correct in their assessment insofar as the Paraíba Valley (parts of Minas Gerais, Rio de Janeiro state, and São Paulo state) was concerned, but claims that they were wrong in the case of western São Paulo where coffee stimulated capitalist development (Amaral Lapa 1983). There, when emancipation became inevitable, planters turned to immigrant labor. Some 3 million southern Europeans emigrated to Brazil between 1880 and 1930, most of them headed toward São Paulo's coffee fields.

These families of workers helped Paulista planters become agro-industrialists on a scale previously unknown in coffee cultivation. Indeed, Paulistas established some of the largest plantations (*Fazendas*) ever built anywhere, at any time. The Cambuhy Estate, for example, spread out over 250,000 acres on which almost 3 million trees were grown, with the whole tied together by 60 kilometers of private railroad track and 300 kilometers of roads.

These Paulista agro-industrialists directed some of their agricultural capital not only to urban real estate, public works, and government bonds but also to railroads, banks, and even factories. The *fazendeiro* was thus transformed from rentier to capitalist, from coffee baron to entrepreneur. He became the leading partner in what is generally acknowledged to be the most progressive national bourgeoisie in Latin America – indeed, one of the most entrepreneurial in the entire developing world. He industrialized São Paulo, and coffee was transformed from a colonial product to the foundation of the nation-state (Dean 1969; Cano 1977; Silva 1981; Levy 1987).

Albert Hirschman (1981) has argued that coffee had special advantages that encouraged the development of a national bourgeoisie and industrialization. He points out that the relative lack of forward and backward linkages, and the simple technology sufficient to grow and refine coffee without great capital requirements, may have stimulated entrepreneurial initiative by keeping foreigners restricted in their participation to the areas in which their comparative advantages lay, namely commerce and transportation. Thus, unlike petroleum, copper, or even sugar, the production and processing of coffee (except roasting and grinding) was done almost exclusively by nationals. Agricultural production profits remained within Latin America and because coffee did not demand great infusions of capital, planters were free to diversify into other areas.

The economic wealth of planters translated into political power which, when wielded to protect their own interests, led to a fundamental transformation of the liberal state and, ultimately, of the world market for coffee. Beginning with the valorization of coffee in 1906 through the creation of the Institute for the Permanent Defense of Coffee in the 1920s and, finally, the *Departamento Nacional de Café* in 1933, the

Brazilian federal and state governments came to finance most of the world's coffee trade and hold most of its visible stocks. Seven years later, one of the first international commodity cartels was established with the Inter-American Coffee Agreement. And in 1962, the rest of the world's producers were brought under the umbrella in the International Coffee Agreement, which persisted until 1989.

Coffee set the precedent that other raw-material producers would later follow, including those of OPEC. It also transformed the state's role in the domestic economy. By the end of the First Republic in 1930, the Brazilian state was responsible for much of the financing, warehousing, transportation, and sale of coffee and controlled one of the world's largest commodity markets. Coffee, thus, carried Brazil from an archaic slavocratic social formation to state capitalism in half a century (Topik 1987), and the state played a similarly large economic role in most other coffee-producing countries.

Spanish-American Production

In other coffee-producing lands, large-scale plantations like those of Brazil were unusual even during the height of the export boom. In Venezuela, for example, despite a tradition of slave labor and haciendas, smaller-scale production eventually prevailed (Roseberry 1983). In Colombia, the eastern part of the country had a strong colonial tradition of peasants, with no slaves or latifundia, whereas in the west there had been both. The east was the leading growing area until the beginning of the twentieth century when western provinces, such as Cundinamarca and Antioquia, rapidly increased production. But in Cundinamarca, coffee was grown on shares; only in Antioquia were haciendas important social units, and there were also many small growers as well. Nationally, by 1932, 87 percent of all coffee farms had less than 5,000 trees (farmers usually placed 500 to 800 trees per acre), and 74 percent of all production came from farms of less than 20,000 trees, meaning less than 40 acres (Beyer 1947; Nieto Arteta 1971; Palacios 1980).

In Central America, coffee was also grown mostly on small and middle-size farms called *fincas.* Although Costa Rica was far from being a rural democracy (71 percent of the peasantry was landless in 1883) and land ownership was concentrated, even the biggest coffee plantations were often discontinuous and fragmented into a number of small or medium-size lots, sometimes several kilometers apart (Cardoso 1977: 175–6; Seligson 1980). In fact, even the "great estates" in Costa Rica were defined as anything over 76 acres, which in Brazil would scarcely have been considered a middle-sized holding.

Elsewhere in Central America, coffee estates were somewhat larger than in Costa Rica. Nicaragua did have some coffee haciendas, but they were neither numerous nor extensive. El Salvador, the most dependent of all countries on coffee, had a dynamic agrarian bourgeoisie with extremely efficient production techniques and concentrated land holdings. But production was intensive, not extensive as in Brazil. Eugenio Aguilar was considered a large, wealthy planter with two *fincas* that held 230,000 trees on less than 300 acres. But in Guatemala and southern Mexico, with larger frontier areas, there were substantially larger holdings. Many were spread over 5,000 acres in Guatemala, and in Tehuantepec, Mexico, there were several coffee estates with 1.5 million trees on some 20,000 acres (Lindo-Fuentes 1990).

Coffee estates, in general, were smaller in Colombia and Central America than in Brazil because of terrain and transportation problems, along with a shortage of capital and labor, the relative absence of a frontier, and the presence of people with preexisting land claims. To compensate for the higher production costs wrought by such problems, growers had to produce a better coffee that would command a higher price at market.

Higher-quality coffee required more labor-intensive harvesting. Shade trees had to be planted, and the berries were picked individually just as they ripened, in contrast to the procedure of stripping entire branches as was done in Brazil. Workers would sometimes have to pass the same tree six or seven times during the harvest instead of just once. Better quality also demanded the more sophisticated and expensive "wet" method of treating the berry.

While inspecting this method in Costa Rica, the Brazilian planter Jorge Dumont Villares marveled that the preparation of coffee was a "true science" there. The berries were picked, hulled, then left 24 to 40 hours to ferment. Next, they were washed to remove the outer membrane and dried for one or two days. From the drying grounds, the beans were taken to dryers where they were left for 25 to 35 hours to dry. The parchment film was then removed mechanically and the beans sorted by size, quality, and color. Finally, the beans were polished (Villares 1927). Producing high-quality coffee, then, demanded substantial capital and technical expertise, as well as abundant labor. The capital was provided more by mill owners than by growers.

The relationship between coffee and the kind of labor applied to it varied from country to country and changed over time. As noted, coffee reinforced slavery in the Caribbean and in Brazil, but slavery was not common elsewhere in Latin America where other coercive forms of labor were applied. Nonetheless, as we have tried to show, coffee, plantations, and slavery or forced labor were not necessarily linked, and coffee did not always yield a strong landlord class. Rather, in Costa Rica, for example, merchants and millers came to predominate because of the smallholding pattern, and elsewhere merchants also became the dominant class. In Colombia, most of the progressive planters were initially merchants, and only in such areas as Cundinamarca were traditional landlords the coffee growers. Many Nicaraguan *finqueros* were urban based, and the El Salvador coffee-grower class was largely composed of merchants and other urban-based capitalists who invested in land in the 1880s and 1890s as coffee prices rose. German merchants in Guatemala and Chiapas followed the same path.

In few cases was there much continuity between the colonial landed elite and the coffee bourgeoisie. In fact, many members of the coffee elite were nineteenth-century immigrants. Thus, it is a mistake to refer to the coffee growers of Central America and Colombia as *Junkers* or to discuss "landlord capitalism" as is often done (Winson 1989). Coffee was developed by a new bourgeois group that was not reluctant to invest in other sectors of the economy as well.

This does not mean that there was no resistance to the rule of coffee. In Guatemala, villagers frequently destroyed coffee *fincas* (Cambranes 1985). Peasants in western El Salvador, the center of coffee cultivation, in collaboration with the Communist party, attempted to overthrow the government in 1932. The result was at least 17,000 peasants dead in the gruesome massacre known simply as *La Matanza* (Anderson 1971; North 1985).

The willingness of coffee growers to use violence has often allowed the essence of their rule to continue while changing its appearance. Colombia never had a truly populist ruler; the traditional Liberals and Conservatives still share power. El Salvador and Guatemala have the most ferocious and brutal regimes of Central America, still overseen by descendants of the coffee elite. São Paulo was the last state to hold out against the populist leader Getúlio Vargas, even waging civil war against him in 1932.

Yet there has been change. São Paulo, for example, although its economy is now based on the cities and factories that coffee gave birth to rather than on the countryside, has become the home of Latin America's largest socialist party, the *Partido dos Trabalhadores.* In Costa Rica, a revolution in 1949 brought to power a semiautonomous state that has presided over Latin America's most vigorous democracy; and in Nicaragua, division among growers and a single family's attempt to monopolize wealth led to the creation of the first truly socialist regime on the American mainland. In all of these cases, however, democratic trends began to grow only *after* coffee ceased to be the dominant export.

Socioeconomic Aspects and a Return to Africa

During the years 1850 to 1930, the world coffee market was fairly homogeneous, with the vast majority of the world's coffee (as much as 95 percent) produced in Latin America. Although there are an estimated 50 different species of the genus *Coffea,* and a much greater number of small species or elementary hybrid-producing forms, over 90 percent of exports before World War II were of the same species, the arabica.

Such apparent uniformity, however, is a bit misleading. Because all coffee is cultivated outside of its natural habitat, under different methods and a wide range of natural conditions, the arabica is different on virtually each plantation (International Institute of Agriculture 1947: 19–20). Beans also differ from year to year. There are 10 generally recognized subspecies.

The international market divided coffee by port of exit and grade of the bean (determined by color, size, and degree of breakage). The main division in the world economy, however, was between "Brazils" and "milds"; the latter, produced in Colombia and Central America, began making inroads into the dominance of the former beginning in the 1920s, when Brazil's coffee valorization program propped up the price of the stronger and more bitter "Brazils." Different national crops also varied substantially according to the harvest season. But the time it took for beans to reach market was not of great consequence because they did not deteriorate over time (as, for example, apples, did) and importers maintained large stocks in the consuming countries to smooth the flow to market.

Despite such differences, the producing countries shared many similarities. They exported almost all of their crop to Europe and North America. And all used fairly similar cultivation techniques demanded by the arabica bush or "tree." In order to increase yield and facilitate the harvest (done almost always by hand), the trees were topped in their third year and only allowed to grow to 6 to 16 feet, though in the wild they grow to 35 feet; hence they were often termed bushes rather than trees. The arabica grows best with deep, permeable, well-aerated soil and a minimum rainfall of 50 to 60 inches during germination (coffee lands in Latin America were almost never irrigated as they were in Yemen and Java). It also needs a long, dry season and mild climate, with the optimum temperature between 59 and 77 degrees Fahrenheit.

Coffee-producing countries have also shared a secondary position in the industrialization of coffee. Since the consumers were in the rich countries, the retailing, wholesaling, roasting, grinding, and packaging were done in those countries. Growers were, thus, excluded from the most technologically sophisticated aspects of the production of coffee, from which the greatest innovations such as packaging, vacuum sealing, and soluble coffee emerged. These, along with roasting and advertising, have also constituted the most lucrative of the forward linkages. Thus the Santos price was at most half the New York retail price, and if the coffee were sold by the cup rather than the can, the additional labor cost and markup meant that as much as 90 percent of the value added was created in the consuming countries.[2]

Today the supermarket price of standard roasted or ground coffee is 3 to 4 times the New York green price. Restaurants sell coffee by the cup for 6 to 10 times the retail bean price. And the specialty brands are even more expensive. Thus, upwards of three-quarters of the value is added in the consuming countries. The only dent in the consuming countries' market command has been made by the increasing ability of some of the major exporting countries to produce and export soluble coffee.

For most of the coffee-producing Latin American countries, the cultivation of coffee became important toward the end of the nineteenth century or early in the twentieth century, and coffee came to dominate national exports, creating monocultures. In 1929, coffee cultivation was responsible for 71 percent of exports in Brazil, 61 percent in Colombia, 77 percent in Guatemala, 77 percent in Haiti, 54 percent in Nicaragua, 67 percent in Costa Rica, and fully 93 percent in El Salvador (Ukers 1935).

Since World War II, however, coffee cultivation has slowly shifted back to Africa. Although Latin America still produces most of the world's coffee, the crop is no longer responsible for more than half of the exports of any one of its countries. In Africa, however, in the late 1960s, coffee represented more than half the exports of Angola, Burundi, Ethiopia, and Rwanda, and almost half of Uganda's (Barbiroli 1970), and the continent now supplies about 18 percent of total world exports. Africans usually plant the more disease-resistant and faster-maturing robusta bush. It produces a less desirable brew but has been particularly successful in the soluble coffee market.

Coffee has come full circle in Africa. Ethiopians had vast forests of wild arabica trees but did not enter the trade until this century. Indeed, a nineteenth-century Dutch observer wrote that "the plant is not only no object of culture there, but is abandoned to persecution in some parts through the rage of blind fanaticism" (Kok 1864: 210).

European colonial regimes and planters initiated the coffee export economy in Ethiopia, as well as in Kenya, Angola, Uganda, and elsewhere. Africans were sometimes pointedly excluded by law from growing the arabica or robusta, although in Zaire and Ethiopia they were forced to grow or harvest the beans. In the last 40 years, however, decolonization has transformed the situation. Today, the Ivory Coast, Ethiopia, and Uganda are the principal coffee-growing nations of Africa, and African peasants, not European plantation managers, are the overwhelming producers (Clarence-Smith 1994).

Conclusion

Throughout its history, coffee has stimulated ideas, debates, commerce, and development, not to mention numbing people to routine and exposing them to vice and exploitation. And it has helped to subvert cultures, social systems, and governments. In the consuming countries, coffee moved from the mystical and mercantile to become one of the most traded bourgeois products in the world. Coffeehouses operated as centers of a bourgeois lifestyle for literati and businessmen alike, as well as meeting places for those who agitated for democratic politics. Coffee became the fuel of the industrial age.

In the fields of Latin America, however, European and North American demand led first to an intensification of slavery and then, in various places, to the appropriation of village lands, the expulsion of native peoples, and coerced labor. But, although there were large planters, there were also plenty of smallholders.

The story of coffee is clearly one of diversity. Geography, history, and local resistance combined to create a wide variety of social arrangements. To trace the history of coffee is to trace the path of the world economy over the last six centuries. From an Asian monopoly, to a European colonial product, to a global commodity grown on four continents, coffee has linked the different worlds of the producer and the consumer, the underdeveloped and the developed, the free and the enslaved, the rich and the poor, and the bourgeois and the archaic. Sufi Sheikh, sitting in the shade in Mocca, had no idea what a global force he was putting into motion when he sipped the first cup of coffee.

Steven C. Topik

The author would like to thank Gervase Clarence-Smith for his insightful comments.

Notes

1. According to the United States Department of Agriculture (1993), total world consumption in 1991 was 72 million sacks of 60 kilograms each. I multiplied by the recommended 40 cups of coffee to the pound to arrive at the number of cups.
2. This estimate assumes the New York raw material to be 50 percent of the New York wholesale price. It also assumes a 50 percent markup to the Midwest, and a 25 percent profit for the wholesaler and for the retailer. Finally, it reflects the conservative estimate that a retail cup of coffee costs the consumer about twice one made at home. A restaurant cup of coffee costs 7 to 13 times the retail price of coffee.

III.5 Distilled Beverages

Alcoholic beverages have been a part of human culture since at least the Neolithic period. Yet until recently, beverages made from fruits, grains, or honey were considered to be what historian Wolfgang Schivelbusch (1992) has called “organic,” meaning that the amount of sugar in the ingredients produced the amount of alcohol in the drinks. Examples of such beverages are beer and wine. Beginning in the period from about A.D. 800 to 1300, however, people in China and the West learned to distill alcoholic liquids. This chapter traces the history of distilled alcohol and discusses the nature of several kinds of liquor.

Distillation and Alcoholic Beverages

Distillation is a method for increasing the alcohol content (and, thus, the potency) of a liquid already containing alcohol – the existing alcohol content usually the result of the fermentation of vegetable sugars. The distillation process separates the alcohol from other parts of the solution by the heating of the liquid to 173° Fahrenheit, a temperature sufficient to boil alcohol but not water. The resulting steam (vaporized alcohol) is collected and condensed, returning it to liquid form – but a liquid with a much higher proportion of alcohol than before. Repeating the process increases the liquor's potency yet further. Because distilled alcohol contains bad-tasting and dangerous chemicals called fusel oils (actually forms of alcohol) and congeners, both by-products of the distilling process, it is often aged in a procedure, originating in the eighteenth century, that rids the beverage of these chemicals. As the liquid ages, its container (preferably made of wood) colors and flavors it to produce a smoother and better-tasting product (Ray 1974).

A constant theme in discussions of distilled liquor is that of fire, which has three different metaphoric meanings. First, beverages are "burnt," or distilled, over the flame of a still. Second, although it is a drinkable liquid, distilled alcohol is capable of combustion. The third meaning is an apt description of the sensation experienced by consumers of distilled spirits. "Firewater," *aguardente, aguardiente* (meaning rough or burning water), and ardent (burning) spirits are all terms referring to such a sensation (Needham 1984).

Stills are the traditional equipment needed to distill alcohol. There are many different types. The earliest known is the *ambix* (plural *ambices*) used by Greek alchemists. *Ambices* were ceramic or metal pots with heads shaped so that liquid would condense inside the head and drain out through a collecting tube. Later, during the Middle Ages, Muslim alchemists, who also employed the *ambix,* added the Arabic article *al-* to its name, hence the term "alembic" for a still (Forbes 1948). When larger amounts of alcohol began to be distilled in the fifteenth and sixteenth centuries, the *ambix* was improved, giving rise to several types of stills.

A common one, the pot still, dates from the sixteenth century. The fermented beverage is boiled in a large pot having a curved top that allows the steam to pass to a coiled cooling pipe called the "worm," in which the vaporized alcohol condenses into a liquid. The distillate then flows from the worm into a receiving vessel. Pot stills, like those used in the sixteenth century, were later carried to the Americas and to other European colonies and remain in use in traditional distilleries. In Europe and the United States, pot stills are employed for the production of such beverages as French brandy, Italian grappa, and Scotch whiskey (Maresca 1992). The liquids produced by a pot still at the beginning (termed "foreshots" by American distillers) and end ("aftershots") of a particular distillation are undrinkable or, at least, foul tasting because of the fusel oils that they contain and are consequently either redistilled or discarded. The liquid produced in the middle of the distillation process is the valuable fraction, and proper separation of the liquor from the by-products requires both experience and skill.

The early nineteenth century saw the invention, by Aeneas Coffey, of a still that permitted more or less continuous distillation (Forbes 1948). This device consisted of two hollow metal columns through which vaporized alcohol rose to condense on metal plates. One column served for distillation and the other for rectification – a process of adjusting the potency of an alcoholic beverage, often by redistillation. But because distillation was continuous, the Coffey still did not permit the separation of the bad-tasting beginning and end by-products from the vital middle of the run. All of it tasted the same, being of uniform but lesser quality. Today, such mechanical stills can process thousands of gallons of liquid at a time, but pot stills are said by many to produce better-quality beverages.

Redistillation is sometimes called "rectification," but this is an ambiguous term, which, legally, can also mean blending one distilled beverage, or "spirit," with other spirits or flavorings. In many cases, tasteless neutral spirit becomes an esteemed beverage with a little help from the rectifying process; examples include some Scandinavian akvavits and Polish vodkas (Grossman 1989). Spirits are also blended with water to make them drinkable.

Alcohol and Distillation – 5500 B.C. to A.D. 1500

Alcoholic beverages were made as long ago as the sixth millennium B.C., as has been documented by the discovery of wine remains in a container at Çatal Hüyük, an archaeological site on the Konya Plain in Turkey (Mellaart 1967). It is probable, however, that wine was produced from dates and figs even earlier (Tannahill 1988). Beer (or, more properly, ale) was in use in ancient Sumer by at least 2500 B.C. and at about that time, or soon afterward, in Egypt (Lichine 1981).

As populations became more crowded, with consequent pollution of water supplies, nearly everyone drank ale or wine. The Romans scorned the ale of the Germanic tribes but made wine a regular part of their own daily regime (Pliny 1940). As a rule, it was mixed with hot water, spices, and perhaps honey (Lichine 1981). People who drank undiluted wine were thought to be depressed or alcoholic (or both), which suggests that the Romans probably would not have been interested in diverting their distillation techniques from alchemy to the production of beverages stronger than wine, even had they thought of it (Tannahill 1988).

Nonetheless, some investigators have sought the origins of distilled beverages in ancient Rome. Pliny the Elder (Gaius Plinius Secundus) mentioned a "wine" that had to be diluted several times before it could (or should) be drunk (Pliny 1940). But this reference is to a wine kept in ceramic vessels and allowed to evaporate over many years, until the result was a thick sludge (Lichine 1981). Pliny also wrote of Falernian wine that could be ignited, that would keep for a decade, and that was strong in flavor. But at that time, wine was often boiled down into a kind of jelly to season foods and make drinks, and it was already known that the vapor from hot wine could be ignited. Thus, in the absence of archaeological evidence of "worm" coils or other kinds of still-head cooling devices, it appears that the manufacture of distilled spirits, at least on any large scale, remained in the future (Needham 1984).

The Greek alchemists, whose stills are portrayed in drawings from the Hellenistic period, may have preceded the Romans in producing small amounts of alcohol. Alchemy, which originated in Egypt and Persia and was then practiced by the Greeks and the Arabs, was a quasi-magical process by which the alchemist sought the "essence" of matter to perfect it in accordance with mystical laws (Needham 1984). Arab alchemists produced a cosmetic eye makeup, the name of which – *kohl* or *kuhl* – conveyed the notion of something fine and subtle emerging from a process of distillation, and it was from *al-kohl* (or *al-kuhl*), and various subsequent renderings like the Portuguese *álcool,* that the English word "alcohol" was derived (Forbes 1948).

Moreover, despite the Islamic prohibition against alcohol consumption, the Arabs are credited, at least in legend, with the spread of liquor to Europe. One well-known account, set in the early fifth century, tells the story of an Irish monk – who later became Saint Patrick – spreading the gospel in the Near East. There, he learned about stills and, on his return to Ireland, brought one with him (McGuire 1993). A more modern version of the tale has the Crusaders learning about alcohol and distillation from the Arabs and bringing home to Europe both taste and technique. Whether there is truth in either story, the historical record of these centuries does not indicate any widespread use of distilled spirits that would also have triggered their widespread misuse – a misuse that certainly would have rated mention in the literature (Schivelbusch 1992).

Distillation, then, continued to remain the property of the alchemists, who in the Middle Ages were distilling water hundreds of times over, reducing it to a residue of mineral salts that was said to be its "essence" (Forbes 1948). About A.D. 800, the Arab scholar Jabir ibn Hayyan invented a much-improved still, and during the centuries from 800 to 1000, Arab alchemists are said to have distilled wine, with its resulting "essence" employed in still further alchemical experimentation (Toussaint-Samat 1987). This may have been the first time that brandy was made. But with alcohol consumption forbidden by the Islamic religion, there was little incentive to distill such beverages in any quantity (Forbes 1948).

Meanwhile, in China, rice wine – *chiu* (actually an ale) – had long been produced and was as popular there as were grape wines in the West; Chinese ales made from millet also had been brewed for some time (Simoons 1991). However, the fermentation procedure used to make rice wine generally resulted in a stronger beverage than Western ales and beers (Chang 1977).

Like Greece and the Arab world, China also had its alchemists, but Chinese stills were different from those used in the West, having a tube on the side to drain the distillate and allow more of it to be produced. Although the date when this type of still originated is unknown (Needham 1984), fourth-century documents mention a "wine" from the "western regions" that kept for a long time and was extremely strong. This beverage might have been produced by Chinese stills; however, noted sinologist Joseph Needham (1984) has suggested that it came not from Chinese stills but from remote regions of central Asia, where a technique of concentrating alcohol by freezing it had been invented. Although Needham believes that such a technique was a precursor to distillation, he acknowledges that the evidence is confusing and that the references that describe this particular beverage are ambiguous. Moreover, one authority has suggested that, given the paucity of references to distilled spirits in Chinese history (until relatively recently), even if liquor were known, its use could hardly have been common (Simoons 1991).

By the fourteenth century, however, this may no longer have been the case. The *Ying-shih ssu-chi,* a medical work dated to 1368, draws attention to the dangers of overindulgence in distilled alcoholic beverages, and Li Shih Chen (writing in the sixteenth century) stated that liquor had reached China only with the Yuan (Mongol) dynasty of the thirteenth and fourteenth centuries (Chang 1977). Chen mentioned such beverages as "fire wine" and "burnt wine," equating the latter with arrack or distilled palm wine. It is interesting to note that this chronology of alcohol use in China parallels that of brandy, and perhaps even whiskey, in Europe (Simoons 1991).

From about 1000 to 1500, alchemists in Europe repeatedly distilled wine (adding salts to absorb the water portion of the liquid) to produce a distillate that would burn. That the eleventh-century Italian alchemist and scholar Michael Salernus had successfully produced alcohol, for example, is indicated by the following statement: "A mixture of pure and very strong wine with three parts salt distilled in the usual vessel, produces a liquid which will flame up when set on fire but which leaves other substances unburnt" (McCusker 1989: 85). (In Salernus's original manuscript, the words underlined here are written in cipher to prevent others from learning his procedures and formulas.)

Salernus was not alone in reporting such results, and collectively, the alchemists believed that they had extracted the "essence" or "spirit" of wine and that repeated distillations resulted in *aqua vitae* – the "water of life" – which, in this case, was a kind of brandy that until about 1400 was used mostly as a medicine (Braudel 1973). Because the processes of aging and the separation of the different fractions of the distillate were unknown, this liquor would have been harsh, and even harsher if bad wine had been used for the distillation.

Albertus Magnus was another distiller and alchemist who wrote about the virtues of this substance. Its potency seemed to recommend it as a treatment for a variety of illnesses. Indeed, the distillate was acclaimed as the "quintessence," a union of all the elements, even the key to everlasting life (Schivelbusch 1992).

The first real brandy that was not thought of as medicine is said to have been distilled in 1300 by Arnaldus de Villa Nova, a professor at the medical school of Montpelier. He said: "We call it aqua vitae, and this name is really suitable, since it is really a water of immortality" (Christian 1990: 25). On the other hand, both the Irish and the Scots claim to have produced liquor from grain (in contrast to brandy from wine) since the beginning of the last millennium; the Scots called it *uisge beatha* (pronounced wisky-baw), and the Irish called it *uisce beatha.* Both meant "water of life," and the English term "whiskey" derived from them.

The precise dates when Irish and Scotch whiskeys originated may never be known. But we do know that, in the aftermath of Henry II's invasion of Ireland (A.D. 1171), Irish "wine" was taxed. The reference to "wine" could mean honey mead, or ale, but it might also mean whiskey. Indeed, the Old Bushmills brand claims its origin from this date, suggesting that even if the St. Patrick tale is a bit fanciful, whiskey from the Emerald Isle may well have predated brandy in Europe, at least for recreational purposes (McGuire 1993). Certainly the archaeological discovery of a worm cooler and alembic pots in Ulster suggests that at least some distillation had taken place in Ireland by the late Middle Ages (McGuire 1993). However, the size of the vessels indicates domestic distillation on a small scale (E. C. 1859).

In the fifteenth century, better methods of cooling a still's head were developed, and these allowed increased production of distilled beverages (Forbes 1948). The technology spread quickly across Europe, and practically every country developed its own national distilled spirit. Those countries also soon developed laws to tax, restrict, and sometimes even ban such spirits, because by the sixteenth century, drunkenness had become a serious social problem. People who had previously drunk beer as if it were water were discovering that they could not drink liquor as if it were beer (Schivelbusch 1992).

Centuries earlier, Paracelsus (Philippus Aureolus) had employed the Arabic term *alcool vini* to describe spirits. But it was not until 1730, when the Dutch physician Herman Boerhave used the word alcohol to mean distilled spirits, that it became commonly understood that ale, wine, and distilled beverages all owed their mood-altering capabilities to this chemical (Forbes 1948). Yet because "aqua vitae" and other such appellations continued to be used, it is difficult to discover exactly what kinds of spirits were actually being produced. Indeed, even Scotch whiskey was called aqua vitae (Jackson 1988).

From this point forward, however, the historical picture is sufficiently clear to permit treatment of the individual liquors, and we will attempt to do this in some semblance of chronological order. But before we begin, a word or two is needed about the strength, or "proof," of an alcoholic beverage. The term *proof* originated in connection with the early use of gunpowder in war: "Proof," or good, armor was that which proved resistant to a gunshot. The word entered alcohol terminology as a means of identifying the quality of rum and brandy. "Proof" beverages were of the approved strength – half spirit and half water (McCusker 1989). Their purity could be measured by weighing or by setting the spirit alight. Later, the term came to mean twice the percentage of alcohol in the drink. In the twentieth century, neutral spirit leaving the mechanical still is 180 proof, or 90 percent alcohol (Grossman 1989).

Distilled Spirits in the West

Brandy

First called "brandy wine" (from the Dutch *brandewijn*), brandy means "to burn" or "burnt" in Dutch as well as in other languages, such as the German *Brand* and the Middle English "brand." Brandy is more expensive to make than grain spirits because it must be distilled from fruit and, in the case of cognac, from wine (Ray 1974). As noted, brandy first emerged as a medicine in the eleventh century and only later became popular as a beverage. In Nuremberg, it had apparently become a bit too popular by 1450; in that year, a law was passed to ban the drinking of *aquavit,* which we are told was brandy wine (Forbes 1948). Because in northern Europe beers and ales had long been made by women, during the fifteenth and sixteenth centuries many distilleries were located in private homes. Nonetheless, by 1500, brandy production was subject to taxation in many principalities (Braudel 1973).

Gradually, the French wine country became the center of the brandy industry. Louis XII granted the first license to manufacture brandy in 1514, and the product was employed (among other uses) to fortify wines, which strengthened them at the same time that it stopped fermentation (Braudel 1973). A less expensive brandy for the poor was made from leftover grape skins and seeds. It was and is called *grappa* in Italy, *marc* in France, *aguardente* in Portugal, and *aguardiente* in Spain (Maresca 1992).

A countermovement that pushed up the price was the aging of brandy, a procedure begun about the middle of the eighteenth century (Ray 1974). This process made for a decidedly smoother drink and certainly helped to promote what has been termed the "cult" of brandy, just as the aging of Scotch and Irish whiskeys in oak barrels established a whiskey "cult" (Morrice 1983). Then, as now, the most famous brandies came from the Charente region of France and were named for the town of Cognac. Twice distilled in pot stills from the white wines of the Charente, cognac is blended according to certain formulas and aged for a minimum of three years in oaken barrels. The drink can continue to improve through aging for as many as 50 more years, but that is the effective limit of the process; thus, the legend of fine brandy surviving from the time of Napoleon is a myth. Experts agree that even if such brandy existed, it would be undrinkable (Ray 1974).

Cognac leaves the still at 140 proof, but its potency is reduced by aging because alcohol evaporates through the porous material of the cask, whereas water does not. In addition, sufficient water is added so that cognac is shipped at 80 to 86 proof. The age and quality of a cognac are indicated by a confusing array of letters, stars, and symbols on the label. Armagnac, a well-known brandy from another region of France although much like cognac, is said to retain the flavor of the wine to a greater degree, and its method of distillation is different (Ray 1974).

By the late nineteenth century, the brandy industry was in near ruin because of a vine blight caused by the American vine louse, *Phylloxera,* that destroyed virtually all the vines in Europe (Lichine 1981). A visitor to the Continent at the end of the nineteenth century reported that the "brandy" available was not brandy at all, but rather an ersatz mixture concocted with grain spirits and plums (Spencer 1899). However, the European wine industry, along with the manufacture of brandy, was saved by the introduction of resistant rootstocks of muscadine and scuppernong grapes, native to North America, onto which the famous vines of Europe were grafted (Lichine 1981).

The term, brandy, refers not only to drinks made from grapes and wine but also to a wide variety of beverages made from other fruits and even from honey. Some are true brandies, made entirely from fruit, but many are grain spirits that are merely flavored with fruit. One fruit brandy is kirsch *(Kirschwasser),* a fiery cherry brandy of Switzerland. *Poire* brandy is made from pears, and *framboise* from raspberries. Hungary produces *Barack Palinka,* perhaps the most famous of apricot brandies. Another important beverage is slivovitz, the plum brandy of the Balkans, sold at 70 and 87 proof. Most of these brandies are bottled as uncolored spirits to preserve the fruit bouquet. In addition, there are countless brandies made from apples in Europe and wherever else apples are grown. Examples are calvados, made in Normandy from hard cider, and applejack, made largely in North America. Calvados is aged, whereas applejack frequently is not, and historically, applejack has been made by freezing as well as by distillation (Grossman 1977; Lichine 1981).

In the Americas, the agave plant contains a juice that is fermented into *pulque,* a beverage that dates from the Aztec period. The brandy *mescal* that is distilled from *pulque* comes in many varieties, with the most famous being tequila (Grimes 1988). In Peru, grape wine has been produced since 1566, with *pisco* the local brandy. Both Mexico and Chile also produce brandy made from grape wines (Lichine 1981).

Moving northward, in colonial New England and in Canada, hard cider was first processed into applejack by freezing, a technique reported much earlier in central Asia (Dabney 1974). In the Appalachian Mountains, whole valleys were planted with fruit trees to make apple and other brandies until the early twentieth century (Marcus and Burner 1992). Although there are references to "British brandy" in seventeenth-century texts, these actually deal with an early grain spirit related to gin; Britain produces virtually no wine or brandy. However, a few British distillers have made brandy from mead, the honey-based wine of the ancient Britons. This beverage, called "honey brandy," has never been common because mead itself is costly, and distilling it yields a very expensive liquor (Gayre 1948).

Spirits from Grain and Cane

The kinds of grain used to make spirits have usually been determined by custom (although sometimes by law, as in the case of licensed distillers) and, perhaps most importantly, by what is available. As a rule, lower-cost and lower-status grains have been employed: To make spirits from wheat would have been a waste of bread grain, and in the sixteenth century, several German states banned the manufacture of grain spirits so as better to control the price of bread (Forbes 1948). Rye has commonly been used in areas with colder climates, such as Canada. In the United States, the abundance of maize has made it the grain of choice (Inglett and Munck 1980), and barley constituted the base of the first whiskeys made in Ireland and Scotland. Many of these grains were ingredients for beers long before whiskeys were made (Jackson 1988).

Irish and Scotch whiskeys. To produce either Irish or Scotch whiskey, soaked barley is permitted to sprout and become malt, as in making beer. However, the mash for whiskey does not include hops. The Scotch malt has traditionally been dried over peat fires that imparted a smoky flavor, whereas Irish malt was dried in ovens. After the grain is made into a mash and allowed to ferment, it is distilled in a pot still –twice to make Scotch and three times to make Irish whiskey (Jackson 1988). The spirits are then permitted to age in oaken casks (from which they acquire their color); then blending takes place. This is a procedure that employs whiskeys that have been aged for different periods of time and that are often made from different ingredients (Morrice 1983). In the case of Scotch, for example, the unblended or "pure" malt can be blended with whiskeys made from other grains, such as oat, rye, and maize.

Modern Scotch seems to date from about the middle of the eighteenth century, its production spurred by a 1745 increase in the tax on ale. Private distillation was banned in the nineteenth century (Morrice 1983). However, the distillation of whiskey was an important source of income for the Highlanders, who raised grain but encountered much difficulty in getting it to market over the rough mountain roads. Consequently, the ban gave rise to a thriving illegal industry that, in distilling the grain, put it into a much more compact (and valuable) form. Doubtless the industry became more profitable after the *Phylloxera* blight that devastated European wine grapes from the 1860s on, made brandy virtually unaffordable, and as a result, increased demand for other alcoholic beverages.

Pot stills were hidden away in the Scottish Highlands and in Ireland, where clans made illegal whiskey, as their kinsmen in America were soon to do as well. The government struck back with raids on the illegal stills; in 1834, there were 692 seizures in Scotland and 8,192 in Ireland. But in 1884 there were only 22 seizures in Scotland, and in Ireland they had fallen off to 829. Clearly, the government was winning the war. Perhaps the greater amount of government activity in Ireland had to do with the fact that in the 1880s, there were only 28 legal distilleries, in contrast to 129 in Scotland (Barnard 1969). Government licensing was profitable: In the 1880s, the government of the United Kingdom derived 40 percent of its revenue from alcohol (Christian 1990).

Scotch whiskey continues to enjoy a certain mystique. But its manufacture has changed considerably, with coal employed to dry the malt instead of peat. The grain spirit most used to blend Scotch is now made from American maize, and Scotland imports all of its maize and much of its barley (Morrice 1983). Somehow, too, much of the romance has disappeared.

Gin. Gin, on the other hand, never had all that much romance attached to it, especially after William Hogarth depicted the excessive drinking of Londoners in his 1751 engraving, "Gin Lane" (Schivelbusch 1992). Less than a century before, the consumption of spirits had been uncommon in England (Austin 1985); most people drank ale or beer, and the wealthy, although inclined to a little French brandy, mostly prized imported wines, especially those that were fortified, such as port and Madeira from Portugal and its islands and sherry from Spain (Lichine 1981). Indeed, the dramas and diaries of the Restoration period indicate that these wines were preferred by many over even the "great growths" of France.

The individual said to have pushed Britain onto the path toward "Gin Lane" is William of Orange, Stadtholder of Holland, who ascended the English throne in 1689 as joint sovereign with Mary II. William's homeland made gin, and to encourage its importation into England, he discouraged the sale of French brandy and taxed English beer and cider (Watney 1976). The liquor he sponsored with such determination was then called *genever* or *jenever,* the Dutch name for juniper, a medicinal plant whose berries were used to flavor gin, which was itself a distillation of hopped barley mash (Butler 1926). Also named "Hollands gin" by the English, the drink became so popular in the Netherlands that it replaced beer as the beverage of the military (Austin 1985). In fact, by 1787, there were more than 200 distilleries making gin in the Dutch Republic, and only 57 breweries (Schama 1977).

Many of the gin distilleries had doubtless come into existence to supply the English market that William had engineered. In 1700, some half-million gallons were exported to England (George 1965). But it did not take the English long to begin making their own gin, which, they found, was a good way to use up surplus grain. After all, gin could be made from practically any grain, or even from molasses; its distinctiveness lay in the juniper flavoring (Watney 1976). In 1714, 2 million gallons were produced, and by 1737, English distillers were making 5.4 million gallons annually – nearly a gallon for every man, woman, and child in the population (George 1965).

As early as 1725, London alone held 6,187 gin shops, where people unaccustomed to strong spirits were working hard to overcome this handicap (Monckton 1966). It was called a "gin epidemic": Tavern keepers offered to make one "drunk for a penny, dead drunk for two pence, and straw for nothing" (Schivelbusch 1992: 156), meaning that drunkards were thrown into cellars strewn with straw to sleep off their intoxication. In London during a week in 1750, some 56,000 bushels of wheat were used to produce gin, not quite as many as the 72,000 bushels devoted to breadmaking, but close (Monckton 1966).

At this time, however, gin consumption was about to decline. The Gin Act, passed by Parliament in 1736, prohibited the public sale of gin in London and raised taxes on spirits (George 1965). At first, this statute had little effect on gin consumption: Bootleggers, some employing subterfuges such as the labeling of gin as medicine, helped perpetuate the "epidemic" (Watney 1976). Then in 1751, Parliament slapped a very high tax on gin and tightened restrictions on its sale. This effort, coupled with a sudden rise in grain prices, pushed the price of gin beyond the reach of the poor, who switched back to ale and beer, or to coffee and tea, beverages that were becoming increasingly popular (Mintz 1985). By 1782, annual gin production had fallen to 4 million gallons, and a century after that, Britons were consuming annually only about 1.25 gallons per capita of all spirits combined, although per capita beer and ale consumption was 34 gallons (Johnston 1977).

The Beefeaters distillery was established in 1822, and during the nineteenth century, gin was flavored with angelica, cassia, cardamom, coriander, and ginger, as well as juniper berries (Lichine 1981). The martini cocktail is said to have been invented in 1863 by San Francisco bartender Jerry Thomas (who is also credited with inventing the Tom and Jerry). He allegedly named the drink after the town of Martinez upon learning that this was the destination of a departing guest. However, the use of gin in martinis and "gibsons" (the latter garnished with a pearl onion instead of an olive) has chiefly been a twentieth-century phenomenon. In addition, gin is used in many mixed drinks because of its somewhat neutral taste (Lanza 1995). Modern gin is made in industrial stills and is between 80 and 97 proof (Grossman 1977). The most common type of gin is "London dry" made in both Great Britain and the United States. English gins are 94 proof; American versions are between 80 and 94 proof. Dutch gin survives today as a strongly flavored beverage distilled at a lower proof and drunk neat because of its taste (Grossman 1989).

Vodka. Vodka's distillation apparently dates from the sixteenth century, as the Russians followed the example of others in northern Europe and distilled rye – their most abundant grain – into vodka, using the pot still (Pokhlebkin 1992). As with other liquors, the distillation of vodka produced much leftover mash that could be fed to livestock, making it possible to maintain more animals over harsh winters (Christian 1990). Later, in the nineteenth century, potatoes were employed for distillation, but the thick potato mash required special stills. It has been mostly in the twentieth century that maize and wheat have found their way into Russian and Polish stills.

Vodka is thought of by some as a relative of gin, and many of its uses are the same. On the other hand, the Russians and the Poles point out that vodka "is the only beverage that goes with herring, a fish that makes beer taste insipid and wine metallic" (Toussaint-Samat 1987). Vodka means "little water," and the drink has been valued for its colorlessness and purity. It was also much valued by the Russian government for producing revenues (Christian 1990). Prior to the creation of vodka, the bulk of the country's alcohol production was in the form of beers and meads made locally by the peasantry and, thus, not taxable. But vodka was taxable and, in 1861, provided 45 percent of the revenue of the Russian state. Throughout the nineteenth century, more than 70 percent of expenditures for the Russian army were paid for by vodka taxes (Christian 1990). At the turn of the twentieth century, Russia established its Kristall vodka monopoly (under the control of the ministry of finance), which produced Stolichnaya vodka and some 70 other brands of liquor (Lichine 1981). The monopoly was suspended from 1914 to 1921, as the various Russian governments during World War I, the Bolshevik revolution, and the Russian civil war attempted prohibition (Pokhlebkin 1992), and was finally abandoned following another wave of government-encouraged temperance begun in the 1980s. Vodka is normally between 80 and 100 proof (Grossman 1977).

Grain spirits similar to gin and vodka are common across northern Europe. One example is Scandinavia's akvavit (Lichine 1981) – a name that is variously spelled. This liquor is distilled from a grain or potato base as a neutral spirit, then redistilled with flavoring. Like gin, akvavit is not aged (Grossman 1977). German and Scandinavian schnapps are usually made from fruit or herbs; Dutch *genever* is flavored with sweet-smelling herbs and is also called schnapps in Europe (Lichine 1981).

Rum. In North America, grain and cane spirits were favored over ale, beer, and wine from the beginning of European settlement (Rorabaugh 1979). English ale would not ferment properly in America's climate; cold winters froze it and hot summers caused the top-fermenting yeast to spoil. (Modern American beer is made with German lager yeasts brought by immigrants in the 1840s. These live at the bottom of the vat and can thus withstand extremes of temperature.) Nor did European wine grapes do well on the Eastern seaboard. Some distillation of grain spirits took place and, though never completely abandoned, was put aside as it became evident that the most expedient course was to ship grain to the sugar islands of the West Indies and to make into rum the molasses sent northward in return.

Rum became the favorite American alcoholic beverage until the Revolution. It is produced by distilling the fermented alcohol made from sugarcane juice (sometimes called "dunder" or "burned ale"). The best rums are distilled twice and, in some cases, aged. Rum was made in Barbados in the 1630s and received its name in 1651, when traveler Thomas Ligon remarked that the island's inhabitants were fond of "Rumbullion alias Kill Devil, and this is made of sugar canes distilled, a hot, hellish and terrible liquor" (Ritchie 1981: 116). Both "rumbullion" and "rumbustion," two early dialect names, may have referred to the violence that the drink was said to engender. Rum was shipped to England in the 1660s, but a taste for it there was slow to develop. In 1698, the English imported only 207 gallons. By contrast, the West India colonists drank so much of it that a visitor said they had "bodies like

Egyptian Mummies" (McCusker 1989). Slaves often drank a colorless raw alcohol made from sugarcane juice, called *clairin* in Haiti, *aguardiente* in Mexico, and *cachaça* in Brazil (Lichine 1981). Distilled only once, and devoid of the flavoring and aging that makes a good rum, these harsher beverages actually were rums, although not called by that name; the term "raw rum," however, is sometimes used to refer to *clairin.*

The demand for rum was great in Africa, where it was traded for slaves to be carried to the West Indies to make more sugar. Much rum was also issued to the slaves of the Caribbean, where it subsequently was incorporated into Afro-Caribbean religious and magical rituals (Lichine 1981). The spirit also became part of the medical lore of the region for a few brief decades spanning the end of the seventeenth century and the first half or so of the eighteenth century, when slaves, soldiers, and sailors, who could afford (or were given) only the cheapest rum, came down with the "dry bellyache." The almost unbearable cramps characteristic of this disease were, in fact, symptoms of lead poisoning – the lead having entered the rum from lead fittings in the stills (Handler et al. 1987). Although diminished in frequency, the dry bellyache persisted as late as the Victorian period (Spencer 1899).

Demand for rum in the North American colonies was intense, requiring distilleries in the sugar islands and in New England, South Carolina, Pennsylvania, and the Canadian Maritime Provinces to satisfy it (McCusker 1989). William Penn's thirsty colonists drank rum, and by the 1720s, Marylanders were managing a per capita consumption of at least 2 gallons annually. Rum was relatively cheap: In 1738, rum from any of Boston's 8 distilleries (they numbered 63 by 1750) cost 2 shillings a gallon. In Georgia, a day's wages could keep a laborer drunk for a week. By 1770, the 118 recorded colonial distilleries were producing an annual total of 4,807,000 gallons of rum, an average of 41,000 gallons each (McCusker 1989).

The West Indies sugar industry inexorably became the foundation of British mercantilism that in 1733 led to the passage of the Molasses Act by Parliament. This law heavily taxed molasses and rum shipped to North America from the non-British Caribbean. It drove up the price of inexpensive molasses from French St. Domingue which caused a substantial increase in rum prices. As a consequence the Molasses Act began decades of rum and molasses smuggling that ended only with the American Revolution. In addition to rum being their favorite drink, much of the prosperity of the North American colonists depended on the molasses trade (McCusker 1989).

In 1759, British grain crops failed, leading to an increase in grain prices throughout the following decade, with the result that the English (especially those of the upper classes) began to develop a late appreciation for rum. Indeed, by 1775, England was importing 2 million gallons of rum each year. Much of this was used to make rum punch, although many thought this drink was inferior to Madeira punch, made from the fortified wine of Madeira (Tannahill 1988).

Rum became even more profitable for British planters after the Molasses Act. In 1798 in Jamaica, for example, planters who made £3,000 net profit from sugar could count on an additional £1,300 from rum (Deerr 1950). By this time, the French had been all but removed from the sugar and rum production of the West Indies because of the revolution of St. Domingue and the emergence of an independent Haiti. Yet Britain was about to be more or less eliminated as a major sugar producer as well. In 1807, the British abolished the slave trade and, in 1833, slavery itself. At this point, Brazil and Cuba became the world's most important sources of sugar, with Cuba outdistancing Brazil as the nineteenth century progressed. The Bacardi Rum Company, founded in Cuba in 1862, became the producer, in the twentieth century, of the most popular brand of rum in the world.

Cuban rum tends to be light, as compared with the darker rums from Jamaica and Barbados, the latter often double distilled and aged (Deerr 1950). Haitian rum is midway between these extremes. There is also *arak* rum from Java, made from sugarcane juice fermented with rice and yeast (Grossman 1977). The yeast strains used to ferment sugarcane juice are said to be responsible for the variations in flavor among different kinds of rum (Lichine 1981). However, as sugarcane always ferments within a short time after being cut, it seems clear that wild yeast is adequate to the task of fermenting the cane juice.

Rum has a strong association with the sea and sailors. Those of the United States, Canada, and Britain were huge consumers of rum, and "grog" rations in the latter two navies continued into the 1970s. The term "grog" comes, allegedly, from the eighteenth-century British Admiral Edward Vernon, who wore a grogham (heavy wool) cloak, and to reduce drunkenness among his crews, ordered their rum diluted with water, resulting in the famous rum-based drink named after his outer garment (Tannahill 1988).

Bourbon and other New World whiskeys. Although rum was the drink of colonial Americans, independence from Great Britain severed much of the sugar connection, forcing a greater reliance on local resources. The result was a change to corn whiskey or "bourbon" (as it came to be called), made originally in Bourbon County, Kentucky. By 1800, Americans were drinking some 3.5 gallons of liquor – mostly whiskeys – per capita each year, which seems to represent a substantial increase in consumption over that of rum in previous decades.

Not that Americans had ever relied solely on rum. Grain whiskeys made from rye and corn had been produced on the eastern seaboard practically from the beginning of the colonies, and whiskey was also imported. In fact, each family that arrived with the Winthrop fleet of 1629 was required to carry *aqua vitae* to the Massachusetts Bay Colony, presumably as a medicine (Cressy 1995).

During the eighteenth century, Scottish and Irish settlers brought with them the techniques of whiskey making. Many settled in the southern colonies as farmers, and following the American Revolution, distillation was one way in which farmers might add to their yearly income. Although such activities were pursued virtually everywhere in the new United States, a special enthusiasm for operating stills developed in the back country of the Blue Ridge and Great Smoky Mountains, where (as in Scotland and Ireland) rugged terrain hindered the transportation of grain to market. Although an acre of land might produce 40 to 60 bushels of corn, a horse could carry only four bushels at one time. The same horse, however, could carry 16 gallons of whiskey, which was the equivalent of 24 bushels of grain. Clearly, for the mountain people, distillation represented the most efficient method of preparing corn for sale. In the 1830s, consumption of distilled spirits in America reached a peak of more than 5 gallons per capita annually (Rorabaugh 1979); by this time, whiskey made from corn accounted for most of that amount (Dabney 1974).

Private distillation, though illegal, continued even after roads were constructed through the mountain areas, partly because of tradition, partly because of remoteness (stills were easy to conceal), but mostly because it was increasingly profitable, as taxes on liquor continued to be raised. Thus, although illegal whiskey has been made as far afield as Alaska (where it was called "hooch" after the Hoochinoo, a tribe that made a distilled drink), 60 percent of all arrests for the offense have been made in the mountains of the South (Carr 1972).

Corn, however, was no longer always the primary ingredient in illicit distillation. Sugar was sometimes used to speed up fermentation, resulting in a kind of rum that was, nevertheless, still called whiskey. Sugar whiskey was notorious for the hangovers and headaches it produced. In addition, illegal whiskey was sometimes adulterated with everything from manure to lye (to speed fermentation). It was often distilled in soldered tanks that put lead salts into the liquid, and it was condensed in old automobile radiators. Clearly, illegal whiskey could be dangerous: It killed some people, blinded more, and helped destroy the brains, livers, and stomachs of many others (Dabney 1974).

Today, Kentucky is the center of whiskey production in the United States, although some is made in Tennessee and Virginia (Jackson 1988). Starchy varieties of corn are best for whiskey making. They are wet or dry milled, then fermented before distillation. The two major yeasting processes are sweet and sour mash. Sweet mash whiskey comes from new yeast, whereas yeast from a previous fermentation constitutes one-fourth of the yeast added to grain to produce sour mash whiskey. Sour mash is easier to make, and sweet mash tends to go bad (Grossman 1977). In the United States, a significant portion of the corn crop goes into brewing and distillation (Inglett and Munck 1980). Obviously, bourbon remains an American favorite. It is made from at least 51 percent corn mash distilled at 160 proof, diluted to 80 to 100 proof, and matured for no less than three years (Lichine 1981).

Canada, which produced its share of rum in the Maritime Provinces, turned to whiskey made from rye, now mostly called Canadian whiskey (Jackson 1988; Morrison and Moreira 1988). Straight whiskeys are the products of distillation with nothing added, whereas blended whiskeys are mixtures of whiskey from different distilleries or different years. These two kinds, straight and blended combined, make up about half of the American whiskey market. The remainder is "light" whiskey, which is less flavorful, always blended, and reduced in proof. Like Canadian whiskey, it is often made from rye.

Liqueurs. Liqueurs are grain or cane spirits that have been flavored, are usually sweet, and are normally enjoyed after dinner. Their origin lies in the early years of alcohol distillation, when sugar and flavorings were employed to mask the bad taste of raw alcohol, and until the sixteenth century or so, they were mostly regarded as medicines. Early in that century, however, this began to change. In 1532, Michael Savonarola, a Florentine physician, authored *The Art of Making Waters,* a book of recipes and instructions for producing liqueurs. By the following century, Italy had a flourishing liqueur industry (Austin 1985).

Many of the old liqueur recipes, with "secret" mixtures of flavorings, originated in monasteries. The most famous liqueurs made from such recipes are Chartreuse (from the Chartreuse monastery at Paris) and Benedictine (Grossman 1977). Perhaps the most notorious liqueur is no longer made. This was absinthe, flavored with hallucinogenic wormwood *(Artemisia absinthium)* that caused a variety of physical and mental symptoms, and even death (Conrad 1988). It was produced by Henri-Louis Pernod (Lanier 1995). France finally outlawed absinthe in 1915, and now it is illegal virtually everywhere (Lichine 1981). Liqueurs are flavored with ingredients as mundane as coffee (Kahlua, made in Mexico) and as exotic as the rare green oranges of the Caribbean (Curaçao, from the island of that name). Other famous coffee liqueurs are Tia Maria from Jamaica and Pasha from Turkey (Grossman 1977).

Distilled Spirits in the East

Spirits are not as popular in the East as in the West, despite remarkable historical exceptions, such as the hard-drinking Mongols, who have even been credited with the discovery of distillation. The lukewarm eastern attitude toward liquor has existed in part because of the popularity of tea, in part because opium, betel nut, and other stimulants have historically substituted for strong drink, and in part because of a widespread devotion to beer. Another reason may be that the livers of Asian peoples tend to be low in aldehyde dehydrogenase isozyme (ALDHI), which helps to metabolize alcohol. This condition can cause the face to flush with the ingestion of even very moderate amounts of alcohol – a telltale signal among many who live by Confucian rules of conduct that frown on intoxication. In nineteenth-century imperial China, when strong drink was served, a gentleman not wishing to offend his host might pay someone else to drink it for him (Chang 1977).

Nonetheless, several grain alcohols are produced in the East. In China, *mao tai* – a whiskey made from millet and wheat – is the best known, and has been known to the world since it was served to U.S. President Richard Nixon during his 1972 visit there (Simoons 1991). *San-shao,* meaning "three times burnt," is another Chinese liquor. It is made from sorghum and distilled three times, but is not to be confused with *shao-chiu,* which is distilled from grain ale (Simoons 1991). In Japan, the latter is called *shochu* and competes with local whiskey that is modeled on Scotch (Jackson 1988).

In Mongolia and Siberia, the drink best known from lore and literature is *kumyss* (or *kumiss*), an alcoholic beverage (fermented and sometimes distilled) made from mare's milk. In about the seventh century, the Mongols introduced it in China, where it was popular for a time. Later, however, it acquired a reputation as a drink of barbarians and was so regarded after the Mongols conquered China in the thirteenth century (Chang 1977). A high level of lactose intolerance among the Chinese may also help to explain the disdain for *kumyss,* as well as for other milk products. The distilled form of the drink is sometimes called *arak,* a common Asian name for all kinds of liquor (Lichine 1981).

In Southeast Asia, "toddy," a distilled palm wine made from fermented sap, appears in many varieties that may actually be thought of as brandies. Historically, toddies have been made in primitive stills, although a few are commercially produced (Lichine 1981). However, toddy, and other distilled beverages that exist in Oceania, are poorly documented. The latter have resulted from the distillation by Europeans of local alcoholic beverages; one example is the *okelahao* of Hawaii. This drink, made from *ti* roots fermented in the bilge of a canoe and distilled in a ship's cookpot, has yet to find a market outside the islands (Grossman 1977).

Distilled Spirits and Human Health

Chemically, any distilled beverage consists largely of ethyl alcohol. Other components include esters, fusel oils (isobutyl and amyl alcohols) and, of course, the ingredients added to flavor and color the beverage. Unflavored grain spirit is merely alcohol and water. It is the impurities and additives that largely contribute to hangovers (Dabney 1974). As mentioned, early distilled alcohol was used only as a medicine because distillers did not yet know how to separate the unpleasant beginning and end fractions of the distilled liquid from the middle, and because aging, which mellows the product, was unknown. The effect of the early medicinal wine brandies must have been strong indeed.

Nutritionally, distilled beverages are high in calories but contain little in the way of other nutrients. Because each gram of 86 proof alcohol imparts 7 calories, the average drink bristles with 106 calories, in addition to any calories in the mix (Robertson et al. 1986). Some researchers, however, contend that the calories in alcohol have, in the past, served as an important source of energy for the poor (Braudel 1973). One study suggests that in France during the 1780s, 10 percent of an individual's caloric intake was supplied by alcohol (Austin 1985). The same was probably the case for slaves in the Caribbean: Jamaican rum yields twice the calories of a similar measure of molasses. A counter-argument, of course, is that alcohol was allowed to replace more nutritional foods. John McCusker (1989) has noted that alcohol calories are more quickly absorbed than those from other sources; he credits the ability of early Americans to consume such large amounts of rum and whiskey to this propensity.

Yet, a large amount of any kind of alcohol can be nutritionally disastrous because it destroys vitamin C and the B-complex vitamins. Indeed, about the only remaining cases of frankly nutritional diseases (such as pellagra) found in the developed world are among alcoholics. In addition, although it appears that moderate alcohol consumption can help prevent heart disease, large amounts can help cause it. Alcohol is also suspected of being a factor in the etiology of some cancers and is known to be a culprit in causing much liver damage, including cirrhosis.

Another unfavorable aspect of distilled spirits is the social and physical harm they have historically brought to peoples unaccustomed to them (Mancall 1995). In America, Asia, Africa, and Australia, rum and whiskey became instrumental, in the hands first of European traders and then of European imperialists, in destroying aboriginal life (Miller 1985). It is significant that in Mexico and Peru, where some alcoholic beverages existed at the time of European contact, the aboriginal peoples and their traditions have fared much better than those in places like Australia, where alcohol had been unknown.

Clearly, distilled spirits have had a tremendous impact on human history and health. In a relatively few centuries, their manufacture has moved from the quasi-magical procedure of the alchemists to a global industry that undergirds the economies of entire regions. But from the "gin epidemic" of England to the endemic drunkenness of the Australian aborigines, spirits have also caused such misery that practically every society in the world has laws and customs to regulate their consumption, and many states have tried to outlaw them. That such attempts have been largely unsuccessful demonstrates the existence of a worldwide, collective opinion about the pleasures and profits provided by alcohol, which outweighs the harm it continues to cause.

III.6 ~ Kava

Kava is both a plant and a drink made from that plant for ritual occasions. Kava usage is limited mostly to the Pacific basin, where it occurs widely from New Guinea in the west to the Marquesas in the east, and from Hawaii in the north to the southern Cook Islands. Some societies have ceased using it in recent times, whereas others ceased but began again after missionary prohibitions lessened and national independence brought kava to the fore as a mark of national identity (Brunton 1989).

A narcotic effect is commonly thought to be the main reason for kava's consumption, but elaborate rituals have developed with kava as their centerpiece, together with complex rules about who can drink the substance and when. Powerful cultural elements that persisted into the 1990s led to the commercialization of the root; kava is now drunk by overseas island communities in Auckland, Sydney, Honolulu, and Los Angeles. Indeed it seems that kava has evolved as a major force in the maintenance of the identities of Pacific islanders at home and abroad.

"Kava" is the term for the whole plant, which according to Western botanical terminology, is *Piper methysticum,* placing it among the pepper families (Lebot, Merlin, and Lindstrom 1992). But "kava" may also refer to the beverage made from the roots or stem of the plant. Moreover, the term can mean a ritual in which the crushing of the root to make the beverage is a noteworthy activity.

Kava is a reconstructed Proto-Oceanic term within the large Austronesian language family (Biggs, Walsh, and Waqa 1972: 30). It, or a similar word, such as *'ava,* is still widely used throughout the eastern Pacific to refer to the same root. In Pohnpei in Micronesia, the word is *sakau,* a close cognate. In Fiji, kava is referred to as *yaqona,* a term that probably reflects its bitter taste, *qona/kona.* Throughout Vanuatu, which has some 170 vernacular languages and dialects, the terms for kava are quite varied (see Lebot and Cabalion 1988: 54–67 for a list). In northern Vanuatu, kava is known as *maloku,* meaning quiet, subdued (Crowley 1990), while *nikawa,* a close cognate, appears only in Tanna in southern Vanuatu. The local term for kava in Papua New Guinea is also quite varied (see Lebot and Cabalion 1988; Brunton 1989).

Origin and Spread

The origin of the kava plant and the relationships among the many different cultivars found today have both been subjects of detailed study by botanists (Lebot, Aradhya, and Manshardt 1991). Using material collected from throughout the Pacific, they have traced genetic links among the various samples, concentrating particularly on diversity in the Melanesian area.

Vincent Lebot and P. Cabalion (1988) have produced an inventory of the names of local cultivars around the Pacific. From chromosome counts they distinguish the genus *Piper wichmannii* from that of *Piper methysticum. P. wichmannii,* the wild form, has been located only in Melanesia, that is, in parts of New Guinea, the Solomon islands, and northern Vanuatu. In contrast, *P. methysticum,* the cultivated form, has been found throughout the high islands of Polynesia and on the high islands of Pohnpei and Kosrae in eastern Micronesia, and in Melanesia. *P. wichmannii* has been found to have higher isozyme variability than *P. methysticum,* but the two overlap for zymotype 9, leading the authors to suggest that there is no taxonomic distinction between the two plants.

Lebot and Cabalion, along with Vincent Lebot et al. (1991: 181), suggest that what was being selected for was the kavalactones, which have a physiological effect when the product is drunk. They indicate that *P. methysticum* was "domesticated through vegetative propagation from a narrow genetic base in wild fertile progenitor . . . becoming sterile through mutations affecting fertility. . . . Because *P. methysticum* must be cultivated, this plant has resulted from human selection of somatic mutants. . . . That selection process has resulted in variability in both morphological characteristics and the kavalactones" (Lebot et al. 1991: 181). The root of *P. wichmannii,* which according to Vanuatu oral tradition was made into a drink, was too powerful in its effect and induced nausea (Weightman 1989: 236). This may be a reason that *P. methysticum* was developed instead.

Identification of these two closely related species leads botanists and a historical linguist to suggest that northern Vanuatu is the center of origin of kava cultivars, which have been domesticated probably in the last 2,500 to 3,000 years. From Vanuatu, varieties of kava were introduced to Papua New Guinea, eastern Micronesia, and Polynesia. This mainly west-east spread was followed by an east-west spread, from Tonga and Samoa to East Futuna, from which some Futunan speakers sailed westward to settle an island off south Vanuatu that they named West Futuna. From there it spread to the other Polynesian outliers and the islands in southern Vanuatu (Crowley 1990). According to Lebot et al. (1991: 184): "Kava is a relatively late introduction into Polynesia, since there is no variation in isozymes in that region." Further details of the genetic history of kava are given in Lebot, Merlin, and Lindstrom (1992).

Botanical Description

The kava plant is a perennial shrub that reaches one or two meters in height. It has many stems and bears a light foliage of heart-shaped leaves. The stems are notable for being distinctly segmented by a dark band, similar to bamboo.

The plant is dioecious; that is, it bears male and female flowers on separate plants. To propagate kava, a stem bud is taken from a *P. methysticum* male plant, and from this a root system and shoots develop. Vegetative reproduction, thus, allows a high degree of selectivity in which plants are selected for propagation. The importance of the plant as a ritual drink has led to considerable human intervention in its evolution with resulting diversification.

Kava is cultivated along with other root crops, such as taro and yams, in household gardens and on shifting agriculture plantations. Preferred locations vary: In Futuna in the 1960s, the plants were cultivated high on the mountainside because large ants attacked them nearer the coast (Gaillot 1962); today, however, kava is cultivated in the plantation area behind the houses of coastal areas (Pollock 1995a).

To harvest the root in Vanuatu, the plant is dug out after three to four years of growth when the rootstock and mass of fibrous roots may weigh 5 to 10 kilos. In Futuna and Tonga, the root with its stem still attached but leaves removed may be offered as a tribute at an important occasion, such as the induction of a chief. For example, in Tonga for the induction ceremony of the crown prince, some 300 stems and roots of kava were cultivated and donated by the families living on lands belonging to the Tongan royal family. In Samoa the roots may be dried before they are presented at a kava ceremony; each honored guest is presented with his (or her) stem of kava, so that some stems may change hands several times before they are finally pounded to make a kava drink.

Distribution

We surmise that many changes over time have affected the distribution of the plant, as well as the beverage and the ritual. Thus, in precontact times, all three are likely to have been different than those of today.

There is no reported evidence of the kava plant on New Caledonia, Easter Island, Belau, Yap, and parts of Papua New Guinea, nor on the atolls. In the case of the atolls, the soils are too poor and there is too much exposure to salt spray. In New Zealand it is likely that the climate has been too cold for the plant to grow.

Kava, as a drink, also shows no clear patterning. Records of its employment as a beverage come from those places that grew kava, which makes sense because the plant has to be vegetatively propagated and, consequently, was grown for a reason. But in places such as Tikopia, the plant continues to grow even though its usage has disappeared.

In those societies which do employ the plant ritually, a number of variations have developed over time and space. In some societies, these ritual occasions are still very formal, as in Futuna, Samoa, and Tonga, while in others a more secular consumption of kava has become popular, as in Pohnpei and Vanuatu. In Fiji, Tonga, Futuna, Pohnpei, and Vanuatu, both ritual and secular uses are practiced today.

According to missionary accounts, the nineteenth century saw the customary utilization of kava disappear in Tahiti, the Cook Islands, Hawaii, and Kosrae. This also happened in southern Vanuatu in the 1920s, but there kava drinking was revived after independence in 1979 (Brunton 1989). By contrast, on Wallis, widespread kava ceremonies declined after World War II and today are held only for very special occasions. Still another variation is found on the neighboring islands of Tikopia and Anuta, where in the 1930s kava was prepared as a drink. But the people did not drink it; rather, the ritual libation was poured to the gods (Firth 1970; Feinberg 1981).

Difference may also be found in the ways the root is prepared for drinking. In some societies it has been chewed (mainly by young women), while in others it is pounded or grated. Missionaries exerted a strong influence to discourage chewing kava because they considered it to be unhygienic and a way of spreading disease. In Vanuatu, young men have taken over the role of preparing the root, but in western Polynesia it still belongs to women, particularly on very important occasions.

Some societies process the root when it is green, whereas others prefer a beverage made from the dry root. In Fiji, at a highly formal welcoming ceremony, a whole fresh green plant is presented to the chief guest. If the fresh green plant is unobtainable, then an appropriate amount of dried, or even powdered, root is presented (Ravuvu 1987: 25).

The patchy nature of kava use has intrigued anthropologists, botanists, and others for a century or more. Edwin Burrows, for example, in his comparison of cultural features of western Polynesian societies (which he saw as distinct from Melanesian and other Polynesian societies), noted that "the western Polynesian kava complex appears as a local elaboration on a widespread Oceanic base. The occurrence of the whole complex in parts of Fiji is probably due to diffusion from western Polynesia. . . . Distinct resemblances to western Polynesian kava customs elsewhere in Melanesia and Micronesia are also probably due to diffusion from western Polynesia" (Burrows 1939: 114–15). In western Polynesia he included Samoa, Tonga, 'Uvea/Wallis, and Futuna along with Fiji.

W. H. Rivers (1914) had earlier attempted to account for this scattered distribution by distinguishing "kava people" from "betel people," suggesting that exploitation of the two forms of the *Piper* plant were mutually exclusive. Betel is a combination of two plant substances, the *Areca catechu* nut and the *Piper betle* leaf, in which the nut is wrapped so that it can be chewed. The leaf contains the narcotic substances.

Ron Brunton (1989), in his society-by-society reexamination of Rivers's thesis, however, indicates that the distribution is not quite so mutually exclusive. His review of the linguistic and archeological evidence suggests to him that the Bismarck Archipelago is the "homeland" of kava, where it was part of an early social complex known as Lapita culture. From there it was traded along a coastal route to southern New Guinea and, later, to Fiji and Polynesia. He hypothesizes that kava moved with the eastward spread of Lapita culture some 3,000 years ago (Brunton 1989: 82). Such a spread was not unidirectional, and kava usage later diffused back westward from Samoa and Tonga. It, thus, reached southern Vanuatu, and Tanna in particular, he argues, several hundred years after it had become a part of the culture of northern Vanuatu. The most likely agents of transmission were the Polynesians of Aniwa and West Futuna, two islands just off the coast of southern Vanuatu (inhabited by Polynesian speakers), who brought kava customs developed in eastern Oceania back to Melanesia (Brunton 1989: 83).

Brunton also considers it likely that kava was once drunk by many peoples in Melanesia who subsequently abandoned it for unknown reasons. Similarly, he argues that betel, too, may have dropped out of use in some societies that may have subsequently exploited kava. Thus, he considers the belief that kava and betel are mutually exclusive to be largely mistaken. Both have been in and out of use over time in various parts of the Pacific (Brunton 1989: 85).

It can be concluded, therefore, that not every island society has employed kava, that the plant does not occur everywhere, and that the ways in which it was employed also differ from place to place. Such fluctuations in occurrence of the plant and the customs associated with it are likely to have marked its long history. This may be because a particular society chose to drop such customs, or was forced to do so after cyclone damage rendered the plant unavailable, as happened in Futuna in 1986 (Pollock field notes 1987). Yet at a later time, the plant could have been reintroduced from a neighboring island along with new ways of employing it. Consequently, today we can see a range of kava usage from very ritual occasions to more secular ones, which may reflect differences in its social importance.

Ritual Uses

Kava rituals have become differentiated in both practice and ideology as societies have dispersed over time and developed their own distinctive cultural characteristics. The rituals took two broad forms: those in which the kava was prepared and drunk, usually in a kava circle, and those in which the whole root was presented to an honored person. But in either case, the root symbolizes the ties between ancestors and present-day peoples, represented by their chiefs and nobles; it, thus, symbolizes both past and present.

The most formal rituals at which kava is drunk begin with the appropriate people seated in an inner circle, with the community assembled around its outer edge. The processing of root to make the beverage is under the direction of the chief officiator for kava ceremonies. The ritual ends when the chief dignitary signals that the circle should break up – often when he himself has moved out of the circle.

Kava rituals take place outdoors as well as in specially designated houses. In Futuna, a house known as *tauasu* is specially set aside for men's nightly kava sessions. For large formal kava ceremonies, at which many communities are present, an outdoor venue is obviously necessary. In Vanuatu, the kava-drinking grounds are outdoor sites, usually under banyan trees.

Processing

The processing of kava, which transforms the whole root into a mass of fibers and pulp, is also highly ritualized. It consists of three steps: pulverizing the root, adding water to the pulp, and serving the liquid. The main person making kava in western Polynesia is usually a young woman, who is aided by several young men.

Processing begins once everyone is seated and the necessary pieces of equipment are in place, including the wooden kava bowl, whole roots, water, the fiber strainer, and serving cups. The kava root, whether green or dried, is cut into small pieces and chewed, pounded, or grated, according to local custom. In the past, chewing the root was the most widespread practice; this task was assigned to several young girls or young men, chosen for their perfect teeth. They washed out their mouths before commencing to chew until all the pulp was macerated, leaving a fibrous ball that each girl took from her mouth and placed in the kava bowl.

The mode of reducing the kava root to pulp has changed over time. As already mentioned missionaries discouraged chewing the root on the grounds that the practice spread disease. Alternative methods call for pounding the root, grinding it between two stones, or grating it. Upon the command of the chief of the kava ceremonies, water is added to the balls of pulp and fiber in the wooden kava bowl. The chief calls out the order as to when the kava should be mixed, how much water is to be added, and when the mixture should be strained. Adding the water is the most significant part of this ceremonial preparation. According to Futunans, it transforms one substance, the root, into another, the beverage. The root, thus, becomes the medium for communication with the gods, a means of both honoring and supplicating them.

The third stage begins once the mixture is ready to be served. Cups are carried to individual participants in the kava circle by young men designated for the task. The chief officiator calls the name of the person to be served. In Samoa these names are exclusively for use in the kava ceremony (known as kava cup names) and are not used in other situations (Williamson 1939).

Upon receipt of the cup, the recipient claps and pours out a small libation to the gods before drinking the remaining liquid in one gulp. In Samoa the first cup, designated for a particular god, used to be poured out by the chief officiator before others were served. The Tikopian practice of pouring out the carefully prepared liquid (Firth 1970) was thus in line with the general ritual procedures, but represented an alternative kind of development in that no living person drank the kava.

Clearly, such rites performed in front of the assembled community are very formalized. All movements and gestures have become stylized, especially in western Polynesia, where those eligible to perform the tasks undergo elaborate training.

Kava Drinking Circle

The seating order at each ceremonial event in western Polynesian societies is established by the kava officiator, who uses his knowledge of the relative status of the participants. The individual with the highest status sits in the center of the arc, with others seated to his left and right according to their relative status. In western Polynesian systems, a *matapule,* or talking chief, sits next to his chief. The circle may consist of between 15 and 40 persons.

The serving of the kava cups according to the order called by the chief officiator, thus, serves to reiterate the community hierarchy in a very visual and visible manner. The status of particular titles relative to one another and the incumbents holding those titles are displayed for community knowledge and affirmation.

Degrees of Formality

The most formal kava circles occur for the investiture of a new supreme chief. Such a ceremony was performed in Tonga in 1976 for the investiture of the crown prince of Tonga, an event that coincided with the Tonga Constitutional Centenary celebrations.

In Futuna and the neighboring island of Rotuma, a number of lesser rituals involving the kava plant were practiced, and some still are. A morning cup of kava was drunk together by chiefs of friendly hamlets to propitiate the spirits for the right outcome of the day's events (Rozier 1963). On 'Uvea/Wallis, by contrast, the range of kava occasions has been reduced to the very formal one for the installation of a new Lavelua (chief) and to some others associated with the Catholic Church's annual first communion celebration.

Although their island is nominally part of western Polynesia, Niueans have had a cultural ideology that differs from that of their neighbors. Edwin Loeb (1926) reported that only the priest was allowed to drink a potion to the gods, doubtless because the island's poor soils make it difficult to grow kava. Hence, its use was limited to priests.

Pohnpei, though in Micronesia, has shared much of the formality of western Polynesian societies, where kava (known as *sakau*) was used to support an elaborate chiefly system. Today, major events that draw the districts together are still marked by a kava ceremony, but much is also drunk informally (Peterson 1995).

In Vanuatu, only the island of Tanna has maintained the ritual use of kava. There, the emphasis is less on the hierarchy of the circle; the focal part of the ritual is when each man spits out the last mouthful of his cup by way of sending messages to the ancestors (Brunton 1989; Lindstrom 1987).

In other parts of Vanuatu, kava is drunk but with considerably less ceremony. The heaviest users have been the healers or controllers of magic, who are said to use the drink to improve their communication with the gods (Young 1995).

In those parts of Polynesia where kava rituals are no longer practiced, we can still glean a notion of their formality from the written accounts by Europeans. In Tahiti, kava was used only by chiefs, but not as part of any religious ritual (Oliver 1987). Similarly, the chiefs in the Marquesas were reported to follow the steps in ritual processing, but no elaborate ceremonials were practiced (Dening 1980). In the Cook Islands, reports indicate only that a bowl of kava was made at an installation ceremony (Gill 1876), but we have no further detail.

In Hawaii, the practice of drinking *'awa* died out in the mid-nineteenth century. It was drunk mainly by the *ali'i* or chiefs, though it was not forbidden to commoners. As E. S. C. Handy summarized the practices: "'Awa's ceremonial uses were simply the expression of the belief that gods like the same good things of life that men did" (1972: 191).

In earlier times, kava usage was also highly ritualized on Tikopia, a small island north of Vanuatu with a Polynesian culture, though geographically among Melanesian peoples. But it differed markedly from western Polynesian practices in one small but important detail. As Raymond Firth (1970: 203) noted, "it was poured out, not drunk." Otherwise its preparation and presentation followed the practices of other Polynesian societies. According to Firth: "the whole ideology of kava concentrated upon its religious significance in ritual. There were no social kava-drinking ceremonies, nor any consumption of kava as a beverage apart from [a very few] casual instances. In such a religious context the material properties of the kava were of less importance than its signalization function" (1970: 204).

Thus, ritual uses of kava across the Pacific vary considerably. Kava drinking almost everywhere has been predominantly the prerogative of chiefs and priests. Where other men are allowed to participate, it linked the more highly ranked senior men with the more lowly ranked. The main function of kava in these rituals is to communicate with the ancestral spirits, thus imbuing kava with an important mediating role. The whole ritual has a social rather than an individual character; it is a group experience.

Exchanges of the Root

Presentations of the kava root to a chief or an honored guest were ritually made to ask for a favor, or to atone for a wrong, or to ask a priest to propitiate the gods for a special service, such as stopping destructive winds (Rozier 1963). Moreover, at ceremonial functions where it was not appropriate to make a kava drink, whole roots might be presented to a visiting dignitary. Such a procedure still occurs in New Zealand within the Samoan community; a visiting dignitary from Samoa or elsewhere is presented with a root as a token of respect.

In Tanna, Vanuatu, kava was at the center of a network of exchanges that linked villages through "paths" or "roads" that connected the various kava-drinking grounds. Social relationships were developed and maintained along these roads, over which knowledge, information, and goodwill also passed (Brunton 1989; Lebot, Merlin, and Lindstrom 1992).

The kava root is also given in exchange for medicine or as a gift between friends. Such exchanges are noteworthy because they demonstrate that the root itself can be more important than the narcotic properties it bears when made into a drink. In other words, it is not necessary for the root to be processed for it to have honorific meaning (Brunton 1989; Lebot, Merlin, and Lindstrom 1992).

Secular Usage

Kava has also been employed informally in Fiji, Futuna, Pohnpei, Tonga, and parts of Vanuatu where ritual preparations were minimized and there were fewer restrictions as to who could drink. Kava was drunk communally at designated meeting places, and kava sessions, lasting all night, were held several times a week. These sessions, although less ritually structured, nevertheless emphasized the symbolic nature of kava drinking and communication with the ancestors.

In Futuna, each village had (and has) its *tauasu* house for the men. In Tonga, the men may meet in the house of a prominent person. In Vanuatu, kava-drinking grounds were the nightly meeting places in villages, whereas kava clubs are the meeting place in towns. At these nightly sessions in Tonga or Futuna, the root is chewed or crushed by a young man or young woman, who is seated at the kava bowl in order to maintain the supply of the beverage by replenishing the cups of the drinkers and crushing more of the root as needed. The drinkers, all male, sit on mats in an oval around the edge of the house with the kava maker at one end. Such sessions can last until three or four in the morning, but some men quietly drift away as they become sleepy. There is a light buzz of conversation, and the occasional clap as a drinker receives his new cup (Pollock field notes, Tonga 1976).

Such occasions are mainly social, with conversation ranging around political issues and local affairs. In Tonga, Futuna, and Fiji, these sessions enable men to relax in the company of other men of the village and share information. Indeed, a young man is expected to attend if he wants to be viewed as interested in village affairs, and thus a candidate for a leadership position (Sepeliano 1974).

By the 1980s, kava drinking in Vanuatu was also a nightly occasion, though customs varied throughout the islands. The village gathering place, often under a banyan tree, gave way to a kava bar where women and young men also drink. The kava is drunk in one gulp, after which one is expected to spit loudly. Such bars have become very lucrative for their owners.

In Vanuatu certain varieties of the plant have been designated for everyday use, whereas other varieties are drunk only by persons of high rank, and still others are used as traditional medicine. Depending on the varieties available, together with the way they are prepared, kava can precipitate drunkenness, but a bleary-eyed, staggering, and comatose sort, "never hilarious or pugnacious" (Gunn quoted in Weightman 1989: 239). In fact, with the custom of modern kava drinking in Vanuatu, there has arisen a whole range of slang phrases, such as *fowil antap,* "four wheel on top," to describe just one form of drunkenness.

Narcotic Properties

Kava has been labeled a narcotic containing certain pharmacologically active substances long recognized by Western chemists, pharmacists, and others. Certainly missionaries and other outsiders judged drug properties to be the reason for kava usage and took steps to ban its cultivation, processing, and use as a beverage. The main objection seems not to have been to drunkenness but to the soporific effects it produced, which prevented many men from doing a full day's work after a night of drinking kava. Recent ethnographic accounts from Vanuatu have stressed the druglike or narcotic properties of kava (Lindstrom 1987; Lebot and Cabalion 1988; Brunton 1989).

The main chemically active constituents identified by chemists are kawain and the kava lactones. However, despite many years of investigations, mainly in German laboratories (see Lebot and Cabalion 1988) but also in Sydney (Duffield and Jamieson 1991), the precise physiological action of these substances on the human neurological and chemical system is not fully understood.

Kawain is said to be an emotional and muscular relaxant that stabilizes the feelings and stimulates the ability to think and act. It has bactericidal properties and can be used as an antimycotic. It is also a diuretic. Fresh kava has a local anesthetic effect on the chewer's mouth. But its main effect is as a muscle relaxant (Lebot and Cabalion 1988: 35).

The chemical properties of kava and other local plants have long been of interest to visitors to the Pacific. Gilbert Cuzent, a naval pharmacist based in Tahiti from 1858 to 1860, claimed to be the first to identify (in 1858) a substance he called "Kavahine" as a result of experiments carried out on various parts of the kava plant. This claim led to a scientific argument with another French pharmacist, who had also published his analysis of the kava root in April 1857 in the newspaper *Le Messager de Tahiti* and, in 1858, in the *Revue Coloniale.* However, the French Academy of Sciences recognized Cuzent's claim (Cuzent 1860: 189–90).

The major physiological effects are quiescent and numbing, in contrast to the enervating effects of alcohol. The kava drinker may feel a slight numbness around the mouth, but the strongest effect is on the legs; anyone who sits drinking kava for a long period of time finds it hard to stand or walk. There is no loss of consciousness, though the kava drinker may fall asleep after seven or eight cups and be hard to awaken. Some Vanuatu cultivars are more potent than others and so are more favored by drinkers for the quick effect they produce (Crowley 1990).

Kava is also said to lead to loss of appetite and to reduced libido, but such effects are reversible if the person stops drinking it for several weeks (Spencer 1941). Redness around the eyes is also a mark of a heavy drinker, as is a scaly skin.

In his studies of the plant's usage in the eastern Pacific, Edwin Lemert (1967) noted how kava produced a nonaggressive, anaphrodisiac, mildly tranquil and dreamy state. He suggested that it depressed bodily functions such as heart and respiration rates and temperature. He labeled kava drinking "a form of retreatist or avoidance behavior, related to onerous claims which Polynesian social organization periodically makes on individuals" (Lemert 1967: 337). Many authors have noted that the quiescent and soothing effects of kava place it in direct contrast to alcohol. For this reason, kava has been introduced as a counter to heavy alcohol drinking, whether in Vanuatu or among Australian Aborigines (D'Abbs 1995).

It is true that modern writers tend to think that those who drink enough kava become drunk, yet a number of other writers over the past century and a half have either not mentioned any drunkenness, or have said that kava does not lead to such a state and that drinkers only become sleepy and quiescent.

Kava and Alcohol

The relationship between kava and alcohol is one of contrast rather than one of similarity. As W. T. Wawn wrote in 1870: "Kava has a very different effect from alcohol. It is soothing, and a pint of strong kava, or even half that quantity for a beginner, will apparently have no more effect than to make a man desirous of being left alone and allowed to sit quietly and smoke his pipe. . . . Alcohol excites, kava soothes and then stupefies" (quoted in Weightman 1989: 237–8). Other authors have made similar observations. Thus, alcohol and kava satisfy different needs (Lemert 1967: 337).

One major difference between the two substances is that kava is a very social drink (it is almost unheard of for someone to pound a batch of kava for personal drinking), drunk in association with others in ritual settings or in the modern-day kava clubs, where a group of people share a bucketful (or one "brew") of kava.

Nonetheless, as a result of institutionalized drug-classification principles in the West, kava and alcohol have been placed alongside one another. Kava has been a banned substance in the United States since 1958, though there has been a campaign to lift that ban (Lebot and Cabalion 1988: 91). It is also considered a harmful substance in New Zealand, Australia, and Fiji.

Commercial Developments

Kava has been a cash crop for more than 100 years. Since the second half of the nineteenth century, several South Pacific countries have been exporting the dried root to Germany and France for pharmaceutical uses. In the 1880s, a trading house in Wallis sent 30,000 pounds in 18 months at a price of 30 to 35 cents a pound to meet a growing demand in Europe, where it was employed both as a diuretic and for its calming effects (Deschamps 1883).

Today, markets for kava in Germany and France still exist, and processing laboratories import the equivalent of some 200 tons of fresh root from Fiji and Tonga. A study of such demand showed a recognition of the therapeutic properties in kava for antiseptics, expectorants, diuretics, and urogenital stimulants. One product with the brand name Kaviase had been on the market for about 20 years, and in Germany an attempt was made to launch a kava-based soft drink (Weightman 1989: 241).

Certainly, kava has become an important alternative cash crop for several Pacific island societies, and for farmers in parts of Fiji and Vanuatu, it is now their most important cash earner. The crop is widely sold by the bundle of dried roots in the markets throughout Fiji. Purchasers are mainly urban Fijians who have no access to *yaqona* from their own lands. Similarly, in Vanuatu, kava already yields a higher net income per hectare to the farmer than cocoa and coffee (Lebot and Cabalion 1988: 92). It thus provides a form of economic buffer against downturns in tourism due to oil prices and political instability.

Conclusions

The evolution of kava usage over millennia has been marked by a waxing and waning of its popularity, as well as by changes in the plant and its mode of processing. During this time it has been eliminated from some islands by cyclones, salt water inundations, and even warfare when the plants were pulled out by the retreating forces (Gill 1876).

Yet vegetative reproductive properties have enabled varieties to be selected that could be processed into an ever more pleasant beverage, and the range of cultivars has increased markedly in island societies, such as those of Vanuatu where it is of great cultural importance.

The geographical range of kava, however, is more narrow today than it was a hundred years ago. Missionaries sought to eliminate it because it reduced productive work efforts, and other Westerners have included it under the negative rubric of a drug, although there is no medical evidence for long-term harmful effects.

The employment of kava in recent times has been marked by a considerable increase in its secular, as opposed to its ritual, use. In Fiji, Futuna, Pohnpei, Tonga, and Samoa, the Catholic, Methodist, and Congregational churches have taken a less rigid stance against kava drinking, so the rituals have continued and broadened in scope to include welcoming ceremonies for Western visitors and such church activities as first communion. The kava parties now are open to men of all ages and status in the community, although women do not often participate.

Yet the overall development of kava throughout the Pacific during some 3,000 years has been one of ritual usage. Those societies that have maintained kava drinking to present times have done so because it is an important medium in their cultural system. It is steeped in a strong body of local ideology that places the root as central to a communication process, linking the ancestral spirits to the incumbent chiefs and priests, and, thus, the whole living community to those associated with its past.

III.7 Khat

Khat (*Catha edulis* Forsk., Celastracae) is a flowering evergreen tree that grows in parts of eastern Africa and the southwestern highlands of Arabia. Its young leaves and tender stem tips, also called khat, are stimulating and produce a mild euphoria when chewed and their juices ingested. Khat has various psychostimulant alkaloids, of which the main one, cathinone, is amphetamine related and highly unstable. Khat leaves and shoots contain various alkaloids, of which cathinone and cathine are the primary and secondary active ingredients in stimulating the central nervous system. As with other psychoactive plants, the effects of the active constituents differ from one specimen to another according to the cultivar's size, age, health, and the site conditions of growth, such as exposure, soil, soil moisture, and drainage.

Most of the world's khat is grown in Yemen, Ethiopia, and Kenya, where its use is long established. Khat is a major import of Somalia and Djibouti, and demand in both countries far exceeds domestic production. During the past half-century, the number of users has increased substantially, and emigrants from the khat-chewing countries have introduced (on a small scale) the use of the drug to some countries in Europe and North America.

International trade in khat is a multimillion-dollar business in the Horn of Africa and southwestern Arabia. Daily consumption of the drug is estimated to be about 5 million portions of khat (Kalix 1994: 69), or about 500,000 kilograms of the leaf material chewed. The various estimates of the total number of regular users range from 3 to 6 million. Methcathinone, a synthetic, white, chunky powder, known in the United States by the street name "cat," is a substance very dissimilar from khat.

Orthography

"Khat" (pronounced "cot") is an inexact transliteration of the Arabic name of the plant, and is also spelled "qat," "kat," "gat," and "ghat." Philologists consider that the spellings "qāt" or "ḳat" (with diacritical marks) most closely approximate the transliteration of the Arabic in Roman characters.

The Khat Plant

Botanical Description

There are two known species of the genus *Catha: Catha edulis* and *Catha spinosa.* Both were first described by Peter Forsskal in 1775. Only *C. edulis* is cultivated, and in eastern Africa and the southwestern Arabian peninsula it grows at higher, wetter elevations than *C. spinosa,* which occurs wild in northern Yemen.

Khat is a straight, slender tree with a thin bark that varies in color from light gray to dark brown. The trees bear persistent, leathery leaves that are elliptical with finely toothed edges. The leaves are approximately 50 to 100 millimeters (mm) long and 20 to 50 mm broad (Revri 1983: 37). Young leaves are shiny and vary in color from pale green to red, becoming green or yellowish green at full growth. The flowers are small (diameter 4 to 5 mm) and either white or greenish in color. Freshly cut twigs that carry tender new leaves and buds near the end of the branch are most highly appreciated for chewing.

The height of mature trees under cultivation ranges from about 2 to 10 meters (Brooke 1960: 52; Kennedy 1987: 177). The leaves grow rapidly if the plant is well watered, and if heavy harvesting continues throughout the year, the trees retain the form of bushes (Tutwiler and Caprisco 1981: 53). Under very favorable conditions in eastern and eastcentral Africa, wild *C. edulis* grows to a height of about 25 meters (Greenway 1947: 98).

Khat requires a yearly minimum of approximately 400 mm of water from rainfall or irrigation and an average temperature not less than 17 degrees Celsius. Growth is retarded by successive night frosts at high elevations and by rainfall in excess of 800 mm if the soil is not freely drained (Revri 1983: 18–19). Healthy trees may yield for at least 50 years.

C. edulis has been cultivated in greenhouses at various botanical gardens and has been grown in the open for scientific purposes in Egypt, Sri Lanka, Bombay, Algeria, Portugal, southern France, Florida, and southern California.

Cultivation

Khat is reproduced vegetatively from shoots (suckers or sprouts) cut from the basal root or the trunk of the tree. These provide more rapid growth than cuttings from branches. Three or four shoots, 25 to 50 centimeters (cm) long, are planted together in rows of shallow holes at 1 to 2 meter intervals (Revri 1983: 62). Harvesting of leaves usually begins 3 to 4 years after planting. (Brooke 1960: 53; Morghem and Rufat 1983: 215–16).

Kinds of Khat

The total number of the kinds of khat consumed throughout the world, if known, would well exceed 100. There are at least 7 kinds marketed at Dire Dawa, Ethiopia, and more than 40 kinds are recognized in Yemen on the basis of geographical origin (Krikorian 1984: 160). Consumer differentiation among the various kinds is based on the potency of psychostimulation, flavor, and the tenderness of the leaves. These characteristics differ according to growing conditions, husbandry, and farm practice, such as irrigation or lack of it, soil types, and other ecological variables. According to Bob Hill (1965: 16): "It is said that the palates of some chewers are so sensitive that they can distinguish not only in what area the products originate, but the individual field as well."

The health of the plant is also a marketing factor. *C. edulis* is subject to attack by a wide range of insect pests, and a kind of khat called *kuda,* when damaged by a leafhopper (*Empoasca* spp.), is considered to be the best quality in the Alamaya district of Harer. A toxin contained in the saliva that the insect injects into leaf tissue during feeding produces a milky taste that is preferred by connoisseurs of this expensive kind of khat (Hill 1965: 21).

Khat is sold at the retail level in leafy bundles (*rubtah* in Arabic), each bundle wrapped in banana leaves or plastic to preserve freshness. A rubtah contains the minimum quantity of leaves and stem tips that most consumers chew in one day (Weir 1985: 89; Kennedy 1987: 80).

Historical Overview

Uncertain Origin of Domesticated Khat

Neither khat's place of origin nor the manner in which it was diffused has been determined, although most experts accept the view that *C. edulis* was probably first domesticated in the Ethiopian highlands. Based upon his field studies in Ethiopia, Eritrea, and Somalia in 1927, botanist and plant geneticist N. I. Vavilov (1951: 37–8) designated Ethiopia as the center of origin of cultivated khat. According to anthropologist George P. Murdock, khat and coffee are two of some eleven important agricultural plants originally domesticated by the Agau, Cushitic speakers of the central highlands of Ethiopia and "one of the most culturally creative people on the entire continent" (1959: 182–3).

Revri was among the minority of khat specialists who challenged the belief of an Ethiopian genesis of the plant. In his view, Yemen is probably the primary center of origin of khat and Ethiopia the secondary center. On the basis of cytogenetic evidence, Revri concluded that *C. edulis* appears to have evolved from *C. spinosa,* found wild in the Serat Mountains of Yemen. He suggested that *C. edulis,* known to the Arabs as a medicinal plant, may have been taken to Ethiopia in the sixth century A.D. and that it was returned to Yemen as a social stimulant in the fourteenth century (Revri 1983: 4).

Historical Highlights

According to Armin Schopen (1978: 45) and others, the earliest reference to khat is found in *Kitab al-Saidana fi al-Tibb,* a work on pharmacy and materia medica written in A.D. 1065 by the scholar Abu al-Biruni (Abu r-Raihan Muhammad al-Biruni) in collaboration with a physician. The work described khat as "a commodity from Turkestan. It is sour to taste and slenderly made in the manner of *batan-alu.* But qat is reddish with a slight blackish tinge. It is believed that batan alu is red, coolant, relieves biliousness, and is a refrigerant for the stomach and the liver."

Batan-alu is presumably an extract of khat prepared like preserves of fruits and vegetables (Schopen 1978: 45; Krikorian 1984: 136). The fact that al-Biruni, who lived in Ghazni, Afghanistan, identified "Turkestan" (the name loosely applied to the large area of central Asia between Mongolia on the east and the Caspian Sea on the west) as the origin of *batan-alu* is interesting because this and other references to either wild or cultivated *C. edulis* in the region are uncorroborated. It is plausible that khat used in the preparation of *batan alu* were dried leaves grown in Ethiopia and brought to central Asia as one of the myriad trade articles carried along the great caravan routes of the Old World.

The earliest work in which khat was identified as a plant is a book of medicinal remedies written in A.D. 1222 by Nagib ad-Din as-Samarkandi. The author, who resided in the ancient city of Samarkand, a major center of trade in Turkestan during the Middle Ages, recommended khat for its healing properties.

The earliest reliable reference to the general practice of khat consumption is in a chronicle of the wars between the Muslim and Christian states of Ethiopia during the early fourteenth century. The chronicler, a Christian, mentioned that khat was popular and widely consumed among the Muslim population (but shunned by Christians). He also wrote that a Muslim sovereign, Sabr ad-Din, boasted of what he would do when he conquered the Christian realm of King Amda Syon: "'I will take up my residence at Mar'adi, the capital of his kingdom, and I will plant chat there,' because the Muslims love this plant" (Trimingham 1952: 228).

According to John G. Kennedy (1987: 60-78), the popular use of khat in Yemen probably began in the southern part of the western highlands near Ta'izz during the fourteenth or fifteenth century. Customary use of the plant spread slowly northward, and by the end of the eighteenth century, khat was regularly sold in San'a. During the nineteenth century, use of the drug was widespread in the country, and Yemenis began to export khat overland to Aden (the annual trade grew from 1,000 camel loads in 1887 to 2,000 in 1900). Greenway (1947: 99) mentioned that the use of the leaves of *C. edulis* was well known to Ethiopians, Somalis, and Arabs at the time of World War I and that the knowledge of such use was spread to other African tribes through their encounters with the khat-chewing custom during war service in Ethiopia and Kenya.

The earliest concise account of khat in European literature was that of the Swedish physician and botanist Peter Forsskal (1736-63), who was a member of a Danish expedition led by the German geographer Karsten Niebuhr that visited Yemen in 1763. Khat, given the name *Catha edulis,* was among the plants collected in Yemen. Niebuhr, the only survivor of the five members of the expedition, published Forsskal's botanical papers in 1775, and in memory of his friend extended the name *Catha edulis* to "Catha edulis Forsskal" (Revri 1983: 3).

Religious Role of Khat

In most of the legends and early historical accounts of khat, a common theme has been its capacity to enhance wakefulness and, therefore, the ability of the user to carry out religious observance and worship (Trimingham 1952: 228). A frequently heard comment in praise of khat by Muslim users is that it enables them to pray without becoming drowsy even throughout the nights of Ramadan (Brooke 1960: 53). In Ethiopia and in Yemen, stories are told of divine guidance in the discovery of khat and the high regard in which the drug was held by Muslim saints.

A well-known legend tells of Sheikh Ibrahim Abu Zarbay (Zerbin), one of 44 Muslim saints who came from the Hadhramaut (eastern Yemen) to Ethiopia in about A.D. 1430 on a proselytizing mission. He traveled to Harer, converted many to Islam, and is said to have introduced khat to Yemen upon his return (Burton 1910: 66-7).

Khat has long been known in predominantly Christian northern Ethiopia, although it was consumed there almost exclusively by the Muslim minority. Frederick Simoons (1960: 115-16) found that nearly all adult Muslims in the town of Gondar chewed khat, but that among the Wayto of Lake Tana only Muslim holy men did so. In Begemder and Semyen, Christians who are supposedly possessed by Muslim evil spirits use it to appease those spirits and to encourage them to leave (Simoons 1960: 115-16).

In the course of some 400 years (thirteenth to seventeenth centuries) of protracted struggle for territory between Christian and Muslim states in Ethiopia, the Christians came to identify the eating of khat as a distinguishing characteristic of the Muslims and disdained its use. However, in Yemen where Moslems and Jews have regularly used the drug, khat did not become an object of religious identification.

Yemeni Jews have used khat since at least the seventeenth century. Sholem bin Joseph al-Shibezi (1619-86) is the author of a poetic play in which a dialogue between coffee and khat is presented (Krikorian 1984: 151-2, citing J. Kafih 1963: 224-5). The play is still performed in Arabic by Yemeni Jews in Israel (Weir 1985: 75).

Within Islam, khat is at the center of controversy. Richard Burton observed during his visit to Harer, Ethiopia, in 1855 that khat produced "a manner of dreamy enjoyment and the Ulema [authorities in Muslim law and religion] as in Arabia, held the drug to be 'Akl el Salikim,' or the Food of the Pious." Burton also wrote that the literati thought khat had "singular properties of enlivening the imagination, clearing the ideas, cheering the heart, diminishing sleep, and taking the place of food" (1910: 232).

Such an expression of esteem for khat, however, represents a minority view in the Islamic world, and for centuries, its consumption has been the subject of debate by doctors of Islamic law. Khat is not mentioned in the Koran, and the persistent question is:

Does the use of khat contravene the Koran's general injunction against the use of intoxicants? Although not of one mind on the question, Muslim religious leaders in most of the Islamic countries have taken the position that it does.

The following resolution was adopted by the World Islamic Conference for the Campaign against Alcohol and Drugs that met at Medina, Saudi Arabia, in May, 1983:

> After reviewing reports submitted to the Conference on the health, psychological, ethical, behavioral, social and economic damages resulting from khat, the Conference judges khat to be a drug prohibited by religion and accordingly the Conference recommends to Islamic states to apply punishment of the basis of Islamic Shari'ah [canon law] against any person who plants this tree and markets or consumes khat (Al-Hammad 1983: 228).

Earlier, in 1971, the government of Saudi Arabia had banned the importation or use of khat in the kingdom and prescribed severe penalties for violations.

In the Muslim countries where khat is legal, there is an ambivalent attitude toward its use, and opposition to the drug is not necessarily based on religion. Many intellectuals in these countries deprecate the use of khat on the grounds that it is a deterrent to economic and social progress (Weir 1985: 66).

Although, traditionally, khat has appealed more to Muslims than non-Muslims, its use in the Islamic world is and has been minute. As A. D. Krikorian (1984: 163) has pointed out, the Turks in Ottoman-occupied Yemen never adopted the practice, nor did the 60,000 Egyptian soldiers stationed in Yemen from 1962 to 1967. In fact, less than half of one percent of the world's Muslims use the drug.

Geographical Perspective of Khat

Asia

Yemen. Khat is the paramount crop of Yemen, where it is widely consumed and its use is legal. According to The Economist Intelligence Unit Limited (1994–5: 47–8): "It is hard to overestimate the social and economic importance of the stimulant shrub, *qat.* The majority of Yemenis, women less than men, chew the drug most days from early afternoon to evening. The habit is less prevalent in the southern governates and is rare in the eastern regions."

Data on khat are largely unrecorded in Yemen's official statistics, and quantitative assessments are estimates. Some aspects, however, are palpable. According to Tutwiler and Caprisco (1981: 52): "Compared to other perishable crops khat has the highest market value, the lowest water requirements, and demands the least output of heavy labor." Beyond all question, khat is the preeminent cash crop of the country.

In fact, a 1992 report of the *Yemen Times* suggested that the value added by the khat sector of Yemen's economy is equivalent to approximately a quarter of the recorded gross national product and about twice the value resulting from cultivation of all other crops (The Economist Intelligence Unit Limited 1994–95: 56). The khat industry of Yemen involves landowners and growers, pickers, packers, transporters, wholesalers, and retailers – some 500,000 people, equivalent to about 20 percent of the working population (The Economist Intelligence Unit Limited 1994–95: 56). A substantial part of government revenue is derived from taxes on khat, although there is little doubt that a large part of the crop escapes levy (The Economist Intelligence Unit Limited 1994–95: 56).

Until the 1970s, khat was too costly to be used frequently by most of the population. But concurrent with the Gulf oil boom that began in 1973–4, an unprecedented number of workers (more than a third of the potential male labor force in North Yemen) migrated for temporary employment to Saudi Arabia and other petroleum-producing countries in the Gulf (Varisco 1986: 2). Remittances sent home by the migrants (annually about 600 to 800 million dollars in the 1980s) created new wealth and a vastly increased demand for khat at home (Varisco 1986).

The early 1980s were exceptionally profitable years for khat farmers. A survey by Shelagh Weir (1983: 67) of a khat-growing community of 4,000 people in Razih Province, North Yemen, near the Saudi Arabian border, found that the market value for land yielding two harvests of khat per year was the equivalent of 90,000 U.S. dollars per hectare. Terraced land, on which two to three harvests of khat per year are common, sold for the equivalent of 200,000 to 600,000 dollars per hectare (Weir 1983: 67). Most holdings range between 0.15 and 0.5 hectares. In 1980, in the district of Rada, a major area of khat production, the estimated net profit of a khat farmer in the second year after the crop matured was the equivalent of about 37,000 dollars per hectare (Varisco 1986: 4).

Critics of the institutionalized use of khat have argued that the transcendent position of *C. edulis* in agriculture has depressed the production of other crops, including the staple grains, and that the large expenditure for khat drains family income that would better be spent on food. Indeed, since the 1970s, importation of foodstuffs has greatly increased in Yemen, and highly processed imported foods have brought changes to the traditional diet (Nyrop 1985: 108). Cereal imports increased 133 percent between 1987 and 1990 and accounted for 16 percent of total imports, compared with 11 percent in 1987 (The Economist Intelligence Unit Limited 1992: 39).

The economy suffered a severe blow, however, when in late 1990, the government of Saudi Arabia expelled all Yemeni migrant workers, terminating Yemen's main source of foreign exchange. The sudden return of some 850,000 Yemenis to their homeland,

and the additional loss of about 1 billion dollars annually in foreign aid from the Arab oil-producing states, had drastic effects on the economy. In mid-1994, unemployment was about 25 percent, and the rate of inflation was about 100 percent annually (The Economist Intelligence Unit Limited 1994–95: 48–9).

Although export of khat from Yemen had ceased in 1974, there are unofficial reports that the depressed economy has prompted efforts in Yemen to increase its export of khat by air to markets in Africa and Europe.

North Yemen (the former Yemen Arab Republic). According to Kennedy, who directed an extensive program of team research on the sociomedical aspects of khat in Yemen during the mid-1970s, "No other society is so influenced by the use of a drug as is North Yemen by the use of qat" (1987: 78). He added that from 80 to 90 percent of adult men and 30 to 60 percent of adult women chew khat more than once each week.

About 70 percent of the country's khat is produced in three areas of the western highlands: the district of San'a; the province of Ibb, Yemen's overall leading agricultural region; and Jabel Sabr (elevation 3,005 meters), the terraced mountain that overlooks the town of Ta'izz and is the oldest and most famous khat-growing area in Arabia (Revri 1983: 16). The greater part of Yemen's khat is consumed in the western interior mountains and plateaus where the majority of the population is located, but freshly harvested leaves are trucked daily from the high elevations, where it is grown, to settlements in the hot, dry coastal plain bordering the Red Sea.

Chewing during the long afternoons in gatherings of friends and acquaintances is a ritual in Yemeni culture that provides a focal point for social contact, informal business dealings, discussion of current events, mediation of disputes, and the free exchange of ideas in a friendly, relaxed milieu. In general, the ubiquitous afternoon "khat party" is a social ritual that underscores the institutionalized role of khat in Yemeni culture and accounts for the major part of the consumption of the drug in the country. Most such parties take place in private residences. They are "open house" affairs, and anyone may participate.

The houses of wealthy urban families have a special room for khat parties called *al Mafraj,* "a place for joyful gatherings" (Weir 1985: 110–11). As a paradigm, it is located with a pleasing overlook on the highest floor of the house, and a large window, extending almost to floor level, provides a good view for the seated guests. Yet, it is the custom that the door and the windows of the mufraj be closed during a khat party. During even ordinary sessions, the room is usually crowded with participants who exult in the oppressive heat and humidity and the smoke from cigarettes and the waterpipe. Users believe that the use of tobacco is essential to the enjoyment of khat chewing (Kennedy 1987: 86). Because khat inhibits urination and defecation by the constriction of muscular vessels, chewers have the ability to remain seated throughout the session for the customary 4 or 5 hours (Kennedy 1987: 115).

The societies of the khat-chewing countries are segregated by sex, and although men are the main users of the drug, women constitute a significant minority of users. The widespread popularity of khat with women is a fairly recent phenomenon. During the 1970s and 1980s, a period of unprecedented prosperity in Yemen, the domestic chores of both urban and rural women were greatly reduced by technological innovations, such as powered flour mills, piped water supply, and the availability of motor transport. The time available to women for social gatherings was substantially increased, and at a growing proportion of these gatherings, khat was consumed (Weir 1985: 90–1).

South Yemen (the former People's Democratic Republic of Yemen). The strong market for khat in South Yemen is only to a small extent supplied by local production, and (despite some interruptions) for more than a century and a half, the farmed land near Ibb in North Yemen has been the main source of South Yemen's khat. From this major center of production, the drug is transported to markets in the port of Aden (population about 420,000), Yemen's commercial capital.

Until about the time of World War II, khat was transported from Ibb to Lahej by camel caravans, which were subject to pillage en route. Armed raiders pulled the camel loads to pieces in order to "extract a few choice bundles [of khat], with the result that the loads arrived in Aden dried up and unfit for human consumption" (Ingrams 1966: 106).

The government adopted an anti-khat policy, and in 1977, the use and sale of the leaf were limited by law to one day per week (Friday). This restriction, however, ended in 1990 when the two Yemens united.

Saudi Arabia. The small province of Jizan in the southwestern corner of Saudi Arabia is the only part of that country in which consumption of khat is of consequence. The mountain tribespeople in Jizan, settled in rugged highland terrain and in relative isolation, have historically maintained a large measure of autonomy in their internal affairs. The growing and usage of *C. edulis* is centuries old in the uplands of the province, but at present, because of the government's determination to abolish the plant and its use, cultivation of khat exists chiefly, if at all, covertly in the Fayfa area of Jizan. Schopen (1978: 65) identified Jebel Fayfa as the northern limit of khat cultivation in Arabia.

Israel. In the nineteenth century, khat growing was introduced by Yemenite Jews to the region of

Ottoman-ruled Palestine that later became the modern state of Israel (Erich Isaac 1995, personal communication). Large-scale migration of Jews from Yemen began in 1882. By 1948, when Israel was established, about a third of the Jewish population of Yemen had emigrated. The exodus of almost all Jews remaining in Yemen (about 50,000) was accomplished by air transport to Israel, beginning with "Operation on Eagles' Wings" in 1949 (*Jerusalem Post* September 19–25, International Edition 1982: 20).

It was a common practice of Yemeni migrant families to bring shoots of "gat" *(C. edulis)* with them to be planted in home gardens of their new settlements, and in Israel, the cultivation and consumption of khat remain almost exclusively the practices of Yemenite Jews. Immigrant Ethiopian Jews are reported to chew the leaf, as do some young Ashkenazis, who are attracted by the exotic nature of the drug (High on gat 1996: 16). Most khat is consumed by its growers, but the fresh leaves can be found for sale (legally) in some of the open-air "oriental markets" (Arnon Soffer, 1995, personal communication; D. Hemo, 1995, personal communication). A khat-based frozen concentrate, "Pisgat," is made and sold in Israel as a health food. Its maker is reported to claim that the psychotropic effect of two tablespoons of Pisgat (mixed with water or soya milk, or added to ice cream) is equivalent to that achieved by several hours of chewing fresh khat (High on gat 1996: 17). In 1952, the ministry of health reported to the Knesset that although *C. edulis* was a stimulant, there was no reason to ban the leaf; since then, this official view has prevailed.

Afghanistan and Turkestan. In scientific literature, there are a few brief uncorroborated references to the occurrence of the khat plant in Afghanistan and "Turkestan," that is, southcentral Asia. One reference, the most credible, is a two-paragraph communication titled "Catha Edulis," by F. J. Owen, published early this century in a British chemical journal. Owen, an analytical chemist employed by the government of Afghanistan, reported his observations of the use of khat as a beverage by Afghans in Kabul:

> The plant is found in the south of Turkestan and certain parts of Afghanistan to the east of Kabul. . . . After inspecting a specimen brought to me for analysis I recognized it as the *Catha edulis* plant. The natives say that men by its aid can do long marches at night without feeling the least fatigue, also that among the wrestling fraternity here it is used on a large scale, as it greatly increases the muscular powers of the men. . . . It is drunk by many Afghans as a substitute for tea (1910: 1091).

Although more than 80 years have passed since the publication of Owen's communication, however, the existence of khat in Afghanistan (or in any other country in southcentral Asia) is still unconfirmed.

Africa: General Distribution

C. edulis occurs wild and as a cultivated plant in eastern and eastcentral Africa. Wild stands grow sporadically in highlands from the northeastern Horn of Africa to the Sneeuberge Range in the far south of the continent. The plant is reported to be found in Eritrea, Ethiopia, Somalia, Kenya, Uganda, Tanzania, Rwanda, Burundi, Zaire, Zambia, Malawi, Mozambique, Zimbabwe, and the Republic of South Africa.

Ethiopia. Khat is grown in at least 9 (of the 14) administrative areas (provinces) of Ethiopia (Revri 1983: 5). The plant is a prominently cultivated crop in the plow- and grain-farming complex of Harerge and eastern Arsi provinces and is frequently part of the planting complex of the Kefa and the Galla (Oromo) ethnic groups in the Kefa Province where khat ranks second to coffee as a cash crop (Westphal 1975).

The main area of khat cultivation is the Harer Plateau – in the eastern section of Ethiopia's Central Highlands – with commercial centers of production in the administrative subdistricts of Harer, Webera, Garamulata, Chercher, and Dire Dawa (Assefa 1983: 73). All of these are within a radius of 100 kilometers (km) from the city of Harer, where according to local tradition, khat was first domesticated. In any case, its cultivation and use at Harer is older and economically more significant than in other areas in Ethiopia.

Small farm villages are scattered throughout these highlands of Harer, and at elevations between 1,500 and 2,100 meters, climate and soils are favorable for the production of a wide variety of field, garden, and tree crops. Rotation and terracing are practiced, as is irrigation where possible. Durra grain sorghum *(Sorghum vulgare)* is the predominant food crop, and khat is the most valuable cash crop (Brooke 1958: 192) – replacing coffee, which held that position until the middle of the twentieth century. Coffee fell from favor with Hareri farmers after World War II, chiefly because of low prices fixed by the government.

In 1949, Ethiopian Airlines introduced commercial air transportation of freshly cut khat from Ethiopia to Djibouti (French Somaliland) and to the British Crown Colony of Aden (now South Yemen). Transport of the perishable leaves by air was a commercial success from the start. However, the military junta that deposed the Ethiopian emperor, Haile Selassie, and held power during the years 1975 to 1991, sought to suppress its cultivation. Strong measures were employed to achieve that goal (Rushby 1995: 17), but since the end of civil war and the inauguration of a new coalition government in 1991, khat production has resumed without interference.

The export of khat officially earned 16 million U.S. dollars in 1993–4, establishing the drug as Ethiopia's fifth-largest source of revenue (Rushby 1995: 17). Illicit trade in the leaf (smuggling and by other means avoiding excise) probably generates at least as much revenue as the official figures.

Khat is airfreighted twice weekly from Dire Dawa to London and Frankfurt, where it is sold to Ethiopian, Somali, and Yemeni expatriate communities. A small bundle of the leaves, sufficient for two or three hours of chewing, sells in Germany and the United Kingdom for the equivalent of between 6 and 7.50 U.S. dollars (Rusby 1995: 16–17). Ethiopian exports of khat to Europe compete with those from Kenya and Yemen.

Djibouti. The Republic of Djibouti (population about 400,000) is a major consumer of khat. Almost all of the drug is airfreighted from Dire Dawa, Ethiopia, where international cargo flights with freshly cut khat were inaugurated in 1949. The Economist Intelligence Unit Limited (1989: 56) has estimated that as much as 12 tons of khat, valued at about 40 million U.S. dollars, enter Djibouti daily.

Somalia. Indigenous production of *C. edulis* in Somalia is small, and most of the khat consumed in this country is imported from Kenya and Ethiopia. Prior to the creation of the Somali Republic by the merger in 1960 of the (British) Somaliland Protectorate and Italian Somaliland, khat, on a small scale, was mainly used in the city of Hargeysa, the administrative center of the British dependency. After World War II, khat use in the protectorate increased considerably in spite of an official ban on the drug. Severe measures were taken by the colonial government to suppress the khat trade – drivers of trucks used for its transport were jailed and their vehicles destroyed (Elmi 1983: 166). But prohibition proved futile and, in 1957, the protectorate replaced the ban on khat with an import tax on the leaf (Brooke 1960: 57).

After the two Somalilands joined as a republic in 1960, the use of khat rapidly gained popularity in the "Southern Regions" (the former Italian Somaliland), coinciding with increased urbanization and the improvement of surface and air transportation. For two decades the government attempted simply to discourage the practice and finally proscribed it in 1983.

Enforcement efforts, however, were not effective, and as a consequence of the civil war that began in 1991 and the continuing political turmoil, there are no legal restrictions on khat in Somalia at the present time. In fact, it is believed that strife in the capital, Mogadishu, is fueled by the struggle among clan leaders for control of lucrative khat imports and distribution. The value of khat, it is reported, far exceeds that of any other commodity that Somalia imports, including food and weapons (Randall 1993: 15).

In the northern administrative regions of Somalia, the chief market for khat is the city of Hargeysa. A small amount of khat is locally cultivated, but most is imported by trucks from the Harer area in Ethiopia.

Kenya. The preeminent khat-growing area of Kenya is the Nyambeni Hills of the Meru District, extending northeast from the foot of Mt. Kenya for about 120 km. Khat that is cultivated and sold under license by farmers of the Meru ethnic group is the main source of the leaf for consumers in Kenya and for export to Somalia, Uganda, Tanzania, Zaire, and Zambia (Matai 1983: 88).

From local market towns, khat is transported to Nairobi – a fast four-hour drive – or by air from Isiolo to northern market towns. The khat trade is highly seasonal. Shortages and high prices prevail at markets during the months from June to October, when new growth of leaves and shoots is at a minimum (Hjort 1974: 29).

Somalia is the main export market. Every day at dawn, some 15 to 20 airplanes, each with about a ton of khat stuffed in burlap bags, take off for Somalia from Nairobi International Airport. Other flights leave from the town of Meru to smaller markets for khat in Tanzania and Uganda (Lorch 1994: A8). Khat is also flown as cargo from Nairobi to Britain, where it is a legal import. London and Cardiff, where many of the dockworkers are Somalis, are major markets.

The Western Indian Ocean Region

Madagascar. The cultivation, sale, and consumption of khat are legal in Madagascar, where the drug is grown and consumed chiefly by members of the Antakarana ethnic group in the northern extremity of the island. Local names for the plant are "katy" and "gat" (Thomas Herlehy and Daniel Randiriamanalina, 1995, personal communication).

The introduction and early history of khat in Madagascar is obscure. It is possible that *C. edulis* was first brought to the island by Arab traders and immigrants several hundred years ago. Louis Molet (1967: 25) postulated that khat was introduced and spread by Yemeni Arabs and later by Muslims from the Comoro Archipelago. Traders from Kilwa and from Zanzibar may also have played a role in the introduction of khat to Madagascar. In any case, for generations, immigrants from Yemen and the Comoro Islands have settled among the Antakarana and Sakalava ethnic groups in northern Madagascar.

A minority of the population, commonly referred to as "Arabs," are of mixed Yemeni, Comoran, and Malagasy ancestry. They profess Islam, affect Arab (Yemeni) dress, and are said to be foremost in the commercial production of khat (Sharp 1995, personal communication).

It is mostly men that use khat, but the number of women users is said to be increasing. The retail price of a bundle of khat is about 5,000 Malagasy francs (approximately $1.25), which is expensive for most consumers (Sharp 1995, personal communication). As in Yemen, saliva and the juice of the leaves are swallowed, and the residue of chewed leaves is expectorated.

Methods of Khat Consumption

Khat as a Beverage

The practice of drinking water infusions and decoctions of khat is very old but today accounts for a smaller part of khat consumption than in the past. Fresh leaves for chewing, now widely available, provide users with much more psychostimulation than desiccated, boiled leaves. Nevertheless, khat prepared as a beverage is mildly stimulating, and some writers have extolled it as "an excellent beverage plant and worthy of exploitation" (Hill 1952: 481). "The leaf [has] a slightly bitter flavor with a strong, sweet taste of liquorice and has been regarded as nourishing" (Watt and Breyer-Brandwijk 1962: 179).

Catha edulis is one of many plants in Africa used to make "bush tea." In the Cape Province of South Africa, bush teas are popular as tonics and as treatments for urinary and digestive problems. J. M. Watt and M. G. Breyer-Brandwijk (1962: 590) have described two methods of preparing bush tea from young twigs and leaves of the khat tree. In one, flowering shoots are first fermented by being piled in a heap and then allowed to dry. In the other, the leaves are "sweated" in an oven before they are dried in the sun. According to Watt, well-prepared bush tea has a sweet aroma (Watt and Breyer-Brandwijk 1962: 590).

W. Cornwallis Harris, who traveled widely in Ethiopia during the years 1841 and 1842, reported that leaves of khat, well dried in the sun, were either chewed, boiled in milk, or infused in water. "By the addition of honey," wrote Harris, "a pleasant beverage is produced, which being bitter and stimulative, dispels sleep if used to excess" (1844: 423–4). In the region of Ifat (Welo Province), he found that the fresh leaves were chewed as an astringent medicine or taken to dispel sleep, "a decoction in water or milk being drunk as a beverage, which tastes bitter enough" (Harris 1844: 407). According to Simoons (1960: 115), Christians in Debra Tabor (Gondar Province, Ethiopia) use khat leaves to flavor mead *(tedj)*. The addition of *tedj* to a water infusion of khat yields a brown, bitter, mildly intoxicating beverage (Schopen 1978: 85).

Khat as a Masticatory

The chewing of fresh leaves and stem tips is the most common way of using khat as a psychostimulant. Everywhere the technique is much the same. Derek Peters (1952: 36) describes how khat is used as a masticatory in Somaliland. From the user's supply of fresh khat, tender leaves and shoots are carefully selected and stripped from a few branches, compressed into a small mass, placed in the mouth, and chewed. Saliva and plant juices are swallowed. Copious amounts of cold water or other cold beverages are drunk. After 10 to 15 minutes of chewing, most of the juices are extracted from the wad. The process is repeated until – after 3 or 4 hours – the user's supply of khat is exhausted. According to Weir (1985: 97), most consumers chew about 100 to 150 grams of picked leaves in one session; some chew as few as 50 grams, and a minority chew more than 200 grams.

In Yemen, the residue of chewed leaves in the mouth is not swallowed but compressed into a wad and stowed in one cheek (Kennedy 1987: 88). At the end of the chewing session it is expelled into a spittoon. In Ethiopia and East Africa, the chewed parts of the leaves are swallowed with the juice and saliva. Amare Getahun and A. D. Krikorian (1973: 371–2) have suggested that ingested residue may be an important part of the daily intake of food, especially in the case of heavy users of the drug. Other investigators suspect that tannin in the residue may be responsible for the gastrointestinal discomfort that is common among khat chewers.

Khat as a Paste

In Ethiopia, water and honey are added to crushed, dried leaves of khat, and the ingredients are worked into a paste. In Somalia, a paste is made of finely ground dried khat, water, sugar, cardamom, and cloves. Khat paste is commonly eaten by the elderly and by travelers, according to Schopen (1978: 84–5).

Other Modes of Use

Not uncommonly, elderly persons, if unable to chew effectively, pound fresh leaves of khat in a small mortar (which they carry on their person) and drink the juice (Brooke 1960: 53; Kennedy 1987: 88). In eighteenth-century Yemen, travelers and old persons used *madquq,* which is simply khat that is pressed and left to dry in a darkened room for seven days and then pulverized by mortar and pestle. A portion of the dry, granular khat is placed in the mouth, mixed with saliva, and swallowed (Schopen 1978: 86).

There are also brief references in the literature to the practice of smoking khat. For example, "The dried leaves [in Africa] are also sometimes smoked" (Margetts 1967: 358), and "In Arabia the leaves may be dried and smoked like tobacco" (Greenway 1947: 99). Y. Z. Hes mentions that in the towns of Yemen, there are places where one may go in order to make and smoke khat cigarettes (1970: 283–4). But today, with the widespread availability of the freshly cut product, this method of consumption appears to be little used.

Food and Nutritional Characteristics

Karsten Niebuhr, in his book on travels in Arabia published in 1792, ascribed to khat "the virtues of assisting digestion and fortifying the constitution against infectious diseases. Yet its insipid taste gives no indication of its extraordinary virtues" (Niebuhr 1792, Vol. 2: 353–4, cited by Krikorian 1984: 119).

The astringent effect of khat induces intense thirst, and in addition to water, such beverages as tea, coffee, and commercial colas are consumed during the chew. Beer, both commercial and homemade, is a popular thirst quencher with chewers in Kenya and Somalia. Sometimes the host of a khat party in Yemen provides sherbet for the guests during a chewing session.

The nutritional value of khat is important because, to some unknown extent, the leaf is a substitute for conventional foods that would be eaten by the majority of users who chew khat regularly. Solid food is avoided during the chewing session, and for some hours after. Indeed, a well-known effect of khat is the temporary loss of appetite. "The laborers and shopkeepers take khat and regard it as the best substitute for food," write Mulugeta Assefa (1983: 74).

In a 1952 analysis of samples of miscellaneous tropical and subtropical plants and plant products by Margaret Mustard (1952: 31), khat was found to contain "exceptionally large amounts" of ascorbic acid (vitamin C) in leaves and branch tips, and "the ancient custom of qat chewing in Arabia may be inadvertently supplying the people of that country with some of their daily requirement of ascorbic acid" (1952: 34). It is interesting to note that ascorbic acid has been reported to act as an antidote to amphetaminelike substances, such as khat (Krikorian 1984: 154).

The Ethiopian Nutrition Survey (Khat [or chat] 1959: 169), in a nutritional analysis of samples of fresh khat leaves and tender stems, reported that in addition to its vitamin C content, "khat can contribute important amounts of niacin, beta-carotine [sic], calcium and iron to the user's diet" (See Table III.7.1).

According to Weir (1985: 42–3), the diet of khat chewers conforms to traditional Greco-Arab medical doctrine about the functioning of the human body. A healthy body is thought to be one in which an equilibrium is maintained among the four constituent humors – blood, phlegm, yellow bile, and black bile. Each humor has qualities drawn from the categories wet/dry and hot/cold. Blood is moist and hot, phlegm is damp and cold, yellow bile is dry and hot, and black bile is dry and cold. All substances that are taken internally, including khat, food, and medicines, are capable of upsetting the balance among the four humors by causing an excess or a diminution of their qualities when ingested. Khat is cooling and drying:

> In order to achieve the most enjoyable results from an afternoon's qat party, and to offset the "cooling" effects of qat, a man should make himself as hot as possible by eating beforehand a good lunch composed of "hot" foods, and avoiding those classified as "cold." Hot foods are boiled mutton, mutton broth, fenugreek *(hilbah)* broth, chili pepper, white radish, wheat bread and sorghum porridge. . . . The cooling effects of qat are also counteracted during the qat party by closing all the windows of the room and generating a warm and stuffy atmosphere (Weir 1985: 43).

Weir (1985: 172) mentions that fenugreek is, next to mutton, the most important component of the midday meal, which is the main Yemeni meal. In Kennedy's opinion, there is traditional wisdom in the belief that fenugreek soup and a meat sauce gravy are essential components of a "greasy carbohydrate meal [that] nullifies at least some of the potentially negative side effects of the qat" (1987: 82).

Kennedy (1987: 81–2) also points out that it is essential that spicy and well-salted foods be eaten in order to heighten the thirst of the khat user during the chewing session. Pleasure in drinking cool water during the session is an important part of the chewing experience.

Medicinal Uses of Khat

Khat is included in only a few of the many Arab pharmacopoeias and has been very little used in formal medicine. As might be supposed, however, it has a place in folk medicine and traditional remedies. For example, according to Peter Merab, among the dervishes and other Muslim holy orders, chewed khat is spat upon patients as a preliminary step in treatment of the sick. He also mentions that infusions of khat are drunk to treat illness (1921: 176).

In Somalia, khat is believed to have curative properties in treating urinary problems and gonorrhea (Peters 1952: 36). In Tanzania, coughing, asthma, and other respiratory problems are dealt with by drinking khat infusions, and pieces of the tree root are eaten to relieve abdominal pains (Greenway 1947: 99).

In the eighteenth century, Yemenis believed that the use of khat prevented epidemics and that, wherever the khat plant grew, pestilence would not appear (Schopen 1978: 87–8). Khat is used as an analgesic in Madagascar, where "teas" of many different plants are consumed for medicinal purposes. Tea from khat is used by elderly persons to relieve rheumatic ache and by women to ease the pain of menstrual cramps (Sharp 1995, personal communication).

The Psychophysiological Effects of Khat

The psychotropic effects of khat first drew international attention in 1935, when two technical papers on the plant were discussed in the League of Nations' Advisory Committee on the Traffic in Opium and Other Dangerous Drugs (*Bulletin on Narcotics* 1980: 1).

For many years, it was believed that the alkaloid cathine, *d*-norpseudoephedrine, was the main stimulant in khat. But in 1975, a laboratory study – using samples of fresh khat (instead of dried leaves as had been used in previous work) – resulted in the detection and isolation of cathinone, a phenylalkylamine characterized as (-)a-aminopropiophenone (Szendrei 1980: 5). Cathinone, 8 to 10 times stronger than cathine in its effect, is the predominant psychotropic agent in khat (Kalix 1994: 71), which is the only plant known to produce cathinone (LeBelle 1993: 54).

The transformation of cathinone into other less-potent products, such as cathine, begins shortly after the leaves and shoots are removed from the tree (Kalix 1994: 72). With a plasma half-life of only 1.5 hours, cathinone's potency is lost within 48 to 72 hours after harvesting (Kalix 1994: 72), which is the reason khat users prefer to chew only fresh leaves and shoots of the plant. However, deep-freezing prolongs its potency for months (Drake 1988: 532–3).

Alkaloids from khat, used in patent medicines manufactured in Europe during the 1920s and 1930s, were derived only from dried leaf material and, therefore, contained little or no cathinone.

Table III.7.1. *Nutritional components of khat* (Catha edulis)

Vitamins and minerals	Sugars and sugar alcohols	Miscellaneous substances
Ash: 11.59 gm/100 gm dried leaves (includes Mg, Fe, Ca, Cl)	Mannitol	Rubberlike substances
Ascorbic acid: .136 gm/100 gm leaves and twigs 0.324 gm/100 gm leaves only	–	–
–	–	Rubberlike substances: volatile oil (traces)
Gm/100 gm plant material Ash 1.6% Ascorbic acid 0.161 Thiamine <0.00005 Niacin 0.0148 Riboflavin <0.00005 β-carotene 0.0018 Iron 0.0185 Calcium 0.290	–	Protein: 5.2% Fiber: 2.7%
–	–	Free amino acids, aspartic acid; threonine; serine; glutamic acid; proline, glycine; alanine; valine; leucine; isoleucine; tyrosine; α-aminobutyric acid; histidine; ornithine; arginine; tryptophan; phenylalanine.
–	Reducing sugars: as hexose: 1.4 gm/100 gm plant material (portion of total sugars may be galactose); dulcitol	Free amino acids: lysine; α-aminobutyric acid; phenylserine; phenylaline choline (0.05%) (dried plant)
–	Glucose, fructose; rhamnose (free); xylose, galactose; dulcitol	–
–	–	Flavonoids; glycosides or carbohydrates; volatile oils
–	–	Steam distillate of dried leaves and young twigs (of Yemen origin) yielded 0.04–0.08% of a yellow essential oil. There were 5 hydrocarbons (α and β-pinens, terpinolene, β-phellandrene, and ocimene); and 6 oxygenated terpenes (α and β-thujone, fenchone, linalool, α-terpineol, and nerol.

Source: After Krikorian and Getahun (1973).

The Khat Experience

A subjective account of khat-induced psychophysiological effects is given by Kennedy. The account is derived from his own experimentation with the drug and from interviews with 803 Yemeni users of khat:

> The first experiential effects of qat are a gradually developing mild euphoria, i.e., alertness, feelings of contentment, confidence, gregariousness, and the flowing of ideas, called the kayf. ["Kayf" is a general term in Arabic for a state of pleasurable well-being]. Under certain variable conditions such as amount of the drug, food intake, personality and physical condition, this kayf phase occasionally develops into confusion. Ordinarily however, the experience gradually transforms into an "introvert phase" of quiet contemplation in which the stimulation of thought processes continues at a rapid pace while physical and vocal activities diminish. Since this is often accompanied by fatigue, previous problems or pessimistic personality characteristics may transform this phase into a mild temporary lowering of mood.
>
> The postsession effects of qat continue for several hours, and, again depending upon the same variable conditions, many of them are rather negative. Sleep is inhibited, hunger is diminished, sexual desire and performance may positively or negatively be affected, and irritability may occur. However, often people experience positive aftermaths, such as feeling closer to Allah, more understanding, and a desire to work. When we look at our interview data pertaining to the experiential aspects of qat-use we find consistent male-female differences, with more males generally reporting the experiences. In the eyes of the average chewer the rewarding experiences associated with qat chewing outweigh the unrewarding ones; they are much more regular and predictable (Kennedy 1987: 130–1).

Adverse Effects of Khat

An apocryphal account of khat's introduction into Yemen from Ethiopia is given by the historian and traveler, Ibn Fadl Allah al'Umari in his work, *Masalik al-Absar,* written between A.D. 1342 and 1349. The king of Yemen, curious about khat, asked an advisor, an Ethiopian familiar with the drug, to describe the effects of chewing the leaf:

> Upon learning that it virtually eliminated the desire to eat, to drink [alcohol?], and to have sexual intercourse, [the king] told him: "And what other pleasures are there in this base world besides those? By God, I will not eat it at all; I only spend my efforts on those three things; how am I going to use such a thing which will deprive me of the pleasures that I get from them?" (Krikorian 1984: 26–7).

Beyond question, a temporary loss of appetite is effected by khat chewing. In laboratory tests, cathinone and cathine markedly inhibit the food intake of rats (*Bulletin on Narcotics* 1980: 84). In addition, nearly all users experience difficulty in sleep following the use of the drug. Only daily heavy chewers reported that their sleep was not inhibited by khat (Kennedy 1987: 128). There is also little doubt that sexual experience is affected by khat, but opinions vary as to whether sexual desire is heightened and ability to perform is enhanced, or whether there is a loss of libido. Examples of both effects are found in the literature: "While sex interest is heightened at first, depressed *libido* and *potentia sexualis* come as the drug effect is maintained, and chronic users may develop impotence" (Margetts 1967: 359; see also Krikorian 1984: 151).

A negative view of the drug, based on its anaphrodisiac properties, is paradoxical, however, because relevant demographic characteristics of the chief khat-using countries suggest that "depressed libido" is hardly a problem. Yemen, for example, has a total fertility rate (the average number of children a woman will have throughout her childbearing years) of 7.7, which is the world's highest, save for Gaza's 8.1 (Population Reference Bureau 1995).

Perhaps the most common ailments related to the level of khat use are gastritis (acute and chronic) and constipation (Kennedy 1987: 218). Tannins in khat (chiefly flavenoids) have long been suspected of adversely affecting the gastric system. At the present time, it is known that tannin content is high, probably between 5 and 15 percent (Kennedy 1987: 185). Many of the most expensive kinds of khat have reddish tints to leaves and shoots, and these kinds are purported to have a lower content of tannins than the others (Drake 1988: 532).

Among women, there is a strong association of the level of khat use with liver and urinary problems. Khat chewing may also be a maternal practice harmful to the fetus. It has been found that healthy full-term infants have a significantly lower average birth weight if the mothers were either occasional or habitual khat chewers (Eriksson, Ghani, and Kristiansson 1991: 106–11).

Legal Considerations

Since the 1950s, khat has been on various agendas of meetings under the auspices of the United Nations Commission on Narcotic Drugs and of the World Health Organization. For many years, the attention of these organizations was directed to the question of agreeing upon a pharmacological definition of *C. edulis.* Eventually, in 1973, it was placed in a group of "dependence-producing drugs," although there is a lack of evidence that khat chewing produces "dependence" in the usual sense of the word.

At the present time, 137 countries are parties to at least one of the three Conventions (1961, 1971, and 1980) of the United Nations International Drug Control Programme. Because khat contains the alkaloids cathinone and cathine, it is a scheduled drug on the 1971 Convention's List of Psychotropic Substances. Parties to the Convention agreed to prohibit the entry of khat without an import permit. However, most parties to the U.N. conventions do not strictly enforce the control measures for khat as required by the treaties.

Europe

The Scandinavian countries are among the minority of European nations that strictly enforce a ban on the import and export of khat. Consumers in the United Kingdom and Germany may purchase khat legally, airborne from Ethiopia, Kenya, and, recently, Yemen (Rushby 1995: 16). In Rome, where use of the drug is popular among Somali expatriates, it is rumored that airport customs inspectors of flights arriving from Ethiopia, Kenya, Yemen, and Israel seldom inquire closely as to the nature of fresh bundles of stems and leaves identified on import declaration forms as "floral stuff" (Nencini et al. 1989: 257).

The United States

Under United States federal law, it is illegal to possess khat for personal use or to import, cultivate, dispense, or distribute it. The alkaloid cathinone is placed in Schedule I, subsection (f) Stimulants, of the Controlled Substances Act (CSA). The CSA defines Schedule I drugs as "highly abusable substances . . . which have no currently accepted medical use in the United States" and which may be used lawfully only in research situations authorized by the Drug Enforcement Administration (U.S. Department of Justice 1988: 4). As provided by the CSA, the penalty for simple possession of khat is imprisonment of not more than one year and a minimum fine of $1,000, or both (Code of Federal Regulations, 21 1994: 1308.12, 841[a], 841[b], 844[a]).

It is believed that most khat enters the United States from Canada in small quantities concealed in luggage aboard aircraft or in private vehicles. Seizures of khat have been made at international airports in Champlain, N.Y., New York City, Newark, Chicago, Dallas, and St. Louis. A total of about 800 kilograms of khat was seized by the U.S. Customs Service between August 1991 and October 1992. In March 1993, the retail price of a kilogram of khat ranged from 30 to 60 dollars (U.S. Department of Justice 1993: 2).

Canada

Khat is currently classified as a "New Drug" in Canada, that is, "new" in the sense that "it has not been sold in Canada for sufficient time to establish the safety and effectiveness of the substance for use as a drug" (Langlois 1995, personal communication). As a New Drug, the sale of khat is prohibited, but not its possession import, export, or consumption. New legislation would place fresh leaves of khat in Schedule II and confine import, export, cultivation, sale, and possession to medical and scientific purposes. Importation would require an official permit. Violations would be subject to fines not to exceed 5,000 dollars and or imprisonment not exceeding three years (Langlois 1995, personal communication).

III.8 Kola Nut

Kola nut is an important stimulant and masticatory in Africa. It is about the size of a walnut or a chestnut and varies in color from dark red to creamy white (Chevalier and Perrot 1911; Cohen 1966; Agiri 1972; Lovejoy 1977–8, 1980). This fruit of the kola tree grows in pods that contain from 3 to 15 or more nuts. Pink and white nuts are generally valued highest because they have a sweeter taste and a greater caffeine content than other kola nuts. Kola is richer in caffeine than coffee and most teas and has 3 times as much starch as cacao (Heckel and Schlagdenhauffen 1884; Kraemer 1910; Chevalier and Perrot 1911; Pratt and Youngken 1956; Ramstad 1959). Known by various African names – *goro* or *gourou, ombéné, nangoué, kokkorokou,* and *matrasa* – kola is known as a heart stimulant because it contains kolanin along with caffeine, traces of the alkaloid theobromine (which exists in cacao as well), glucose, and strychnine (Table III.8.1). Both caffeine and theobromine stimulate the nervous system and the skeletal muscles, making kola a psychoactive substance (Kennedy 1987; Jones 1995).

Table III.8.1. *Chemical composition of the pod husk, testa, and nut of kola (dry matter %)*

Composition	Pod husk*	Testa*	Nut*
Crude protein (NS × 6.25)	10.22 (7.69–12.50)	14.00 (12.25–17.00)	8.06 (7.25–9.81)
Ash	6.05 (5.75–7.58)	11.00 (9.23–13.11)	2.55 (1.95–3.08)
Crude fiber	16.43 (15.72–18.26)	14.36 (13.33–15.77)	2.18 (1.83–2.57)
Ether extract	1.0 (0.8–1.4)	1.37 (0.94–1.56)	0.98 (0.96–1.0)
Nitrogen free extract	66.30 (61.52–70.04)	59.00 (52.56–64.25)	86.23 (83.54–88.01)
Caffeine	trace	0.44 (0.32–0.48)	1.58 (0.8–3.0)
Pectin	10.0 (9.24–11.57)	5.00 (4.54–5.50)	–
Total Polyphenols	8.80 (8.24–9.8)	3.63 (2.50–4.20)	6.7 (5.6–8.5)
Total nitrogen	1.63 (1.23–2.0)	2.24 (1.96–2.72)	1.28 (1.16–1.56)
Nonprotein nitrogen	0.69 (0.5–0.93)	0.34 (0.30–0.82)	0.88 (0.76–1.16)

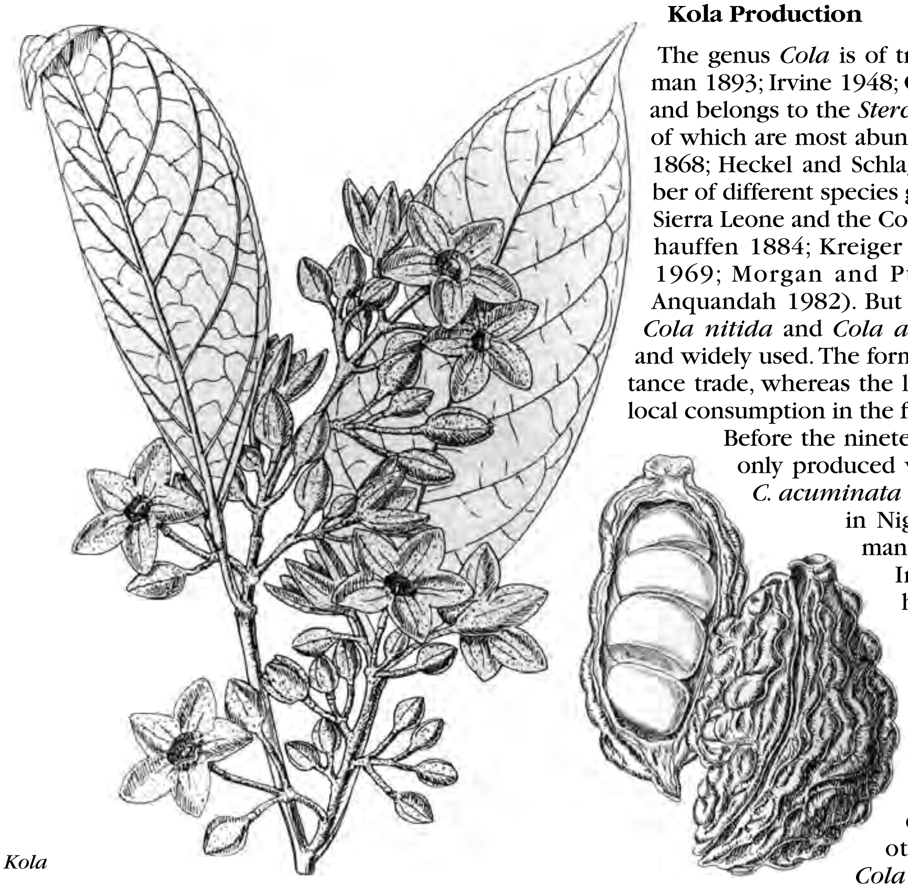
*The diagram above shows the chemicals that are contained in kola nuts, which make kola such an important masticatory in Africa.

Source: Ogutuga (1975), pp. 121–5.

Kola Production

The genus *Cola* is of tropical African origin (Freeman 1893; Irvine 1948; Cohen 1966; Dickson 1969) and belongs to the *Sterculiaceae* family, the species of which are most abundant in tropical Asia (Oliver 1868; Heckel and Schlagdenhauffen 1884). A number of different species grow in the region between Sierra Leone and the Congo (Heckel and Schlagdenhauffen 1884; Kreiger 1954; Kola 1957; Dickson 1969; Morgan and Pugh 1969; Brooks 1980; Anquandah 1982). But of some 40 varieties, only *Cola nitida* and *Cola acuminata* are well known and widely used. The former was the kola of long-distance trade, whereas the latter was grown mainly for local consumption in the forest regions of Africa.

Before the nineteenth century, *C. nitida* was only produced west of the Volta River, and *C. acuminata* grew to the east, especially in Nigeria (Lovejoy 1980; Goodman, Lovejoy, and Sheratt 1995). In the nineteenth century, however, the cultivation of *Cola anomala* and *Cola ballayi* had spread to southern Cameroon, with the nuts exported to the savanna region (Goodman et al. 1995). In Ghana, in addition to *C. nitida* and *C. acuminata,* there are other varieties that include *Cola cardifolia, Cola togoensis*



Kola

(Engl & Krause), *Cola johnsonii* (Stapf.), and *Cola verticilata* (Stapf. & Chev.) (Irvine 1969).

Although kola is indigenous to the forest zone of West Africa, the plant has traveled widely. It can be found in East Africa around Lake Nyanza, along the north coast of South America, and in portions of South Asia. In large part, this is because of European colonization. The British, for example, introduced kola into the East Indies, the Seychelles, Ceylon (Sri Lanka), Demerara (Guyana), Dominica, Mauritius, and Zanzibar. Similarly, the French introduced kola into Martinique, Guadeloupe, and Cayenne (Heckel and Schlagdenhauffen 1884).

Cultivation

Kola does well in forest soils and also in savanna areas of forest outliers so long as there is adequate moisture in the rooting zone and the soil has a high content of organic matter. The tree likes low elevations, deep, well-drained soils, and moderate rainfall. Good drainage is essential because the plant cannot withstand flooding (AERLS *Guide* 1982). It grows best in rich, deep soil in forest zones where rainfall does not exceed 50 to 60 inches annually – conditions characteristic of areas where the kola industry has persisted on a commercial scale (Heckel and Schlagdenhauffen 1884; Miles 1931).

The kola tree also flourishes in moist lands either at sea level or a little above. In Labogie in Nupe (Nigeria), kola plantations are situated in sheltered valleys at an elevation of 450 to 550 feet above sea level, where, according to a Royal Botanical Garden bulletin, "[t]he soil is a deep, black, sandy loam and is kept in a continuous state of moisture by streams that are in the valley" (1906: 89). The annual rainfall in this region is about 40 to 50 inches. Similarly, in southwestern Nigeria, kola is generally found in the better-drained areas with light, loamy soils of good depth (Russell 1955; Agiri 1972).

Germination

Polyembryo (in which more than one embryo results from a single ovule) occurs in *C. nitida* (Bodard 1954) and *C. acuminata,* along with multiple shoot/root production and adnation of auxiliary shoots to the main stem axis (Oladokun and Adepipe 1989). In fact, splitting or cutting the nuts brings quicker germination, although this reduces nut size, as well as initial growth after germination is slowed down. In addition, some of the cotyledons produce multiple roots and shoots, whereas others produce roots with no shoots (Oladokun and Adepipe 1989; Brown 1970).

High temperatures and light seem to have no effect on kola germination. Seeds that are freshly harvested take 3 to 9 months to germinate, although seeds stored for about 7 months usually do so within 3 or 4 months of sowing. There is also a pronounced difference between the germination patterns of stored and fresh kola seeds, with seedlings from stored seeds tending to grow faster, larger, and more vigorously than those from fresh seeds (Ashiru 1969; Brown 1970; Karikari 1973).

Propagation

The propagation of kola nuts takes place after the land is prepared at the beginning of the rainy season. The farmer initially clears a portion of the forest and scrapes the soil into "hills" that are "beds" for yam, cassava, and cocoyam. Kola seeds are planted between these beds and spaced about 20 to 27 feet apart so that the food crops will provide shade for the young seedlings (Ashiru 1969; Brown 1970; Karikari 1973).

A kola tree bears fruit after 4 or 5 years and reaches maturity by the tenth year. Because it is a tree of the tropical forest, it is useful to interplant with food crops or with shade trees, such as coffee and cacao. Many of the kola groves or plantations in Ghana are found growing together with cacao (Ossei 1963). Because growth is very slow (about 3 meters in 4 years), the use of seed, rooting of cuttings, grafting of shoots on suitable rootstocks, budding, and aerial layering – or marcottage – are all techniques that have been employed to make seedlings available to farmers who have embraced the crop.

If kola is to be propagated from the seed, the nuts are taken from the pod and wrapped in plantain leaves. Then they are buried in the ground and watered every day until they sprout, after which the young seedlings are transplanted to bear fruit some 4 to 5 years hence (N.A.G. [Kumasi] 1905; Quarcoo 1969; AERLS *Guide* 1982; Szolnoki 1985). Seedlings are also raised in bamboo pots before being transplanted in the field. In some cases, bananas and plantains provide shade for the young plants (Ossei 1963).

Kola is also planted by one or another of four methods of vegetative reproduction (Pyke 1934). In the first, a branch of a healthy kola tree is cut into 2- to 3-foot-long pieces, which are then planted. After germination, these bear fruit in 2 or 3 years (N.A.G. [Kumasi] 1905; AERLS *Guide* 1982). Plant cuttings, one of the most frequently used present-day techniques in cloning fruit trees, is also one of the most ancient methods of vegetative propagation (Archibald 1955; Jones 1968; Ashiru and Quarcoo 1971; Ibikunle 1972; Ashiru 1975). It is very important that cloning be done only from high-yielding kola trees and, more importantly, from trees with a high degree of self- and cross-compatibility.

A second method of vegetative propagation is grafting. Various methods of grafting have been used in the production of kola clones (Ashiru and Quarcoo 1971; Gnanaratum 1972), with wedge grafting, saddle grafting, and the splice and whip-and-tongue grafts said to yield the best results (Jones 1968). In Nigeria, the side-and-wedge grafting technique is widely used.

Budding is a third method of vegetative propagation of kola. Nursery budding ensures the production of vigorous budlings and offers the possibility of virtually all of them continuing to bud in the field. By contrast, *in situ* budding cannot guarantee that 100 percent of the buds will take, although these usually do grow faster than those transferred from the nursery (Archibald 1955; Are 1965; Ashiru and Quarcoo 1971; Ibikunle 1972; Ashiru 1975).

Aerial layering (also known as marcottage) is the fourth method of vegetative propagation by which "an intact branch of a kola tree is induced to produce roots before it is severed from the mother tree" (Ashiru and Quarcoo 1971). After being severed, the cutting may be raised in a nursery or planted directly in the field. Branches that are growing vertically, or nearly so, are the best types to select for marcotting, and such branches should be between 2 and 3 years old. As a method of kola propagation, marcottage is old and well known, but it is also very cumbersome (Toxopeus and Okololo 1967).

Kola is – or at least was – sometimes planted on special occasions. In some cultures of sub-Saharan Africa, for example, it was the custom to bury the umbilical cord of a newborn baby with a kola seed. This indicated a safe delivery, and the kola tree that subsequently grew up became the property of the child. Cultural taboos also play a role in kola planting: In some parts of West Africa, a belief (perhaps spread to limit competition) that "he who plants kola will die as soon as the plant has flowered" militated against its cultivation. Instead, farmers looked for self-sown seedlings and transplanted them (Russell 1955).

The Kola Trade

From time immemorial, the forest and the savanna regions of Africa have been complementary in basic natural products. This complementariness – based on the very different requirements of forest and savanna dwellers – stimulated long-distance exchange between the Volta basin and the Upper Niger (Denham and Clapperton 1826; Lander 1830; Dupuis 1894; Hallet 1965; Bowdich 1966; Arhin 1987). Gold, kola nuts, and salt from the coast constituted the most important items of trade in the Volta Basin of West Africa (Wilks 1962; Fynn 1971).

Evidence from the *Esmeraldo de Situ Orbis* – penned by one of the earliest Portuguese explorers, Duarte Pacheco Pereira – attests to the existence of the West African kola trade as early as the sixteenth century. A materia medica written in 1586 for the Moroccan sultan, Ahmed al-Mansur, mentions that kola was brought from the western Sudan – from "a place called Bitu where there are mines of gold and gold dust" (Wilks 1962: 15).

C. nitida, as an export crop, is reported to have originated in the hinterland of what is now Sierra Leone and Liberia, where it appears to have been commercialized by people who spoke a language of the West Atlantic family of Niger-Congo. People of the Mande branch, who subsequently moved to the forest zone, became the major producers in the fourteenth century. The kola nut trade was then monopolized by Muslim Mande traders who traveled widely throughout the western Sudan (Goodman et al. 1995). By the fifteenth century, the cultivation of *C. nitida* had spread throughout the Ivory Coast region and the Volta basin. It was also being grown in the forests of Sierra Leone, Liberia, and the Ivory Coast, and in the Volta basin of Ghana.

Coastwise trade in kola led to the creation of two diasporic communities – the Bahun commercial network, linking the lower Cacheu River with the Casamance River and the Gambia River, and a parallel Mandinka network to the east, linking the Upper Geba and Upper Casamance with the Middle and Upper Gambia and Upper Niger (Brooks 1980). Although this kola trade antedated the arrival of the Europeans, when Portuguese traders did reach West Africa, they quickly recognized the commercial importance of kola. With the help of African mariners, they began to participate in the kola trade while systematically concealing that participation from royal regulation and sanction (Brooks 1980).

In the eighteenth and nineteenth centuries, the Gold Coast and Sierra Leone supplied kola to northern and, later, southern Nigeria (*Gold Coast Blue Books* 1884–1925; Miles 1931). During the last half of the nineteenth century, however, demand for Gold Coast kola nuts mounted in Britain (Table III.8.2), France, Germany, and the United States, where the nuts were employed in the production of "neo kola," cola-based soft drinks, and pharmaceuticals (*Gold Coast Blue Books* 1884–1925).

The overseas kola trade from the Gold Coast to Europe and the United States developed in three phases. It began with the export of two packages of unknown weight to England in 1867 (Dickson 1969) and continued to grow until, in 1884 and 1885, 400 packages of kola, worth more than £2,000, were sent to Europe and the United States (*Gold Coast Blue Books* 1884, 1885; Freeman 1893; Dickson 1969).

Table III.8.2. *Kola exports to England*

1867	2 pkgs
1884	400 pkgs
1885	400 pkgs
1898	1 ton
1899	9 tons
1900	< 9 tons
1901	< 9 tons
1902	< 9 tons
1903	1 ton
1904	1.5 tons
1906	1.6 tons
1907	2 tons
1908	1.5 tons
1910	< 2 tons
1915	3.5 tons

The second phase of the southern kola trade, which saw the export of kola to Brazil from the 1890s until the 1920s, took the form of exports directly from Ghana, as well as reexports of Ghanaian kola nuts from Nigeria to Brazil (*Gold Coast Blue Books* 1888–1920; Alex 1890).

The third and final phase of the southern kola trade involved exports to Nigeria in the first decades of the twentieth century. The ports of Accra, Winneba, Saltpond, Apam, and Cape Coast became outlets for the these shipments of kola by sea.

The southern axis of the kola trade was also spurred by the purchase of kola by African and European companies trading along the coast of Ghana and by improvements in communication, such as the construction of roads and railways and the introduction of motor transportation, along with mail boats, steamers, and ferries (Danquah 1928; N.A.G. [Accra] 1959; Dickson 1961). The result was a significant increase in kola trade volume.

From the mid-1920s onward, however, the market demand for Ghanaian kola began to decline. One reason was the beginning of large-scale kola cultivation in Nigeria in the 1920s and 1930s (N.A.G. [Accra] 1959; Cohen 1966; Agiri 1977). But another factor was that cacao, now an international crop, had gradually supplanted kola as the backbone of the Gold Coast economy. It is worthy of note, however, that because of interior African markets, the decline in kola exports to Nigeria did not mean a collapse of kola production in Ghana.

Uses of Kola

In the Past

Initially a luxury item, kola later became an item of common usage. Those who grew it, as well as those who used it, often ascribed therapeutic, dietetic, and pharmacological properties to kola. In addition, according to volume 14 of the *American Druggist* (1885), kola was to some extent employed as a substitute for food, in much the same way as coca has been used by residents of the Andes. Indeed, kola is to the African what tobacco or coffee is to the European or betel is to the southeastern Asian – a stimulant and a psychoactive substance (Simmonds 1891; Kumm 1907; Goodman et al. 1995).

The importance of kola as a drug was first recognized outside Africa in the twelfth century by an Arabian physician, who wrote that it was used in the form of a powder for colic and stomachache and had warming properties. A later Portuguese observer testified to the importance of kola nuts thus: "The Black population would scarcely undertake any enterprise without the aid of kola" (Fluckiger 1884: 524), which, among other things, was supposed to protect against the pangs of thirst. However, the first definite mention of kola as a drug came in the work of Odoard Lopez in 1591, and shortly afterward, Andre Alvares de Almada, who had visited Guinea in 1566, wrote his *Tratada Breve dos Rios de Guiné do Cabo Verde* (1594), in which he claimed that kola and betel were used in more or less the same way. At the end of the sixteenth century, James Garet, an apothecary and amateur collector of foreign curios, brought the nuts to the attention of the celebrated Flemish botanist-physician Carolus Clusius (Charles de l'Ecluse) (Fluckiger 1884).

As knowledge of kola reached the outside world, the plant itself began to travel, apparently reaching the Caribbean as early as the seventeenth century. This came about following an urgent request, sent through a Guinean trader by an agent for Jamaican slaveholders, for kola seedlings – urgent, because of kola's well-known property as "a medicinal prophylactic agent or as an ordinary article of food, to avert, as far as practicable, those attacks of constitutional despondency to which . . . Negroes were peculiarly liable" (Attfield 1865: 456–7).

Many accounts of the properties of kola by early writers were borrowed from travelers and were therefore probably exaggerated or distorted to some degree. Since the 1850s, however, research has been carried out by botanists, chemists, and pharmacists on some of the properties ascribed to the kola nut. For example, A. M. F. J. Palisot-Beauvois (1805) asserted that the Negroes of Oware used kola nuts because of the nuts' remarkable ability to impart a pleasant taste to all food or water consumed. Subsequent experiments have confirmed this observation, at least for drinking water, which, even when comparatively stale or impure, becomes quite palatable to the consumer after chewing kola. It is possible that the action of the chemicals in kola on the palatal mucosa creates the "illusion" of sweetness, or perhaps this is the result of kola's high caffeine content.

Another report – this by N. Hudson (1886), a medical inspector in the U.S. Navy – on the results of administering kola paste to a patient suffering from rheumatism, dyspnea, and headache, amply demonstrates some of the pharmaceutical and pharmacological properties of the kola nut. Hudson wrote:

> The patient, a lady of 36, had suffered during childhood from rheumatism. Up to a recent period, however, she had been in good health and able to lead a busy, active life. Eighteen months since, she was attacked with severe endocarditis, from which she recovered slowly, and with a damage to the mitral valves. . . . The action of the heart was feeble and irregular, and there was a good deal of dyspnoea, faintness, and fatigue upon even slight exertion. She had always been subject to occasional headaches, and these now became periodic and severe, occurring at first at intervals of four or five weeks, and lasting two days. Latterly they had increased in frequency and intensity, coming on about twice a month, each

> attack causing three days of suffering so severe as to fill the patient's mind with constant dread of a recurrence. The discovery of a ratio of urea much below that of normal urine, with the existence of an occasional granular cast, established the conviction that the headaches were uraemic in character (1885–6: 711).

After about three months of administering kola paste in hot milk at a dosage of about 10 grams once or twice daily, Hudson reported:

> During the first nine weeks of its use there was no recurrence of headache. Then there was a comparatively mild attack, which may fairly be attributable to a suspension of the use of the kola in consequence of the marked improvement. The general condition has materially improved, the heart's action is more regular, and the attacks of dyspnoea and faintness have nearly disappeared. The most characteristic effect seems to have been an immediate relief of a sense of fatigue, a sense of *bien-être* and cheerfulness to which the patient had been long a stranger. The employment of the kola seemed to be satisfying the appetite, for whenever taken, it appeared to serve as a substitute for the following meal. But the nutritive processes were not impaired: on the contrary, the bodily weight increased from ninety-eight to one hundred and five pounds. No marked change in the character of the urea has been observed. The quantity voided has somewhat increased, but the total urea excreted remains at about ten or twelve grammes daily (1885–6: 711).

As Hudson noted, the results of the administration of kola paste were marked and immediate, producing a definite and positive change in the well-being and comfort of the patient (Hudson 1885–6: 712). Thus, as stated by another observer who was a contemporary of Hudson, kola can become a "sustaining and stimulating adjunct in exhaustive and wasting diseases" (Simmonds 1891: 10).

It was also believed that kola "exercises a favourable influence upon the liver, and that white people, living in those regions [where it grows], who chew a small quantity before meals escape constitutional changes due to affections of that organ" (Heckel and Schlagdenhauffen 1884: 585). Finally, kola was said to be advantageous for sportsmen, athletes, and "brain workers" in reducing tension (Uses of kola nut 1890).

Current Ethnopharmacology in Africa

Kola nuts are used for the treatment of certain infections and conditions, such as guinea worm, migraine, and ulcer (Mr. Ansong, Kumasi Cultural Centre, March 5, 1995, personal communication). In the case of guinea worm, the nut is chewed into a paste and applied to the affected portion of the body, and in Ghana, such a paste is used to treat a skin ailment commonly called *ananse.* Fresh kola nuts are also chewed as a stimulant to counteract fatigue (Szolnoki 1985; Burrowes 1986). Kola is used in beverages – such as coffee, tea, and cocoa – to cure indigestion and nervous or bilious headache. It should be pointed out that the medicinal action of kola is not the same as that of an analgesic taken for pain. Kola is not used because of an isolated chemical ingredient; it is used as a complex whole.

Along with the nut, other parts of the kola tree are also employed for their medicinal properties by traditional healers and the peoples of rural Africa (Mr. Anin-Agyei, Dwaben State Oil Palm Plantation, February 28, 1995, personal communication; Mr. Forster, Dwaben State Oil Palm Plantation, February 28, 1995, personal communication; Mr. Ansong, Kumasi Cultural Centre, March 5, 1995, personal communication). The bark is used to treat swellings and fresh wounds, and the roots provide excellent chewing sticks for cleaning the teeth. The pod bark is mixed with other ingredients to become a traditional medicine for reducing labor pains during childbirth (Akhigbe 1988). The latter is very important because traditional birth attendants play a dominant role in rural Africa's health delivery system. Most of the people live outside the cities, and the overwhelming majority of these cannot afford the expense of Western-style medicine. Thus, kola-bark preparations for reducing labor pains are highly prized by traditional birth attendants, even though very little research has been done to determine the properties in kola bark that make childbirth more comfortable for African mothers.

Many people use kola because of its very high caffeine content – one nut contains more caffeine than two large cups of American coffee. It is generally believed that chewing small amounts increases mental activity and reduces the need for sleep (Attfield 1865; Ogutuga 1975; Lovejoy 1980). Consequently, kola is widely used by Ghanaian watchmen (who call it the "watchman's friend") in the course of their vigils, as well as by students who work late into the night. Chewing kola also massages the gums and exercises the teeth.

Yet, that kola can be poisonous to animals raises flags of caution. The chemical composition of kola paste makes it a good bait for trapping mice, who often die when they eat it. Similarly, dogs do not survive when they are given *maasa* (a baked flour meal) mixed with kola paste (Mr. Ansong, Kumasi Cultural Centre, January 30 and March 5, 1995, personal communication). There has, however, been no laboratory analysis to explain the action of the kola paste on either mice or dogs.

Social Uses

Kola provides flavoring for beverages in Africa, Europe, North and South America – indeed, in all parts of the world (Freeman 1893; Irvine 1948; Bovill 1958;

Dickson 1969). In the 1870s, kola was mixed with sugar and vanilla as a tonic for invalids and convalescents and was recommended to travelers as an antidote to fatigue and even hunger (Freeman 1893). In 1886, John S. Pemberton, a druggist in Atlanta, Georgia, invented Coca-Cola when he combined coca and kola extracts as a headache and hangover remedy (Louis and Yazijian 1980). Over time, Coca-Cola (minus the narcotic coca) has become the most popular nonalcoholic beverage in the Western world.

The most common social use of kola in several African countries is as a gift of welcome to friends and guests. Doubtless in part, at least, because of the Islamic prohibition against alcohol consumption, kola is widely used by Muslims (Dalziel 1948; Cohen 1966; Dickson 1969; Morgan and Pugh 1969; Church 1975; Agiri 1977; Lovejoy 1980; Anquandah 1982). A Sokoto tradition not only associates kola with the prophet Muhammed but also asserts that he relished it and gave the nuts as gifts to his favorites. His wealthier followers, in turn, gave kola as alms during high festivals (Tremearne 1913, cited in Ferguson 1972; Russell 1955; Lovejoy 1980).

Dietetic Uses

Kola possesses physiological properties that enable those who eat it to undergo prolonged exertion without fatigue or thirst. Kola has also been said to serve as a preventive of dysentery and other intestinal disorders (Fluckiger 1884), and it has been claimed that kola makes people brave in – even eager for – battle. For all these reasons, kola nuts have historically been dispensed to troops on African battlefields. Askia Mahmoud is reported to have supplied kola to his troops in the sixteenth century, and at the beginning of the nineteenth century, soldiers of the Asante army often chewed kola for days during their campaigns, when there was frequently not enough food to go around (Kreiger 1954; Quarcoo 1971).

In 1852, the German explorer Heinrich Barth thought that soldiers of the Sokoto army were addicted to kola because it was usually distributed to them in the evenings before campaigns (Goodman et al. 1995). Similarly, James Richardson observed that the Emir of Zinder used kola to incite his soldiers before slave raids. In 1890, the German war office ordered 30 tons of kola for the army after conducting experiments with the plant during autumn maneuvers the previous year (Uses of kola nut 1890). At about the same time, troops of the West African Frontier Force stationed in East Africa were given kola rations to enhance their battle readiness (Anyane 1963).

Toward the end of the nineteenth century, a series of interesting experiments on the possible military importance (in dietetic and pharmacological terms) of kola was conducted by R. H. Firth on British soldiers in India. Ordered by the surgeon-general of Her Majesty's forces, these studies indicated that chewing kola nuts not only seemed to depress the appetite and keep thirst at bay but also increased the individual's energy level and sense of well-being. In addition, the nuts may have proved efficacious in curing hangovers (Firth 1890).

Nearly a century later, studies carried out on the biochemical effects of kola nut extract administered to rats once again demonstrated the stimulating properties of kola in relatively large doses (Ajarem 1990). This is doubtless explicable in part by the caffeine content; however, many more such efforts are required to show why it is that kola has a long-standing reputation as a laxative (but prevents dysentery and other intestinal disorders) and as a heart stimulant (but can also be a sedative). Also demanding explanation are kola's alleged ability to make foul water palatable and its historical fame as an aphrodisiac, a restorer of potency, and an aid to childbirth (Nzekwu 1961; Quarcoo 1969; Goodman et al. 1995).

Certainly kola seems potent as a drug, but save for the research just mentioned, its potentiality remains to be investigated. Given its many current uses in Africa, as well as its role in the soft-drink industry around the world, it is to be hoped that such research will soon be forthcoming.

III.9 Milk and Dairy Products

Purity and Danger

Milk occupies a curiously ambiguous place in the history and culture of food. It has been pointed to as an archetypal, almost elementally nourishing food, supremely healthful, reflecting the nurturing relationship of mother and infant. In recent times, its whiteness has come to stand as a symbol of natural goodness and purity. But milk also conceals danger. Its nutritional largesse is equally appealing to hosts of putrefying bacteria, and unless milk is consumed almost immediately, it rapidly deteriorates into a decidedly unwholesome mass. Even in the apparently safe period between lactation and curdling, pathogenic organisms may lurk and multiply with potentially more devastating consequences for a new infant than the more immediately apparent problems of an obviously bad food.

The very processes of corruption, however, also provided the ways by which milk became a more widespread and acceptable food. Some contaminating organisms transform milk toward simple forms of butter, cheese, or yoghurt, and it is in these forms, not as a beverage, that milk has been consumed throughout the greater part of the history of human eating. As a highly ephemeral food then, unless milk is transmitted directly between provider (whether human or animal) and consumer, it is fraught with danger. Preservation has thus been the overriding factor in milk's development as an important food for humans.

Initially, preservation was achieved through manufacture into butter or cheese. Later, briefly, fresh milk was kept safe only by cleanliness of production and speed of transport; in the twentieth century, however, milk has been preserved primarily by means of heat treatment, particularly pasteurization. This preservation of milk, particularly on an industrial scale since the late nineteenth century, highlights another contradictory tension in the nature of its consumption. Milk production is a quintessentially female process, and the resonances of the mothering bond imparted a crucially feminine nature to the whole area of dairying in preindustrial times. Even though milk could only become an important foodstuff by transforming the female milk into a different, harder manufactured solidity, commercial dairies and domestic output remained spheres of women's activity. The femininity of dairy production, however, could not withstand industrial dairying methods, and from the end of the nineteenth century, men began to take over dairying as it became concentrated in bigger, more technically sophisticated industrial plants.

There is a further fundamental dichotomy in the culture and history of milk (one almost unique among foodstuffs) in the very ability of people to digest it. Some people do not have the enzyme – lactase – required to digest lactose, the principal sugar in milk, and the pain and discomfort arising from the inability to absorb milk sugars are reflected in cultural traditions that render even the thought of imbibing milk repulsive. Lactase deficiency affects most of the world's peoples, many of whom regard milk drinking as revolting. Thus, milk has been geographically limited, even though it is universally available. It has been consumed in parts of Asia and Africa, but its consumption has been most significant in Europe and in areas of European colonization, such as Australasia and North America.

These tensions and contradictions in the very nature of milk – a pristine, white, and nutritious beverage, which also harbors and conceals corruption; a whole and complete food which, in principle, demands no preparation but which, in practice for most of its history, has required transformation into something else, and which vast numbers of people literally cannot stomach – are reflected in the history of milk production and consumption. In preindustrial societies, dairy produce had a part to play in peoples' diets, although it was probably not particularly important in terms of overall nutrition. Yet, milk had a cultural resonance, beyond its dietary value, that saw it enshrined in several religious traditions as a signifier of promise and plenty, or as a symbolic link between spiritual and earthly nourishment. From the early eighteenth-century commercialization of agriculture, dairying took on greater economic importance, particularly in provisioning urban centers.

In the nineteenth century, increasing urbanization and the development of rapid transportation and communication systems, particularly railways, began for the first time to create a market for liquid milk on a large scale. Dairying and the production of liquid milk acquired nationalistic significance around the beginning of the twentieth century as a result of growing concern in Western countries about the health of infants. Yet although milk had come to be vitally important, the uncertain hygiene associated with it highlighted the necessity of clean production and supply. The original dichotomies regulating the consumption of milk remained, however, because the dissemination of liquid milk required enormous mechanical intervention, and its natural purity could be maintained only by industrial processing.

Throughout the twentieth century, as milk eventually became a readily available, clean, and safe commodity, its consumption as a beverage reached a cultural epitome: Its whiteness evoked an image of goodness – a signifier of health and hygiene. Its ascendancy was short-lived, however; in the overfed northern hemisphere, the same nutritional value that had made it so important in the previous decades consigned it to the ranks of dietary sins. At the same time, inappropriate developing-world feeding schemes (based on dried milk) and the recognition of lactase deficiency have undermined the notion of universal goodness and revealed the dangers of a nutritional imperialism.

Milk in Preindustrial Societies

To drink milk is an inherently natural impulse; an infant placed at the breast knows instinctively what to do. As suitable animals (such as mares, asses, ewes, goats, and various kinds of cows) were domesticated, it appears that drinking animal milk became an acceptable practice. Presumably, folk taxonomic associations between humans and other mammals would have indicated that milk was an animal secretion that could be consumed as food, and there are numerous records and legends of infants suckling directly from animals, as well as from a range of artificial devices (Fildes 1986).

As with most other early foods, the origins of dairy products are unclear. Certain natural fermentations give rise to yoghurt or soft, cheeselike substances that are sufficiently different from putrid milk to have encouraged their sampling. There are stories that cheese originated among Near Eastern nomads who may have stored milk in the stomach bags of cows, a common form of container, in which the natural rennet would have given rise to a sort of cheese. Similarly, one might imagine a horseman setting out with a bag of milk, only to find, when he came to drink it, that the agitation of riding had curdled it into a not unpleasant mixture of curds and buttermilk (Tannahill 1973). Whatever the origins, dairy products have had a place in human diets from very early times.

Equally early on in human history, however, a fundamental split occurred in the history and culture of dairy consumption because, as already noted, drinking more than very small quantities of milk causes the majority of the world's adult population to suffer digestive problems. It has been estimated that although more than 96 percent of northern European peoples are able to digest milk, some 50 to 75 percent of Africans, Indians, Near Eastern Asians, eastern Europeans, and virtually all Asian and Native American peoples cannot digest it. Their bodies stop producing lactase – the enzyme that breaks down the milk sugar, lactose – soon after weaning (Tannahill 1973). It has been suggested that an adult ability to break down lactose spread as people moved northward into colder climates. Covering themselves with more clothes, these people experienced shortages of vitamin D previously derived from the action of sunlight. Vitamin D production in the skin, however, is enhanced with a higher intake of calcium, of which milk is a particularly rich source. There would, thus, have been a selective advantage for those people who retained the capacity to digest milk, and over time, the proportion of the population in northern climates with the ability to digest lactose would have increased (Harris 1986).

Such a starkly biological account, however, does not explain the powerful rejection of milk among many Asian peoples and needs to be supplemented with cultural factors. One suggestion is that Chinese agricultural practices worked to exclude milk from the culture; because planting took place year-round, primarily with human labor in areas of high population density, there were few draft animals that could have provided milk. The main flesh animal was the pig, which was impossible to milk; thus, after weaning, Chinese toddlers were not exposed to milk from other sources. By contrast, in subcontinental Asia, draft animals were more prevalent – indeed, were necessary to prepare land for the shorter planting season dictated by a monsoon climate. Because of greater availability of milk, cultural aversion to it did not develop, and dairy products remained an important feature of the diet (Harris 1986). An alternative hypothesis, and one, apparently, traditionally held by Chinese people, is that the aversion to milk arose from the desire to distinguish themselves from the nomads on the northern borders of China, who drank fermented mare's milk (Chang 1977). It does seem that milk products had become a feature of the diet of the northern Chinese aristocracy between the Han and Sung periods, but it appears that, after the ensuing period of Mongolian rule, milk definitely acquired a barbarian reputation (Chang 1977).

In most of the preindustrial world, however, milk (or, more usually, dairy products) had a place in the diet of all those who had domesticated animals and could absorb lactose. Among nomadic pastoralists of the Near East, sheep and goats provided the main source of milk and cheese. On the great open grasslands of central Asia, and extending into eastern Europe, mare's milk, often fermented into the alcoholic liquor *kumiss,* was consumed in large quantities (Tannahill 1973). On subcontinental Asia, the buffalo was the principal source of milk to be made primarily into ghee – a reduced butter in which most of the moisture is removed by heating – for cooking or ceremonial purposes (Mahias 1988). Pastoralists of Africa, with vast herds of cattle, used a considerable amount of milk in their diets (Pyke 1968). Milk and cheese are also mentioned as foods, medicines, and beauty aids in records of the ancient civilizations of Egypt, Greece, and Rome (Warner 1976).

In Europe, dairy products were a notable part of the peasants' diet wherever they were available. Across the continent, the great majority of people lived on the verge of starvation, particularly during the late winter months and the periodic harvest failures. The basic diet of cereal-based porridge or soup was rarely supplemented with actual meat, and the more prevalent dairy products (or "white meats," as they were called) were welcome sources of animal fat and protein, whether as cheese, butter, beverage, or additions to soup (Mennell 1985). In the early months of the year, however, cheese or butter kept throughout the winter was mostly used up, and cattle not slaughtered the previous autumn struggled to survive until the new grass appeared (Smith and Christian 1984). Thus, though an important source of animal fat and proteins, dairy products (like meat) cannot have been much more than a flavoring for the basically cereal diet of the peasants.

Among the nobility in the late medieval period there was a growing disdain for dairy produce. With upper-class access to often vast quantities of meat, the "white meats" of the peasantry were increasingly scorned, probably especially by the aspiring merchants of the towns. Nonetheless, dairy products did not disappear from the tables of the well-to-do, and in the late sixteenth and early seventeenth centuries, butter became more important in noble larders, although used primarily for cooking and making the elaborate sauces of the new haute cuisine then developing in France and Italy (Mennell 1985).

Perhaps because milk was recognized as a particularly rich and nourishing food, as well as something of a luxury to have in more than small quantities, but also (and one suspects primarily) because of the symbolic importance of the nurturing bond between mother and child, milk has achieved some prominence in myths and religious systems. In the Old Testament, the promised land was one of "milk and honey." The image of a mother goddess suckling her child is a common representation of Earth bringing forth sustenance. The Egyptian mother goddess, Isis, suckled her divine son Horus, while the Greek god Zeus was nurtured by Amalthia (variously depicted as a mortal woman or as a nanny goat). The symbolism of the mother with her infant god passed into Christian representations of the Madonna and Child, which perpetuated the divine linkages between the spiritual and earthly worlds, mediated by the physical nurturing of milk (Warner 1976). Milk and dairy products have a vital role in sacrificial and purifying rituals in Indian religious myths, especially as the life-giving force of the fire god Agni (Mahias 1988).

The place of dairy products in the diet of peoples in nonindustrial societies has remained virtually unchanged over time; they can be an important source of animal protein but remain a minor component of largely cereal or vegetable diets. In northern Europe, however, and particularly in England, the role of milk and dairy products began to change with the wider emergence of commercial agriculture, urbanization, and proto-industrialization, beginning about the end of the sixteenth century and continuing throughout the seventeenth century.

In seventeenth-century England, demand for dairy products increased with the emergence of rural industry and the location of an increasingly higher proportion of the population in towns (Drummond and Wilbraham 1939). Cheese was of growing importance in the diets of urban laborers, particularly in London. It was cheap, nutritious, and also convenient; it could be stored for reasonable lengths of time and could be carried to places of work and eaten easily there. Large quantities of cheese were also required by the navy and by new, large institutions, such as hospitals and workhouses (Fussell 1926–9; Fussell and Goodman 1934–7). This demand was largely met by the commercialized agriculture that had been developing on the larger estates carved out after the Reformation. The numbers of milch cows multiplied, and dairies became necessary and integral parts of English country houses. Dairying was practiced by anyone who had access to a cow, which replaced the sheep as the primary milk provider (Tannahill 1973), and, for the respectable poor in rural areas, could provide an important source of income. The cheese trade also relied on a reasonably efficient transportation system, and London was served by sea as well as by road (Fussell 1966).

Throughout the early phases of expanding commercialization, dairying remained a female domain characterized by an arcane knowledge (Valenze 1991). Although from southern Africa to northern Europe the notion persisted that a woman who handled milk during menstruation might curdle it, the mystery of dairying lay in the special competence of dairymaids (Fussell 1966; Pyke 1968). The dairy in a country house was invariably attached to the kitchen, supervised by the farmer's wife (or the female head of the household in larger concerns), and the production of cheese and butter was a female operation. From the seventeenth century, books of household management included dairying as a routine aspect of the mistress's responsibilities. Hygiene in the dairy was constantly stressed, with detailed instructions provided as to the proper construction and maintenance of the dairy and the duties of the women working in it (Fussell 1966).

By the end of the eighteenth century, wherever dairying continued to be carried out in a preindustrial, subsistence agricultural context, milk products retained their customary position as a minor adjunct to the diet, varying only by degrees among places where dairying was more or less pronounced. But in the industrializing and urbanizing world, large-scale commercial agriculture was beginning to alter the nature of production and consumption of dairy produce and bring about a crucial transformation in the historical culture of milk.

Milk in an Urbanizing World

The tripartite revolution of industrialization, urbanization, and the commercialization and increasing productivity of agriculture had dramatic consequences for food production and consumption. Enough food was produced to fuel enormous population growth, with increasing proportions of that population ceasing to be agriculturally productive. Urban dwellers, as net food consumers, depended on food being brought in from producing areas. Throughout the nineteenth century, this took place not only on a national but an international scale, until most parts of the world became integrated into a global network of food trade, principally geared toward feeding Europe. Thus, surplus dairy producers sent huge quantities of cheese and butter, increasingly manufactured in factories, to northern Europe.

At the same time, there was a growing demand for liquid milk in urban areas, and nearby dairy producers began to concentrate on its supply, partially to offset the competition in manufactured products. Yet, accompanying this expansion of production was an increasing consumer concern about the quality of the milk supply, particularly toward the end of the nineteenth century, when milk was implicated in questions of infant mortality. In the elaboration of a range of measures to control problems of milk adulteration and unhygienic procedures, dairying was completely transformed into a highly mechanized manufacturing and distribution activity, which steadily undermined its traditionally feminine nature. Such a pattern recurred throughout the nineteenth-century developing world – commercial, industrial dairying geared toward a manufactured dairy market, paralleled by the development of liquid milk production in urban areas, which, in turn, gave rise to concern about milk quality.

During the eighteenth century, northern European agriculture became much more productive, with novel crop rotation techniques, new machinery, better land management, and the more intensive methods achieved with enclosure. Dairying benefited from greater attention to fodder crops, which allowed cows to be fed more adequately throughout the winter. Yields still fell during winter months, but more cows survived, and yields quickly recovered with the spring grass (Fussell 1966). Thus, the potential arose for year-round dairying.

By the second half of the eighteenth century, increasing food production was supplying not only a steadily growing rural population but also, in Britain, an explosive increase in urban populations. During the first half of the nineteenth century, the sources of Britain's wealth gradually shifted from agriculture and the landed estates toward manufacturing and industry. This was symbolized by the repeal in 1846 of the Corn Laws, which saw landed and agricultural interests supplanted by the demands of industry for free trade. Yet, as Britain ceased to be agriculturally self-sufficient, free traders had to cater not only to the requirements of industry but also to the need for imported foodstuffs to feed urban industrial workers (Burnett 1989).

Across the globe, producers of agricultural surplus geared up to meet this need (Offer 1989). Australia and New Zealand sent butter and meat to British markets; Ireland and Denmark developed dairying to meet British demand. Danish farmers, recognizing the likely requirements of their rapidly urbanizing neighbor across the North Sea, organized in cooperatives to develop highly efficient methods for producing butter and bacon. In the process, Denmark's national economy became modernized and export driven, yet still based on agriculture (Murray 1977; Keillor 1993).

Ireland had been characterized by very high dairy production and consumption patterns from medieval times, although by the eighteenth century, the continued reliance on dairy foods may be seen as a mark of poverty. As was the case in Denmark, nineteenth-century Irish dairying became more commercialized to supply Ireland's urbanized neighbor, though at the expense of an important source of animal food for its own consumption (O'Grada 1977; Cullen 1992).

In the United States, between the end of the eighteenth century and the middle of the nineteenth, westward expansion had brought new, high-yielding agricultural lands into production. By midcentury, cheese was being shipped down the Erie Canal from upstate New York. But across the vast open spaces of North America, rail transport was the key to the development of dairying. Also crucial was the hand cream separator (Cochrane 1979), which allowed even small farmers to cream off the butterfat that railroads could then take to regional factories to be made into cheese and butter. Industrial methods for manufacturing these products spread across the northeastern and north central states (Lampard 1963; Cochrane 1979). By the second half of the nineteenth century, production and transportation were such that cheese manufactured in the United States or Canada, and butter made in New Zealand, could reach British markets at lower prices than those required by British farmers (Burnett 1989). In addition, an outbreak of rinderpest in England during the 1860s wiped out most of the urban cows, which helped North American dairy products gain a prominent place in British markets (Fussell 1966).

As in the United States, railways in Great Britain were fundamental in enhancing the importance of liquid milk as a beverage. From the 1840s, liquid milk could be brought from the countryside to the towns and sold before it became sour. The perishability of milk had always restricted its scope as a drink. But speed, together with the development of coolers and refrigerated railway cars, increased its viability, and in all areas within reach of an urban center, dairying was increasingly concerned with liquid milk supply. By the second half of the nineteenth century, milk was being carried to London from as far away as Derbyshire, and Lancashire and Cheshire emerged as major dairy counties to supply the conurbations of Liverpool, Manchester, and Stoke (Whetham 1964; Taylor 1974, 1976, 1987). Effectively, the whole of Britain could now be regarded as an urban area, which had an enormous demand for milk.

In North America, the manufacturing of dairy products was concentrated in the lake states of Wisconsin, Minnesota, and Illinois, whereas liquid milk to supply major urban areas was produced in the northeastern and Atlantic seaboard states (Lampard 1963; Cochrane 1979). Thus, better communications and large-scale manufacturing prompted a functional division in dairying. Although manufactured goods, such as cheese, could be carried long distances to urban markets more cheaply than those of a small, local producer, dairying in urban areas enjoyed a protected market for liquid milk that was not susceptible to more distant or foreign competition.

In England, toward the end of the nineteenth century, liquid milk came to be seen almost as an agricultural panacea, and not just for hard-pressed dairy farmers in urban areas. During the great depression of English farming from the mid–1870s to the 1890s, when the full economic impact of imported food began to be felt, farmers increasingly turned to the naturally protected production of liquid milk. More acres reverted to pasture, which was condemned by commentators bemoaning the apparent decline of cereal-based farming, but liquid milk production provided farmers with a welcome respite from foreign competition and helped alleviate the agricultural slump, furnishing a regular cash income throughout the year, helping to clear debts, and bringing some semblance of profitability (Taylor 1974, 1987).

Although few other nations relied so heavily on imports as Britain, by the end of the century, farmers in many countries were feeling the effects of competition in the international food market. In the United States, grain farmers of the mid–nineteenth century found themselves threatened by even higher-yielding lands opening up in the west and sought to diversify, notably into dairying. Delegates were sent from the north central states to study Danish methods, and many Danes forged new careers in the United States, ultimately to the consternation of the Danish government, which feared rivalry for the British market (Keillor 1993). State agricultural colleges and the new experiment stations also sought to improve upon the (popularly perceived) low standards of American dairying. Scientific "book farming," popular with progressives, found an ideal outlet in dairying, with rational and efficient farming methods based on calculated feeding plans, milk recording schemes, and analyses of butterfat content (Johnson 1971; Peagram 1991). Dairying was becoming self-consciously modern.

Some of the grain states, where there has been an overreliance on single crops, saw dairying as a useful means of diversifying. The North Dakota agricultural experiment station, for example, tried in the early twentieth century to offset the state's reliance on spring wheat by promoting dairying. Although for a while North Dakota did become a notable butter producer, it seems that cereal farmers did not adjust happily to the rather different demands of dairy farming (Danbom 1989).

Ultimately, the general pattern of dairying common to urbanizing countries was established in the United States. Liquid milk was the mainstay of farmers with access to urban markets, and the manufacture of other dairy products was concentrated in the north central states (Michigan, Minnesota, and Wisconsin) on the principal rail routes to the East (Haystead and File 1955; Lampard 1963; Cochrane 1979).

The growing industrialization of dairying and the manufacture of dairy products steadily eroded the femininity of dairying. Butter production, especially, had remained an essentially female activity throughout most of the nineteenth century, occupying an important role not only in the domestic economy but also in the wider social relations and status of women in farming communities. Household manufacture of milk products, however, was increasingly replaced by the transportation of milk to railways and factories and by industrial production (all male spheres of activity), and a marked decline occurred in the number of women involved in dairying. In a typically paradoxical process, the more natural, feminine state of liquid milk gained greater prominence, but only through the intervention of mechanical artifacts operated by men. As dairying left the household, an important element of rural female employment, skill, and authority went with it (Cohen 1984; Osternd 1988; Nurnally 1989; Bourke 1990; Valenze 1991).

Also embattled were milk consumers, increasingly concentrated in urban centers, subject to the vagaries of transport systems for their food supply, and suffering the appalling conditions of massive urban expansion. Many people living in towns simply did not have enough to eat; what was available was of indifferent to abominable quality and, frequently, heavily adulterated. Milk and dairy products were part of the diet, but their supply was highly uncertain. The principal sources were urban milk shops, with cowsheds that provoked bitter condemnation from health reformers. Such places were notorious for squalid conditions, with the cows fed on slops and refuse (frequently the spent grain from distilleries), and disease rife among them (Okun 1986; Burnett 1989). Moreover, milk, whether from urban shops or from roundsmen coming in from the country, was routinely adulterated in the mid–nineteenth century (Atkins 1992). Arthur Hill Hassall, investigating for the *Lancet* in the early 1850s, found that milk was diluted with from 10 to 50 percent water, with that water often from polluted wells and springs (Burnett 1989).

Throughout the second half of the nineteenth century, urban diets in Britain improved noticeably, both in quantity and quality. This was primarily a result of the rise in real wages as general economic prosperity began to percolate down the social strata, but it was also because of an increasing availability of cheap imported food. Food had always been the principal item of expenditure for urban workers, and so any extra real income was invariably spent on food first, both to extend the variety of the diet and to obtain greater quantities. Thus, from the 1890s, more meat, eggs, dairy produce, and fresh vegetables appeared on the tables of the urban working classes (Oddy and Miller 1976, 1985).

The quality of food was also addressed in a more effective fashion. During decades of revelations by such individuals as Frederick Accum about the extent of food adulteration, a series of food purity laws were introduced in Britain. These were initially rather ineffective, but the 1875 Sale of Food and Drugs Act, and the Public Health Act of the same year, began to bring about real improvements in the basic quality of foods (Burnett 1989). This story was a familiar one in most major urban nations during the second half of the nineteenth century. In the United States, for example, reformers (also stimulated by Accum) launched investigations and turned up their own evidence of food adulteration. Effective legislation was introduced by cities and states by the end of the century, culminating in the 1906 Pure Food and Drugs Act (Okun 1986).

Urban populations probably benefited from the volumes of liquid milk brought in by the railways, but fresh milk still became less than fresh very quickly, and although gross adulterants were being eliminated, the problem of the keeping properties of milk remained. Dairy-producing countries had sought means of preserving milk throughout the nineteenth century. During the 1850s, developments in condensing techniques, especially by the American Gail Borden, brought about the formation, in 1865, of the Anglo-Swiss Condensed Milk Company, which soon had factories across Europe. Tinned milk consumption rose rapidly after 1870, and in the early twentieth century, several methods for making dried milk encouraged the emergence of a powdered-milk industry. In New Zealand, a dairy exporter developed the new Just-Hatmaker process of drying milk and this, in turn, gave birth to the giant corporation Glaxo (Davenport-Hines and Slinn 1992). In England, the pharmaceutical company Allen and Hanbury's used a method of oven-drying evaporated milk (Tweedale 1990). Condensed and powdered milk were both popular, as they kept longer than fresh milk; moreover, tinned milk could be diluted more or less heavily according to the vicissitudes of the family economy.

By the beginning of the twentieth century, adult diets had improved (although women remained less fed well into the new century), and the worst excesses of urban squalor, poverty, and deprivation were being addressed. These improvements of diet, sanitation, and housing were reflected in the general falling of mortality rates (McKeown 1969), but infant mortality rates remained stubbornly high. The problem was particularly noticeable in France (which also had a declining birth rate) after 1870 and in Britain during the 1890s. Yet concern for high infant mortality was also expressed in Canada, the United States, Australia, New Zealand, and the Netherlands. The underlying issue was the same: With an increasingly tense international situation brought on by the formation of rival power blocks in Europe and the imperial maneuverings by the United States, greater significance was accorded to the health of a nation's people. Populations began to be seen as national assets, and both their sizes and quality were viewed as of national political, economic, and military importance. Attention was focused on the health of urban populations and, particularly, the health of infants who would be the soldiers, workers, and mothers of the future.

Beginning in France in the 1890s, governments, charities, and local authorities campaigned to promote breast feeding, primarily, but also to provide subsidized milk to mothers with new children (Fildes, Marks, and Marland 1992). There were also increasing demands to improve further the hygiene of the dairy industry and milk supply. Bacteriologists had been studying the flora of milk to investigate its keeping properties and the transmission of infectious disease from animals to humans, with special attention to tuberculosis (TB) and the question of whether bovine TB could be passed to infants in milk. In Britain, the problem was thoroughly examined in a series of royal commissions on TB that effectively created a semipermanent body of bacteriologists investigating questions of milk and meat hygiene. In 1914, the Milk and Dairies Act was passed to prevent the sale of milk from tuberculous cows, while giving local authorities considerable powers of inspection (Bryder 1988; Smith 1988; Atkins 1992).

Similar measures were pursued in many other countries. In Australia, milk institutes were established in Brisbane and Melbourne in 1908 to ensure clean milk supplies (Mein Smith 1992). The same year saw the Canadian Medical Association devise a system of standards for milk hygiene in the dairy industry, which was implemented by local authorities. Toronto and Hamilton established pure milk depots before World War I (Comacchio 1992). Free or subsidized milk was available in the Netherlands from *Gouttes de lait* – modeled closely on the pioneering French milk depots (Marland 1992). In American cities, the emphasis was more on ensuring the quality of milk supplies than on providing subsidized milk, and schemes for regulating standards were devised by many cities, including New York, Philadelphia, and Memphis, and the state of Illinois, with particular emphasis on eradicating TB and promoting the pasteurization of milk (Helper 1986; Shoemaker 1986; Meckel 1990; Peagram 1991).

Such attention given to infant welfare was incorporated into the wider schemes of social welfare developing in the early twentieth century (Lewis 1993). Enthusiasm for the provision of free milk seems to have been relatively short-lived and was replaced with an increasing emphasis on the education of mothers on matters of child care and good housekeeping. But the public-health principles underlying campaigns for clean milk persisted, and the ever-increasing volumes of liquid milk coming into the towns were carefully scrutinized.

Milk in the Twentieth Century

The twentieth century was marked by a massive expansion in the production and consumption of dairy commodities, particularly liquid milk. Rationalized, scientific dairy farming, based on calculated feeding, careful milk recording, and artificial insemination, has produced cows that are virtually milk machines. The production, manufacturing, and distribution of dairy products has become ever more concentrated, yet the continual growth of dairying has required equally prodigious efforts to find markets for the produce.

Around midcentury, milk was viewed as one of humankind's most important foods. Advertisers and scientists alike had convinced the public that milk was a supremely healthy, nourishing, even life-giving substance. Its almost mystical whiteness was, for perhaps the only time in its history, matched by its hygienic purity and popular appeal. Toward the end of the twentieth century, however, health problems connected with milk drinking were uncovered, and inappropriate Western marketing schemes involving milk were exposed as highly detrimental to infants' health in developing countries.

In the early twentieth century, however, dairying appeared to have a glorious future and, with ever-expanding urban populations, more and more farmers turned to liquid milk production. For particularly hard-pressed British farmers, dairying had become the cornerstone of agriculture, outstripping the economic return from cereals (Taylor 1974). In the United States, too, dairying was a fallback for farmers on relatively low-yielding land and a common means of diversifying a narrowly based state agriculture

(Cochrane 1979; Danbom 1989). Such a recourse to dairying, however, carried with it the danger of overproduction. Several strategies were pursued in an effort to deal with dairy surpluses, but by far the favored means was to promote demand. This had expanded on its own in prosperous times as increasing numbers of people with surplus income were able to extend the scope of their diets to include more fresh meat, vegetables, and dairy produce. Beginning in the 1920s and 1930s, a concerted effort was made to encourage consumption of dairy goods and, especially in Britain, the drinking of milk. Such an effort, however, required that the commodity be safe.

Experiments with various types of heat treatment had been conducted to extend the keeping properties of milk (Dwork 1987a). The principle had been established by Louis Pasteur in his studies of beer and wine, and bacteriologists and inventors were not slow to follow up on it. Well into the twentieth century, however, there was significant resistance to the heat treatment of milk (Pyke 1968). It was commonly believed that heating destroyed most of milk's essentially nutritious and health-giving properties, even a vitalist life force (McKee, personal communication). At the same time, there was a school of opinion within the dairy industry that a certain level of natural contamination was necessary to make milk into cheese or butter, and that pasteurized milk was unsuitable for dairy manufacture (Davis 1983). Although the arguments for pasteurization were accepted more readily in the United States than in Britain, debate continued into the 1930s (Meckel 1990). Opponents argued that heat treatment was a technical fix for sloppy procedures and an excuse to produce unclean milk (Davis 1983). Ultimately, however, an increasingly concentrated dairy industry cut through the controversy by routinely pasteurizing all milk it received, which was becoming a necessity because of the large volumes handled and the long distances now covered by milk distributors (Whetham 1976).

A considerable amount of research on nutrition and health was done during the interwar years, particularly in depressed areas of Britain. Experiments by Corry Mann and Boyd Orr on school children showed that groups given milk for a certain period put on more weight, had higher hemoglobin blood counts, and, according to their teachers, demonstrated a greater attentiveness at school; their parents commented that they were also livelier at home (Burnett 1989). In the controversial debates about diet in depressed Britain, milk was an important factor. It was thought that although welfare could not provide a sufficient quantity of food to maintain good health, this goal might be achieved with food supplements, such as milk, needed in fairly small quantities (Webster 1982).

By the 1930s, a culture of dairy consumption was well established in the major dairy manufacturing countries. On the Continent, this primarily involved manufactured butter and, to a lesser extent, cheese; in the United States and in Scandinavia, where liquid milk consumption had a high profile, there was a sound base upon which marketing campaigns could expand demand (Teuteberg 1992). In Britain, although dairying was a major sector of agriculture (and one in which liquid milk was particularly prevalent), people neither ate as much butter as continental Europeans nor drank as much milk as Americans and Scandinavians. Milk was chiefly something to put in tea or give to children, old people, or invalids; indeed, throughout Europe, liquid milk was associated with sickliness or effeminacy (McKee, personal communication).

Thus, one task of the Milk Marketing Boards for England, Scotland, and Northern Ireland, set up after the act of 1933, was to overcome prejudices against milk and stimulate demand for the products of an industry now suffering the consequences of overproduction from the decreasing prices that manufacturers were paying for milk. The Milk Marketing Boards (MMBs), as producer organizations, tried to regulate the dairy market like benign monopolists. Farmers were paid a fixed price for their milk, which was in turn sold to dairy product manufacturers at one price and to liquid milk distributors at a higher one, thus evening out the differences in income that depended on farmers' access (or nonaccess) to a liquid market. As the MMBs undertook to buy all the milk produced by dairy farmers, they had to find markets for it. From the start, a tariff was levied on each gallon to pay for advertising, and a massive campaign was launched, following American models. It stressed the value of milk for health, strength, and beauty, and featured sportsmen and women, manual laborers, and film stars (Jenkins 1970; Whetstone 1970; Baker 1973).

The emphasis on naturalness, whiteness, and purity reflected the contemporary concern for light, space, and healthy living. Milk was marketed to youth through futuristic, American-style milk bars – all chrome, steel, and modernity. The marketing of ice cream was another area in which the British copied from America and the Continent in trying to improve sales (McKee, personal communication). In 1934, drawing on recent discoveries of the vitamin content of milk, the company Cadbury launched a new advertising campaign for its dairy milk chocolate, which was marketed as a food as well as a treat (Othick 1976; Horrocks 1993).

Throughout the 1930s, the virtually unique retail system of doorstep deliveries was established in Britain. Derived from the roundsmen of the eighteenth century who pushed churn-carrying carts through the streets, milk distributors between the wars developed the service of daily deliveries of pint bottles of pasteurized milk to the doorstep (Baker 1973). The MMBs promoted the system and, until recently, the image of the milkman doing his rounds and the bottle on the doorstep were central to the culture of milk in Britain, elevating the milkman to the status of folk hero or comic character. Only with the 1980s or so was there a notable decline in the importance of milkmen, as the greater prevalence of automobiles, refrigerators, and supermarkets have resulted in British consumers joining Americans and other Europeans in buying cartons of milk from stores (Jenkins 1970).

Milk remained important for children during the 1930s, with the Milk Act of 1934 providing subsidized milk for British schoolchildren. The act also continued the practice of baby clinics begun at the turn of the century, which encouraged the habit of drinking milk at an early age (Hurt 1985). Milk for pregnant women and new mothers was also a priority, and the welfare state distributed nourishment for mothers, as well as infants and children, until the program was discontinued in 1972 by the British parliament. The efforts of the MMBs were significant – so much so that as the 1930s came to a close, British people were drinking, on average, a pint of milk more per week than they had in the mid-1920s. Moreover, such a trend continued through the 1950s, when British per capita milk consumption exceeded that of the United States; only Sweden and Ireland had higher levels (Jenkins 1970).

In the last decades of the twentieth century, dairying and dairy products continued to hold an ambiguous status. The market for milk in the major dairy areas of the developed world seemed to be saturated and was even showing signs of diminishing. Consumption peaked sometime during the 1960s and then, depending on place, stabilized or began to shrink (OECD 1976). Nonetheless, dairying has continued to be a significant factor in industrial agriculture throughout the last half of the twentieth century. In Europe, the world's principal dairy-producing region, milk products accounted for between 11 and 35 percent of total farm sales (Butterwick and Rolfe 1968). Such regular cash income is a lifeline for farmers, but the vast sums paid out in subsidies have helped to swell the milk "lakes" and butter "mountains" of surplus production to the absurd point that butter has been used as a feed for the cows that produced the milk to begin with. Since the interwar period, dairy farming has been maintained only by subsidies and tariffs, with overproduction the unhappy outcome (Johnson 1973; Cannon 1987). Developing countries seem to be repeating the experience of the developed West, with liquid milk sectors emerging to supply urban areas (Kurien 1970; Chang 1977; Mahias 1988).

Although dairy farming has been sustained at considerable economic cost, other, more insidious problems have emerged for milk products. The high food value, which made it so important for infants and children until the mid-twentieth century, lead to more or less serious health problems in the overfed late twentieth century. The high-fat content of milk has been implicated in the modern Western illnesses of obesity, coronary artery disease, and a host of digestive and allergic conditions. As a consequence, there has been a marked trend toward skimmed milk and milk powders, and even toward the exclusion of milk from the diet. Similarly, butter has been a victim of concerns about heart disease and body weight and has been steadily replaced by an increasingly more palatable margarine during the twentieth century (Cannon 1987).

To combat health worries, marketers of milk and milk products have focused on their energy-giving properties and high calcium content. Although milk could not realistically be promoted as a slimming aid, as it had been in the 1930s, the industry was still aiming for a pint per person per day, and advertised milk as a provider of instant vitality (Jenkins 1970). Some dairy marketers in recent years have undermined the ground of critics by deliberately proclaiming the richness and luxury of specialized products, such as fresh cream or ice cream. In an ironic reversal of healthy eating advice, cream has been lauded as "naughty – but nice!" and recent advertisements have been aimed at subverting any associations of ice cream with notions of childhood or purity.

A rather more sinister turn of events, however, has also tarnished the pure-white reputation of milk. In the early 1970s, the issue of inappropriate marketing of canned milk and milk powders among developing-world peoples began to receive public attention. In Yemen, for example, a study showed that dried milk and canned milk, provided as part of general food aid, were being fed to babies. This occurred in a country where Western medicine and high-technology goods had high social cachet and where the natural capacities of women were commonly denigrated. The result of the aid was that women neglected to breast-feed their babies and turned instead to proprietary baby foods or artificial milk. Many of these women were unable to read the instructions and had no access to the necessary sterilizing equipment to keep bottles clean, let alone to an adequate supply of fresh, clean water, with the result being an increase in infant mortality. Although resolutions have been made by dairy manufacturers in accordance with World Health Organization (WHO) and United Nations International Children's Emergency Fund (UNICEF) recommendations not to promote goods that might be used as substitutes for breast milk, contraventions continue (Melrose 1981).

Milk remains a singularly, almost uniquely, nutritious foodstuff, invested with elementally significant cultural and nutritional value. Yet milk has a Janus-faced nature – as it nourishes, so can it harm. Its whiteness evokes purity, but may also conceal corruption. Thus, as a commodity made widely available, milk has sometimes attacked the health it was intended to support and killed infants it was meant to nurture.

III.10 Soft Drinks

In considering the human body's demand for food and nutrition, the simple need for liquid refreshment is sometimes overlooked. Although this fundamental physiological requirement can be satisfied by drinking an adequate supply of pure water, most people, when given a choice, prefer to achieve the required level of liquid intake with a variety of flavored drinks to stimulate the palate.

Soft drinks are usually defined as nonalcoholic, water-based drinks, although a few may contain alcohol, albeit in quantities too small to warrant their classification as "hard liquor." Soft drinks are usually sweetened – soda water being an obvious exception – and flavored with food acids, essences, and sometimes fruit juices. They are often carbonated – that is, charged with carbon dioxide gas – and, indeed, in North America are referred to as carbonated beverages. In some countries, including the United Kingdom, there is a significant retail market for concentrated soft drinks intended for dilution at home before consumption. Soft drinks in powdered form are similarly marketed for preparation at home. In addition, uncarbonated, ready-to-drink soft drinks are also found.

The flavors of soft drinks may be derived from fruits, nuts, berries, roots, herbs, and other plants. Moreover, fruit (and to some extent vegetable) juices, as such, have grown in popularity in recent years and have come to be included among the soft drinks. In many countries, soft drinks are distinguished from hard liquor by the higher taxation of stronger drinks, for example through excise duties, and the term "nonalcoholic" can sometimes mean merely "non-excisable." However, soft drinks are frequently subject to other taxes, though usually at lower levels than those that are levied on alcoholic drinks. Soft drinks are often distinguished from medicines by legislation. In the past, these distinctions were less precise, and a historical study of soft drinks will include products that began with a mainly medicinal purpose but are regarded today as simple refreshment.

Over the years, the names of various classes of soft drinks have been used very imprecisely. The term "mineral waters," originally and properly confined to spa and spring waters, has subsequently been used for artificial spa waters and even for flavored carbonated drinks. Even today, words like "lemonade" or "pop" may be used colloquially to embrace a wide range of drinks – an imprecision that often prevents our determining the flavor or, indeed, the composition of past drinks. It cannot be assumed, merely because a bygone drink bore the same name as a current one, that it necessarily shared the same compositional standards. Another generic term, "aerated waters," is believed to have been coined by the eighteenth-century French chemist Gabriel Venel, who, in preparing an artificially carbonated water, called it "eau aerée" (aerated water), erroneously believing the carbon dioxide gas to be mere air.

The commercial manufacture of prepacked soft drinks began in the last years of the eighteenth century, and some of its products were known in one form or another well before that. The term "soft drink," however, dates only from the last years of the nineteenth century and seems to have originated in the United States. It is, therefore, strictly anachronistic to refer to such bygone products as soft drinks, although admittedly, an appropriate alternate term is lacking.

Small Beer

Before the mid–seventeenth century, the principal European drinks were what today would be considered alcoholic: beer, ale, mead, cider, perry (fermented pear juice), and wine. Until that time, and beyond, there was – certainly in England – a distinct prejudice against drinking water, as such, unless from sources of proven reputation. Nor was this prejudice wholly unjustified given the contamination of much of the water supply, particularly in populous districts. Nonetheless, cheaper and weaker ales ("small ales") and beers ("small beers"), containing insignificant amounts of alcohol, were produced for those who could afford nothing stronger, and for children. In his fourteenth-century *Piers the Plowman,* William Langland refers to halfpenny ale and penny-ale as beyond the pockets of the poorest laborers. In Leicester, the brewers were especially enjoined to make "good wholesome small drink for the poor people" (Bateson 1901, 2: 288).

An English cookery book of the fifteenth century contains a list of "herbs for the cup." Among those to be grown in the garden were sage, rosemary, hyssop, marjoram, and gillyflower; these were as likely to be used for flavoring mead (made from honey) as for small beers. Nettle beer and heather ale were also found among the small beers. Not surprisingly, small beer was despised by the more hardened drinker. "Doth it not show vilely in me to desire small beer?" asked Shakespeare's Prince Hal before his reformation (*Henry IV, Part II* 2.2.7). And, in mentioning Shakespeare, it is humbling to note that for him, "to chronicle small beer" was to deal in very minor matters indeed!

The strength of church ales is less certain. They were drunk as both a social custom and as a fund-raising exercise. In the seventeenth century, John Aubrey recalled the church ales of his youth as a means of raising funds for the poor before the introduction of a formal system of taxation by local government: "In every parish is, or was, a church house to which belonged spits, crocks etc., utensils for dressing provision. Here the housekeepers met, and were merry and gave their charity: the young people came there too, and had dancing, bowling, shooting at butts, etc., the ancients sitting gravely by, looking on. All things were civil and without scandal" (Barber 1988: 184).

Church ales were numerous but their names distinguished them more by use than by strength. Among them were bride ale, wake ale, and Whitsun ale, all intended for fund-raising of various sorts. Aubrey noted that "the clerk's ale was in the Easter holidays, for his benefit" (Barber 1988: 184). These ales were probably stronger than the small beers; despite Aubrey's assertion of their innocent intent, they certainly attracted clerical and Puritan criticism as giving rise to licentiousness and disorder.

Small beer, however, survived the years. It was to be found in the coffeehouses of late Stuart and Georgian London. In the early nineteenth century, William Cobbett noted that the grass mowers' drink allowance was "two quarts of what they call strong beer, and as much small beer as they can drink" (Jekyll and Jones 1939: 112). An inventory of the cellars of a Berkshire squire at his death in 1822 showed 210 gallons of small beer out of 2,630 gallons of beer and ale of all sorts. Small beer, indeed, but still a measurable quantity.

In his 1833 report *The Poor Laws in London and Berkshire,* Edwin Chadwick noted that every convict on board hulks in England was allowed one pint of small beer a day as part of his diet, and Dr. Jonathan Pereira's *Treatise on Food and Diet* of 1843 included small beer – or, as he called it, table beer – among his dietaries of London hospitals and other institutions. Pereira incidentally noted that whereas a barrel of best Burton ale contained 40 to 43 pounds weight more than an equivalent barrel of water, a barrel of good table beer contained 12 to 14 pounds more, and "common table beer" but 6 pounds more than water. Although in the 1790s Dr. Erasmus Darwin's *Zoonomia* had recommended small beer as part of a diet against "gaol [jail] fever" (typhus), we may suspect that the drink was preferred by these institutions as much for economy as for health.

Other brews were not necessarily so weak. Spruce beer, flavored with leaves of the spruce fir, was known to sailors in the Baltic from at least the sixteenth century, and Canadian Indians taught Jacques Cartier to use it against scurvy at much the same time. In New Zealand in 1773, the explorer Captain James Cook brewed spruce beer and reckoned it a useful defense against the same disease. Unlike most small ales and small beers, which continued to be brewed as and when required rather than being bottled for trading, spruce beer made the transition to the commercial market for prepacked soft drinks, and "spruce beer manufacturer" was to be found as an entry in the London trade directories of the early nineteenth century. And whatever its earlier strength may have been, spruce beer was excluded by the Licensing Act of 1872 from its definition of intoxicating liquor.

Ginger beer and ginger ale are products of the commercial era, but their acceptability, no doubt, owed much to the tradition of small beers and herbal brewing, which continued in the production of hop bitters and the like.

Cordials and Other Domestic Drinks

As small beers derived from the arts of brewing, so cordials owed their origins to the secrets of distillation. Heavily sweetened and highly flavored so that they might even be diluted with water before drinking, cordials would vary in alcohol content according to the recipe of their maker, often a well-to-do country housewife, whose object – partly pleasurable, partly medicinal, but at all times designed to tempt the palate – was summed up in Shakespeare's phrase, "a taste as sweet as any cordial comfort" (*Winter's Tale* 5.3.77).

Homemade cordials survived well into the era of commercial soft drinks, and as late as 1856, George Dodd in *The Food of London* described them as "more frequently the handiwork of some Lady Bountiful, some housewife more than ordinarily clever in domestic economy, than of manufacturers who prepare them for sale" (Dodd 1856: 498). Nonetheless, by then, cordials were also available from commercial manufacturers in both alcoholic and nonalcoholic varieties, the latter being popular as temperance drinks, and they continued in essence-based peppermint, ginger, and clove cordials, the thought of their medicinal origins having for the most part faded.

Among other drinks from the domestic sickroom was barley water, an infusion of pearl barley and water dating from late medieval times, which Thomas Fuller in the seventeenth century described as "an invention which found out itself, with little more than the bare joining the ingredients together" (Fuller 1662: 366). For sixteenth-century invalids there was "water imperial," apparently containing sugar and cream of tartar and flavored with lemons, as well as "manays cryste," a sweetened cordial flavored with rosewater, violets, or cinnamon.

Fruit-Flavored Drinks

In view of the heavy Arab influence on Italian Renaissance cuisine, lemonade may have originated with the Arabs. But in any event, sixteenth-century Italians seem to have been the first Europeans to enjoy this beverage made from freshly squeezed lemons, sweetened with sugar or honey, and diluted with water to make a still, soft drink that could be prepared, sold, and consumed on the premises. Its popularity spread to France and gradually to the rest of Europe, until by the eighteenth century, lemonade of this sort was available from the inns of Scotland to the Turkish baths of Constantinople. In France, lemonade was sold by the itinerant *limonadier,* who stored the drink in a tank carried on his back. In 1676 the *limonadiers* of Paris were formed into a company and granted a patent or monopoly by the government, continuing to sell their drink in this way until at least the end of the following century. During the eighteenth century, lemonade was also valued by the medical profession, and Erasmus Darwin recommended it, among other things, for the relief of kidney stones and gout and in cases of scarlet fever.

Orange juice was first introduced into mid–seventeenth-century England; Samuel Pepys in the 1660s noted with approval this drink that was new to him. A little later, orangeade was also to be found, often containing oranges too bitter to be eaten fresh. Orgeat, a cooling drink flavored with almonds and orange flower water, became a favorite of the patrons of eighteenth-century London refreshment houses and pleasure gardens.

Lemons and Scurvy

In the eighteenth century and earlier, citrus juices were among many articles of diet used in attempts to find a cure for scurvy, a disease which only in the twentieth century was discovered to result from a dietary deficiency of vitamin C. Scurvy particularly affected sailors on extended voyages of discovery with few opportunities for revictualing with fresh foods. Until its cause was known, any cure could only be found by empirical tests. Beer brewed from the spruce fir was considered effacicious. Unsuccessful, however, was malt, although it too had its advocates for a time.

Lemon juice was favored by the early Spanish explorers as an antiscorbutic, and Dutch and English voyagers also included it in their ships' stores, although it was more likely to find a place among the medicines than as a regular article of diet. In the mid–eighteenth century, James Lind conducted and published the results of experiments at sea. His 1753 *A treatise on the scurvy* showed that sailors treated with lemon juice recovered from scurvy, whereas other sailors given other substances did not. But further practical tests were less conclusive, almost certainly because of the loss of vitamin C during the preparation and storage of the juice.

For instance, Captain Cook on his voyages to the Pacific was supplied with lemon juice as a concentrated syrup, with most of the vitamin C unwittingly boiled out in the preparation. Not surprisingly, he was unenthusiastic about the efficacy of citrus juices, even though Joseph Banks, the botanist on the voyage with Cook, successfully dosed himself with lemon juice against what appeared to be the onset of scurvy. It was not until the end of the eighteenth century that the British Admiralty Board introduced lemon juice into the seaman's diet, where it was usually preserved by mixing with rum. In the mid-nineteenth century, lemon juice was largely replaced on British ships with West Indian lime juice. Botanical differences between lemons and limes were little appreciated at that time, and in fact, lime juice, with its lower levels of vitamin C, was less suited to the purpose (Carpenter 1986).

Artificial Mineral Waters

In 1772, Dr. Joseph Priestley's *Directions for Impregnating Water with Fixed Air* (fixed air being his name for carbon dioxide gas) also excited the interest of those seeking a reliable antiscorbutic. Priestley was by no means the first scientist to interest himself in the possibility of artificially reproducing the properties of natural mineral waters. As Sir John Pringle put it when Priestley received the gold medal of the Royal Society in 1773:

> Having learned from Dr. Black that this fixed or mephitic air could in great abundance be procured from chalk by means of diluted spirits of vitriol; from Dr. Macbride that this fluid was of a considerable antiseptic nature; from Mr. Cavendish that it could in a large quantity be absorbed in water; and from Dr. Brownrigg that it was this very air which gave the briskness and chief virtues of the Spa and Pyrmont waters; Dr. Priestley . . . conceived that common water impregnated with this fluid alone, might be useful in medicine, particularly for sailors on long voyages, for curing or preventing the sea scurvy (Pringle 1774: 15).

Intellectual curiosity, rather than commercial advantage, seems to have prompted the early scientists to find ways of extracting and analyzing the salts from natural mineral waters and reconstituting them in their laboratories. Much the same spirit led Priestley to show how water might be artificially carbonated on a commercial scale, and although carbonated water proved no cure for scurvy, Priestley's invention was soon adapted to the commercial production of artificial mineral waters.

Despite the traditional widespread suspicion of water because of its close connection with disease, natural waters were nonetheless valued so long as they either contained mineral salts found in practice to be healthful or were drawn from an exceptionally pure and reliable source. Such waters, however, had to be highly regarded indeed, in light of the high cost of transporting them, usually in heavy glass bottles, over any but short distances. During the reign of George II, Henry Eyre of London was not only importing from the Low Countries the mineral waters of Spa and dealing in various native waters, but he was also ensuring that all bottles were appropriately sealed to protect his customers from spurious imitations.

Provided the artificial waters carefully replicated the chemical composition of their natural counterparts – which analytical techniques enabled them to do – the economic advantage of manufacture close to the consumer was obvious. As Priestley himself put it: "I can make better than you import; and what cost you five shillings, will not cost me a penny" (Rutt 1831, 1: 177). At much the same time, Torbern Bergman of Uppsala, Sweden, was also experimenting with equipment for the production of artificial mineral waters, and within the next decade, Dr. John Mervyn Nooth was demonstrating to the Royal Society in London a glass apparatus for the production of small quantities of carbonated water.

The first known manufacturer of artificial mineral waters bottled for sale was Thomas Henry, a Manchester apothecary who, by the end of the 1770s, had modified Nooth's apparatus in order to produce artificial Pyrmont and Seltzer waters, as well as to imitate an earlier preparation known as "Bewley's Mephitic Julep," all of which were intended for medicinal purposes rather than for refreshment. Indeed, Henry recommended drinking with the julep "a draught of lemonade, or water acidulated with vinegar or weak spirits of vitriol, by which means the fixed air will be extricated in the stomach" (Henry 1781: 29). This suggestion reflected earlier advice on taking the natural waters; there was no hint, as yet, that flavorings might be added to the waters themselves.

J. H. de Magellan, claiming that Nooth's apparatus took several hours to impregnate water, published (1777) his own method for producing, in a few minutes, artificial versions of "the best Mineral Waters of Pyrmont, Spa, Seltzer, Seydschutz, Aix-la-Chapelle etc." (Magellan 1777: Title), as well as appropriate recipes for doing so. At the same time, he mentioned that he had sent copies of Priestley's pamphlet to different parts of Europe and that a French translation had appeared soon afterward. In 1787, mineral waters were also said to have been manufactured on a commercial scale in Germany.

It was, however, Jacob Schweppe who took up a theoretical suggestion of Priestley's that the use of a "condensing engine" or pressure pump would allow a greater volume of gas to be absorbed in the water than was otherwise possible. Schweppe, German born and a citizen of Geneva by adoption, pioneered the manufacture of artificial mineral waters in that city before setting up business in London in 1792. Producing Seltzer water, Spa water, Pyrmont water, and acidulous Rochelle salt water on something approaching a factory scale, Schweppe also offered a less specific line of aerated alkaline water, soon known as acidulous soda water, which he sold in three strengths – single, double, and triple – according to the amount of soda present, the double being "generally used."

The success of such ventures depended not merely on carbonating the water but on retaining the gas in the liquid until the consumer opened the container, and this in turn depended on the careful corking and sealing of all bottles, which Henry had stressed at the very outset of commercial manufacture. For Schweppe, who was supplying sometimes over long distances, the problem was a real one. As a postscript to a repeat order of 1805: A Birmingham customer complained that many of the bottles from his last order were nearly empty when they arrived because of bad corking.

To prevent the corks from drying out, Schweppe recommended that the bottles be laid on their sides in a cool place or even better kept covered with water – no easy task on a carrier's wagon! Schweppe also made an allowance on empty bottles returned, a custom often retained thereafter in a trade where the bottle represented a significant proportion of the total cost of the product.

Schweppe's partner in Geneva, Nicolas Paul, also made his way to England and operated commercially in London from 1802, having been in business in Paris for a while en route. Like Schweppe, Paul used the process known as the Geneva system or Geneva apparatus, but although he apparently achieved even higher levels of carbonation than Schweppe, the additional gas was, no doubt, largely lost in the pouring out.

By then, soda water had reached Dublin, where it was recommended by Dr. Robert Percival, Professor of Chemistry at Trinity College. Indeed, at one time it was claimed that a Dublin firm had invented soda water, but the product would seem conclusively to have originated with Schweppe. Nonetheless, its early success in Britain, like that of the other artificial waters, was undoubtedly medicinal; in fact, between 1804 and 1833, soda water was subject to stamp duty under the Medicine Tax. The first known manufacturer of soda water in the United States was Benjamin Silliman, operating in New Haven in 1807, and the first United States patent for manufacturing artificial mineral water was issued two years later.

Attempts to match spa waters artificially probably reached their apogee in the 1820s, when Dr. F. A. Struve, of Dresden, opened a range of artificial spas at Leipzig, Hamburg, Berlin, St. Petersburg, and Brighton, supplying careful imitations of the Carlsbad, Ems, Kissingen, Marienbad, Pyrmont, Seltzer, and Spa waters to invalids and a wider public without the necessity of their traveling to the original waters' respective sources.

Elegant and Refreshing Beverages

Gradually, however, the new drinks began to be promoted for refreshment rather than for their specifically medicinal properties. In 1819, an advertisement in the London *Morning Chronicle* described as "elegant and refreshing" the ginger beer and soda water available from one of the new metropolitan makers, and it was by the brewing of ginger beer that the industry expanded from the soda waters, on the one hand, to the sweetened, fruit-flavored drinks of later manufacturers on the other hand.

In Elizabethan times, Arthur Barlowe's "The discovery of Virginia" had referred to the American Indians drinking water "sodden [i.e. boiled] with ginger in it, and black cinnamon, and some times sassafras, and divers other wholesome and medicinable herbs and trees" (Barlowe 1589). A subsequent early American drink was "switchell," a mixture of molasses, vinegar, and ginger. But no reference has been found to ginger beer as such before the first decade of the nineteenth century. After it was first marketed in England, however, its popularity grew swiftly. Perhaps, as Leigh Hunt wrote at the time, because it was found to have "all the pleasantness and usefulness of soda-water without striking cold upon one" (Hunt 1862), ginger beer soon became a staple commodity of even the most modest refreshment stall.

The commercial origins of flavored, sweetened carbonated waters remain more obscure. As early as 1784, Karl Wilhelm Scheele, the Swedish chemist, had produced, from lemon juice, a crystalline substance that he called citric acid. One old trade historian claimed to have seen a manuscript reference to citric acid powder (or concrete acid of lemons, as it was also known) dated 1819, and a recipe for lemonade made with citric acid dated shortly thereafter. Lemonade "syrup" was known at about the same time, and all of these substances may well have been used for making lemonade in the home, employing a variant of Nooth's apparatus later known to the Victorians as the "gazogene" or "seltzogene." Despite such speculation, however, the first positive reference in England to commercially produced effervescent lemonade dates from no earlier than 1833. Such lemonades would have been flavored with citric acid and essential oil of lemon mixed with a sugar syrup, topped up with water, and impregnated with carbon dioxide gas derived in the factory from the action of sulfuric acid on whiting or other forms of chalk. Only at the end of the century did carbon dioxide gas come to be supplied to the soft-drink factory by a specialist manufacturer.

At London's Great Exhibition of 1851, lemonade, ginger beer, spruce beer, seltzer water (by now a generic name), and soda water were among the refreshments available to visitors, alcoholic drinks not being countenanced on the premises. A million bottles of aerated beverages were sold there, according to one contemporary estimate, and the success of the show and of the soft drinks reflected the slowly increasing leisure and spending power of those able to attend, two vital factors in the growth of the industry, not only in Britain but elsewhere in the developed world.

At fairs and race meetings, London costermongers sold lemonade and ginger beer, which they made at home in stone barrels. At the street markets of the mid-nineteenth century, according to Henry Mayhew (1851), soft drinks were available to refresh those shoppers "who have a penny to spare rather than those who have a penny to dine upon." Besides lemonade, raspberryade, and ginger beer, the street markets offered "Persian sherbet, and some highly coloured beverages which have no specific name, but are introduced to the public as 'cooling' drinks; hot elder cordial or wine; peppermint water." Sherbets had been available since at least the seventeenth century as cool fruit drinks originating from Turkey and the East, but later the name became attached to drinks made from effervescent powders containing bicarbonate of soda, tartaric acid or cream of tartar, sugar, and flavorings. As to the drinks with "no specific name," perhaps it is as well that their composition remains a mystery. In the street markets, Mayhew also noted that "some sellers dispensed ginger beer in plain glass bottles which was drank straight from the bottle after the cork obviatry the necessity of a glass."

In France the development of the industry seems to have been slower, with pharmacists holding a monopoly on what remained a localized trade, until their grip was challenged and weakened during the Orleanist years of the 1830s and 1940s. From France, too, at that time, came the soda siphon for dispensing carbonated soft drinks.

The pharmacists of the United States also became adept at producing artificial mineral waters, and as they discovered that the installation of soda fountains brought customers to their retail drugstores, they were encouraged to experiment with an ever wider range of flavored drinks by the mid-nineteenth century. Soda fountains were also taken up in Europe, where, for example, Germany had its *Trinkhallen* and France its *buvettes à eaux gazeuses.* An innovation of the American soda fountains was the addition of sweet cream to many of their products, and the popularity of ice-cream soda, as a vanilla-flavored drink, spread overseas as the century progressed.

Other drinks originating as soda fountain beverages included sarsaparilla, originally a medicinal flavoring derived from plants of the *smilax* species. Curiously, by the time sarsaparilla had become established among the bottled drinks, its flavor had come to be derived from a blend of oil of wintergreen, sassafras, anise, orange, and sometimes licorice. According to Charles Sulz in 1888, sarsaparilla itself was seldom included among the ingredients of what was by then a staple beverage of the American industry, but when it was, the bottler advertised its presence as proof of the superiority of his product over those of his competitors. Root beer was another blend of root, herb, and fruit flavors originating at the American soda fountain but later widely bottled. Sarsaparilla root beer, too, was available in the America of the 1880s. It also contained sassafras, a flavoring derived from the sassafras tree of the eastern seaboard.

Mixer Drinks

Freed from its exclusively medicinal limitations, soda water was found useful in diluting wines and spirits. Lord Byron called for hock and soda water after a drinking bout, and gin and soda water was said to be a favorite tipple of the fast set in the English hunting shires of the 1830s. Brandy and soda later became the drink for gentlemen, and manufactured seltzer and lithia waters were also available as mixers. As soda water became increasingly used as a mixer, many makers gradually reduced its soda content until, eventually, they were applying the name to simple carbonated water. The more scrupulous manufacturer sold such a product as "table water," and if his soda water retained a significant soda content, he was quick to advertise the fact.

Natural spa and spring waters, too, were used as mixers. Even in England, the natural waters of continental Europe were still imported despite local imitations. One London supplier in the 1860s offered not only German, French, and Belgian waters but others from Austro-Hungary and the United States.

The first English soft drink developed specifically as a mixer appears to have been tonic water, which began as a palatable means of ingesting the quinine prescribed for sufferers of malaria contracted in the tropics. In 1858 its inventor, Erasmus Bond, patented it as an "Improved Aerated Liquid," soon known as Indian or quinine tonic water.

Ginger ale seems to have originated a little later, once a method was devised for producing the clear extract of ginger, which distinguished the product from the cloudy ginger beers. A British trade paper of 1876 described the drink as a thing unknown only a few years previously. By then, however, it had become a favorite of the British market and was exported in significant quantities, particularly to America, and principally by the soft-drink firms of Belfast. Indeed, by the turn of the century a trade advertisement was asking: "What go-ahead Mineral Water Maker is there who has not at one time or another longed for the day to come when he would be able to turn out a Ginger Ale equal to the world-famous Belfast Ginger Ales?"

Temperance Drinks

Ginger ale, unadulterated, also took its place among the temperance beverages of Britain and the United States as the powerful social and religious forces moving against the consumption of alcohol gathered momentum on both sides of the Atlantic in the second half of the nineteenth century. Soft-drink manufacturers, serving licensed and temperance outlets alike, generally maintained a diplomatic neutrality in the fierce battles over the drink trade, at the same time expressing occasional ironic amusement at the reformers' description of their nonalcoholic favorites by reference to the names of the very drinks they sought to defeat.

Hop ales, hop beers, dandelion stout: All these and more endeavored to provide alternatives to the workingman's beer, whereas football stout and football punch aimed to attract young men from the sports field. One winter punch was advertised as "the best non-alcoholic substitute for brandy," but in what respect was unspecified. Many such nonalcoholic beverages were fermented, but as one turn-of-the-century writer cryptically noted, "some of them are not fermented and others are not non-alcoholic." Uproar occasionally ensued when analysis revealed that a temperance drink contained as much, if not more, alcohol than the product it sought to supersede.

Further up the market, a full range of nonalcoholic champagnes – sweetened, flavored, carbonated drinks, usually of high quality – resembled champagne in their presentation but not their origins, while nonalcoholic fruit wines, drunk as such or diluted, imitated the syrupy consistency of liqueurs. The American soda fountain, too, flourished under the temperance movement, offering an ever-greater selection of flavors and blends of flavors. This vast increase in choice was the result not only of demand but of the growth of specialist essence houses that supplied the soft-drink industry with flavorings and with careful advice on how best to use them. As a result, essences even came to be used in the manufacture of ginger beer, but the result, although of more uniform consistency, was generally held to lack a certain something of the brewed original.

By then, however, much of the ginger beer available in England was of poor quality, hence this lament from the 1880s: "'Times were' when ginger beer *was* ginger beer, as the name implies; but *now* 'tis generally something quite different" (Good 1880). The writer, Joseph Goold (1880), went on to deplore the widely varying standards by which the drink was being made, in most of which ginger was "conspicuous by its absence," the product having become too often simply another sort of lemonade.

It was also toward the end of the nineteenth century that saccharin became available as an alternative sweetener to sugar in soft drinks. Discovered in 1879, the intensely sweet coal-tar derivative was patented for commercial manufacture in 1885, and early enthusiasts predicted a great future for it in soft-drink manufacture. In practice, although it became a particularly useful sweetener of drinks for diabetics (and later for low-calorie or diet drinks), when it was used in standard products critics considered its no match for the "body" or the palatability given by sugar, which over the years had come to be specially refined for soft-drink manufacture.

Fruit Drinks

The use of lime juice as an antiscorbutic for British seamen has already been noted and the Merchant Shipping Act of 1867 made its provision on shipboard a legal requirement. Until then the method of preserving lime juice had been in a mixture with 15 percent alcohol, but in that year, Lauchlan Rose, a lime and lemon merchant of Leith in Scotland, patented a means of preserving the juice without alcohol. Noting the method of preserving light wines by burning sulfur candles in the casks, Rose prepared a sulfur dioxide solution by passing the gas from burning sulfur through water. When this solution was added to fruit juice, it prevented fermentation and other defects to which unpreserved juices were liable when stored, and Rose marketed the result as lime juice cordial. On shore, the temperance movement and the mixer trade soon found additional uses for the new product.

In the late nineteenth century, squash came onto the market, originally as a still, cloudy, ready-to-drink, juice-based product. In the early twentieth century, John Dixon, an Australian manufacturer, began to put up concentrated fruit drinks, and concentrated lemon squash was introduced into Britain just before World War I. After the war, orange squash followed, then pineapple and grapefruit. Of these, orange and lemon squash proved the most popular.

The origins of barley water as a product of the kitchen have been noted in the section "Cordials and Other Domestic Drinks." The Victorians valued barley water as a drink for the sickroom and also as a temperance beverage, but it was still made at home from commercially available patent barley and, by then, often sweetened and flavored with lemon peel. It was not until the 1930s that bottled lemon barley water was successfully marketed as a concentrated soft drink to which the consumer merely added water. Orange barley water was introduced soon after.

In the 1950s, comminuted citrus drinks were introduced among the concentrates and swiftly rivaled squash in popularity. They were sold as whole fruit drinks, their flavor derived not from the juice alone but also from the natural oils extracted from the peel as the whole fruit was broken down by the process of comminution to provide the base for the drink. Thus, fruit juice became an increasingly important ingredient in soft-drink manufacture. Citrus juices were extensively used: principally orange juice from the United States, Israel, and later Brazil, among other sources, but also lemon juice, traditionally from Italy (or, more specifically, Sicily), and lime and grapefruit juices. Among the temperate fruits, apple juice provided a basis for nonalcoholic ciders.

By the 1890s, an unfermented drink made from cranberry juice was being sold on the streets of St. Petersburg, but this may have been freshly expressed and unpreserved. In England, from the 1930s forward, concentrated black-currant juice drinks exploited the vitamin C available from indigenous sources. Fruit juices, as such, began to be packed for retail sale once ways were found of applying the principles of pasteurization to their preservation. Dr. Thomas B. Welch of New Jersey was said to have set the stage for American fruit-juice processing in this way when, as early as 1869, he began producing an unfermented sacramental wine from grape juice. But it was not until the 1930s that technical advances enabled prepacked fruit juices, including tomato juice, to be retailed on a large scale. Beginning in the 1940s, concentrated and, then, frozen juices also became available.

The citrus juices, especially orange juice, supplied a growing world market during the twentieth century, particularly once the importance of vitamin C in the diet became appreciated. Pineapple from Hawaii, and later from the Philippines, led the rest of the tropical juices in popularity. Apple, pear, and grape were significant among temperate juices consumed as such, and those fruits yielding a more pulpy juice were marketed as fruit nectars. Originally sold in glass bottles or metal cans, fruit juices are now more frequently packed in aseptic cartons, which have also been used for fruit-juice drinks in many countries of the world.

The Coming of the Colas

Amid the plethora of proprietary and patent medicines of the late nineteenth century were tonics of all sorts: These were drinks often containing phosphate and claiming to improve the nervous system and combat lassitude. As soft drinks were themselves taken for refreshment, many of these tonics, designed for a similar purpose, came to be classed under the same heading, and some of the flavors they used were also to be found in drinks designed simply to refresh.

In late Victorian Britain, kola or kaola was a popular soft drink, its essential flavor having been derived from the African kola or cola nut. The nut was known to pharmacists as a source of caffeine, and kola champagne was advertised in London as a tonic and nerve stimulant. Also available was kola tonic, the kola ingredient of which was boldly advertised as "this wonderful food," containing "more nutrient and more capacity for sustaining life than any other natural or prepared article" (Harrod's 1895 *Catalogue* 1972).

Another tonic on the market was coca wine, its stimulant properties derived from the leaves of the coca shrub, which the natives of Peru and Bolivia had long been accustomed to chew as a stimulant, and of which cocaine was a derivative. It was an interest in coca wine that led Dr. J. S. Pemberton of Atlanta, Georgia, in 1886 to combine the coca and the cola in formulating his Coca-Cola, which he, too, marketed as a brain tonic. This is not to say that these were the only flavorings. Like many speciality drinks, then as now, its formulation was a unique blend of flavors closely guarded by successive proprietors.

The word *cola* itself remained generic, and as its popularity increased, so other proprietary cola-based drinks, such as Pepsi-Cola, incorporated it in their brand names. Indeed, it became an objective of the leading brands to distance themselves from their rivals by trademark registration and, if necessary, by litigation. Pemberton and his immediate successors sold their product as a syrup for the soda fountain, which was then still the major outlet for the products of the American soft-drink industry. Only later were the proprietors somewhat grudgingly persuaded to permit others to carbonate and bottle the beverage ready-to-drink.

The licensing of other manufacturers to produce a soft drink from concentrated syrup sold to them by the owner of the brand name set a pattern for the franchising system, which came not only to dominate the twentieth-century American soft-drink industry but, eventually, to promote such brands internationally. Nor was the franchise system confined to colas. The heavy cost of transporting water-based soft drinks in glass bottles was clear from the outset of the commercial industry. There were obvious advantages in carrying a concentrated flavoring rather than the finished product over long distances, provided the proprietor could establish and enforce his standards of quality control on the local bottler so as to maintain the consistency of the consumer's drink and, thus, the product's reputation. Furthermore, a national brand could be advertised much more extensively than a local product, the cost of such advertising being recouped as part of the charge made to the bottler for the concentrate supplied. The franchise system, therefore, offered an attractive option to any owner of a drink or range of drinks, whether in America or elsewhere, looking for a way to expand.

Thus, the Canada Dry Corporation of Toronto established its ginger ale and other products in the United States during the years of prohibition and thereafter in additional markets overseas. Seven-Up, an American lemon-and-lime carbonated drink, was similarly marketed, and the promoters of speciality drinks like Dr. Pepper, a cherry soda that began as a fountain syrup, used the same means to extend their sales of ready-to-drink products at home and abroad.

Franchisers of one brand could also become franchisees of another. In Britain, for example, the old-established firm of Schweppes not only sold its products via associated companies overseas but also linked with the Coca-Cola Corporation to form the production company of Coca-Cola and Schweppes Bottlers in the United Kingdom. But the international success of the franchise system presupposed the existence of a worldwide network of local soft-drink manufacturers available to take it up.

The countries of Europe and North America that had seen the earliest growth of the carbonated soft-drink industry included those nations with the keenest interest in overseas trade. Thus, the techniques of soft-drink manufacture spread overseas along already established trade routes. In an age of imperialism, colonies tended to import from the parent country the machinery, packaging, and many of the ingredients necessary for soft-drink manufacture until such time as they might develop indigenous industries for supplying such essentials. The supply houses of the United States, increasingly important during the nineteenth century, were similarly adept at exporting to local bottlers in countries with which other American merchants were already engaged in general trade.

The success of soft-drink manufacture in different countries depended on a variety of factors: a degree of general sophistication in the country concerned, the competition of other drinks within it, the level of income of its citizens, and their social attitudes to alcoholic and other drinks – even a hot, dry climate was known to encourage soft-drink sales!

The trading nations not only developed existing overseas markets but also fostered new ones. Japan, opened to the world in the second half of the nineteenth century, saw small-scale bottling of carbonated soft drinks by the 1890s, with British techniques, and indeed British equipment, predominating in the early years. After World War II, American franchised soft drinks came onto the Japanese market. Influenced, but by no means dominated, by international trends, Japanese soft-drink manufacturers became adept at introducing new types of drinks and packaging into an increasingly dynamic and sophisticated market.

By the time franchisers began to look overseas, there was – at least in the most promising countries for development – no lack of local bottlers available to take up the franchises. And although international brands competed with local products, they could also stimulate the growth of the local soft-drink market by promoting greater consumption. In some areas where local manufacture was less advanced, the importation of soft drinks could encourage a local industry to develop. For example, many Muslim countries of the Near and Middle East relied initially on a high proportion of imported drinks to meet the demands of a hot climate, a youthful population, and the religious restrictions on – or outright prohibition of – alcoholic drinks. Then, as wealth and demand grew, a sophisticated indigenous industry developed.

Despite the spread of international brands, patterns of soft-drink consumption still varied considerably from country to country, as idiosyncrasies of national palate and social custom determined the way in which a country's total drink market was split among competing beverages. For example, in the Russian states, herbal beverages found a substantial market, with mint, nettle, coriander, and marjoram among the flavorings used. Equally, if not more, popular in Russia was *kvass,* a low-alcohol drink made from stale bread or cereals by the incomplete fermentation of alcohol and lactic acid. It remains to be seen what effect the international brands now being franchised in Russia will have on these traditional flavor preferences.

The Growing Market

Many soft drinks have been seen to owe their origins to notions of a healthy diet current at the time they first appeared, and many continued to remain popular by appealing especially to young people. But in the later twentieth century, other soft drinks were developed that reflected the desire for a healthful diet while also appealing to older people who might hitherto have thought they had outgrown the soft drinks of their youth. Low-calorie soft drinks, designed specifically for weight-conscious adults, arrived in the 1960s. These products used a new artificial sweetener, cyclamate, which blended successfully with saccharin to make a more palatable product. When, later in the decade, cyclamate was banned in many countries, saccharin-only low-calorie drinks proved less acceptable. But with the introduction of new intense sweeteners in the 1980s, the low-calorie market once again expanded.

Natural mineral waters retained their popularity over the years in many countries of continental Europe, but in the final quarter of the twentieth century, vigorous promotion, spearheaded by the Perrier brand, revived dormant markets elsewhere and developed new ones for both carbonated and still waters. Flavored, but still unsweetened, variants of such natural waters further extended their newfound popularity.

A belief in the healthful properties of natural products – and its obverse, a distaste for additives – led to the development of so-called new-age drinks, which are clear and lightly carbonated, with unusual fruit and herbal flavorings, either singly or in combination. They have no added coloring, no salt, no caffeine, and little or no added sugar. For a quite different health market, isotonic or sports drinks were produced, high in sucrose (or sometimes maltose) and designed to quickly replace the body fluids and salts excreted in vigorous exercise.

Alternative refreshment was also increasingly sought in iced tea, a water-based drink, often flavored with soft fruits and, sometimes, with herbs. In these ways the soft-drink industry has continued to innovate and expand in the 200 years of its commercial existence.

Soft Drink Packaging

A history of soft drinks – and certainly of carbonated soft drinks – could scarcely be considered complete without mention of its containers and closures, for if a carbonated soft drink is to be consumed as its manufacturer intended, it must be packed in a container capable of withstanding the pressure of the gas within and sealed with a closure that is not only effective when in place but also readily responsive to the purchaser's efforts to open it. That these several requirements are obvious does not make them necessarily compatible!

The effective sealing of bottles presented problems from the very outset of commercial manufacture. For this purpose, bottles and jars of stoneware or of stout glass were stoppered with corks that needed to be tight or, better still, wired on to the container. Drinks subject to secondary fermentation, such as brewed ginger beer, were especially likely to burst the cork (hence ginger pop) and traditionally came to be packaged in stoneware containers.

Some early glass bottles were oval ended at the base so that they had to be stored on their sides, thus keeping the corks moist and expanded for better sealing. The bottles themselves were usually returnable when empty and were embossed with the bottler's name to promote their safe return. The inconvenience to the customer of the oval-ended bottles – they were sometimes called drunken bottles precisely because they could not stand up – led to their gradual replacement by those with a conventional flat base. These came into use around 1870 but at first were still intended to be stored on their sides.

Early manufacturers despatched their goods in strong wicker baskets, but wooden crates strengthened with wire came to be preferred, particularly once the flat-bottomed bottles arrived. But the modest price of the drinks, relative to their total weight when bottled and crated, made transportation costs an increasingly significant proportion of the whole trading operation. Although the convenience of a flat-base bottle was undoubted, its implications for the drying out of the cork soon led to improvements in bottle sealing.

Beginning in the 1870s, returnable internal screw stoppers became available, made first of hard woods and later of ebonite. Another successful invention of the time was Hiram Codd's bottle with the round glass "marble" stopper in the neck, which the pressure of carbonation kept sealed against the bottle mouth. In the last decade of the century, William Painter's crown cork came to be used for sealing the smaller returnable bottles for mixer drinks. The effectiveness of all the new seals was much improved when fully automatic bottle production superseded hand-blown glass during the first years of the twentieth century.

The internal screw stopper could be opened manually by a sufficiently strong wrist. The Codd's bottle, too, could be opened manually by depressing the marble in the neck, but wooden openers were available to supply any extra force needed. For the crown cork, a bottle opener was necessary and the closure was discarded after use. Returnable bottles and closures had also to be thoroughly washed before reuse, and the inspection of Codd's bottles and stoneware jars after cleaning could cause particular problems for the bottler.

Returnable glass bottles in sizes seldom greater than a quart dominated the industry during the first half of the twentieth century and beyond. They usually bore paper labels, although some had their labeling information permanently embossed or fired onto the container. In the latter half of the century, packaging diversified considerably. Lighter, standardized returnable glass bottles no longer needed to bear their owners' embossed names but consequently became less distinguishable from the throwaway containers of most other bottled goods.

From the 1960s on, often in response to changes in retailing – in particular the growth of supermarkets – carbonated soft drinks were also packed in nonreturnable glass and in steel or, later, aluminum cans. The first cans required special openers, but the ring-pull end was later introduced for manual opening.

In the 1980s, soft-drink bottlers began to make blow-molded plastic containers of polyethylene terephthalate (abbreviated to PET) in sizes larger than the traditional capacities of glass bottles. Even for returnable bottles, the nonreturnable aluminum cap, rolled on to the external screw thread of the bottle neck, gained ground rapidly in the 1960s. Later, resealable closures became commonplace, particularly as bottle capacities increased.

As the second half of the century progressed, draft soft-drink equipment was more frequently introduced into catering establishments. Draft soft drinks were produced either by the premix method, whereby the drinks were carbonated and packed at the manufacturing plant and then taken to the retail outlet to be connected to the dispensing equipment on site, or by the postmix method, whereby the ingredients of the drink were loaded separately into the dispensing equipment, itself designed to mix them with water in preset proportions for dispensing as a finished, ready-to-drink beverage. By midcentury, coin-operated automatic vending machines also sold prepacked soft drinks, and there, too, in the years that followed, new versions were developed that dispensed carbonated drinks into cups by means of either the pre- or postmix method.

Laminated cartons were developed for the packaging of fruit juices and were also used for still soft drinks. This diversification of packaging was also significant in stimulating the growth of the industry in the late twentieth century by ensuring the availability of soft drinks in an ever-increasing number of retail outlets, so that they may now be said to be among the most widely sold manufactured products in the world.

III.11 Tea

Tea, a drink made from the leaves and buds of the shrub *Camellia sinensis,* is the most culturally and economically significant nonalcoholic beverage in the world. Originating in China, it had spread to surrounding nations before European contact, after which it was made a commodity of world importance by the British and Dutch East India Companies. Wars have been waged, nations punished, and fortunes made and lost because of this beverage. One reason that tea has been a very profitable article of trade is that it is a source of caffeine – a major factor in its popularity (Willson and Clifford 1992).

Although there are many kinds of herbal beverages called "teas," in this chapter the term "tea" refers only to *Camellia sinensis.* Both infusions (pouring hot water over the leaves) and decoctions (boiling the leaves in water) have been made from the plant, which has also been eaten raw, cooked, or pickled and has even been snuffed.

Botany and Production

Camellia sinensis is native to the mountainous highlands between India and China and, when untrimmed, can grow to a height of about 10 meters. One variety, *Camellia sinensis sinensis,* is native to China, whereas *Camellia sinensis assamica* comes from India (Harler 1963). A semitropical or tropical climate is necessary for raising tea; the northernmost places where it has been grown are South Carolina (in the United States) and in Asia near the Black Sea. Bushes grown at high elevations produce the best tea (Willson and Clifford 1992). Yields range from 700 to more than 1,800 kilograms (kg) per acre (Harler 1964).

Tea undergoes a long journey from bush to cup. The leaf buds, which appear in the spring, along with the leaves directly below them on the stem, are generally hand plucked by skilled workers (Pratt 1982). The first buds to appear (the "first flush") and the smallest leaves ("two leaves and a bud" is the ideal) command the highest price, whereas the larger leaves that can be cut by machines usually become part of lower-grade teas.

About 98 percent of the tea that enters the world market is black tea, and there are four steps required to ready this tea for Western tastes. The first, "withering," involves drying the leaves to the point at which they are structurally weak. This is followed by "rolling" the leaves (in the past, between the heels of the hands), which crushes their cells and blends their chemical constituents, the characteristic tea polyphenols and the enzyme polyphenol oxidase. Moreover, the twist this imparts to the leaves slows the rate at which their essence blends with hot water. "Fermentation" – the third step – actually involves oxidation by the polyphenol oxidase and is produced by aerating and heating the leaves to between 72° and 82° Fahrenheit for 1 to 2 hours, during which their flavor develops and they turn a brownish color. The final stage is called "firing" the leaves. This further heating process stops fermentation (oxidation) by deactivating the enzyme and reduces the leaves to a moisture content of about 5 percent (McGee 1984). Needless to say, all of these procedures require a highly developed sense of timing on the part of the tea maker.

Although black teas monopolize the international market, the teas drunk in China and Japan are mostly green (Harler 1963). In preparing the latter, the fermentation stage is eliminated, and the enzymes are destroyed by steam or pan heating before the leaves are rolled and fired. In North Africa, too, green tea is common, in this case because the classic word "fermentation," applied to the oxidation process, was misunderstood by Muslim religious and political leaders; they thought the word referred to the formation of alcohol, which their religion prohibited. Thus, this stage of tea preparation was omitted.

The size of the leaves determines the grade of a green tea: The tight, small balls of younger leaves are called "gunpowder"; "imperial" tea comes in larger and looser balls; Hyson varieties are long and looser leaves of mixed ages (McGee 1984). It might be added at this point that Oolong tea stands between green and black teas in that although it is fermented, this is only done briefly for about 30 minutes after rolling.

Grades of black teas, although they may vary, typically conform to guidelines that emerged from the British tea industry in nineteenth-century India and Ceylon (Sri Lanka). Whole leaves, which are generally thought to produce the best flavor, are classified by size and the ways in which they are rolled. For example, Flowery Orange Pekoe leaves are smaller than those of Orange Pekoe, and some of the leaves of Golden Flowery Orange Pekoe have highly prized golden tips (indicating that the tea consists of small, intact leaves), whereas in the case of Tippy Golden Flowery Orange Pekoe, all the tips are golden.

Leaves that have been broken, whether deliberately or not, also make high-quality teas that conform to some of these classifications (for example, Broken Orange Pekoe, Golden Broken Orange Pekoe, or Tippy Golden Broken Orange Pekoe). Small pieces of leaves (debris from the processing of whole and broken leaves) are called "dust," and even smaller ones are called "fannings" (Stella 1992). These go into teabags and brick tea.

Teas are also named for the regions where they grow. For example, black teas from eastern India are known collectively as Darjeeling teas; Oolongs and Lapsang Souchongs come from Taiwan, and Keemun is a black tea from northern China. Teas are sometimes scented: An extreme case is Lapsang Souchong, a large-leafed black tea scented with pinewood smoke (Goodwin 1991). More often, flavoring is done with essential oils before, during, or after firing. This is especially the case with blends – the form in which most teas are generally purchased. Constant Comment, for example, is a blend from Sri Lanka flavored with orange peel; Earl Grey, another blend, is flavored with a citrus oil (McGee 1984).

History

Origins

The true origins of tea are unknown. Wild tea leaves are still used by the tribes of Burma to prepare a beverage and a "tea salad" (made from leaves that have fermented underground for several months and are then mixed with mushrooms, oil, garlic, chilli peppers, and perhaps other ingredients). In that part of the world, tea is also chewed or sniffed as snuff, and many surmise that use of the tea plant originated there and spread to China by the Han dynasty period (206 B.C. to A.D. 221). However, the wild tea plants of nearby Assam, in India, do not produce a palatable brew, and present-day Indian tea culture is wholly the work of the British.

China

The question of whether tea came from elsewhere to Han-dynasty China is obscured by legend. One of the earliest tales would have it that (some 5,000 years ago) a mythical emperor, Shen Nung, drank boiling water into which a wild tea leaf had fallen and, consequently, was the first to taste the beverage. Other legends state that tea bushes first sprang up when a Buddhist monk cut off his eyelids to keep from falling asleep while meditating – this tale, perhaps, was inspired by the Buddhists' heavy use of tea.

Mythology, however, is not as useful to the historian in dating the Chinese use of tea as are the mentions of an herb called *t'u* in the writings of Confucius (551 to 479 B.C.), who remarked "Who can say that *t'u* is bitter? It is as sweet as the shepherd's purse" – which was another herb (Evans 1992: 14). In Chinese, the written character *t'u* later meant tea, so it is at least possible that Confucius knew of the beverage at this early date (Blofeld 1985). At any rate, there seems little question that at least some tea was drunk during the Han dynasty and that the lacquer cups known from this period (the "winged cups") are in fact the earliest teacups (Evans 1992).

Tea was probably used first for medicinal reasons, but the leaf and its lore moved from the medicinal to the artistic during the Tang dynasty (A.D. 618 to 907), a period of increasingly eclectic food and drink choices, which also saw the Chinese enjoying grape wine and butter cakes (Tropp 1982). In about 800, Lu Yu, the first known tea connoisseur, penned the oldest surviving tea manual, the *Cha Ching* or "Scripture of Tea" (Ukers 1935). This book described an elaborate ceremony of tea making, from picking the leaves, to roasting them, to serving the green tea in wide shallow bowls (Lu Yu 1974). All tea at this time was green, which kept rather poorly unless made into cakes (Blofeld 1985), and the Tang-dynasty Chinese also enjoyed spiced tea, made by adding onions, garlic, mint, orange peel, salted black soybeans, or five-spice powder (Blofeld 1985). Although despised by Lu Yu, it was a common drink, and the addition of these flavorings may have either disguised the flavor of poor tea or allowed more bowls to be made from the same amount of leaves. Of course, such beverages also – at least to some extent – prefigured the flower teas, such as "Jasmine" and "Rose Congou" later served in North China, and which subsequently became popular outside China.

Tea ways changed as tea use and tea plantations grew more widespread during the Sung dynasty (960 to 1280). Green tea was powdered, whipped until it was the color of a "river of jade," and served in deeper and wider bowls (Evans 1992). The use of spices and other additives was discontinued. Poets praised tea and referred to *cha tao,* the "Way of Tea" (Blofeld 1985), and the beverage was used in Chan (Zen) Buddhist ceremonies.

Brick tea was employed by the Chinese to buy horses from the central Asian tribes, and in Tibet and Mongolia, it was churned with yak butter and barley or millet into a porridge, the national staple (Kramer 1994). Centuries of Mongol rule in China were followed by the Ming dynasty (1368 to 1644), under which the tea trade widened in scope. To preserve tea for trade, some varieties were fermented into novel black teas that had not previously existed (Evans 1992). Wine pots were employed as teapots for steeping leaf tea, and by 1500, such pots were being made especially for tea (Chow and Kramer 1990). It is entirely possible that the use of a pot, enabling the brew to be poured off the leaves, was connected to the increasing importance of leaf tea, for the brew – especially in the case of black teas – can turn bitter if left in contact with the leaves too long (Chow and Kramer 1990).

Under the Ming, small handleless cups were used with a teapot, and this was the style of tea drinking exported to the West, along with the unglazed earthenware pots of Yixing (favored by tea connoisseurs) and teacups of blue and white porcelain (Chow and Kramer 1990). From the sixteenth through the eighteenth centuries in China, several styles of teapot were in common use, including some with a handle on the side and others with no handle (Kanzaki 1981). These were used for fine green tea, which must be brewed with simmering (rather than boiling) water (Arts 1988). Other types of pots included tiny personal teapots – "personal" because the tea was drunk directly from the spout (Tropp 1982).

Another Chinese development, which never reached the West, was the tea "requiring skill." In this ritual, the finest green tea was packed into a small teapot, boiling water poured over the tea, and the first infusion discarded. The second infusion, however, was drunk as if it were a liqueur, and sometimes even a third infusion was prepared. Such an artistic tea ceremony is still practiced in Taiwan (Blofeld 1985).

Teahouses were social centers in China; they are documented as far back as the Tang dynasty and achieved great prominence from the sixteenth through the eighteenth centuries (Anderson 1994). Patrons bought the "house tea" or had their own brewed for a small fee. Poetry readings, opera singing, or dancers were typical teahouse entertainments. At some establishments, in fact, "singsong girls" (prostitutes) offered the customer other choices in addition to tea (Blofeld 1985). Most teahouses served food: The most common fare was and remains *dimsum,* an array of snacks (Anderson 1994).

In 1644, China was taken over by the central Asian Manchu dynasty, which presided over (among other things) a new fashion of lidded cups called *chung* (Chow and Kramer 1990), in which tea could be both steeped and drunk. *Chung,* however, never became popular in Japan or the West, and even in China, the older types of pots and cups remained in use as well. The origins of many kinds of tea still enjoyed today can be traced to this, China's last imperial dynasty. The Manchu, whose staples on the steppes had been milk and butter, also served milk in black tea, a practice which did become popular in the West (Ukers 1935).

In the early seventeenth century, the Europeans, beginning with the Dutch, sought to trade for tea with China. The Chinese, however, proved to be difficult trading partners. Not only did they claim not to need (and consequently would not accept) anything from the West except the precious metals (silver and gold) and copper but they also kept the secrets of tea growing and processing to themselves – even to the extent of boiling any tea seeds they sold to render them sterile (Goodwin 1991). Indeed, so successful were the Chinese in maintaining European ignorance of matters concerning tea that it was only in the nineteenth century (after some two and a half centuries of tea trading) that their customers learned that black and green tea came from the same plant (Ukers 1935).

The largest of these customers was the British East India Company,[1] which from the 1660s onward carried huge amounts of tea from Canton to Britain but always struggled with the balance-of-payments problem presented by the Chinese insistence on precious metals as the only exchange for tea. One solution for the company was to find products that the Chinese would accept in trade. The other was to grow its own tea, and India became the place where both of these goals were pursued.

In pursuit of the latter solution, Lord Bentinck (William Henry Cavendish), who was appointed governor of India in 1828, created the Tea Committee to foster a tea industry in that land. Several botanists were sent to China to learn about tea cultivation and to recruit Chinese growers to start tea plantations in India. One of these botanists, J. C. Gordon, collected more than 80,000 seeds and sent them to Calcutta, whereupon the British discovered that all varieties of tea came from the same plant (Willson and Clifford 1992).

But it was Robert Fortune – entering China in 1848 as an agent of the Tea Committee and for three years roving about the country's tea regions disguised as a Chinese merchant – who finally unlocked the many mysteries involved in actually producing tea (Beauthéac 1992). Thereafter, Chinese tea was planted in India and, a bit later (after disease had wiped out the island's coffee trees), in Ceylon (Sri Lanka) as well. Tea bushes native to India were subjected to experimentation, hybrids tinkered with, and, ultimately, plants well suited to India's climate were developed. The great tea plantations of British India were born.

Nonetheless, because China continued to supply most of the world's tea, the problem of its insistence on bullion or copper as payment for that tea also continued. Actually, the British had already found one product – cotton from Bengal – that interested the Chinese. Then they hit upon another. Poppies, imported from Turkey, grew well in India, and the British East India Company entered the opium business. No matter that the Chinese government refused to permit the importation of the addictive powder. Intermediaries soon stimulated a lively demand for it across all strata of Chinese society, and as the government continued to object, the British went to war, their gunboats easily overwhelming the Chinese coastal defenses. The Treaty of Nanking (1842) not only forced opium upon the Chinese but also forced open four Chinese ports (in addition to Canton) to European trade. Hong Kong was ceded to the British, and British consuls were admitted to all treaty ports.

The decline of China from its former imperial grandeur continued throughout the remainder of the nineteenth century as foreigners increased their ascendancy, and in the twentieth century, the old China disappeared in the tumult of war and revolution. During these years, a great deal of the ancient art and culture surrounding tea was also destroyed. But it remained (and remains) the national beverage. Throughout the day, people carry with them lidded tea mugs, which, like the *chung,* can be used both for infusion and for drinking (Chow and Kramer 1990). Glass mugs or cups are aesthetically pleasing, because they allow the drinker to view the unfolding of the tea leaves as the tea brews (Chow and Kramer 1990); in fact, there are teas which are specially bred and rolled for this purpose. Teahouses in the new China include opera, television viewing, and even "karaoke" singing as entertainment (Anderson 1994).

Japan

Japan first obtained tea, along with many other cultural practices, from China. Tradition has it that the beverage was carried to Japan by the Buddhist monk Eisai; drinking tea before meditation was for the Buddhists a practical way to keep awake, and early Zen monks drank tea long before it was known elsewhere in the islands. To make it, cakes of tea were powdered, and water was boiled in a kettle and ladled into a bowl. Following this step, the tea was whipped with a whisk – itself made by splitting bamboo fibers and then bending them with steam into a double cone of curved spines. The early monastic "four-headed tea" was a rite in which a man served tea to guests by whipping individual bowlfuls (Hayashiya 1979).

In Japan, tea service evolved into an elaborate ceremony, continuing the Chinese Sung-dynasty use of whipped green tea, which as employed in the Japanese tea ritual still resembles jade in its deep, clear green color (Chow and Kramer 1990). When the country was unified in the sixteenth century after a long era of war among feudal lords, the cultivation and use of green tea became widespread, and the tea ceremony, which had served as an opportunity for ostentation by the nobility, was remade under the guidance of art collector and tea-master Sen Rikyû, who created the "tea of quiet taste" – a ceremony performed in a small, low hut and passed on to future generations as a tradition. Different kinds of sweets, flowers, incense, stylized conversation, calligraphy, bowls, and other utensils became associated with different "schools" of the tea ceremony, as well as months of the year, places, and so forth. Years of instruction became necessary to master the way of tea; Rikyû's sons and grandsons founded several tea schools, which carry on old traditions to this day (Sen 1979).

During the seventeenth century, leaf tea was introduced from China, and the use of teapots became common. For ordinary tea, a teapot with a spout on the front was used. For fine tea, a hot-water pot *(kyusu)* – more convenient than the older kettle – was employed (Kanzaki 1981). Cups of porcelain in the style of the Chinese Ming dynasty became common alongside the *kyusu.* Although the tea ceremony of Rikyû used powdered tea, another ceremony involving fine-leaf tea also developed, and the *kyusu* employed were often beautiful works of art (Arts 1988).

In 1854, the isolation of Japan came to an end with the Shogun's agreement to allow foreign ships to put into Japanese ports, and in the initial rush to modernize, the Japanese tea ceremony was lost. But at the start of the twentieth century, as Japanese culture underwent a revival, the ceremony became popular once again, a popularity that continues into the present. Tea also figures in popular culture. It is used regularly in homes and restaurants and can even be bought from vending machines. Green tea remains the most popular for daily use, although other kinds, including black tea and herb tea, are also drunk. In 1992, Japan exported a mere 290 tons of tea while importing 160,367 tons (FAO 1993).

India

Although a Dutch seafarer wrote of tea being eaten as well as drunk in India in 1598, accounts of earlier Indian history do not mention the use of tea or its cultivation (Pettigrew 1997). Milk and buttermilk, produced by the country's millions of sacred cattle, were the preferred beverages in India (Tannahill 1988).

The tea cultivation begun there in the nineteenth century by the British, however, has accelerated to the point that today India is listed as the world's leading producer, its 715,000 tons well ahead of China's 540,000 tons, and of course, the teas of Assam, Ceylon (from the island nation known as Sri Lanka), and Darjeeling are world famous. However, because Indians average half a cup daily on a per capita basis, fully 70 percent of India's immense crop is consumed locally (Goodwin 1991; FAO 1993). Tea in India is generally spiced and served with milk, thus incorporating two other prominent Indian products. As a cup of tea with sugar and milk may contain up to 40 calories, this is also a source of quick energy (Harler 1964).

In general, even though India leads the world in tea technology, the methods employed to harvest the crop vary with the type of tea and terrain. Fine-leaf tea is hand plucked, and hand shears are used on mountain slopes and in other areas where tractor-mounted machines cannot go. A skilled worker using hand shears can harvest between 60 and 100 kg of tea per day, whereas machines cut between 1,000 and 2,000 kg. The latter, however, are usually applied to low-grade teas that often go into teabags. The tea "fluff" and waste from processing is used to produce caffeine for soft drinks and medicine (Harler 1963).

Russia

Tea from China reached Tsar Alexis of Russia in 1618, and the Russians quickly adopted the beverage. They adapted the Mongolian "firepot" to their own purposes, creating the charcoal-fueled samovar, which boiled water in its tank and furnished the heat to make tea essence in a small pot atop the device. The essence was diluted with hot water from the tank whenever a cup of tea was desired. Samovars (now electrically heated) are still common, especially in offices and at parties and gatherings where much tea must be made at once. Lump sugar is used for sweetening, and Russians often bite a sugar lump in between sips of tea (Schapira 1982).

Tea is served in glasses with metal holders in public places and in china cups at home. Apples or cranberries (instead of costly lemons) are sometimes added along with sugar, and tea is usually drunk with milk. Pastries and sweets often accompany the beverage. The low price of tea led to its great popularity in Russia, and the tea plantations of Georgia (now a separate nation) are the most northerly in the world. The Russians, however, consider Georgia-grown tea to be inferior (Schapira 1982), and some 325,000 tons of tea were imported by the countries of the former Soviet Union in 1992 (FAO 1993).

Continental Europe

Tea first became popular in the Netherlands in the early seventeenth century. Served in the afternoon – in what would become the British style – it was mixed with sugar and, sometimes, saffron. As the custom of afternoon tea in the home developed, hostesses set aside special rooms, furnished with paintings, tables and chairs (Brochard 1992), and large quantities of tea were reportedly consumed: Montesquieu, for example, saw a Dutch woman drink 30 small cups at one sitting (Brochard 1992). In the Dutch colony of New Amsterdam in North America, water for tea was hawked through the streets, and prior to the dominance of the British East India Company, the Netherlands exported much tea to Britain (Israel 1987).

Tea cultivation in Indonesia, which began under Dutch supervision in the mid–nineteenth century (Ukers 1935), specialized in the production of black teas often used for blends. Tea is still popular in the Netherlands today; in 1992, the United Provinces imported 377,803 tons of tea and reexported 201,306 tons, leaving 176,497 tons for local use (FAO 1993).

Germany and France have historically consumed little tea, although the porcelain works of Meissen in Germany have produced excellent tea services. Some tea is consumed in the Dutch or British fashion in both nations, but most people there prefer coffee.

Britain

Despite the British fondness for tea, it does not have a long history in the islands. The first mention of "chaw" in a sea captain's letter dates from 1597, and not until 1658 was tea first announced for sale at a London coffeehouse (Ukers 1935). From that point forward, however, sugar from British-controlled islands of the Caribbean became plentiful enough to make the new beverage palatable to Englishmen's tastes. But leathern or wooden cups – used for ale – were unsuitable for hot tea, and consequently Ming-style pots and teacups were brought to Britain along with the new beverage.

Expensive at first, tea became more widespread as duties fell. By the 1710s, afternoon tea had become an important convivial occasion for women, who were discouraged from drinking alcohol socially because (according to the new bourgeois code of morals) they could not remain "ladylike" while intoxicated. In addition, eighteenth-century Britain saw the rise of "tea gardens," where tea, snacks, and entertainment could be enjoyed by the bourgeois and upper classes. Sidney Mintz (1985) has commented on the "tea complex" of tea and sugary foods (such as jam and pastries) that came to be popular among the British, doubtless in no small part because of the stimulating effects of caffeine and sugar. According to Benjamin Franklin, eighteenth-century Britons and Anglo-Americans drank 10 pounds of tea per head yearly – which translated into 2,000 cups, or about 5½ cups a day (Pratt 1982).

Such demand invariably led to adulteration in order to color the tea and add weight to shipments. Ash leaves, licorice, iron filings, Prussian blue, sheep dung, and numerous other materials could be found in tea packages, and discarded tea leaves were saved from garbage heaps and washed for resale. Even the tea-loving Chinese happily dyed green tea a brighter green to satisfy British customers who disliked the pale color of the "real thing" (Goodwin 1991). It is interesting to note that some popular scented teas are the products of such adulteration: In the case of Earl Grey, for example, buyers came to demand the scent and flavor produced by the addition of oil of bergamot.

Chinese porcelain was painted with designs made especially for English buyers (such as the famous "willow pattern"), and cups began to be made with handles to enable the drinker to cope with tea hot enough to dissolve sugar – unlike the Chinese green tea, which was brewed at a lower temperature (Pratt 1982). Carried as ballast in sailing ships (one ship might carry as much as 20 tons of porcelain), this "china" was very inexpensive (Atterbury 1982; Hobhouse 1986), but attempts were nonetheless made to copy Chinese porcelain. Such efforts eventually met with success, and by 1742 porcelain was being made in Europe.

British tea tariffs, which played such an important part in bringing about the American Revolution, were repealed the year after American independence was achieved (Goodwin 1991), and the adulteration of tea ceased as it was no longer profitable (Hobhouse 1986). In 1786, the East India Company sold a total of 2.4 million pounds of black tea and 1.15 million of green tea (Ukers 1935). Even in those days, green tea was already losing ground to black, but it was still relatively more popular than it would later become with the massive influx of black teas from India and Africa. Broken grades also sold very well in Britain because of their lower prices (Harler 1963).

The Victorian period found tea perhaps at its zenith, with even the homeless of Whitechapel partaking – a victim of Jack the Ripper was carrying tea on her person, along with sugar and a spoon, at the time of her murder (Tully 1997). The temperance movement was greatly aided by affordable tea, as millions were converted to "tee-totaling," or abstinence from alcohol. The British took tea in the morning, at lunch, at "low tea" (afternoon tea, served in the "low" part of the afternoon), and at "high tea" (or "meat tea"), an early supper served at 6 o'clock (Israel 1987). Strongly scented teas, such as Earl Grey, Jasmine, and Lapsang Souchong, were extremely popular, perhaps because the Victorian regimen of meats and sweets demanded strongly flavored teas to match. The rituals of tea became more complex, and from the drawing rooms (the "withdrawing rooms" to which ladies withdrew while gentlemen remained at the table) of London to the South African bush, the British cherished tea, the "cups that cheer."

In the twentieth century, British workmen continued to break daily for tea, made and served collectively for groups of workers or purchased from nearby shops. In the 1980s and 1990s, the British each consumed some 3 to 4 kg of tea annually. In 1992, the nation as a whole imported 503,350 tons of tea and reexported 122,476 tons, leaving 380,874 tons for local consumption (FAO 1993). The rising popularity of coffee and soft drinks have somewhat diminished tea's popularity, but it remains a staple British beverage, and tearooms flourish throughout much of the English-speaking world, although not in the United States.

The United States

Tea in America has a history going back to the colonial era, when it was used by both Chesapeake planters and Massachusetts merchants and was especially popular in Philadelphia (Roth 1988). As in England during this period, most tea was green and often mixed with sugar, fruits, and liquors to make an alcoholic "punch."

The legendary Boston and Charleston "tea parties" sprang from the British tax on tea, which, unlike other taxes, had not been repealed in the face of colonial protest. The result was a series of civil disorders in which shiploads of tea were destroyed (in Boston) or stolen (in Charleston). In retrospect, these acts were clearly precursors of the Revolution. Contrary to legend, however, tea drinking did not cease because of hostility to Britain, and George Washington continued to breakfast on three bowls of tea. The difference was that this tea no longer reached the United States through British channels, but rather in American ships, the first shipment arriving in 1784 aboard the *Empress of China* (Ukers 1935). But it was the case that, a few decades later, an increase in the availability of cheap, Brazilian, slave-produced coffee brought a gradual decline of tea consumption in favor of coffee.

Two great changes in American tea drinking came about in the early twentieth century. One occurred in 1908, when tea merchant Thomas Sullivan, in order to reduce shipping weight, began to package tea samples in silk bags instead of miniature tins. Some of his customers brewed the tea without taking it out of the bags and requested more tea packaged in this way; Sullivan obliged, and teabags were created. Today, in America, most tea is brewed from teabags (Schapira 1982).

The other innovation was iced tea, supposedly invented at the 1904 World's Fair by Richard Blechynden, an English tea concessionaire who had been sent to the United States to promote black tea. But in the sweltering heat of St. Louis, he was unable to sell hot tea or even give it away. In frustration, he poured the tea over ice and began to serve it cold. Because there is much evidence of iced tea before this event, Blechynden gets more credit for his "invention" than he deserves, but it is probably fair to say that he brought iced tea to the world's attention (Pratt 1982; Israel 1987). Indeed, from this point forward in the United States, the sale of black tea (which makes better iced tea) began to edge out that of green, suggesting that Blechynden gave his employers their money's worth.

Still another development, which many find to be no improvement at all, is the invention of "instant" tea, which is an evaporated powder similar to instant coffee (Willson and Clifford 1992). Instant tea constitutes a significant amount of the tea consumed in the United States, but – as it is not made by brewing – it could be said that it is not really tea at all (Schapira 1982). In the early 1990s, the nation imported 305,017 tons of tea and exported 85,363 tons. Included in the latter was a small amount of tea grown in the United States (FAO 1993).

Until at least very recently, tea cultivation in the United States has never been a profitable enterprise because of climate, although, since the nineteenth century, individual tea bushes have been tended in gardens of the South. Between 1848 and 1852, the operators of a plantation in Greenville, South Carolina, tried to grow tea, and in 1880, John Jackson made an attempt in Summerville, South Carolina. Tea was also grown in several places nearby, but all these efforts were eventually abandoned (Ukers 1935).

In the 1980s, however, Mack Fleming, an engineer for the Lipton Tea Company, purchased the Summerville land and, with the help of Canadian tea taster Bill Hall, began experimentally processing leaves from the tea bushes that still remained. Fleming and Hall transferred tea bushes to Wadmalaw Island near Charleston and invented a machine to shear off the tea buds, literally mowing the tea like a lawn. The resulting product, marketed in both bagged and loose forms as American Classic Tea, is the only tea commercially grown in America. Hawaii, California, and Florida also have climates appropriate for tea growing, but labor costs for harvest are prohibitive.

Other Lands

Brazil and Argentina in South America, and Turkey and Iran in the Near East, produce undistinguished teas – mostly for teabags – as do Tanzania and Malawi in Africa. In Kenya, however, which now ranks fourth among the world's tea-producing nations, some teas are emerging as noteworthy. For the most part, these black teas are grown on plantations on the high plateaus that are understandably similar to those of India, as they were founded by British planters who left that country following independence (Willson and Clifford 1992). In addition, South Africa produces an excellent tea from plants that originated in the Darjeeling area of India; in South Africa, as in Kenya, tea plantations are located on the high plateaus.

Tea and Health

In modern times, tea is one of the world's least expensive beverages, which helps to account for the fact that, after water, it is also the most commonly used beverage. Because it is made with boiled – and therefore sterile – water, tea is safe to consume in areas where water quality may be less than satisfactory.

This is doubtless one of the major reasons that, over the millennia, tea has maintained a reputation for contributing to good health (Weisburger 1997). Buddhist monks in China and Japan, who were physicians as well as tea-masters, used tea to help people through their illnesses. Even today, tea is frequently employed in ancillary therapy for individuals who suffer from various infections, colds, or chronic diseases (Yamanashi 1991). Tea is a diuretic and produces both warmth (if it is served hot) and coolness (because it promotes evaporation of water from the skin) in the body; moreover, the steam of hot tea moisturizes the nose, mouth, and throat. The caffeine in tea is also a "pick-me-up."

Perhaps because tea was first used in China and Japan, historically most research on its health benefits was conducted by Eastern research groups. These groups have held conferences to report on findings that have to do largely with disease prevention and, to a lesser extent, with therapy (Yamanashi 1991). But even though tea became a major beverage in some of Europe and all of the English-speaking world, relatively little research of this nature was done in the West until recently.

Beginning in about 1980, however, a number of laboratories and groups in the United States and Canada – and a few in Europe – have shown an interest in researching relationships between tea and human health. Their findings were summarized at the First International Conference on Tea and Health, held in New York in 1991 (Symposium 1992). Included were reports suggesting that people who drink tea regularly have a lessened risk of coronary heart disease. Moreover, some investigators also noted that tea has a beneficial effect in warding off cancers of the stomach, esophagus, and lung (Katiyar and Mukhtar 1996; Weisburger 1996; Yang et al. 1997), and new research suggests that the caffeine in tea may play a role in such cancer prevention. Black tea and green tea had very similar (if not identical) preventive effects, and a few findings showed delayed growth and even regression of cancers in laboratory animals.

Stimulated by such findings, considerably more research has since been conducted in Europe, North America, and Asia. One interesting area of investigation has to do with the incidence of lung cancer in Japanese men, which is lower than that in their American counterparts, even though the Japanese smoke many more cigarettes on a per capita basis. It has been hypothesized that tea drinking by Japanese men is the key factor.

The chemical basis for the preventive benefits of tea seems to be specific polyphenols in both green and black teas that can act as powerful antioxidants. It is suspected that the risk of heart disease and many types of cancer is lowered by the raised antioxidant level in the bodies of those who drink tea and, conversely, that the conditions promoting these diseases involve abnormally low levels of oxidation. Tea polyphenols also modify intestinal bacterial flora, leading to a decrease in the levels of undesirable bacteria and contributing to the maintenance and increase of desirable bacteria. In fact, tea is the culture medium for the "tea fungus" called *kombucha,* actually a symbiotic bacterial culture used in alternative medicine. Tea can have a specific antibacterial action and, perhaps, a limited but definite effect against specific viruses (Hara 1994). Moreover, recent results suggest that Alzheimer's disease may occur less frequently in aging people who are regular tea drinkers.

One kilogram of tea makes about 440 cups, whereas the same amount of coffee makes about 88 (Harler 1964), which helps to explain both the relative cheapness of tea as a beverage and the higher caffeine content of coffee. The caffeine in tea was once called "theine," but is chemically identical to the caffeine in coffee. Depending on the type of tea, a 150-milliliter cup may contain 30 to 50 milligrams of caffeine, only about one-third of the caffeine found in a cup of coffee (Harler 1963).

Nonetheless, this is sufficient to account for its reportedly pleasant, slightly stimulating effect on mental function, and is doubtless the reason for tea's popularity as a morning beverage. However, the amount of caffeine in tea is low enough that an overdose is unlikely, whereas overdose symptoms ranging from headaches to severe gastrointestinal distress do occur in coffee drinkers (Willson and Clifford 1992). Tea is also available decaffeinated; to achieve this, solid carbon-dioxide extraction is employed to remove caffeine selectively without removing the desirable polyphenols. Thus, decaffeinated tea provides the taste and most of the health benefits of its caffeinated counterpart for caffeine-sensitive tea drinkers and can be consumed in the evening without fear of sleep deprivation.

Ordinary tea, however, can be made as free of caffeine as decaffeinated tea. One way to do this is to brew a first infusion, discard it, and brew a second from the same tea. Caffeine is extracted from tea in 1 to 2 minutes, and so a second infusion will have a weaker taste but no caffeine. Another means is to make "sun tea" by placing cold water with teabags in it in direct sunlight, usually for several hours. The result is a tea virtually free of caffeine, normally served iced. However, it is not known whether the health-promoting antioxidant tea polyphenols remain intact after being subjected to the sun's radiation.

How to Make Tea

Starting with Lu Yu and Sen Rikyû, tea-masters throughout the ages have emphasized both the ease of making good tea and the philosophical significance of the beverage. The following is offered as a basic modern outline of how good tea should be treated.

Start with fine tea, whether whole or bagged, and clean, cold water. Avoid water that has a taste of its own. For green tea, bring the water to a simmer; for black or Oolong, it must be at a rolling boil. Warm the vessel in which the tea will brew by pouring boiling water into and out of it, and add about 3 grams of tea per cup to be brewed. Pour boiling water over the leaves and allow to steep for 3 to 5 minutes, depending on the type of tea. Finally, remove the leaves or teabag from the vessel and pour the tea, adding sugar (or other sweetener), milk, or lemon, as desired. On a cold night, tea with rum, brandy, or bourbon whiskey makes a warming and thus a pleasant beverage.

John H. Weisburger
James Comer

Research in Weisburger's laboratory is supported by grants and contracts from the Tea Trade Health Research Association, Toronto, Canada; the National Cancer Institute, Bethesda, Maryland; the American Cancer Society, Atlanta, Georgia; and gifts from Texaco, Inc., Beacon, New York, and the Friends Against Cancer Team.

Note

1. This company of many names was originally founded as two separate companies: (1) the Governor and Company of Merchants Trading into the East Indies, and (2) the English Company Trading to the East Indies. In 1708, the two merged to become the United Company of Merchants Trading to the East Indies, which was more succinctly called the Honourable East India Company and more familiarly referred to as the John Company (Harler 1964).

III.12 Water

The ingestion of water in some form is widely recognized as essential for human life. But we usually do not consider water as food because it does not contain any of those substances we regard as nutriments. Yet if its status as a foodstuff remains ambiguous, it is far less so than it has been through much of human history. Water (or more properly "waters," for it is only in the last two centuries that it can really have been viewed as a singular substance) has been considered as food, a solvent for food, a pharmaceutical substance, a lethal substance, a characteristic physiological state, and a spiritual or quasi-spiritual entity.

This chapter raises questions about what sort of substance water has been conceived to be and what nutritional role it has been held to have. Moreover it also explores what we know of the history of the kinds of waters that were viewed as suitable to drink – with regard to their origins, the means used to determine their potability, and their preparation or purification. It also has a little to say about historical knowledge of drinking-water habits (i.e., how much water did people drink at different times and situations?) and water consumption as a means of disease transmission.

What Water Is

Modern notions of water as a compound chemical substance more or less laden with dissolved or suspended minerals, gases, microorganisms, or organic detritus have been held at best for only the last two centuries. Even earlier ideas of water as one of the four (or five) elements will mislead us, for in many such schemes elements were less fundamental substances than dynamic principles (e.g., in the case of water, the dynamic tendency is to wet things, cool them, and dissolve them) or generic labels for regular combinations of qualities. In one strand of Aristotelianism, for example, water can be understood as matter possessing the qualities of being cold and wet; thus whenever one finds those characteristics, one is coming across something more or less watery. It may even be inappropriate to think of water as wholly a natural substance; as we shall see, springs and wells (if not necessarily the water from them) often held sacred status. The primacy of water in the symbolism of many of the world's religions as a medium of dissolution and rebirth invites us to recognize water as numinous in a way that most other foodstuffs are not (Eliade 1958; Bachelard 1983).

At the very least, it is clear that through much of Western history "water" referred to a class of substances. "Waters" varied enormously both in terms of origin (rainfall, snowmelt, dew, and pond, spring, and river water were seen to be significantly different) and from place to place, just as climate and other geographical characteristics – vegetation, soil, topography – vary. Whereas for most of us the modern taxonomy of water quality includes only two classes (pure and impure), in the past subtle and complicated characterizations were nearly universal, especially with regard to water from springs, a matter that fascinated many writers. Indeed, the uniqueness of a water is a key attribute of place, and waters are linked to places in much the same way in which we now associate the characteristics of wines with their places of origin. This idea is evident in the title of the famous Hippocratic treatise "On Airs, Waters, and Places"; it is a central theme in the treatments of post-Hippocratic classical authors like Pliny the Elder and Marcus Pollio Vitruvius, and much the same sensibility seems apparent in Celtic, Teutonic, and Chinese perspectives.

Water varied from place to place in many ways, but one can generalize about the kinds of qualities that interested classical authors. Many did mention taste, and they usually held that the less taste the water had, the better. Taste, in turn, was associated with a host of other qualities that linked the immediate sensory experience of drinking a water with the effects of its continued consumption on health and constitution. Other key factors were coldness, lightness, and heaviness.

Coldness did not necessarily refer to temperature, which in any case could not be measured except subjectively and indirectly. In Chinese cosmology coldness and hotness were part of the universal system of polarities, applied to foodstuffs as well as to many other substances and activities. Water was by definition cool; steeping or cooking things in it (even boiling them) was accordingly a cooling process (Simoons 1991: 24). For the mechanical philosophers of early eighteenth-century Europe, "cold" and "hot" had become terms of chemical composition: Sulfurous water was "hot," that containing niter or alum was "cold" (Chambers 1741).

Lightness appears usually as a subjective quality akin to ease of digestibility. Pliny, in an unusual outburst of skepticism, observed that unfortunately "this lightness of water can be discovered with difficulty except by sensation, as the kinds of water differ practically nothing in weight" (Pliny 1963: book 31, chap. 21). But occasionally lightness was a parameter that could be objectively measured: Equal areas of tissue were wetted in different waters and their weights compared to determine which water was the lighter, and hence the better to drink (Lorcin 1985: 262).

The Classes of Waters

In general, desirable or undesirable properties were associated with the source of the water one obtained, and there was general agreement on the ranking of these sources. Rainwater was usually held to be the best water even though it was also regarded as the quickest to become putrid (though this in itself was not problematic, since the water might still be used after it had finished putrefying). Though some wealthy Romans made much of its virtues, water from melted snow or ice was generally viewed as harmful, possibly because it was associated with goiter, but more likely because, being deaerated, it tasted flat and led to a heaviness in the stomach (Burton 1868: 241; Vitruvius 1960: 239; Pliny 1963: book 31, chap. 21; Diderot and D'Alembert 1969; Soyer 1977: 296; Simoons 1991: 491–2).

Most deemed water from mountain streams (particularly on north-facing slopes) better than water from wells or streams in hot plains because it was held that the heat of the sun was likely to drive off the lighter or best parts of the waters (though Burton, summarizing classical authors, insisted that waters from tropical places were "frequently purer than ours in the north, more subtile *[sic]*, thin, and lighter" [Burton 1868: 241]). Running waters were to be preferred to stagnant waters; waters stored in cisterns were undesirable because they accumulated "slime or disgusting insects" (Pliny 1963: book 31, chap. 21). But none of these generalizations obviated the need to characterize each individual source of water because, as Pliny noted, "the taste of rivers is usually variable, owing to the great difference in river beds. For waters vary with the land over which they flow and with the juices of the plants they wash" (1963: book 31, chap. 32).

Water and Health

Such descriptions clearly indicate that classical authors were much concerned with the effects of waters on health. One can understand their views in terms of a four-part scheme for classifying waters. Some waters are seen as positively beneficial to health, medicaments to be taken to cure various maladies. Others are viewed as good, "sweet" (the term has long been used to describe waters) waters, of acceptable taste and suitable for dietetic use. Still others are regarded as having undesirable qualities as a beverage. Accordingly, they are to be used sparingly, only after treatment, or with compensatory foodstuffs. Finally, authors recognize some waters as pathogenic in some sense, even lethal.

Beyond taste and health effects, waters (particularly spring waters) were characterized in terms of a host of bizarre properties they were believed to have. Pliny tells us (as does Vitruvius) of springs that turn black-wooled sheep into white-wooled sheep, that cause women to conceive, that endow those who drink of them with beautiful singing voices, that petrify whatever is dipped into them, that inebriate those who drink from them or, alternatively, make those who drink of them abstemious (Pliny 1963: book 31, chaps. 3–17). To this one might add the Levitical "bitter waters of jealousy," which possessed the property of identifying adulteresses.

Sometimes authors were explicit in attributing the properties of springs to a concept of chemical admixture: The water had the properties it had owing to what had happened to it, such as the kinds of mineral substances it had encountered underground. Yet the earth was seen as in some sense alive, and we would accordingly be unwarranted in assuming that a modern concept of solution is implied (Eliade 1978). Waters were earth's vital fluids. The Roman architect Vitruvius noted, for example:

> [T]he human body, which consists in part of the earthy, contains many kinds of juices, such as blood, milk, sweat, urine, and tears. If all this variation of flavors is found in a small portion of the earthy, we should not be surprised to find in the great earth itself countless varieties of juices, through the veins of which the water runs, and becomes saturated with them before reaching the outlets of springs. In this way, different varieties of springs or peculiar kinds are produced, on account of diversity of situation, characteristics of country, and dissimilar properties of soils." (Vitruvius 1960: 241–2)

It is probably right to see this linkage of macrocosm and microcosm as something more than analogical; such linkages would remain a part of popular understanding even after the rise of a mechanistic cosmology in the seventeenth century.

The properties of waters might also be understood as manifesting the spirits or resident divinities of springs, because many springs and rivers were thought of as home to (or the embodiment of) a divinity. Such views were held in many premodern cultures, although perhaps best known are the 30,000 nymphs associated by Hesiod with springs in Greece (their brothers were the rivers) (Hesiod 1953: 337–82; Moser 1990; Tölle-Kastenbein 1990). In many, particularly rural, places in France, Britain, Germany, and elsewhere, worship of such divinities persisted well into Christian, and even into modern times. Periodic efforts of the medieval Roman Catholic church to halt such worship usually failed and, in fact, led to the association of wells and springs as sites of miracles linked with particular saints (Hope 1893; Hofmann-Krayer and Bachtold-Stäubli 1927; Vaillat 1932; Guitard 1951; Bord and Bord 1986; Guillerme 1988).

Where water cults were restricted to specific springs, it becomes difficult to deal with questions of why springs were worshiped and what the rituals of worship signified. R. A. Wild has argued that the Nile-worshiping cult of Isis and Sarapis (important and widely distributed during the early Roman empire) simply understood Nile water as the most perfect water; it was associated with fecundity, for humans as well as for crops, and was known as a fattening water (Wild 1981). One may speculate that in a similar sense the worship of the local water source symbolized and represented the dependence of a community on that water. Mineral springs may also have come to be worshiped for their health-giving properties; equally, a spring's reputation as sacred was an asset to a local economy and made clear to local residents that their locality had a privileged cosmic status (Hamlin 1990a; Harley 1990).

Water as Drink

Water, because it possessed such a broad range of significant and powerful properties, was thus to be used with care in a diet. In the tradition of the Hippocratic writers, authors of medical treatises on regimen had much to say about the conditions of waters and about the circumstances in which water was to be drunk. We should first note that most authors were unenthusiastic about the drinking of water. However much it might seem the natural drink of the animal kingdom, it was also viewed as having a remarkable power to disturb the stability of the human constitution. Summing up the views of classical antiquity on water as beverage, the nineteenth-century chef Alexis Soyer wrote, "water is certainly the most ancient beverage, the most simple, natural, and the most common, which nature has given to mankind. But it is necessary to be really thirsty in order to drink water, and as soon as this craving is satisfied it becomes insipid and nauseous" (Soyer 1977: 299).

The principal later medieval medical text, Avicenna's *Canon of Medicine,* for example, advised one not to drink water with a meal, but only at the meal's end, and then in small quantities. Water taken later, during digestion, would interrupt that process. One was also not to drink water while fasting, or after bathing, sex, or exercise. Nor should one give in to night thirst. To do so would disrupt digestion and would not quench the thirst for long. For Avicenna, a water's temperature was also a crucial determinant of its physiological effect. Too much cold water was harmful, whereas "tepid water evokes nausea." Warm water acted as a purgative; yet too much of it weakened the stomach (Gruner 1930: 228, 401, 407–8; Lorcin 1985). The effects of habitually imbibing certain waters could be cumulative. The Hippocratic text "On Airs, Waters, and Places," for example, held that cold waters had a detrimental effect on women's constitutions: Menstruation was impaired and made painful; breast feeding was inhibited (Hippocrates 1939: 22).

Such a sensitivity to the careful use of water within the diet is also evident in premodern Chinese writings on diet. There, too, one finds recognition of an extraordinary range of properties possessed by different waters (drips from stalactites were seen to enhance longevity) and, accordingly, great interest in classifying sources of water. In China, the preference was for warm (or boiled) water, possibly, though not necessarily, in which vegetable substances had been steeped (i.e., tea). Cold water was deemed to damage the intestines (Mote 1977: 229–30; Simoons 1991: 24, 441, 463).

Although modes of pathological explanation changed over the centuries, concern with the role of waters in regimens remained important up to the mid-nineteenth century and the onset of a medicine more oriented to specific diseases. The Enlightenment authors of the *Encyclopédie* proposed to determine, through a sort of clinical trial, the full physiological effects of water, but they noted that such a project was impossible because one could not do without water (in some form): One could detect only the differential effects of water and other drinks. (They were particularly interested in the claim that water drinking enhanced male sexual performance ["très vigoureux"]; they thought it probable that such tales reflected only the incapacitative effects of alcoholic drink, not the positive effects of water [Diderot and D'Alembert 1969: entry on "eau commune"]). Late-eighteenth-century British medical men were still stressing the emetic and diluent properties of water. Much food with much water could provoke corpulency; too much water with too little food could promote a diet deficient in nutrients, since food would move too quickly through the digestive tract. For some foods, water was not a sufficient solvent; successful digestion of meats, for example, required fermented beverages (though the alcohol in such beverages was seen as a dangerous side effect). Care was to be taken in quenching thirst, which might not simply signal too little internal moisture but instead indicate too much food or the wrong kinds of food (*Encyclopedia Britannica* 1797: entry on "drink"; *Rees Cyclopedia* 1819: entry on "diet").

In antiquity, as in the eighteenth century, the wise physician recognized that general rules like those just mentioned might need modification: One modified them according to a sophisticated explanation of the particular nutritive and other functions of water within the body (further adapted in accord with the constitution and condition of the individual who was to drink it), according to a knowledge of the particular water and the modes of preparation it had undergone. Within the body, water was understood to have a number of effects, both gastronomic and pharmaceutical, but as M. T. Lorcin has noted, in such regimen literature this distinction is inappropriate; health consists of the proper cultivation of the constitution; all ingesta contributed to this (Lorcin 1985: 268).

The chief medical functions of water were as a diluent of food and as a coolant. It acted also as a solvent of food, as an initiator of digestive and other transformations, and as a tonic (a substance that strengthened or gave tone to one's stomach and/or other fibers). It was seen also as a mild purgative (Chambers 1741).

The Treatment of Water

To augment some of the functions just mentioned and retard others, waters might be treated or purified. Some of the harmful qualities of water were understood to be susceptible to neutralization or purification. Avicenna recommended boiling as a good means of purification; he held that the mineral residue left behind contained the congealed "coldness" that was the impurity (Gruner 1930: 223). Water might also be made to pass from a container, by capillary action, along a wick of fleece; the drops falling from the end would be assumed to have been purified. Harmful qualities could also be removed by addition of vinegar or wine or by soaking in the water some substance, such as pearl barley, onions, or wax, which would absorb or counteract injurious matters.

One might also shake a suspect water with sand (a technique remarkably similar to that used by Edward Buchner to obtain bacteria-free water for the experiments that led to the concept of the enzyme). Finally, classical and medieval authors recognized the value of filtration, whether a natural filtration through soil, or an artificial filtration through wool, bread crumbs, or cloth ("in order to make sure there are no leeches or other creatures in it") (Gruner 1930: 222, 454–5; Baker 1948: 1–8; Lorcin 1985: 263). The great potency of water for good and ill, along with its considerable variability from place to place, made it crucial for travelers to be especially careful of the waters they drank: "The traveller is more exposed to illness from the diversity of drinking water than he is from the diversity of foods. . . . it is necessary to be particular about correcting the bad qualities of the drinking water, and expend every effort in purifying it" (Gruner 1930: 454).

Thus, long before there was a clear concept of waterborne disease, there was great deal of appreciation, shared by cultures in many parts of the world, of the various characters of waters and of their manifold effects on health. How assiduously people followed hygienic advice about which waters to drink and how to prepare them, and how far following such advice would have been adequate to prevent waterborne diseases is not clear, but it is clear that in cases where public waterworks existed, such as the aqueducts that supplied Rome, those in charge of their administration were supposed to be concerned, in part, with quality. It seems evident that humans have been subject to waterborne diseases throughout recorded history, and, thus, it is remarkable that there is little mention of epidemics (or even cases) of waterborne diseases prior to the nineteenth century (but see Ackerknecht 1965: 24, 41–2, 47, 134–6; Janssens 1983; Jannetta 1987: 148–9; Grmek 1989: 15–6, 346–50).

One might attribute this lack of waterborne epidemics to relatively low population density or a magnitude of travel that was usually too low to sustain outbreaks of diseases caused by relatively fragile bacteria. In this connection, it is notable that many of the records do deal with diseases that we might now attribute to the hardier parasites. Yet it is surely also the case that a population, aware of the dangers of water and possessing an impressive armamentarium of techniques for improving that water, did much to prevent waterborne disease outbreaks. Even if one does not see the Chinese preference for warmed (ideally boiled) water as representing hygienic consciousness, it surely was beneficial in relatively heavily populated areas where paddy cultivation, with night soil as fertilizer, was customarily practiced (but see Needham: 1970). In other cases, as in the addition of wine to water in early modern France, the action was explicitly a purification, with greater or lesser amounts of wine added according to the estimated degree of impurity of the water (Roche 1984).

The Reclassification of Water

Most clearly for Pliny, but also for many classical, medieval, and early modern authors, "waters" were "marvels," each unique, whether owing to the mix of natural agency to which it had been exposed or to its intrinsically marvelous character (Pliny 1963: book 31, chap. 18). By the seventeenth century, European writers on waters had come to emphasize a binary classification: Water was either common (more or less potable) water or mineral water. "Mineral waters" was the collective term for the remarkable springs Pliny had described. Less and less did they represent the mark of the "hand of providence" on a particular locale; increasingly their properties were understood in terms of the salts or gases dissolved in them (Brockliss 1990; Hamlin 1990a, 1990b; Harley 1990; Palmer 1990).

Far from being unique, any mineral spring could be understood as belonging to one of a few general types. These included chalybeate, or iron-bearing waters, drunk to treat anemia; sulfurous waters, good for skin problems; acidulous waters, full of carbonic and other acids that gave the stomach a lightness; and saline waters, which served usually as purgatives. A good many springs, with a wide variety of constituents (and a few with no unusual chemical constituents at all), were also held to be cures for infertility and other diseases of women (Cayleff 1987).

Springs varied in temperature, which might or might not be significant. That waters in some springs were to be bathed in and that waters from others were to be taken internally was a less formidable distinction than it seems to us now. Bathing was not simply a treatment of the skin; the water (or its essential qualities) was understood to be able to enter the body through the skin or to be able to cause significant internal effect in some other way. Some therapeutic regimens, such as hydropathy, popular among educated Americans and Europeans in the mid-nineteenth century, integrated a wide variety of external and internal applications of water to produce improvements in health, which clients (like Charles Darwin) regarded as dramatic indeed (Donegan 1986; Cayleff 1987; Vigarello 1988; Brockliss 1990; Browne 1990).

The characterization of springs in terms of chemical constituents was not so much a consequence of the maturation of chemical science as one of the sources of that maturation. Such characterizations were necessary for the proprietors of mineral springs to compete in a medical marketplace. People from the rising middle classes, who increasingly patronized mineral waters, were no more willing to trust in miracles in taking the waters than in any other aspect of business. Every spring had its testimonials, miracles, and claims of excellent accommodations and exalted society for its visitors. Thus, the chemical composition of a spring seemed the only reliable means to make a decision on whether one might patronize a lesser-known resort nearby or whether one undertook a lengthy journey (Guitard 1951; Hamlin 1990b; but see Brockliss 1990). Chemistry also provided a means of bringing the spa to the patient through medicinal waters, which could be bottled for widespread distribution (Kirkby 1902; Coley 1984). Following the discovery of the means to manufacture carbonated water by Joseph Priestly and Torbern Bergman, such enterprise gave rise to the soft-drink industry (Boklund 1956).

One effect, of course, of making water part of the domain of chemistry was to reduce "waters" to a mixture of a simple substrate, "water" (whose composition as a compound of hydrogen and oxygen had been recognized by the end of the eighteenth century) with various amounts of other chemical substances. This conceptual transformation was not achieved without resistance, particularly from physicians (often with practices associated with particular springs), who saw their art threatened by the reductionism of chemistry and continued to maintain that each spring had a peculiar "life" that no chemist could imitate and whose benefits could only be obtained if its waters were drunk on-site (Hamlin 1990a, 1990b).

If, in the light of the new chemistry, mineral waters were no more than mixtures of simple substances, common water was even simpler and less interesting. To medical men and to chemists, this *eau commune* was to be evaluated as belonging to one of two mutually exclusive categories: It was either "pure" or "impure." The terms did not refer to the ideal of chemical purity, which was recognized as practically unattainable; they were simply used to indicate whether the water was suitable or unsuitable for general domestic use (including direct consumption).

At the beginning of the nineteenth century, the chemists' chief conception of impurity in water was hardness, the presence of dissolved mineral earths. Initially, this new focus supplemented, rather than replaced, the sophisticated classical taxonomy of waters (no one championed soft water that was obviously foul), and the quantification of hardness (expressed as degrees of hardness) was simply a valuable service that chemists could (easily) provide. Hardness was an industrially significant distinction; for steam engine boilers and for brewing, tanning, and many textile processes, the hardness of water was the key criterion. It seemed a medically significant criterion, too: Just like the steam boiler, the drinker of hard water could clog up with bladder stones or gout, conditions that attained remarkable prominence in medical practice, at least in eighteenth-century England (*British Cyclopedia* 1835: s.v. "water"; Hamlin 1990b).

Waters in the Industrial World

The nineteenth century saw great changes in views of drinkable water and equally great changes in predominant notions of who was competent to judge water quality. Despite the chemists' infatuation with hardness, traditional senses-based approaches to judging water still prevailed in Europe at the beginning of the century. In choosing waters, ordinary people continued to be guided by tradition, taste, and immediate physiological effects. In many cases the standards they used were those found in the classical literature: Stagnant, "foul" water was to be avoided, clear, light, "bright" water was to be desired.

After midcentury, however, expert definitions prevailed. Often experts would insist that water that looked, smelled, and tasted good, and that had perhaps been long used by a local population, was actually bad. Indeed, in some situations, experts' standards were virtually the opposite of lay standards. Light, sharp water had those qualities because it contained dissolved nitrates, which, in turn, were decomposition products from leaking cesspools. The best-tasting well water might, thus, be the most dangerously contaminated (Hardy 1991: 80–1). Less often, experts would insist that waters that laypeople found objectionable (perhaps because they had a strong taste of peat or iron) were wholly harmless.

No longer were chemists restricting themselves to determinations of hardness. Even though the techniques at their disposal did not change significantly (hardness and other forms of mineral content remained the only characteristics they could determine with reasonable effectiveness), chemists increasingly were claiming that they had defined and had the means to quantify what was objectionable in a water beyond its dissolved minerals. They could, they insisted, measure those qualities that had been the basis of the classical water taxonomy better than these qualities could be detected by the senses.

The key quality that interested them, and which at first supplemented and then displaced concern with hardness or softness, was putridity. "Putridity," while a vague concept, had been the centerpiece of an approach to evaluating water based on one's subjective repugnance to it – owing to its odor, appearance, taste, and associations (the German word *Fäulnis* better embodies such a combination of the visceral and technical). Chemists replaced the senses-based definition of putridity with more arcane indicators of putridity or potential putridity. For much of the nineteenth century, however, they were not in agreement about what precisely these arcane indicators were or the best ways to measure them. Some felt it sufficient to determine the quantity of "organic matter," even though they admitted that this parameter was in some sense an artifact of analytical instrumentation.

Such an approach was contrary to the belief that it was some unknown qualitative factor of organic matter (and not such matter itself) that was associated with putridity and disease. In any case, "foulness" or "putridity" ceased to be a physical state of water and instead became an expert's concept indicating an amount or a presumed condition of "organic" matter. This determination, in turn, was usually believed to correspond to a presumed fecal contamination. Henceforth, the repugnance that "putrid" or "foul" conjured up was to operate through the imagination, rather than directly through the senses.

The champion of this novel perspective was the English chemist Edward Frankland, the leading international authority on water analysis in the 1870s and 1880s. Frankland took the view that it was foolish to try to detect quantities of some unknown disease-generating agency. It was much better simply to try to discover whether water had been subject to contamination in its course through or over the ground. The possibility of dangerous contamination was sufficient reason for public authorities to avoid such supplies of water, and the idea of contamination was to be sufficient to compel ordinary people to avoid its use (Hamlin 1990b).

The shift in approaches to the assessment of water that Frankland exemplifies is a far-reaching one. Associating what might be wrong in water with the presumed commission at some time past of an act of contamination made the religious term "pollution" in its traditional sense of desecration the primary construct for a discussion of water quality, and it came to replace "foul" and "putrid" (Douglas 1966). A presumed act done to the water thus replaced a manifest condition of the water. Although laypersons had known whether water was "foul" at one time, it was up to experts to say whether water had been "polluted." Consequently, water became (and remains) one of very few "foods" whose most important qualities were defined wholly by experts, and whose consumption, accordingly, marked complete trust of the individual in some outside institution: a government, a bottled-water company, or the maker of a filter.

There were, of course, good reasons for such a transformation, and underwriting it was the fear of waterborne (or water-generated) disease. That dense urban environments were dangerous to health was a long-standing medical truth, and water was implicated in this danger: Standing surface water, particularly in marshes, was believed to interact in some way with town filth to generate both fever (particularly malaria) and chronic debilitation. Although consumption of water was not the focus of concern, there was medical consensus that drinking such stuff could not be beneficial to health. Yet at the beginning of the nineteenth century, the doctors were unable to say much about how and in what ways such water was bad, or how it became bad, or how serious a problem bad water might be. Some held that water became harmful by absorbing harmful elements from a filthy urban atmosphere and was simply another means of communicating that state of air. Keeping the water covered would keep it pure, they believed. (Others thought that the putridity was inherent in the water itself and infected the atmosphere.)

Whatever the mechanism, the increasing frequency of epidemic disease was evident in the newly industrialized cities of the nineteenth century. They were swept repeatedly by waves of Asiatic cholera, as well as typhoid fever (only clinically distinguished from other forms of continued fever in the 1840s), and other enteric infections (less clearly identified but no less deadly) (Ackerknecht 1965; Luckin 1984, 1986).

Not until after 1850 were these diseases commonly associated with fecally contaminated water, and even that recognition did not provide unambiguous guidelines for determining water quality because such contaminated water sources only rarely caused severe outbreaks of disease. One might assume that they did so only when contaminated with some specific substance, but as that substance was unknown, it could not be measured, nor was there a clear correlation between the quantity of contamination and the amount of disease. Water that was evidently transmitting cholera was, according to the most sophisticated chemical measures available, substantially purer than water that evidently caused no harm. Some, like Frankland, held that any water that had ever been subject to such contamination should be avoided, but in heavily populated areas, where rivers were essential sources of water, this recommendationn seemed impracticable.

Although these contradictions demonstrated the inadequacy of the lay determinations of water quality, the techniques of the experts were little better prior to the twentieth century. Nonetheless, in the nineteenth century, judging waters became a consummately expert task, so much so that the European colony in Shanghai felt it necessary to send water samples all the way to London to be analyzed by Frankland (MacPherson 1987: 85). And even after the microbes responsible for cholera and typhoid were identified in the 1880s and means were developed for their detection, many experts remained skeptical, unwilling to accept negative findings of their analyses (Hamlin 1990b). But by the early twentieth century, the institution of chlorination, more carefully monitored filtering, and a better understanding of the microbe-removing actions of filters finally led to a widely shared confidence in the safety of urban water supplies (Baker 1948). Such confidence, however, appears to have peaked, and is now in decline.

Town Supplies – Water for All

The fact that cities and towns throughout the world recognize the provision to dwelling houses of piped-in, potable water as an essential component in achieving an acceptable standard of living is remarkable indeed. It involves, in fact, two kinds of public decisions: first, a recognition of a need for a supply of water to be readily available to all settled areas, and second, a recognition of a need for a supply of water to be piped into each dwelling unit.

We usually associate both these features (household water supplies from a public waterworks) as exemplifying the organizational genius of Imperial Rome and lament that it was only in the nineteenth century that authorities, guided by new knowledge of disease transmission and new standards of public decency, again acknowledged water supply as a public duty. Yet a "hydraulic consciousness" was well developed in many medieval and early modern European towns (as well as existing far beyond the Roman empire in the ancient world) (Burton 1868: 241). This consciousness manifested itself in the building of public fountains and pumps, the diversion of brooks for water supply, and even the use of public cisterns and filters, as in Venice. All of these means were used to supply water for industrial purposes, for town cleansing, and for the fighting of fires, as well as for domestic use, but it would appear that the piping of water into individual homes was not felt to be important (Baker 1948: 11–17; Guillerme 1988; Vogel 1988; Dienes and Prutsch 1990; Grewe 1991). High-volume domestic uses of water did not exist; water closets would not become popular until the nineteenth century; bathing was, at least in early modern France, seen to be dangerous to health; and clothing (other than linen) was rarely washed (Vigarello 1988).

By no means was the provision of good drinking water atop this list, but that it was on the list at all is remarkable. How much water people drank, when and where they got it, how public authorities assessed the need for drinkable water and understood their role in supplying it are all questions about which far too little is known. Summarizing pre-nineteenth-century sources, M. N. Baker presented evidence to suggest that urban dwellers did not expect to find raw water drinkable and that knowledge of effective means for treating waters was widespread.

These means ranged from simply allowing sediment in water to settle and then decanting the water to the addition of purifiers (vinegar or wine) or coagulants (alum), or to drinking water only in boiled forms, like tea (Baker 1948: 24–5). The excessive consumption of alcohol was also seen by nineteenth-century temperance advocates as a public response to the unavailability, particularly in poor neighborhoods, of drinkable water (Chadwick 1965: 135–50). It was probably a prudent response: Beer, in particular, was cheap, usually made with a higher-quality water than that readily available, and often more accessible to the poor than water. In Britain it was drunk in hospitals and schools, not just in taverns (Harrison 1971: 37–8, 298–9).

Temperance advocates were often among the champions of public water supplies. But other kinds of reformers became involved, too, sometimes for curious reasons. Those concerned with the morals of the poor worried that a central pump or well was often a locus for the spread of immorality. Children, waiting to fill water containers (sometimes for several hours, if the sources are to be believed), were exposed to bad language, immoral activity, and dangerous ideas. An in-house supply of water could prevent all that. A public drinking fountain movement, begun in Britain in the late 1850s (initially supported by brewers and, surprisingly, not by temperance advocates), received critical support from the Royal Society for the Prevention of Cruelty to Animals, which was concerned about thirsty animals ridden or driven into towns that lacked facilities for watering animals (Davies 1989: 19).

In the century from 1840 to 1940, in almost all of the industrialized world, a public responsibility for providing town dwellers with in-home water was recognized. The timing and circumstances of that recognition varied from society to society (and, significantly, sometimes from town to town), with "public health" considerations usually providing the warrant for that recognition. Adequate sanitary provisions came to include the provision of a water closet in some form and a continuous supply of water that could be drunk without treatment. Whatever its merit on epidemiological grounds, this notion of sanitary adequacy represented the successful promulgation of an ideology of cleanliness and decency that was quite new, and in this transition the status of water changed. No longer was it an aliment whose quality one judged independently for oneself, nor was it something one had to hunt for and sometimes secure only after much labor (Chadwick 1965: 141–2). Instead it was (or was supposed to be) truly a "necessity" of life, something easily and immediately available, nearly as available (and often almost as cheap) as breathable air.

Although the image of water as a public good essential for meeting universal standards of health and decency usually supplied the rationale for undertaking water-supply projects, the ulterior motives of private interests were often more important in actually getting waterworks built. Perhaps the most significant of these private interests were industrial users. Many industries required large quantities of relatively high-quality water, and the capital costs of obtaining such supplies were prohibitive for individual firms. Consequently, they sought to obtain those supplies (sometimes at subsidized prices) through the sanitary betterment of society. In port cities with much warehouse space, the threat of fire was another underlying incentive for a public water supply.

Some towns took early action to secure control of important watersheds, either with the expectation of profitably selling water to their neighbors or of acquiring commercial advantage. Investors found waterworks projects attractive for a number of reasons, among them a steady dividend, or the possibility of selling land or shares at inflated prices. New York's first waterworks project attracted speculators because it functioned as a nonchartered and hence unofficial, bank. Some of the capital raised was used to build a waterworks; the rest went into the general capital market (Blake 1956). It need hardly be said that contractors, plumbers, and lawyers were delighted to support waterworks projects. Water is not usually viewed as an article of commerce in the way that most foods are, yet once it had been defined as a public necessity, there was plenty of money to be made from it (Blake 1956; Hassan 1985; Brown 1988; Goubert 1989).

Although this transformation in the availability of water made water drinking much more convenient, the resultant technologies were by no means regarded as an unmitigated benefit. Networks of water mains (and sewer lines) linked people physically across classes and neighborhoods in ways that they had resisted being linked and sometimes in ways that proved hazardous. A common complaint about sewer systems was that they spread disease rather than prevented it because sewer gas frequently rose through poorly trapped drains into houses. It was believed that one was exposed to any infection that the occupants of any other dwelling on the sewer line permitted to go down the drain. More serious, from the perspective of modern epidemiology, was the potential of water mains to distribute infection – precisely what took place in the 1892 Hamburg cholera epidemic (Luckin 1984, 1986; Evans 1987).

Yet for most of the twentieth century, events like the 1892 outbreak of cholera in Hamburg have been rare in the industrialized world. When properly maintained and supervised, the water networks work well. By the end of the nineteenth century, water engineers, finally possessing the torch of bacteriological analysis to illuminate their work, made the filtering of water a dependable operation, even when the water was heavily contaminated. In the first two decades of the twentieth century, they acquired an even more powerful technique in chlorination. Initially used only when source waters were especially bad or in other unusual circumstances, chlorination quickly became a standard form of water treatment. Even if it was almost always unnecessary, and merely supplementary to other modes of purification, chlorination provided a measure of confidence. That it interfered with (ruined, many might say) the taste of water was no longer of much importance (Baker 1948: 321–56; Hamlin 1990b; O'Toole 1990). Thus, the concept of water as a substance that was necessary to ingest occasionally (even if it was potentially a mode of disease transmission) had, in much of the modern world, very nearly displaced the older concept of "waters" as unique substances, varying from place to place, some of them downright harmful, others with nearly miraculous healthful qualities.

Water in the Present

In recent years, there have been signs that a further transformation of the status and concept of water is under way. In the United States, the authorities responsible for supplying drinkable water are no longer as trusted as they once were (in many parts of the world, of course, such authorities have never known that degree of trust). In some cases that loss of trust reflects a real inability to maintain standards of water quality. But it also reflects public concern about new kinds of contaminants, such as toxic organic chemicals, viruses, and giardia (McCleary 1990; Hurst 1991). In some cases the effects of these contaminants may only be manifest after many years and only through use of the most sophisticated epidemiological techniques (Hand 1988). Nor are customary methods of water analysis or approaches to water purification yet well adapted to such contaminants.

The response of the public has been to revert to a technology, the home water filter (or other water purification devices), that had been popular in the nineteenth century before water authorities were trusted. For some, drinking water has again become a commodity that we think we must go out of our way to secure; something that we haul home in heavy fat bottles from the supermarket. Yet these responses are not adequate to the problem of trustworthiness. The capabilities of domestic water purification devices vary enormously, as does the quality of the product sold by the bottled-water industry and the degree of inspection it receives (Fit to Drink? 1990). Indeed, these responses say less about our need for water we can trust than they do about the institutions we trust.

The rise of the elite bottled mineral waters industry is a reversion too. Pliny tells us that the kings of Persia carried bottled water taken from the River Choapsis with them (Burton 1868: 242); Herodotus and Plutarch referred to an export trade in bottled Nile water – some of it used by devotees of the cult of Isis and Osiris (Wild 1981: 91–4). Such trade was still widespread in the seventeenth and eighteenth centuries. Then, as now, quality control was a problem and customers complained about the excessive price (Kirkby 1902; Boklund 1956; Coley 1984).

The revival of this industry makes it easier for us to appreciate the fine distinctions among waters made by Pliny, Vitruvius, and the medieval and early modern therapists of the regimen. Modern elites have agreed with their predecessors that the taste (can one say bouquet?) of a water really is important, and that through the drinking of fine waters one can cultivate one's health in ways far more delicate than simply keeping one's insides moist and avoiding cholera.

III.13 ~ Wine

Wine is the fermented juice (must) of grapes, and for thousands of years humans have been attempting to perfect a process that occurs naturally. As summer turns into fall, grapes swell in size. Many will eventually burst, allowing the sugars in the juice to come into contact with the yeasts growing on the skins. This interaction produces carbon dioxide, which is dissipated, and a liquid containing alcohol (ethanol) in combination with a plethora of organic compounds related to aroma and taste that have yet to be fully enumerated. Many people have found drinking this liquid so highly desirable that they have been willing to expend enormous effort to find ways of improving its quantity and quality.

In some places both viticulture (grape growing) and viniculture (wine making) emerged as specialized crafts, which today have achieved the status of sciences within the field known as enology. In general, three basic types of wine are produced: (1) still or table wines with alcohol contents in the 7 to 13 percent range; (2) sparkling wines from a secondary fermentation where the carbon dioxide is deliberately trapped in the liquid; and (3) fortified wines whereby spirits are added to still wines in order to boost their alcohol contents into the 20 percent range.

Vine Geography

Grape-bearing vines for making wine belong to the genus *Vitis,* a member of the family Ampelidaceae. Vines ancestral to *Vitis* have been found in Tertiary sediments dating back some 60 million years, and by the beginning of the Pleistocene, evolution had produced two subgenuses – *Euvitis* and *Muscadiniae.* Both were distributed across the midlatitude portions of North America and Eurasia. Glaciation, however, exterminated the Muscadines with the exception of an area extending around the Gulf of Mexico and into the southeastern United States, where one species, *Vitis rotundifolia,* has been used to make sweet wines that go by the regional name of scuppernong.

The distribution of wild *Euvitis* in North America was concentrated east of the Rocky Mountains. In excess of 30 species have been identified, with *Vitis labrusca* being by far the most important in terms of wine making. Its genes are found in all the major grape cultivars such as the Concord, Niagara, Catawba, Dutchess, Delaware, and Elvira. Other species that have made some significant contributions include *Vitis riparia, Vitis aestivalis,* and *Vitis bourquiniana.*

Across Eurasia, the geography of *Euvitis* reflects the cultural importance of wine. From southwestern Asia through Europe one species, *Vitis vinifera,* dominates, but from central Asia to Japan and Southeast Asia, where drinking wine made from grapes is not a traditional practice, a number of species still can be found. The wine-making superiority of *V. vinifera* undoubtedly led to its replacing competing species. It achieves a balance between sugars and acids that is unmatched by any of the others, and it evolved with human assistance into a self-propagating hermaphrodite capable of producing a virtually unlimited number of cultivars possessed of different colors, aromas, and taste characteristics. Some of the better known of these include Cabernet Sauvignon, Pinot Noir, Chardonnay, Riesling, Syrah, and Nebbiolo, but there are many hundreds of others, most with highly localized distributions.

In the late nineteenth century, French scientists began systematically to hybridize *vinifera* with *labrusca* and other native American vines. Their efforts were aimed at producing varieties that were more disease resistant (ones that could, in particular, resist the two scourges of phylloxera and oidium) and were better able to withstand winter cold. Often called French–American hybrids, they were planted in many parts of Europe during the early twentieth century, but currently most of the vines are being uprooted because of dissatisfaction over their wine-making capabilities. In the eastern United States and Ontario, Canada, however, the hybrids have become increasingly important, and research continues into developing new varieties.

During the last 500 years, humans have carried *Euvitis* to areas outside its natural range. It is now found growing in the tropics, as well as in the midlatitude portions of Chile, Argentina, South Africa, Australia, and New Zealand, where wine making has achieved considerable prominence. Virtually all of the vineyards are planted with *V. vinifera.*

Early History

The earliest archaeological evidence indicating wine that might have been made from domesticated vines comes from a pottery jar, dated to between 7400 and 7000 years ago, which was found at the Neolithic site of Hajji Firuz in the northern Zagros Mountains. Whether this is wine's precise hearth remains for future research to determine. But the general area from the Zagros to the Caucasus Mountains is a reasonable possibility – it lies within the natural range of *V. vinifera* and it is included within the broader Southwest Asian region of plant and animal domestication. From here, wine seems to have diffused in two directions.

One was into Assyria and thence to the Mesopotamian city states of Kish, Ur, and later Babylon, among which it attained the status of a luxury drink meant for priestly and noble classes. The hot, dry, and saline soil conditions of Mesopotamia were not well suited for growing grapes, and thus most of its wines probably were imported from the north.

As with many other facets of culture, wine seems to have entered Egypt from Mesopotamian sources. Vines were established along the Nile by at least 5000 years ago, and during New Kingdom times a highly sophisticated technology of wine growing was in place, including an appreciation of vintages and aging. Wine growing followed the Nile upstream to Nubia, where it persisted until Islam's hegemony over the area was established early in the second millennium A.D.

By 3000 years ago, wine drinking had become widespread in southwestern Asia. It was found among the Canaanites and the closely related Phoenicians, and wine consumption became customary among the Hebrews, who seem to have employed it as a ceremonial drink that was taken in moderation by everyone in the community. Elsewhere, the evidence indicates that wine continued to be restricted to those at the top of the socioeconomic ladder and that it was appreciated largely for the intoxicating effects of its alcohol. Intoxication, indeed, was undoubtedly the reason why almost from its inception wine and religion were bound closely together – wine served as a medium for contacting the gods.

The second route carried wine across Anatolia to the shores and islands of the Aegean. It was adopted by the Minoan civilization on Crete and in Mycenaea, where its production became a specialization of some islands and an important item of commerce. Most significant for later developments, wine became a part of Greek culture, and wherever the Greeks planted their colonies in the Mediterranean, wine drinking, wine growing, and wine commerce followed. Sicily and southern Italy became especially prominent and were given the name Oenotria, the land of vines. Another important site was Massilia (Marseilles), from where the Greek method of wine growing spread inland following the Rhone River valley.

Wine became even more popular because of the cult of the Greek god Dionysus (Bacchus to the Romans). Originating as a minor fertility symbol among the Anatolians, he was transformed into a complex figure representing wine in the context of religious and political protest. These protests often took the form of ecstatic revelries, aided by drunkenness, that were intentionally designed to violate prevailing behavioral norms. The cults spread widely throughout the Mediterranean world and apparently were highly instrumental in creating a greater demand for wine among the populace at large.

The Roman Factor

The Romans are usually credited with having contributed more to the advance of wine than any other people. In fact, they probably were not wine drinkers, or at least not wine growers, when they first embarked on their expansion, but instead acquired the habit from the Etruscans, a people derived either from Minoan or Mycenaean migrants who settled in central Italy. But there is little doubt that wine growing flourished under Roman influence. It was established virtually everywhere on the Italian peninsula, both on large noble-owned estates and as a part of peasant farming systems.

Wine also expanded with the empire. A nearby source of supply was needed for garrisons and administrators, and within Rome itself there was a continuous demand for new wines among the upper classes. Although archaeological evidence indicates that some of the Celtic, Iber, Germanic, and Slavic peoples knew how to make wine, they appear to have been largely beer or mead drinkers. Wherever the Romans imposed their rule, however, fundamental changes in wine's regional significance followed. The Romans not only brought with them a wine-drinking tradition that was copied by others but also set about systematically identifying and developing those areas best suited to vineyards. Key considerations included a nearby market, usually an important town, a riverine or coastal location to facilitate transport, and where possible, slopes for correct exposure to the sun and for facilitating the flow of air and soil moisture drainage.

The greatest amount of Roman wine-growing attention was focused on Gaul and the Rhineland. Today, virtually every important wine region in France and Germany, such as Champagne, Burgundy, Bordeaux, and the Rhineland (and many lesser ones as well) can find prominent Roman influences in its history. Viticulture was a particular specialty of the Romans; they created numerous new grape varieties that were better adapted to more northerly sites and they improved methods of vine cultivation, especially techniques related to pruning and training. Although there is, perhaps, a tendency to credit the Romans with too much in many facets of culture and technology, it is quite clear that the map of wine growing would have been drawn much differently without them.

Decline and Rebirth

The demise of Roman political and military authority led to a reversal of wine's fortunes in Europe. This was not because successors, such as the Franks, Vandals, Goths, Visigoths, and Huns, eschewed wine; rather it resulted from the unsettled conditions that plagued the countryside for several centuries. Vineyards were difficult to maintain in the face of repeated raiding and pillaging, and markets all but disappeared as cities went into decline with the disruption of trade. Wine growing persevered, if on a much reduced scale, and it managed to do so largely because of its role in the Christian liturgy. Wine was needed in order to celebrate the mass, and thus the numerous bishoprics established following Rome's conversion managed to keep small vineyards in production during the difficult times of the middle of the first millennium A.D.

Of longer-term significance, however, were the monasteries, which provided bastions of security amid general insecurity. In terms of wine, the most significant monastic orders were the Benedictines and their offshoot the Cistercians, followed by the Carthusians. Experiments by the monks led to new cultivars and to improvements in numerous aspects of viticulture, especially with regard to site selection. Many of today's most celebrated vineyards in such places as Burgundy, the Reingau, and the Mosel were laid out by monks nearly a thousand years ago.

By contrast, from Persia through western Asia across northern Africa and into Iberia, viticulture was confronted by the advance of Islam and the Koranic injunction against drinking alcohol in any form. Although the spread of Islam was very swift, the elimination of wine growing proceeded much more slowly. Minority Christian and Jewish communities often were allowed to continue to use the beverage largely for the tax revenues wine provided. Thus during the early centuries of Islamic rule, the ban on alcohol varied in terms of how rigorously it was enforced. It never seems to have taken a strong hold in Iberia, and consequently wine growing continued there without serious interruption during the period of Moorish rule. But wine in western Asia and the eastern Mediterranean was under greater pressure, and with the rise to power of the Ottomans, it virtually disappeared over much of the area.

Although Norse raids had slowed the pace of vineyard developments in Europe, expansion was once more under way by the beginning of the twelfth century, even in such northerly locales as the Low Countries and England. The monasteries continued with their plantings and were joined in this endeavor by noble estates, many of which employed wine-growing specialists. Local demand was expanding as wine, at least in Western Christendom, became a more common drink among the populace at large. It was a substitute for unsafe drinking water and widely prescribed as a medication for a variety of ailments. In addition, profits could be gained from exports, particularly to the trading states of the Baltic and North Seas. Much of the wine headed in this direction seems to have come from the Rhineland, including Franconia and Alsace.

Markets and Politics

By the close of the twelfth century, the history of wine growing in Europe was being shaped to an ever increasing extent by a combination of politics and market demands in which England played the most prominent role. Vineyards had been planted in the southern part of that country during Roman times, and as noted, further developments occurred with the establishment of monasteries.

The Domesday Book recorded in excess of 40 vineyards, and over the course of the next several centuries their numbers multiplied severalfold. Most, however, seem to have been quite small, and the wine they produced never achieved any esteem. It was thin and acidic and used primarily for sacramental purposes. Thus the English had to begin looking elsewhere for the wine they were consuming in ever larger volumes. The future of wine growing in England was further dimmed by the advancing cold of the Little Ice Age. By the seventeenth century, all the English vineyards had fallen into disuse.

Much of the wine the English initially imported came from the Rhineland, but the source of supply shifted to the Loire River Valley and its hinterlands when Aquitaine was joined to England during the middle of the twelfth century. An important commercial center in Aquitaine was Bordeaux, and here a new kind of wine was encountered. Unlike the white to golden-colored wines from the Rhineland and the Loire, the wine here was red, or at least pink. Termed claret, it became the royal favorite and thus the wine in most demand among the upper classes. Yet at this time, only a very small amount of claret actually came from the Bordeaux region itself. Most of it was shipped down the streams converging on the Gironde estuary from the *hauts pays* of the interior, from such places as Bergerac, Gaillac, and Cahors.

In the mid-fifteenth century, following the end of the Hundred Years' War, all of Aquitaine, including Bordeaux, was incorporated within France. This development did not end the flow of claret to England, but the supply became less regular and depended to a great extent on the state of relations between the two countries. English merchants looked for alternatives, which took them southward to Portugal, their political ally against the Spanish and French.

Some red wines were exported from the Minho region of Portugal, but they never developed much of a following. As wars and plans for war grew more frequent toward the close of the seventeenth century, the search for reliable supplies of claret substitutes intensified. Some merchants traveled up the rugged and underdeveloped Duoro Valley from their base at Porto. Only very rough reds were encountered, and their initial reception in England was not very positive.

What caught on eventually, however, was the practice of adding brandy to the still wines. At first this was done at the end of fermentation to increase alcohol content. High-alcohol wines were preferred not only because they were more quickly intoxicating, but also because they did not spoil as rapidly and thin into vinegar. Although not discovered until much later, the wine-spoiling culprits were oxidation and bacterial contamination, and the reactions they produced slowed down at higher alcohol levels.

In the eighteenth century, it was discovered that if brandy was added during fermentation, a sweet wine of much higher quality could be produced, and thus the port of today was born, named for Porto, the place where it was processed and from which it was shipped. It became a highly fashionable drink for English gentlemen, which set off a wave of vineyard plantings that transformed the upper Duoro Valley into a landscape almost totally devoted to wine.

Perhaps the most highly prized wine in England was malmsey. It arrived in Genoese and then Venetian galleys from Cyprus and other Christian-held lands in the eastern Mediterranean, where vineyards had been reestablished by monastic orders in the wake of the Crusades. These sun-drenched lands produced a sweet, golden wine naturally high in alcohol, and thus the malmsey also traveled well. However, the Ottoman advance cut off the source of supply, which once again set in motion a search for alternatives that eventually led to Spain. A wave of vineyard plantings there had accompanied the Reconquest, and the expulsion of the Jews had provided an opportunity for English merchants to set themselves up in business, particularly at the active ports of Cadiz and Sanlúcar. The wine exported from this southern coastal region was initially called sac, and later sherry. The latter was an English corruption of the word Jerez, the town in which most of the wine was made. Like the port wines, sherries were fortified and initially sweet. Later developments led to dry styles gaining preference, with England maintaining an almost exclusive hold on the market. A similar type of wine was produced on the island of Madeira, but because of the papal division of the world, its exports were directed mostly to the Americas.

The other major participant in the wine trade was Holland, where cool growing-season temperatures, poorly drained soils, and high winds virtually precluded the establishment of vineyards. Satisfying most of the Dutch thirst for wine were the vineyards of the Rhineland and the Mosel Valley, but the destruction wrought there by the Thirty Years' War caused the Dutch (like the English) to turn to the Loire Valley and to Bordeaux, where they encouraged the growing of grapes to make white wines.

Dutch tastes, however, were increasingly moving in the direction of spirits, especially brandies. In addition to vineyards, ample timber supplies were required in order to fuel the distilleries, and the Dutch found this combination in two locales, the Charente (Cognac) and Armagnac, two names that have come to define the standards by which brandy is judged.

The Search for Quality

The emergence of noble classes and wealthy merchants in Europe generated a greater concern for wine quality, with those in Burgundy leading the way. There, in the fourteenth century, the combination of the tastes of the dukes and the wine-growing skills of the Cistercians resulted in a purposeful attempt to reduce the quantity of wine produced in order to raise its quality. The monks had determined that the best vineyard sites lay along a faulted escarpment that has since gained the name Côte d'Or, and a Duke, Philippe the Bold, declared the high-yielding Gamay grape banned in favor of the lower-yielding but more aromatic and complexly flavored Pinot Noir (then known as the noirien). At about the same time, quality considerations were singling out the Riesling grape in the Rhineland and the Mosel Valley. Both cases illustrate an important trend in the making – the development of a hierarchy of quality wine regions based in large measure on grape varieties.

Two advances of the seventeenth century were crucial in the quest for wine quality. The first was the discovery of how to make stronger glass bottles, thus providing an inert container in which wine could be stored instead of in wooden barrels, jugs, or, in some instances, leather bags. The bottle then needed a stopper to protect the wine from the deleterious effects of too much oxygen contact. Wood plugs and cloth were tried with limited success, but the solution to the problem proved to be cork. It deterred the passage of air, and cork's pliability meant that it could be made to fill the space between the walls of the bottle's neck. It was now possible to keep new wines fresh longer, and a medium was available to allow wines to age.

One region that profited almost immediately from the use of improved bottles and corks was Champagne. By the fourteenth century, its wines had gained the reputation of being good values. Champagne was close to the Paris market, and reds and whites were made in styles similar to those in Burgundy. Matters began to change, however, in the seventeenth century under the leadership of the Benedictine abbey at Hautvilliers and, most particularly, when the legendary Dom Pérignon assumed the position of cellarmaster. He set meticulous cultivation and vinification standards designed to elevate Champagne's wines to the very top of the quality ranking. Consistency seems to have been what he was seeking most, and to this end he perfected the art of wine blending, something that has been a hallmark of champagne ever since.

One of the problems Dom Pérignon had to deal with was a fizziness that frequently appeared in the wine during the spring following vinification. The cold weather of the late fall sometimes shut down fermentation before it was completed, and it would start up again when the warmer weather of spring arrived. Yet the fizziness produced by the carbon dioxide in the wine was precisely what consumers began to find attractive. It became fashionable to serve this kind of champagne at the court of Louis XIV during festive occasions, and the habit soon spread to other European royal families, setting off a demand that could not be met by relying on an accident of nature. Thus, by the early part of the eighteenth century, secondary fermentation was being purposefully created through the addition of a dose of yeast and sugar to already bottled still wine. Because the carbon dioxide created enormous pressure, strong bottles and a tight seal were both required. During the remainder of the eighteenth century and on through the nineteenth, numerous technological changes continued to improve champagne's quality and thereby its image. It was a different wine than that which Dom Pérignon envisioned, but it achieved the ranking he sought.

No region is more closely associated with the image of wine quality than Bordeaux. As noted, the politics of the seventeenth and eighteenth centuries meant that the supply of claret for the English market was highly unreliable, and often it fell far short of demand. Consequently, claret became a prestigious commodity with attendant high prices. This situation initiated a twofold response from Bordeaux. One was an effort by some producers to make better wines and then to let consumers know with a label which properties or estates had produced them. The wine was thus not just a claret but a claret from this or that estate. The other was to expand markedly the amount of vineyard land. Most of the plantings initially were near the city of Bordeaux, in an area known as the Graves because of its gravelly soils. Because of drainage work carried out by Dutch engineers earlier in the seventeenth century, a considerable amount of land was available in the Médoc promontory to the north of the city, and by the end of the century, most of the best sites, also on gravel, had been planted. Expansion continued during the next century and soon enough wine was being produced in Bordeaux so that supplies were no longer needed from the *hauts pays.* Indeed, these wines were restricted from entering in order to protect local prices.

Wine and wealth in Bordeaux had come to feed on one another. The port was significant in its own right, connecting the southwest of France not only to England but also to the markets of Scotland, Ireland, Holland, and the northern German states. As profits grew, more and more was invested in wine, both by merchants and the landed aristocracy. The latter began to build country estates marked by grand chateaux, which helped to further the elite image of the Bordeaux wines. In terms of prices paid and profits earned, Bordeaux had risen to the top of the wine world.

Imperial Expansion

Wherever possible, wine growing accompanied European imperial expansion. It was introduced into Mexico during the first decades of the sixteenth century and from there spread southward in rapid order to Peru, Chile, and Argentina. Its northward expansion was slower, but eventually by the late eighteenth century it had reached what is now California. Catholic missions had established the first vineyards in both directions. They were small, and the wine produced went mainly to celebrate the mass, but some was also consumed at meals by priests and monks and by nearby Spanish settlers. Wine, however, was not to be given to the local Indians.

Where and when wine was first made in the eastern part of the United States remains in dispute. Some give the credit to French Huguenots at a settlement near Jacksonville, Florida, in the 1560s; others point to the settlers of a contemporaneous Spanish colony on Santa Elena Island off the coast of Georgia; and still others say it was the Jamestown settlers. Whoever they were, they would have used wild native American grapes, including the muscadines. The pungency of wines made from these grapes was not greatly appreciated, and throughout the colonial period attempts were made to grow *vinifera* varieties. Without exception, however, the vineyards died within a few years of planting (we shall see why in the next section). Reconciling themselves to this fact, wine makers turned their attention toward domesticating and improving the indigenous vines, the first of which, known as the Alexander, appeared at the end of the eighteenth century.

Vinifera found a much more hospitable environment at the very southern tip of Africa. Here the Dutch East India Company chose Table Bay as the site for establishing a colony in 1652 to revictual their ships rounding the Cape of Good Hope, and vines were among one of the first crops to be planted. In the late 1680s, a group of French Huguenot refugees arrived; they brought wine-growing expertise with them and extended the area devoted to vineyards. The vines did so well in the mild Mediterranean climatic conditions of the Cape region that not only were the ships resupplied with ample quantities for their crews, but exports were also sent to Europe. One result was a rich dessert-type wine known as Constantia that gained considerable renown in the early 1700s.

Wine growing was attempted by the first Australian settlers who arrived at Sydney Harbor in the 1780s using seeds and cuttings obtained from Europe and the Cape. But the prevailing high heat and humidity militated against success and, in any event, more money could be made raising sheep. It was not until the 1820s that wine growing in Australia finally found a congenial environment in the Hunter Valley. Other areas in Victoria, southern Australia, and western Australia came into production in the 1830s and 1840s when wine-making efforts were also occurring on the North Island of New Zealand.

Disasters in the Making

By the middle of the nineteenth century, wine was entering what many have termed its golden age. It had been an everyday drink among Mediterranean

Europeans for many centuries and was becoming ever more common across the Alps, where a succession of good vintages helped to spur an increase in the areas given over to vineyards. Profits had never been greater, and some areas, notably the Midi of France, became virtual monocultures supplying the demands of the general public. Side by side were other areas catering to the wealthy, now augmented by newly emergent industrial and professional classes. Burgundy, Champagne, and the Rhine/Mosel each had its markets, but no place could challenge the primacy of Bordeaux.

Most of the wine being produced was, in fact, of ordinary quality, but a few properties, mostly located in the Médoc, had managed to distinguish themselves. This led to numerous attempts at classification, the official codification of which was achieved in 1855 for the Paris Universal Exposition. At the top, it divided the wines of the Médoc into first through fifth growths *(crus),* and it then added lower rungs of *crus exceptionneles, crus bourgeois,* and *crus artisans.* The appearance of such a listing, which no other wine region had, created an even greater demand for the top growths, and Bordeaux's image reached new heights.

Nevertheless, disaster was lurking in the background. It started with a powdery mildew, termed oidium, that in the early 1850s was infesting vineyards virtually everywhere in Europe. The fungus retards vine growth by attacking both leaf and stalk, and it also desiccates grapes by breaking their skins. Consequently when it first appeared, yields declined, as was especially the case from 1852 to 1854. Nevertheless, a treatment in the form of sulfur dusts was quickly found, and by the end of the decade oidium, although not eliminated, was being controlled.

But no sooner had oidium come under control than reports of mysterious vine deaths began to emerge. The first came from the lower Rhone Valley, and by 1870, it had become evident that the problem was on the verge of universality. The plague of vine destruction made its way through France (the last region to be visited was Champagne in 1901) and the rest of Europe, and eventually into most of the wine-growing world. Chile was the only major exception, being spared by a combination of distance, desert, and mountains.

In 1868 the culprit was shown to be a minute aphid, *Phylloxera vastratrix,* that destroys vine roots. It is native to North America, and may have entered France on vines that were imported for experiments on ways to better control oidium. With the collapse of the wine industry at hand, numerous, often desperate, attempts were made to rid vineyards of the aphids. Some chemical treatments were moderately effective, but the ultimate solution turned out to be one of grafting European vines onto American roots. Experiments had determined that several species of the latter were tolerant of the aphid's presence and thus North America, which was the cradle of phylloxera, turned out to be the cradle of the cure.

But the diffusion of phylloxera had drastically altered the wine-growing world. Those regions hit later were able to realize short-term profits. For example, the price of champagne soared, and Italy and Spain filled in the gaps left by the fall of French production in the 1880s and 1890s. In addition, wine growers themselves were on the move. Algeria was a favorite destination for those leaving France, and small numbers also relocated in the Rioja region of Spain, bringing with them new ways of growing vines and making wine with an eye on the larger market. When, at the turn of the century, phylloxera finally hit hard in Italy, Spain, and Portugal, an exodus to Chile, Argentina, and Brazil ensued, leading to the reenergization of these long dormant regions.

Yet a third natural disaster had to be faced, that of downy mildew, which also found its way to Europe on American vines. In a manner similar to oidium, it reduced crop yields and required dusting, this time with a mixture of copper sulfate and lime, to keep it under control.

The labor and cash requirements of grafting and repeated sprayings drove many farmers in Europe out of the wine business, which was no longer something that one could do in a small way. Rather it required new skills and greater financing in order to be competitive, and these were best obtained by specialization. Virtually everywhere, the making of wine was rapidly changing from a craft into a business and a science.

In the United States, oidium, phylloxera, and downy mildew had also taken their toll. Indeed, it was phylloxera that had been responsible for the repeated failure of *vinifera* to survive east of the Rocky Mountains, and in the 1850s an outbreak of oidium had put an end to the country's first wine region of note – the so-called Rhine of America along the Ohio River near Cincinnati. A far more significant disaster, however, was social and political in nature, namely Prohibition. Its origins go back to the temperance crusades of the nineteenth century designed to purify America of all vices, and most especially those thought to be associated with alcoholic beverages. The purification urge culminated in 1919 in passage of the Eighteenth Amendment to the U.S. Constitution (popularly known as the Volstead, or Prohibition, Act), and its 13 years of existence brought nearly total ruin to the country's wine industry. By this time, California had achieved top rank in terms of both quantity and quality, but wineries abounded in many other states. Very few managed to survive Prohibition. Those that did sold sacramental and medicinal wines, as well as grape concentrate for making wine at home, all of which could be done under provisions of the Volstead Act.

Over most of the first half of the twentieth century, the world's wine industry remained in a depressed state. In addition to the ravages wrought by disease and Prohibition in America, the industry had to contend with two world wars, the Russian Revolution (which eliminated an important market for French wines, particularly champagne), and economic depression. In retrospect, the golden age truly glittered.

Recovery and Transformation

Recovery was fueled by the widening base of prosperity of the immediate post–World War II years and by a Europeanization of food habits in many parts of the world. Outside of Europe, wine drinking tended to be relatively uncommon even in those areas settled by Europeans. In general, members of the working and middle classes drank mainly beer and spirits or abstained from alcohol altogether. However, by the 1950s more people could afford wine, and many discovered it as an enjoyable accompaniment with dinner. For others, wine served as a symbol of their upward mobility.

The French were the first to prosper. They had solidified their image as the world's quality leader by developing a legal classification of wines known as *Appellation d'Origine Contrôlée* (AOC). Its outlines were formed early in the twentieth century in order to counter an outbreak of fraud following the wine shortages caused by phylloxera. Fraudulent practices included such things as the marketing of wine from one region under the name of another; placing non-French wines under French labels; and fermenting a range of fruits and other substances in place of grapes.

As the AOC system evolved into its present form, the emphasis was placed on guaranteeing the authenticity, especially the geographic authenticity, of wines. The system defines specific regions, dictates where the grapes that go into the wine of those regions must come from, and also requires adherence to precise viticultural practices that are deemed essential to achieving a wine's particular character. A certain level of quality is implied, but only in a very few instances are taste tests actually performed. The success of the AOC system in heightening the image of French wines meant that other countries began creating their own versions. Each is constructed differently, but the message is basically the same – the government certifies what is in the bottle.

Wineries in California led to other trends. Of special significance was the state's abilities to produce large volumes of consistently good-quality wines at relatively inexpensive prices. Three related factors made this achievement possible. One was the high grape yields attainable in the rich, irrigated central valley of the state; another involved the development of new quality-control technologies, especially ones designed to control fermentation temperatures, permitting bulk manufacturing; and the third was the formation of large companies that could afford to adopt these technologies as well as to engage in mass advertising campaigns. Thus, while meeting a demand, the companies were also creating it.

At the same time, other California producers were heading in a somewhat different direction. Following the repeal of the Volstead Act, several smaller-volume wineries in the Napa Valley north of San Francisco had decided to compete with French wines in the prestige market. Their success in the 1950s and early 1960s sparked a wave of winery openings that spread out from the Napa Valley to adjacent Sonoma County and then to other areas of the state. Leading both branches of the industry were researchers at the Davis branch of the University of California. As early as the 1930s they had begun mapping the state into microclimates based on growing-season temperatures, and this work emerged as a guide to what areas should be planted in vineyards. In addition, basic research was initiated into all phases of wine making and the results obtained were quickly disseminated into the vineyards and wineries through various degree-granting and training programs. The application of science to wine began in Europe, but in California it reached new heights that set the standard for the late twentieth century.

During the 1960s and 1970s, wine was in a new golden age, and virtually all predictions made at the time foresaw even better days ahead. Many older wine-producing areas of the globe were modernized so that they could market their products abroad. Suddenly wines were appearing from such places as Hungary, Romania, Yugoslavia, and Algeria. However, the most spectacular change took place in Italy, which quickly went from being a producer of wines meant mostly for local consumption to the world's leading exporter. Wine growing also expanded into many nontraditional areas including China, Japan, Kenya, and American states such as Oregon, Texas, and New Mexico. It even returned to England.

The events of the 1980s and early 1990s, however, did not bear out the optimism of the previous two decades, which to a great extent was built around trends in the U.S. market – a market that seemed to be headed in the direction of making Americans into regular wine drinkers on a par with the Europeans. But the course of upward per capita consumption did not proceed as predicted. The adoption of wine as a mealtime beverage has not spread to the population at large; for most people wine retains its image as something either foreign, elitist, or reserved for special occasions. In addition, a growing neoprohibitionist movement centered around the issues of drunk driving and health has exerted its influence on all alcoholic beverages. Information about wine's contribution to cardiovascular functioning has reversed the decline somewhat, but it is too early to tell if that will turn out to be just another health fad.

In Europe, wine consumption has fallen everywhere, and bottled water and soft drinks are becoming preferred by more and more people. In this instance as well, health and safety issues seem to be major reasons for the change in drinking habits.

The impact of declining demand has, to this point, fallen most heavily on lower-priced, so-called jug or country wines. In areas such as the Midi of France, southern Italy, and the central valley of California, supply is greatly in excess of demand. With no signs of change in the offing, the future portent is one of considerable vineyard abandonment in such areas.

By way of contrast, the demand for prestigious high-priced wines has never been greater. Each year they sell out even as their costs escalate. To some extent, this results from wine drinkers preferring quality to quantity – one or two bottles a week instead of four or five. But wine has also become a collectible for the world's affluent. It is not so much a matter of investing in financial terms, but of investing in status. To hold certain types of wine and then to serve them in the appropriate circumstances is to mark one's social standing. The competition among wine producers for this market is intense, with much of it centering on extolling the geographic features that give a wine its special character. The French, for example, argue for the influence of *terroir,* a term that encompasses all the physical characteristics of the growing site. A variation on this theme is increasingly seen in California, where smaller and smaller wine-producing areas and the individual vineyards are indicated on the label. Very recently, Chile has begun exporting larger volumes of wine, stressing that wine makers there attain a unique quality because in that country they grow ungrafted *vinifera* vines. Oregon and Washington State also employ the same selling technique.

To a large extent, the minutiae of locational differences are emphasized in order to counteract a worldwide trend toward uniformity. Only a small number of grapes are considered suitable for making fine wines. These are dominated by Cabernet Sauvignon and Chardonnay, which along with Riesling, Pinot Noir, and two or three others (depending on who is making the list) constitute the so-called noble family of grapes. The standards are set at numerous wine-tasting competitions and by a small group of wine writers whose opinions are enormously influential in shaping the market. As the preferred grapes spread, they provide an underlying sameness to the wines made from them and pose the likelihood of extinction for many long-standing local varieties.

Uniformity results not only from using similar grapes but from similar ways of doing things in the vineyard and winery. Science and technology have created the means for standardizing wine making around the world, and their application has been facilitated by more and more wine coming under the control of large transnational corporations. The regional distinctions of the past are blurring as wine from places as distant as the Médoc in France, the Maipo Valley in Chile, and the Napa Valley in California all begin to look, smell, and taste alike.

PART IV

The Nutrients – Deficiencies, Surfeits, and Food-Related Disorders

The discovery of the chief nutrients has been essentially a twentieth-century phenomenon. In 1897, Dutch researcher Christian Eijkman, while investigating beriberi in the Dutch East Indies, showed that a diet of polished rice caused the disease and that the addition of the rice polishings to the diet cured it. Fifteen years later, Polish chemist Casimir Funk proposed that not only beriberi but scurvy, pellagra, and rickets were caused by an absence of a dietary substance he called *vitamine;* and the age of vitamins was under way.

This is not to say that much earlier research did not undergird such twentieth-century breakthroughs. The importance to human health of some minerals, such as iron, had long been at least vaguely recognized, and by 1800, it was understood that blood contained iron; since the eighteenth century, some kind of dietary deficiency had been a periodic suspect as the cause of scurvy; and protein was discovered in the nineteenth century. But in addition to both water- and fat-soluble vitamins, the importance and functions of most of the major minerals and the trace minerals, along with amino acids, were all twentieth-century discoveries, as were the essential fatty acids and the nutritional illness now called protein–energy malnutrition (PEM).

One important consequence of the new knowledge was the near-total eradication of the major deficiency diseases. Pellagra, which had ravaged southern Europe and the southern United States, was found to be associated with niacin deficiency; beriberi, the scourge of rice-consuming peoples in the Far East, was linked with thiamine deficiency; and scurvy was finally – and definitively – shown to be the result of vitamin C deficiency.

But as rapidly as these illnesses were conquered, new conditions were identified. There was PEM (mostly in the developing world) and anorexia nervosa (mostly in the developed world). Goiter, the result of iodine deficiency, proved to be a problem in both, and Keshan disease was associated with selenium deficiency and the death of children in China.

In addition, faulty nutrition has been implicated in the chronic diseases that are especially prominent in the countries of the West, such as diabetes, heart-related ailments, and cancer. Much of the problem seems to lie in diets significantly higher in sugar, salt, and fats than those of most other peoples – diets of affluence, which among other things produce obesity that can predispose to heart diseases and diabetes. Yet the link between diet and diseases of a chronic nature has often been sufficiently vague as to result, thus far, in more questions than answers. Consequently, many sensible hypotheses abound, and we have included one of these. Our last chapter in Part IV connects a specific nutriment, milk, and lactose tolerance – an ability to absorb milk after childhood, not shared by most of the world's population – with the high rates of coronary artery disease among the people of northern Europe and those descended from northern Europeans in the United States.

IV.A

Vitamins

IV.A.1 ◆ Vitamin A

Definitions and Nomenclature

Vitamin A is a fat-soluble substance essential to the health, survival, and reproduction of all vertebrates. As with all vitamins, it is needed in only small amounts in the human diet, about 1 to 1.5 milligrams a day. Vitamin A does not occur in the plant kingdom, but plants supply animals with precursors (or provitamins), such as beta-carotene and other carotene-related compounds (carotenoids), that are converted to vitamin A in the intestinal mucosa of animals and humans. Beta-carotene (and other carotenoids) are abundant in all photosynthesizing parts of plants (green leaves), as well as in yellow and red vegetables. Vitamin A, also known as "retinol," is itself a precursor of several substances active in the vertebrate organism; these are collectively termed "retinoids." One retinoid is retinoic acid, an oxidation product of retinol, formed in the liver and other organs and existing in different chemical isomers, such as all-*trans*-retinoic acid and 9-*cis*-retinoic acid, with different functions. Other retinoids are all-*trans*-retinaldehyde and its 11-*cis*-isomer. The latter is active in the retina of the eye, forming the light-sensitive pigment rhodopsin by combination with the protein opsin. In the liver, retinol is stored in the form of its ester (retinyl palmitate).

Retinoids in the animal organism are generally not found in the free state but are bound to specific proteins. Thus, in the blood, retinol is carried by a retinol-binding protein and, within cells, by an intracellular retinol-binding protein. Retinoic acid and retinaldehyde are carried by specific intracellular binding proteins. When carrying out its hormonal function, retinoic acid combines with another set of proteins, called retinoic acid receptors, located in the cell nucleus. The retinoic acid-receptor complex can then interact with specific genes at sites known as retinoic acid response elements, thereby activating these genes and causing them to stimulate (or repress) the expression of specific proteins or enzymes involved in embryonic development, cell differentiation, metabolism, or growth.

Units

At an earlier time, before pure, crystalline retinol and beta-carotene became available through chemical synthesis, the units used to express vitamin A activity were international units (IU). One IU of vitamin A activity was defined as 0.3 microgram (µg) all-*trans*-retinol (Figure IV.A.1.1a). Because of inefficiencies of

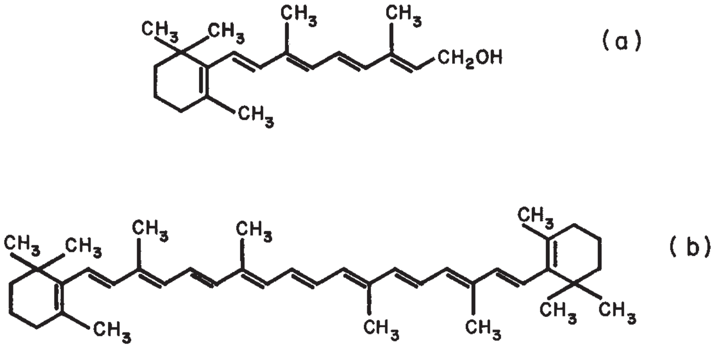

Figure IV.A.1.1. Chemical structure of all-*trans*-retinol (a) and all-*trans*-beta-carotene (b).

absorption and conversion to retinol, 1 IU of beta-carotene was defined as equivalent to 0.6 µg all-*trans*-beta-carotene (Figure IV.A.1.1b). More recently, the accepted unit has become the retinol equivalent (RE), a dietary concept (Underwood 1984). One RE equals 1 µg retinol. Taking into account beta-carotene's average absorbability and conversion to retinol, 1 RE was defined as 6 µg beta-carotene. Of course, it should be noted that absorbability and conversion of dietary beta-carotene can vary greatly with other components of the diet, such as fat or protein.

The Recommended Dietary Intake of vitamin A per day, published by the United States National Research Council, is 500 RE for children, 800 to 1,000 RE for adults, 1,300 RE for pregnant women, and 1,200 RE for lactating women.

History of Vitamin A Deficiency

Night blindness (nyctalopia), meaning defective vision at low illumination, is one of the earliest signs of vitamin A deficiency and was probably the first nutrient-deficiency disease to be clearly recognized. Although the relationship of night blindness to a dietary deficiency of vitamin A was not discovered until the nineteenth century, a cure for an unspecified eye disease, *sharew,* was described in ancient Egyptian texts. Papyrus Ebers (no. 351, c. 1520 B.C.) states: "Another [recipe] for *sharew.* Liver of beef is cooked and squeezed out and placed against it [the eye]. Really excellent." The London Medical Papyrus (no. 35, c. 1300 B.C.) states: "Another recipe [for *sharew*]. Beef liver placed on a fire of straw or emmer or barley and smoked in their [the straw's] smoke; their [the liver's] liquid is squeezed against the eyes" (Wolf 1980: 97).

The word *sharew* apparently refers to a disease of the eyes, and because liver is an especially rich source of vitamin A, and *sharew* was apparently cured by liver, scholars assumed until recently that this disease was caused by vitamin A deficiency and that, therefore, *sharew* meant "night blindness." However, no mention of "night" or "night vision" occurs in any Egyptian source,[1] and we now know that topical application of vitamin A would not be effective in curing night blindness. Much of Egyptian medical practice involved a magic element – the "transfer" of the strength of the ox to the afflicted organ. But the liver would have to be eaten to relieve night blindness. One way that the latter might have occurred has been suggested by A. Sommer, who describes a magical ritual whereby the juice of roasted lamb's liver is applied to the eyes as a cure for night blindness in rural Java today. The liver, however, is not discarded; it is eaten by the patient after the ceremony is finished. Sommer comments that the consumption of the liver is not actually considered part of the ritual. Perhaps the ancient Egyptian ceremony also ended with the patient eating the liver.

The first indisputable recognition of night blindness was by the ancient Greeks, who called it nyctalopia (*nyx, nyktos,* "night"; *alaos,* "blind"; *ops, opteos,* "eye") and prescribed the oral administration of liver as a cure. The development of Greek medicine was heavily indebted to Egyptian medical theory and practice, and Egyptian medical ideas had an overriding influence on both the Ionian school of medicine and the school of Cos. However, whereas Egyptian physicians considered disease the result of external, supernatural influences, the Greek physicians observed the patient, thought of disease as a condition of the patient, and designed therapy to fit into a rational system, such as the humoral theory in Hippocratic medicine. Hippocrates and his school produced the collection of writings *Corpus Hippocraticum* (Alexandria, c. 300 B.C.), within which the treatise "Concerning Vision" mentioned nyctalopia as an eye disease that usually afflicts children, along with other ailments such as otitis, sore throat, and fever.

The essay recommends this prescription: "Raw beef liver, as large as possible, soaked in honey [presumably to make it more palatable], to be taken once or twice by mouth" (Hirschberg 1899: 100). This is exactly what modern medicine would prescribe if it was not possible to obtain fish-liver extract or vitamin A pills. Today, it is well known that vitamin A deficiency afflicts principally children, predisposing them to infections because of an impaired immune system. Furthermore, fever coupled with infections is now understood to lead to excessive loss of vitamin A from the body stores, aggravating an incipient deficiency state. Thus, one might marvel at the Hippocratic school's acuity of observation and knowledge of effective therapy.

Galen (A.D. 130–200) provided a precise definition of night blindness, as did Oribasius (born c. A.D. 325), a follower of Galen, who defined night blindness this way: "Vision is good during the day and declines at sundown; one cannot distinguish anything any longer at night" (Guggenheim 1981: 267). Although Galen recommended as a cure the "continuous eating of roasted or boiled liver of goats" (Kühn 1821: 803), he also advised topical treatment: The juice of roasted liver should be painted on the eyes – a residue, perhaps, of the Egyptian influence. Much later, around A.D. 540, Aetius of Amida suggested goat liver, fried with salt but not oil, eaten hot. He also suggested that the "juice that runs out of the liver be applied topically to the afflicted eye" (Guggenheim 1981: 267).

The authors of the Assyrian medical texts (c. 700 B.C.) thought night blindness was caused by the rays of the moon and cured by the application of ass's liver to the eyes. Chinese medicine recognized night blindness, and Sun-szu-mo (seventh century A.D.), in his *1000 Golden Remedies,* described a cure by administration of pig's liver (Lee 1967). Arabic medicine, often derived from the translation of Greek medical texts, leaned toward topical application of liver extract (Hunain Ibn Ishaq, ninth century A.D.). So did a Hebrew treatise from Muslim Spain (Abraham Ibn Ezra, twelfth century), but it added eating liver to the prescription.

The Hippocratic tradition of liver therapy for night blindness survived through the Middle Ages. But with the long sea voyages of discovery that began at the end of the fifteenth century, dietary deficiency diseases, including night blindness, began to appear on board ships. Jacob de Bont (1592–1631), a Dutch physician of the East Indies, described a night blindness that can end in total blindness and prescribed a specific medicament for its cure, namely liver of shark (Lindeboom 1984).

There were many descriptions of night blindness penned by eighteenth- and nineteenth-century Europeans that mentioned that a poor or defective diet was suspected as the cause. In the nineteenth century, for instance, Reginald Heber, Bishop of Calcutta, in *Narrative of a Journey through the Upper Provinces of India: From Calcutta to Bombay* (1824–5), noted:

> In our way back through the town a man begged of me, saying that he was blind. On my calling him, however, he came forwards so readily to the torches, and saw, I thought so clearly, that I asked him what he meant by telling me such a lie. He answered that he was night blind ("rat unda"), and I not understanding the phrase, and having been a good deal worried during the day with beggars, for the whole fort is a swarm of nothing else, said peevishly, "darkness is the time for sleep, not for seeing." The people laughed as at a good thing, but I was much mortified afterwards to find that it was an unfeeling retort. The disease of night blindness, that is, of requiring the full light of day to see, is very common, Dr. Smith said, among the lower classes in India, and to some professions of men, such as soldiers, very inconvenient. The Sepoys ascribe it to bad and insufficient food, and it is said to be always most prevalent in scarcity. It seems to be the same disorder to the eyes with which people are afflicted who live on damaged or inferior rice, in itself a food of very little nourishment and probably arises from weakness of the digestive powers. I was grieved to think I had insulted a man who might be in distress, but Dr. Smith comforted me by saying that, even in respect of night blindness, the man was too alert to be much of a sufferer from the cause which he mentioned. (Wolf 1980: 99)

In another nineteenth-century example, during a journey round the globe by an Austrian sailing ship (1857–9), a young ship's doctor, Eduard Schwarz, carried out what appears to have been the first modern rational experiment undertaken to prove or disprove the ancient theory that night blindness could be cured by eating liver. During the long voyage, several cases of night blindness were observed, and Schwarz reported the following:

> [A]t dusk, objects appeared to the afflicted darkened, vague, with indistinct contours and as though moved into the far distance; light-absorbing objects could not be perceived, even close by, and the afflicted walked into the ships' walls or railings. Indoors, everything seemed completely dark to them. We experienced the most convincing proof of the efficacy of beef liver against nightblindness on the return journey, when . . . about 20 nightblind sailors were given ox liver to eat, whereupon they were all permanently cured. (Schwarz 1861: 166)

Interestingly, Schwarz also observed that when the night-blind sailors were kept in complete darkness for three days, their night vision recovered, only to be lost again after a few days in daylight. We can conclude from modern knowledge that during dark adaptation, small amounts of vitamin A reserves remaining in the body reached the retina to reform the depleted visual pigment and were lost again upon exposure to light.

It was also in the nineteenth century that the lesion was noted called xerophthalmia (dryness of the conjunctive and cornea), caused by more severe vitamin A deficiency. V. von Hubbenet described night blindness, associated with "silver scales at the cornea" (Guggenheim 1981), that was caused by a faulty diet but could be treated with beef liver. In 1857, David Livingstone, the explorer of Africa, noting corneal lesions in African natives who subsisted on a diet of coffee, manioc, and meal, wrote: "The eyes became affected as in the case of animals fed pure gluten or starch" (Moore 1957: 4).

At the beginning of the twentieth century, an important contribution was made by M. Mori, who in 1904 described widespread xerophthalmia in Japanese children, including large numbers showing keratomalacia, a softening of the cornea ending in corneal ulceration and necropsis and characteristic, as we now know, of severe vitamin A deficiency. Mori reported that the diet of Japanese children consisted of rice, barley, other cereals, "and other vegetables," and he found that liver, and especially cod-liver oil, were curative. He thus connected the disease with a nutritional cause and a cure (the ingestion of a fat or an oil).

Close on the heels of the discovery of vitamin A (described in the next section) were the observations of C. E. Bloch, who, during World War I, studied children in Denmark afflicted with night blindness and keratomalacia (Guggenheim 1981). As a result of the war, the children had subsisted on a diet of fat-free milk, oatmeal, and barley soup. In an important early experiment, Bloch worked with 32 institutionalized children (1 to 4 years old), dividing them into two groups. One group received whole milk instead of the fat-free milk; the other was given vegetable fat (margarine) but not whole milk. The latter showed 8 cases of corneal xerosis, the former remained healthy. All the xerosis cases were cured rapidly with cod-liver oil. Bloch correctly surmised that whole milk, cream, butter, eggs, and cod-liver oil contained lipid substances protecting against corneal and conjunctival xerosis.

History of the Discovery of Vitamin A

The first animal experiments with a vitamin A–deficient diet were those of F. Magendie in 1816 (McCollum 1957). He fed dogs a diet of wheat gluten, or starch, or sugar, or olive oil and described the corneal ulcers that developed (as we now know) because of a lack of vitamin A.

The effects of vitamin A deficiency on growth were first described by G. Lunin in 1881. He found that mice could not survive on a diet of pure casein, fat, sucrose, minerals, and water, but they lived and grew normally with whole dried milk. The outcome of similar experiments led F. G. Hopkins (1906) to postulate "minimal qualitative factors" in the diet necessary for growth and survival (Moore 1957).

An interesting and exciting account of the beginnings of experimental nutrition, which ultimately led to the discovery of vitamin A, was written by E. V. McCollum (1964). At the time McCollum began his research (1907), chemical analysis of foods and animal feed was well advanced. He fed cows rations of hay with wheat, or oats, or yellow maize, of identical composition as far as protein, carbohydrate, fat, and minerals were concerned.

The wheat-fed cows did not thrive but, rather, became blind and gave premature birth to dead calves. The oat-fed cows fared somewhat better, but the maize-fed cows were in excellent condition, produced vigorous calves, and had no miscarriages. McCollum spent four years in trying to determine the reasons for these remarkable results. He addressed questions such as: Did the wheat contain a toxic substance, and what was lacking in wheat that was present in yellow maize? He then conceived the important idea that nutrition experiments could be done much faster and better with small animals, such as mice or rats: They eat much less than larger animals, they can be given purified diets, they reproduce rapidly, and many can be housed at one time (McCollum 1964).

Raising rats, however, was not a popular idea at the Wisconsin College of Agriculture, where McCollum worked, because, as he was told by the dean, "rats were enemies of the farmer." Thus, he surreptitiously started a rat colony in a basement of the Agricultural Hall. In 1915, he found that whereas young rats on a diet of pure protein, pure milk sugar, minerals, and lard (or olive oil) failed to grow, the addition to their diet of butterfat or an ether extract of egg yolk restored their health. Soon after, he determined that adding an ether extract of alfalfa leaves or, even better, of liver or kidney, greatly improved the diet's growth-promoting quality. Clearly, he had found a fat-soluble factor that promoted growth in rats.

He saponified butterfat, extracted the unsaponifiable mixture into ether, and added the extract to olive oil: Now the olive oil, with pure protein, sugar, and minerals, supported growth. This experiment, and subsequent ones, proved that butterfat contained a fat-soluble growth factor (other than fat itself) that could be transferred from one fat to another. McCollum ultimately showed that this factor was essential for growth and survival: This was the discovery of vitamin A, then named "fat-soluble factor A" to distinguish it from other accessory dietary factors that were grouped under the term "water-soluble B." Simultaneously, biochemists T. B. Osborne and L. B. Mendel made the same discovery; they published their findings five months later (1915).

In 1919, it was noted by another investigator, H. Steenbock, that active growth-promoting extracts, such as those made from butter, egg yolk, or certain plants (carrots), were yellow, whereas extracts from lard, inactive in growth promotion, were white (Table IV.A.1.1). He realized, however, that active fat-soluble factors existed in white extracts from liver or kidney. Steenbock and P. W. Boutwell thereupon proposed the hypothesis in 1920 (it was not fully confirmed for another 10 years) that fat-soluble factor A was associated with a yellow pigment (now known to be beta-carotene) and suggested that the yellow pigment could be converted to an active colorless form (vitamin A or retinol).

In the meantime, L. S. Palmer (in 1919) threw the subject into confusion by feeding chickens white maize, skimmed milk, and bone meal, a diet free of yellow pigments. When the birds stopped growing and began to fail, he supplemented their diet with a small amount of pork liver, containing no yellow pigment, and found that though the birds had received no yellow pigment, they grew normally and laid eggs. The egg yolks were colorless, but the eggs, when hatched, produced normal chicks.

Table IV.A.1.1. *Association of vitamin A potency with yellow color in food*

Active (yellow) (white)	Inactive, or low potency
Butter	Casein
Egg yolk	Egg white
Cod-liver oil	Lard
Yellow maize	White maize
Carrot	Parsnip
Sweet potato	Ordinary potato
Red palm oil	Palm kernel oil
Outer green leaves of cabbag	Inner white leaves of cabbage
Tomato	Onion
Apricot	Apple

Source: From Moore (1957).

It was not until 1929 that T. Moore resolved the conflict by proving that the yellow pigment extracted from plant sources, butterfat, or egg yolk, and purified as carotene, was converted to the active factor in the animal body. He fed pure, crystalline carotene (yellow) to young rats and observed the accumulation of retinol (colorless) in their livers. He correctly concluded that yellow carotene is the provitamin or precursor of colorless vitamin A (retinol).

Discovery of the Functions of Vitamin A

In the 1930s, the isolation and synthesis of both carotene (now more precisely defined as beta-carotene) and retinol were accomplished, along with an understanding of their chemical structures. The enzymatic conversion of beta-carotene to retinol was later shown to take place in the intestinal mucosa of animals and humans. The requirements and recommended daily allowances of beta-carotene and retinol for animals and humans were also determined.

Early research into the function of retinol was based on physiological and biochemical observations of the responses of experimental animals to diets lacking in beta-carotene or retinol. When weanling rats were fed a vitamin A–deficient diet, their liver stores of retinyl esters became exhausted after about four weeks, and their growth began to decline after five weeks. They then became night blind, and their corneas began to show lesions and to ulcerate after about six weeks on the deficient diet. After this they lost weight precipitously, became sick, and died. This simple feeding experiment highlighted three of the most important physiological functions of vitamin A: It promotes vision, normal differentiation of epithelia (such as the cornea), and growth. Vitamin A deficiency detracts from these functions and, in addition, leads to abnormal bone growth, inhibition of spermatogenesis in male animals, and resorption of the fetus in pregnant females.

The visual function of vitamin A was elucidated in great detail and with exceptional brilliance (culminating in a Nobel Prize) by G. Wald. As we have already noted, night blindness (defective vision at low illumination) was recognized in the eighteenth century as an early symptom of a dietary deficiency; later research indicated that night blindness, and its associated lesions, resulted specifically from a deficiency of vitamin A. It was, therefore, fitting that the function of vitamin A in vision was the first to be defined with a precise mechanism at the molecular level. As Moore (1957: 263) commented: "It may be an inspiring thought . . . that Man's knowledge of the existence of the stars and the vast universe which appears in the heavens each night, comes in the first place from the stimulation by the light rays of delicately poised molecules of vitamin A."

As long ago as 1878, W. Kühne recognized that retinas from dark-adapted frogs, purple in color, changed to yellow when exposed to light. The connection with vitamin A was made in 1925 by L. S. Fridericia and E. Holm, who observed that vitamin A–deficient, light-adapted rats, when put into the dark, formed visual purple at a slower rate than normal rats. Then, in 1929, Holm observed the presence of vitamin A in the retina. However, it was Wald, beginning in 1935, who found that the visual purple of the retina, called rhodopsin, consists of a protein, opsin, combined with "retinene" (later shown by R. A. Morton to be retinaldehyde). Wald and his co-workers (Wald 1968: 230–9) described the visual cycle thus: The 11-*cis*-isomer of retinaldehyde, while attached to opsin in rhodopsin, is isomerized to the all-*trans* form by light; this is the event that triggers the nerve impulse to the brain as perception of light. The all-*trans*-retinaldehyde is released from the opsin and reduced to all-*trans*-retinol. This, in the dark, is isomerized to 11-*cis*-retinol, oxidized to 11-*cis*-retinaldehyde, which recombines with opsin to re-form rhodopsin (dark adaptation), thus completing the cycle.

Elucidation of the metabolic function of vitamin A lagged behind the recognition of its role in vision. The observations of S. B. Wolbach and P. R. Howe (1925) defined the epithelial lesions resulting from vitamin A deficiency, particularly the keratinization of epithelial cells, especially of the cornea, but also of the respiratory, intestinal, and genitourinary tracts. It seemed that vitamin A influenced the differentiation of epithelial cells from the normal simple and pseudostratified phenotype to squamous, metaplastic lesions, starting focally and, ultimately, spreading throughout the epithelium.

Apart from the function of maintaining normal epithelial differentiation, the pathology of vitamin A deficiency also revealed a function of vitamin A in bone growth, shown by the thickened bones in growing, vitamin A–deficient animals. In addition, the deficiency is manifest in reproductive functions; in the male, by cessation of spermatogenesis and atrophy of the testes; in the female, by a defective uterus, placental necrosis, and, ultimately, resorption of the fetus. Indeed, as long ago as 1933, the teratogenic effect of only marginal vitamin A deficiency, which resulted in ocular and genitourinary defects in pig embryos, underlined the necessity of vitamin A to support normal fetal development.

In the 1950s and 1960s, the metabolism of vitamin A was delineated by J. A. Olson and others, and recognition of the importance of its transport proteins followed. This discovery was made by D. S. Goodman with regard to the plasma retinol-binding protein, and by F. Chytil and D. E. Ong with respect to the intracellular-binding proteins. K. R. Norum and R. Blomhoff and others established the basic facts of absorption and liver-storage mechanisms for retinol.

In the 1970s and 1980s, the discovery by U. Saffiotti of an anticarcinogenic action of vitamin A (although still a matter of some controversy) led to an outburst of research effort. In animal experiments, retinol, and particularly its metabolite, retinoic acid, have been demonstrated indisputably to have anticarcinogenic properties. But as applied to human cancer patients, a search for similar activity was disappointing, although a number of isomeric forms and synthetic chemical derivatives of retinoic acid were found to be active against some forms of cancer. For example, acute promyelocytic leukemia has been successfully treated with all-*trans*-retinoic acid; certain skin and head-and-neck cancers have yielded to 13-*cis*-retinoic acid, and retinoic acid and some of its synthetic chemical derivatives have exhibited spectacular cures in a number of skin diseases.

A new era of vitamin A research dawned in 1987, when P. Chambon in Strasbourg, France, and R. M. Evans in San Diego, California, and their respective co-workers, simultaneously discovered the retinoic acid receptors in cell nuclei (Mangelsdorf, Umesono, and Evans 1994). These receptor proteins can bind retinoic acid and, when thus liganded, can activate a number of specific genes to stimulate the cells either to produce specific proteins (enzymes) or to inhibit the activity of other enzymes. In this way, one can arrive at an explanation at the molecular level of the many metabolic functions of vitamin A with regard to embryonic development, differentiation, and growth. This type of action – gene activation – establishes vitamin A (in the form of its metabolite, retinoic acid) as a hormone, similar to the steroid hormones and the thyroid hormone. As was predicted in 1970: "[T]here is no *a priori* reason why a hormone should have to be made by the animal itself. It is quite conceivable that a hormone can be taken in the diet [as vitamin A], stored in the liver, and secreted into the bloodstream when needed. The liver then acts as the endocrine organ" (Wolf and De Luca 1970: 257).

Clinical Manifestations of Vitamin A Deficiency

Vitamin A deficiency diseases appear primarily in the young because, like other mammals, humans are born with low liver reserves. The latter probably results from a placental transport of retinol, which, although generally sufficient for normal development, is not sufficient for building any surplus. After birth, colostrum (and later breast milk) provides the needed vitamin, so long as the mother's intake of vitamin A is adequate. If, after weaning, vitamin A stores have not been built up, and malnutrition plagues the child, deficiency signs will appear. Other causes for vitamin A deficiency are protein malnutrition, when the retinol transport system in blood does not function normally, and chronic malabsorption diseases such as cystic fibrosis.

The first sign of deficiency, as already discussed, is night blindness. With increasing severity of the deficiency, the following ocular signs are exhibited: conjunctival xerosis; Bitot's spots (white, foamy spots on the conjunctival surface, consisting of sloughed-off cells); corneal xerosis; and corneal ulceration (also called keratomalacia), which often ends in irreversible blindness, a direct consequence of the liquefaction of the corneal stroma. Recently, increased morbidity and mortality, frequently connected with diarrhea and respiratory diseases, has been observed in children with marginal vitamin A intake and no eye lesions (see next section), no doubt caused by a compromised immune system (Underwood 1994). It has also been noted that measles in marginally depleted children can precipitate severe vitamin A deficiency diseases. Figure IV.A.1.2 presents a diagrammatic representation of the deficiency signs.

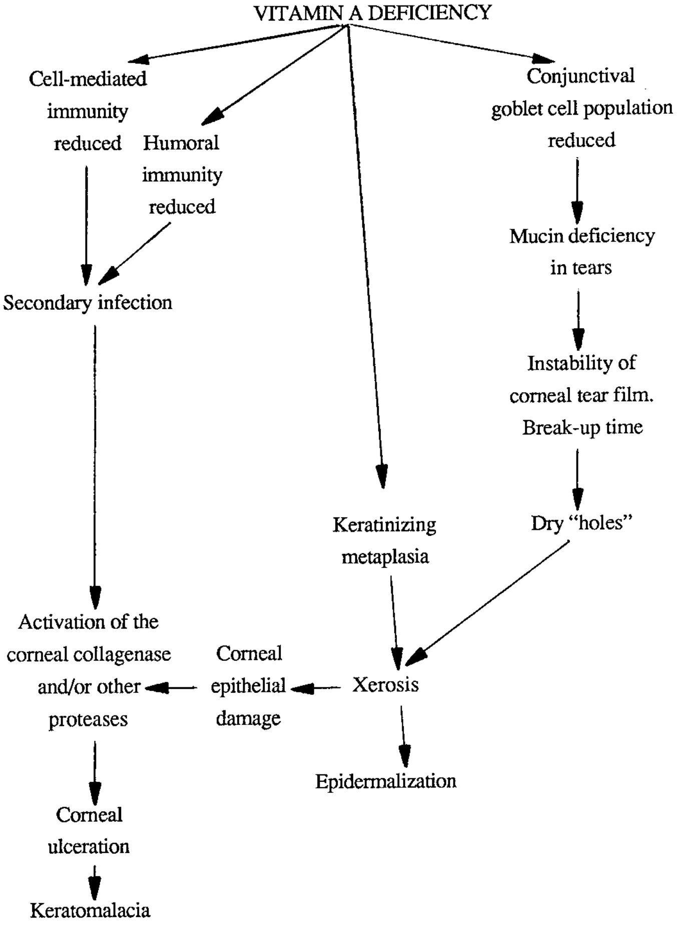
In adults, vitamin A deficiency gives rise, apart from night blindness, to skin lesions (hyperkeratosis of hair follicles). Moreover, experimentally induced vitamin A deficiency in adult human volunteers caused raised cerebrospinal fluid pressure, loss of the senses of taste and smell, and abnormalities in vestibular function (Wolf 1980: 146–50).

Dangers of Vitamin A Excess

If too little vitamin A is harmful, so also is too much, and emphasis needs to be placed on the dangers of hypervitaminosis A. In technically developed countries, many cases of vitamin A intoxication by ingestion of large doses of retinol or retinyl ester supplements (25,000 IU or more over a prolonged period, i.e., one month or longer) have been reported. It is not difficult to understand the reasoning behind this behavior ("if a little is good for me, a lot must be better"), and such reasoning is encouraged by popular literature, media exaggerations, a vague idea that vitamins generally are beneficial, and incomplete reports of the anticancer effects of vitamin A.

Unfortunately, such reasoning with vitamin A can lead to vitamin A intoxication, with symptoms such as skin rash, desquamation and pruritus of the skin, hair loss, weakness and fatigue, liver damage, bone and joint pain (associated with osteopenia of vertebrae and calcification of spinal ligaments and periosteal tissues in extreme cases), anorexia, and an increase in cerebrospinal fluid pressure, sometimes prompting a misdiagnosis of brain tumor. Hypervitaminosis A is rapidly reversible after the patient stops taking the vitamins. (It should also be emphasized, however, that for metabolic reasons, the provitamin A, beta-carotene, is nontoxic at any dose.)

In addition, recent oral use of an oxidation product of retinol (13-*cis*-retinoic acid) as a drug for the very successful treatment of acne has led to cases of fetal malformations, and there is a risk of abnormalities in the babies if the drug is taken during pregnancy, even at the very earliest stages after conception. Extreme caution is, therefore, indicated to avoid this drug if there is a possibility of pregnancy.



VITAMIN A DEFICIENCY
Cell-mediated immunity reduced
Humoral immunity reduced
Secondary infection
Conjunctival goblet cell population reduced
Mucin deficiency in tears
Instability of corneal tear film. Break-up time
Dry "holes"
Keratinizing metaplasia
Xerosis
Epidermalization
Corneal epithelial damage
Activation of the corneal collagenase and/or other proteases
Corneal ulceration
Keratomalacia

Figure IV.A.1.2. A postulated mechanism for the pathogenesis of keratomalacia in vitamin A deficiency (From unpublished documents, Nutrition Unit, World Health Organization, Geneva, Switzerland, 1994. With permission)

Geographic Distribution and Epidemiology of Vitamin A Deficiency

Vitamin A deficiency clusters in periequatorial areas and is closely associated with areas of poverty and malnutrition. Estimates suggest that about 350,000 preschool children become blind every year because of severe vitamin A deficiency; of these children, 60 percent die within a year (Underwood 1994).

Recent epidemiological surveys have demonstrated that mortality rates of preschool children receiving low or marginal dietary vitamin A, *yet not showing ocular signs of vitamin A deficiency,* could be lowered by 20 to 50 percent through vitamin A supplementation. Meta-analysis revealed a protective effect in lowering mortality by 23 percent in eight different studies done in Indonesia, Ghana, Nepal, India, and Sudan. From these data it is estimated that worldwide, 13 to 14 million children suffer from mild deficiency (no night blindness) with consequent increased risk of childhood infections (measles, respiratory infections, diarrhea). Vitamin A supplementation lowered the risk of death from measles in areas where subclinical vitamin A deficiency was prevalent. The cause of the protective effect of vitamin A is not known, but vitamin A depletion probably compromises the immune system.

Clearly, vitamin A deficiency and depletion are very serious public health problems. The World Health Organization actively monitors and obtains data on the worldwide occurrence of clinical and subclinical vitamin A deficiency and recommends ways to improve the situation. Intervention programs to eliminate the deficiency have been successful in Indonesia and are being implemented in India, Bangladesh, and Tanzania (Underwood 1994). Such programs involve food fortification, distribution of supplements, dietary diversification, and control of infectious diseases. The latter is important because there is a synergistic relationship between infectious diseases and vitamin A deficiency: Subclinical deficiency makes children prone to infectious diseases, and such diseases, in turn, can increase the need for the vitamin and precipitate or worsen a deficiency.

It is ironic and tragic that vitamin A deficiency occurs mostly in periequatorial regions where the

populations are surrounded by sources of the provitamin, beta-carotene, in the form of green leaves. It is thought that in rice-dependent countries (India, Bangladesh, Indonesia, and the Philippines, for example), vitamin A depletion is caused by the practice of providing weaned children a mostly rice diet, which lacks both vitamin A and beta-carotene. Such ignorance of good nutrition practices could be combated by nutrition education that would lead to the preparation of beta-carotene-rich foods for children.

The principal causes of the deficiency, however, are poverty and infectious diseases. To quote B. A. Underwood: "Rural areas in the affected regions are generally characterized by economic and social underdevelopment, including the quality and distribution of health services, sanitary facilities and potable water. These factors, characteristic of deprivation, are associated with high morbidity and consequently increased nutrition needs." Underwood stresses the "... environmental factors that can alter requirements and increase risks of hypovitaminosis A. Such risks are clustered in households and neighborhoods where poverty, poor personal and environmental sanitation, functional illiteracy, social isolation, inadequate access to health and social services prevail" (Underwood 1984: 355).

Vitamin A deficiency is generally found in regions of the globe where protein–energy malnutrition is also prevalent. Animal experiments have shown that a low-protein diet reduces the intestinal enzymes necessary for conversion of beta-carotene to retinol. Thus, a double danger threatens children in such regions: a short supply of beta-carotene *and* protein depletion that may reduce the conversion of available beta-carotene to retinol.

Awareness of this huge problem has finally galvanized governments, and plans were put in motion by the World Health Organization to eliminate vitamin A deficiency by the year 2000.

Vitamin A and Carotenoids in Food

Preformed vitamin A (retinol) is found only in animal foods, with the highest levels in mammalian, fowl, and fish livers, and in fish-liver oil, but with great seasonal variation. The next highest levels are in kidneys and fatty fish (e.g., salmon), whereas a third tier consists of milk, butter, and eggs, again with seasonal variation.

Carotenoids (beta-carotene and related compounds) are precursors of vitamin A that occur in green leaves and yellow and red vegetables and constitute the main source of vitamin A in the human diet. In decreasing order of beta-carotene content, these sources include parsley, sweet potato, broccoli, lettuce, tomato, and cabbage. Smaller, but significant, amounts are in legumes such as chickpeas and green and black grams. Yellow maize also contains beta-carotene. Fowl that eat grains and seeds absorb and accumulate carotenoids in their fat, so that their flesh can also be a source of this provitamin.

A special case as a source of beta-carotene is red palm oil, a vegetable oil used for cooking in several areas of Africa, Southeast Asia, and South America. It contains 0.6 to 1 RE per gram of oil and, in these areas, represents an important source of the provitamin (Underwood 1984: 290). The oil is extracted from the fleshy mesocarp of the palm nut and is prepared by boiling the fruit in water, cooling, and removing the oily layer. Unfortunately, substantial losses of beta-carotene can occur during cooking and storage.

Foods that lack vitamin A or carotenoids are wheat, oats, rice, potatoes, cassava, manioc, onions, nuts, sugar, olive oil, pork, and lard. In light of this lack, it is of interest to consider traditional diets of children in countries where vitamin A deficiency is a widespread public health problem. J. M. May and D. L. McLellan (1970), for example, have described the foods given to children in rural Ethiopia after weaning (at about 18 months of age). These included pancakes (*injera* – made from a local low-protein cereal grain called *toff* [tef], fermented and wet-cooked on a large griddle over an open fire) and a stew (*wot* – made of legumes, barley, onions, and garlic). The *wot* may contain some meat, although two-thirds of rural Ethiopians never eat meat. The children of a family are especially disadvantaged in terms of nutrition because the order of feeding is first the father, then guests, male persons, mother, and, last, children. Often, by the time the children eat, the *wot,* containing small amounts of carotenoids, is gone, and only *injera* is left.

Another example is drawn from Ghana, where the principal diet in rural areas consists of either fermented maize flour *(keuke)* made into a dough and cooked, or a soup or porridge of millet *(tuwonsafe).* In tropical forest regions, sun-dried cassava is ground to a flour *(konkote)* and boiled to a puree. Any oils in the diet are from groundnuts. Once again, fathers eat first, then other males, with women and children last. Moreover, there are taboos against women consuming eggs in some parts of Ghana. Clearly, with such a diet and such cultural habits, vitamin A deficiency is likely to be widespread.

A final example is found in India, where a public health problem exists with respect to vitamin A deficiency: The poor eat principally parboiled rice, or millet or wheat flours mixed with water and cooked as pancakes *(chapattis).* Cooking oil is from seeds; legumes are cooked with spices, and fat and vegetable intake is low (1 percent of the diet). Children are weaned at 2 years, then given boiled milk, diluted with water, along with rice or *chapattis.* No wonder that vitamin A deficiency diseases are prevalent among the poor.

Future Prospects

Basic Biology

Since the discovery, in 1987, of the mechanism of gene activation by retinoic acid, establishing vitamin A as a hormone, progress in the understanding of its basic biology has been breathtakingly rapid. The pleiotropic action of vitamin A (i.e., the multiple physiological functions of this vitamin) in development, growth, and differentiation, and the legion of enzymes affected by it, has been a puzzle since the early work of Wolbach and Howe (1925). This puzzle is now in the process of being solved.

The regulation and control of growth factors, hormones, enzymes, and homeobox genes (i.e., genes controlling embryonic development) by retinoic acid can now be explained on a rational basis because of the discovery of nuclear retinoic acid receptors (RARs), proteins that bind metabolites of retinol (all-*trans*-retinoic acid and 9-*cis*-retinoic acid) and, in a variety of combinations, interact with the DNA in the promoter regions of a large number of genes. These genes are then activated to express specific mRNAs (messenger RNAs) and proteins that can regulate and control development, growth, and differentiation.

Researchers are sequencing the relevant genes and tracing their evolutionary development. They are also in the process of elucidating the genes' interaction with RARs and the functions of the specific proteins expressed (enzymes, hormones, growth factors). Thus, the fields of biochemistry, endocrinology, genetics, embryology, evolution, and oncology will be greatly expanded, all on the basis of our recognition of the nuclear RARs. It has now become clear that the immune system is also influenced by vitamin A, and important advances in research on the action of vitamin A on the immune response can be expected.

Cancer and Other Diseases

Acute promyelocytic leukemia and skin cancer have been successfully treated with vitamin A derivatives. On the basis of experimental work, one can expect other forms of cancer to yield to efforts at treatment by retinoids. Chemoprevention treatment by retinoids of persons at high risk (e.g., recurrent squamous carcinoma of the head and neck) will certainly expand. Skin diseases (acne, psoriasis, and others) have been successfully treated with retinoids, and the possibility exists that rheumatoid arthritis and other inflammatory diseases may ultimately yield to retinoid treatment.

Public Health

Future prospects for the alleviation of the horrendous tragedy of preventable childhood blindness and children's infectious diseases by vitamin A or beta-carotene now lie in the hands of governments, international organizations, and nongovernmental agencies. The problem is not one of science but of economics, education, and, ultimately, politics. The science is merely concerned with methods of determining in which population groups the children are at risk of vitamin A deficiency and the severity of the deficiency. This assessment can be done by blood tests, but simpler methods are being sought. Once the deficient population group has been ascertained, it is necessary to direct efforts for a cure in such a way that the vitamin reaches the children in need. This implementation involves improving the children's overall diet and sanitation, removing parasites, educating the mothers, diversifying the food supply, fortifying foods, and supplementing with vitamins. Considering the millions of children and the multitude of countries affected (see Table IV.A.1.2), each with its own government, bureaucracy, and dietary and cultural traditions, the elimination of vitamin A depletion and deficiency will be a daunting task.

IV.A.2 ~ Vitamin B Complex: Thiamine, Riboflavin, Niacin, Pantothenic Acid, Pyridoxine, Cobalamin, Folic Acid

The history of the discovery of the B vitamins includes both the recognition that particular diseases can result from dietary inadequacies and the subsequent isolation of specific nutrients from foods that have been found to prevent and to cure those diseases. Most of these dietary deficiencies were first recognized in humans, but in certain instances, the deficiency was produced by feeding restricted diets to experimental animals.

After each of the B vitamins was isolated, extensive biochemical and physiological studies were conducted to define their specific functions. States of B vitamin dependency were also discovered in which the need for a particular vitamin exceeded the physiological level. These vitamin dependencies were found either to have a genetic basis or to be drug-induced.

Moreover, recognition that certain synthetic compounds bearing close chemical resemblance to B vitamins could block the activity of naturally occurring vitamins has led to a better understanding of vitaminic functions and has provided us with certain drugs that are used in cancer chemotherapy and in the treatment of infections and inflammatory diseases.

Vitamin B research, as well as clinical and public health information, is summarized here to emphasize some significant advances in our knowledge of these compounds. But first a note on nomenclature seems appropriate.

B Vitamin Nomenclature

The confusing nomenclature of the B vitamins can only be understood historically. In 1915 E. V. McCollum and M. Davis concluded that young rats needed two unknown "growth factors," one fat-soluble and the other water-soluble, and for convenience they called them "factors A and B," respectively. Casimir Funk had already coined the term "vitamine" in the belief that any unknown factors would prove to have the chemical structure of "amines." J. C. Drummond then suggested that the term be modified to "vitamin," which had no chemical significance, and he called the antiscurvy factor "vitamin C."

Further research showed that "factor B" was made up of at least two components, one heat-labile and the other more stable; these were termed vitamins B_1 and B_2 respectively. Vitamin B_1 was later shown to be the anti-beriberi vitamin, known as thiamine. The B_2 factor was again found to be complex. Among other things, it included riboflavin, which was first named "vitamin G" in honor of Joseph Goldberger, who had made classical studies of pellagra in the United States. The designation vitamin B_3 was given to a compound that seems to have been pantothenic acid but was sometimes incorrectly used to mean niacin. Biotin was first called "vitamin H" by workers in Germany who had shown that its deficiency in rats resulted in abnormalities of the skin (in German *Haut*), and folic acid, at one time, was termed "vitamin M" because it was first shown to be needed by monkeys. Today, however, these three letters, namely, G, H, and M, are no longer used, and the vitamins are known by the names riboflavin, biotin, and folic acid and classified as parts of the vitamin B complex.

Other workers claimed higher numbers in the B series when they believed that they had discovered new growth factors. But many of these assertions seem to have been erroneous claims and only two "B" numberings are still in use: B_6 for pyridoxine and closely related compounds, and B_{12} for cobalamin and its derivatives. The coding is convenient because in each case it covers more than one precise chemical compound.

In recent years, some entrepreneurs engaged in selling materials that have been claimed to cure cancer and other diseases have named their products as vitamins in attempts to portray them as essentially natural materials, and so to escape the strict regulations applying to drugs. An example is B_{17}, or "laetrile," which is not recognized by orthodox nutritionists.

Thiamine

Use of polished rice as a dietary staple has long been known to lead to the development of a disease known as beriberi, which was first described as affecting Japanese sailors as well as prisoners in the Dutch East Indies. Signs of beriberi include paralysis due to polyneuritis and congestive heart failure. Christian Eijkman, a medical officer in Java, was the first to show (1890) that a paralytic illness resembling beriberi could be produced in chickens by feeding them polished rice (Jansen 1950). He, and his successor Gerrit Grijns, also demonstrated that the polyneuritis of beriberi could be cured by feeding rice bran.

In 1912, Funk extracted a substance from rice bran that he believed was the anti-beriberi substance and that he characterized chemically as being an amine. He then coined the term "vitamine" as a contraction of "vital amine." With the discovery of other organic compounds that were "vital" but not amines, the term "vitamin" was used instead. The anti-beriberi vitamin was named thiamine. The biologically active coenzyme form of thiamine is required for the oxidative decarboxylation of pyruvic acid. Thiamine is also required in the metabolism of glucose and many other enzyme-catalyzed reactions.

It has been shown that alcoholics may develop an acute thiamine deficiency if they drink heavily and concurrently go without food. Their condition of acute thiamine deficiency, which is manifested by a confusional state and paralysis of certain eye muscles, is designated as Wernicke's encephalopathy. It responds to high doses of intravenously administered thiamine. If this confusional state is not recognized and treated with thiamine, a chronic organic brain disorder develops, associated with dementia. Those who have this disorder may require institutionalization. Korsakoff's psychosis is believed to be a chronic form of Wernicke's encephalopathy, and the health costs of caring for persons with this disease have led to the fortification of beers with thiamine in an experimental public health intervention in Australia (Yellowlees 1986).

Nicotinic Acid, or Niacin

Pellagra is a disease that we now recognize as being caused by a deficiency in nicotinic acid (niacin). It is characterized by development of a dermatitis, which appears on areas of the body exposed to strong sunlight; by diarrhea, associated with malabsorption of nutrients; and by a severe confusional state. This disease was first described by Gaspar Casal, who wrote of the diet of Spanish peasants with pellagra or *mal de la rosa,* as it was then called (the book was published posthumously in 1762).

Because the Spanish peasants who had this disease subsisted on cornmeal, and because corn, particularly moldy corn, was also the dietary staple of other poverty-stricken populations in southern Europe that developed pellagra, it was believed that the disease was caused by eating a corn-based diet, particularly when the corn had been improperly stored and became moldy. It was also observed that the diet of those with pellagra was especially lacking in animal protein.

It was not until 1914, when pellagra had become a problem in the southern United States, that Goldberger began his studies, which ultimately demonstrated that the nutritional etiology of pellagra produced a comparable condition in dogs called "black tongue" and identified foods that were pellagra-preventing (Roe 1973). Later investigators extracted some of these foods, including liver, and attempted isolation of nutrients lacking in the diets of those with the disease. During this period, independent studies by Otto Heinrich Warburg and Walter Christian identified nicotinic acid as one of the substances forming "coferment," which was thought to be important in normal metabolism. Shortly after this discovery, nicotinic acid was found to be an essential factor for the growth of certain bacteria.

Conrad Elvehjem and his co-workers, who carried out extensive studies at the University of Wisconsin in the 1930s, tested various liver-extract fractions for activity as growth factors in experimental animals. One sample was found to contain a substance that was identified by Wayne Woolley as nicotinic acid. Subsequently, others in Elvehjem's laboratory cured "black tongue" in dogs by feeding them the nicotinic acid obtained from such liver extracts (Kline and Baumann 1971).

Once it was known that nicotinic acid could cure this disease in dogs, Tom Spies gave nicotinic acid to several subjects with pellagra and found that the human disease responded to it as well. The nutrient nicotinic acid was subsequently given the alternate name of niacin in order to avoid lay confusion of the term with nicotine.

Later studies of the metabolism of niacin in experimental animals showed that they could synthesize it from a precursor, which proved to be the amino acid tryptophan. Because animal proteins are particularly rich in tryptophan, this finding helped to explain the old observation that diets of pellagrins were invariably low in meat and milk (Goldsmith 1964).

Nicotinic acid is active biochemically in several coenzyme forms, and it is necessary for the synthesis and breakdown of fatty acids, carbohydrates, and amino acids. In human studies conducted soon after the discovery of its activity as a vitamin, it was found that when large doses of niacin were administered, individuals became flushed. Although this observation was an early indication that niacin might be toxic if given in excessive amounts, it also suggested that high doses might relieve conditions associated with constriction of blood vessels. In fact, the vitamin failed to yield the hoped-for therapeutic advantage, but it was found later that niacin in high doses could reduce blood cholesterol levels (Havel and Kane 1982).

Riboflavin

Riboflavin, another of the B-complex vitamins, was first isolated from the greenish yellow pigment in milk. Its deficiency occurs in populations whose diets are lacking in dairy foods and green vegetables and produces a disease characterized by cracks at the corners of the mouth, sore tongue, dermatitis of the folds of the body, and changes in the eyes that make them sensitive to light exposure. It was realized that some pellagra sufferers in the United States were deficient in riboflavin as well as in niacin. The condition was also described in very low-income, rural populations in India (Sebrell and Butler 1938). In more recent years, this same condition has been identified in alcoholics. Flavins, including two major active forms of the vitamin designated riboflavin, have also been isolated from liver. Furthermore, it has been shown that flavins are necessary for energy utilization and that requirements for riboflavin increase during periods of physical activity (Roe 1991).

Vitamin B_6

The term "vitamin B_6" embraces a group of closely related compounds: pyridoxine, pyridoxal, and pyridoxamine. Laboratory investigations resulting in the identification of vitamin B_6 were launched after it became known that a particular form of dermatitis, which developed in rats fed purified diets, could not be cured with any known nutrient but could be prevented by giving the animals a particular yeast extract.

The early clinical studies of vitamin B_6 deficiency were based on observations of infants fed an autoclaved formula diet. Then, during the 1950s, when active research was being conducted on the biochemical functions of vitamin B_6, further insight into the clinical manifestations of its deficiency was obtained by putting human volunteers on a diet that lacked the vitamin and giving them a vitamin B_6 antagonist at the same time.

Following this study, vitamin B_6 deficiency was observed in patients who were given the drug isoniazid for the treatment of tuberculosis. It was then realized that the drug was also a vitamin B_6 antagonist. In both the experimentally produced vitamin B_6 deficiency and the drug-induced disease, dermatitis and neurological symptoms developed, and later an anemia surfaced as well, in which iron was improperly utilized. Biochemical studies showed that there were three physiologically active forms of vitamin B_6 and that these forms are interconvertible. They have been found to function in amino acid metabolism, in the synthesis of heme from which hemoglobin is formed, and in neurotransmitter activity (Roe 1985).

Pantothenic Acid

Metabolic pathways that depend on pantothenic acid include those involved with the biosynthesis of cholesterol and steroid hormones. Abnormalities have been described in several different types of experimental animals placed on diets deficient in pantothenic acid. In rats, these changes included slow rate of growth in young animals and graying of the fur in older animals. The fertility of rats has also been shown to decline, and gait disorders have been observed in pigs. In addition, destruction of the adrenal glands, associated with bleeding into these glands, has been found in postmortem examinations of several species in which the deficiency has been induced.

Little is known of human requirements for the vitamin, but because it is widespread in foods, there is little danger of deficiency. Thus, pantothenic acid deficiency has been described only in humans who are very severely malnourished and in volunteers who have been fed both a pantothenic acid–deficient diet and a pantothenic acid antagonist (Fox 1984).

Biotin

Biotin is another B vitamin that is involved in the biosynthesis of fatty acids. Biotin deficiency has been described in infants as a result of an inborn error of metabolism. A biotin deficiency has also been described in infants and in older individuals with intestinal diseases. Both groups were fed formula diets lacking in biotin, and both were concurrently receiving broad-spectrum antibiotics that prevented the intestinal synthesis of this vitamin (Mock et al. 1985).

Folic Acid (Folacin)

In 1929–31, Lucy Wills and her colleagues described a severe anemia among pregnant women living in conditions of purdah (seclusion) in Bombay. Because of cultural taboos, these women ate a monotonous and limited diet in which green vegetables and fruits were lacking (Wills and Mehta 1929–30; Wills and Talpade 1930–1). The anemia was characterized by a severe lowering of the red blood cell count and the appearance of large immature cells in the bone marrow and in the peripheral blood. This so-called macrocytic (large-celled) anemia was cured by giving the women a yeast extract. Subsequent studies showed that certain crude liver extracts could also cure it.

Wills also reported poor pregnancy outcomes for the Indian women who were anemic. She subsequently described the anemia in other populations who lived on diets that lacked fruit and green vegetables. Later investigations led to the isolation of a nutrient, both from liver and from green vegetables, that prevented and cured the same macrocytic anemia. This nutrient was named folic acid, or folacin. Early investigations of folic acid showed that it existed in several different forms that had a number of critical functions in cell maturation.

In other studies, researchers deliberately synthesized chemical analogues of folic acid and demonstrated that these substances not only blocked the normal activity of folic acid but also prevented cell division. Such findings led to the development of specific folic acid antagonists, including aminopterin and methotrexate, which inhibit the division of malignant cells. Methotrexate, which was the less toxic of the two substances, is now employed to control certain forms of cancer and leukemia (Roe 1990). However, it was also found that if aminopterin or methotrexate was taken during the first trimester of pregnancy, birth defects occurred in the offspring. The defects were shown in rat studies to develop if one or another of these drugs was administered during the gestational period of embryogenesis (Nelson 1963).

Another association of folic acid nutriture has been revealed more recently, namely that the risk of women bearing infants with neural tube defects, such as spina bifida, is greatly reduced if they are given supplementary folic acid from the time of conception through the first trimester. Currently, a debate continues about whether or not it would be desirable to fortify cereals with folic acid as a public health measure to prevent neural tube defects (MRC Vitamin Study Research Group 1991).

Vitamin B_{12} (Cobalamin)

Vitamin B_{12} was first isolated as the active factor in liver extracts that, given by injection, maintained subjects suffering from pernicious anemia. This disease was first described by Thomas Addison in the nineteenth century, who observed that it occurred primarily in older men and women and is characterized by the presence of a macrocytic anemia. The changes in the blood picture are identical to those seen in folic acid deficiency. In addition, patients with pernicious anemia may develop an irreversible neurological disorder that leads to sensory loss, including loss of balance. A confusional state may also be present.

Studies of pernicious anemia have revealed that it is an autoimmune disease in which cells in the lining of the stomach are destroyed. As a result, the so-called intrinsic factor found in normal gastric secretion is no longer produced in the stomach and there is a loss of capacity to absorb vitamin B_{12}. Vitamin B_{12} deficiency can also develop when it cannot be absorbed because of surgical loss of the absorption site in the lower part of the small intestine. Aside from these circumstances, a very low intake of vitamin B_{12} can also cause pernicious anemia, although such a low intake is unlikely to occur except with people who are strict vegans, since the vitamin is present only in animal foods. Deficiency signs may, however, take several years to develop because of body stores of the vitamin built up in earlier periods.

Investigations of the cause of the neurological complications of vitamin B_{12} deficiency followed recognition that the same complications may develop in those who are exposed to nitrous oxide (Roe 1985). More recently, more such neurological studies have been carried out on the metabolic defect existing in children with genetic disorders of vitamin B_{12} metabolism (Metz 1993).

Vitamin B_{12} has essential functions in the synthesis of the amino acid methionine and is also required for the interconversion and cellular uptake of different forms of folic acid (Buchanan 1964).

IV.A.3 Vitamin C

In delineating the history of a vitamin, we can often recognize four chronological phases. First, there is the description of a disease of unknown etiology, and second, there is the description of an empirical cure for the disease. Following this step, and often closely associated with it, is the identification of the curative factor – which perforce then becomes known as a vitamin. In the fourth phase the mode of action of the vitamin in preventing the deficiency disease is characterized.

The history of vitamin C (ascorbic acid) conforms to this general pattern. The characterization of the deficiency disease (scurvy) and the empirical discovery of a cure for it are, properly speaking, a part of the history of scurvy and have been dealt with elsewhere in this work. But this chapter is concerned with the subsequent history of the antiscorbutic factor, which conveniently presents itself in three chronological stages: (1) the somewhat ill-defined and open-ended period – from the beginning of the nineteenth century to the 1920s – when the vitamin had the existence of an "unrevealed presence" and was known to exist only because of its preventive influence on the disease scurvy (just as, during the same period, the perturber of Uranus was known to exist long before the "discovery" of the planet Pluto); (2) the 1920s and the 1930s, when vitamin C was named, isolated, and its molecular structure revealed (in that order); and (3) the modern post-1940 period, with its emphasis on the characterization of the biochemical role of vitamin C in preventing scurvy and, more recently, the debatable "extra-antiscorbutic" roles sometimes attributed to it.

The Antiscorbutic Factor

The early history of vitamin C cannot readily be separated from that of the demise of scurvy. By the beginning of the nineteenth century it was generally accepted that it was possible to prevent and cure scurvy by the use of citrus fruits: James Lind's contribution in establishing this belief was of paramount significance. But it was in essence a pharmacological concept rather than a nutritional one; the belief that the citrus fruits were replacing a missing dietary component would have been alien to medical thought at the beginning of the nineteenth century; even Lind himself did not regard fruit and vegetables as obligatory dietary principles in the prevention of scurvy. In other words, not until the end of the nineteenth century was there any general acceptance that scurvy was a deficiency disease resulting from a lack of a specific dietary principle and that the disease could be prevented or cured by appropriate dietary manipulation. Moreover, even this acceptance was complicated by the advent of the germ theory of disease which, some have argued, caused reversion to an infection theory to explain scurvy's etiology.

One of the earliest thinkers to discuss these new ideas was George Budd (1808–82), Professor of Medicine at King's College, London – although as K. C. Carter has indicated, Budd should perhaps be regarded as a developer rather than as an innovator of the "deficiency disease theory" (Hughes 1973; Carter 1977). In 1842, Budd published in the *London Medical Gazette* a series of articles entitled "Disorders Resulting from Defective Nutriment." He described "three different forms of disease which are already traced to defective nutriment" and argued that such conditions resulted from the absence of dietary factor(s) other than carbohydrate, fat, and protein, and that the absence of each of these specific factors would be associated with a specific disease – an idea that lay in abeyance for some 40 years until experimentally proved by N. Lunin. There can be little doubt that the three diseases described by Budd were avitaminoses A, C, and D.

L. J. Harris, himself a significant figure in the later history of vitamin C, aptly described Budd as "the prophet Budd" and referred to an article in which Budd expressed the belief that scurvy was due to the "lack of an essential element which it is hardly too sanguine to state will be discovered by organic chemistry or the experiments of physiologists in a not too distant future" (Budd 1840; Harris 1937: 8).

Little happened, however, to fulfill Budd's prophesy until the beginning of the twentieth century. In 1907, A. Holst and T. Fröhlich of Norway reported experiments in which they had demonstrated that scurvy could be induced in guinea pigs and cured by dietary manipulation (Holst and Fröhlich 1907; Wilson 1975). They used guinea pigs to assess the antiscorbutic value of different foodstuffs and to show the thermolabile nature of the antiscorbutic factor. At the same time there were parallel, but independent, developments in the general theory of vitamin deficiency diseases. F. G. Hopkins, developing earlier work by Lunin, C. A. Pekelharing, W. Stepp, and others, in 1912 published his classic paper in which he demonstrated the presence of growth factors in milk and showed their essential dietary nature (Hopkins 1912); in the same year, Casimir Funk introduced his "vitamin hypothesis," in which he attributed scurvy to the absence of an "anti-scurvy vitamine" (Harris 1937: 1–21).

The use of the guinea pig assay technique for the assessment of the antiscorbutic factor was extended, and in 1917, H. Chick and M. Hume published an important paper in which they reported the factor's distribution in a number of foodstuffs (Chick and Hume 1917). The following year A. Harden and S. S. Zilva published their fractionation studies on lemon juice, in which they demonstrated that the antiscorbutic potency was not attributable (as had been suggested by earlier workers) to the citric acid content (Harden and Zilva 1918). The year after that, J. C. Drummond designated the factor "Water soluble C" (Drummond 1919).

Identification of Vitamin C

Work now began in earnest to identify and isolate the antiscorbutic factor. The Medical Research Council's 1932 publication *Vitamins: A Survey of Present Knowledge* may be referred to for a detailed account of the large number of papers published during the 1920s on what was by then known as "vitamin C." Foremost in these early efforts was Zilva, working at the Lister Institute, London. The essential feature of Zilva's procedure was the precipitation of the factor with basic lead acetate after removal of the bulk of the other organic acids with calcium carbonate. He applied this technique to a variety of sources, such as lemon juice and swede (rutabaga) tissues, and he succeeded in increasing the concentration of the antiscorbutic factor some 200 to 300 times (Hughes 1983).

Other workers were similarly occupied, notably N. Bezssonoff in France and C. G. King in the United States. King has stated that during this period "many investigators had abandoned or failed to publish their work for various reasons." He referred, specifically, to Karl Link of Wisconsin, who had prepared several grams of crude calcium ascorbate during the 1920s but carried his work no further because of lack of financial support (King 1953).

The purest of these early "concentrates" still contained much impurity, and it was not until 1932 that W. A. Waugh and King published their paper "The Isolation and Identification of Vitamin C," which included a photograph of vitamin C crystals (Waugh and King 1932).

These attempts to isolate and characterize vitamin C were paralleled by two separate, but nevertheless highly relevant, developments in related areas. J. Tillmans and P. Hirsch, German government chemists, extensively studied the capacity of lemon juice preparations to reduce the redox dye 2,6-dichlorophenolindophenol, and they claimed that the reducing power of their preparations was always in proportion to their antiscorbutic potency; the indophenol dye technique later became a standard method for the assay of vitamin C. Zilva, however, disagreed with the German findings and appears, at that point, to have been diverted from his main endeavor by an attempt to disprove them (Zilva 1932).

The other significant development at this time was Albert Szent-Györgyi's isolation of hexuronic acid. Szent-Györgyi, a Hungarian biochemist working on plant respiration systems at Groningen in Holland, became interested in a reducing compound present in his preparations. Hopkins invited him to Cambridge to extend his studies, and in 1927, Szent-Györgyi isolated his "Groningen reducing agent" in a crystalline, from oranges, lemons, cabbages, and adrenal glands (Szent-Györgyi 1928).

He proposed to name his crystalline sample "ignose" – thus indicating its apparent relationship to sugars while at the same time underlining his ignorance of its true nature. But Harden, the editor of the *Biochemical Journal* at the time, according to Szent-Györgyi, "did not like jokes and reprimanded me." A second suggestion "godnose" was judged to be equally unacceptable. Szent-Györgyi finally agreed to accept Harden's somewhat more prosaic suggestion "hexuronic acid" – "since it had 6 Cs and was acidic" (Szent-Györgyi 1963: 1–14).

Hexuronic acid was a strongly reducing compound. So, too, according to Tillmans and Hirsch, was the antiscorbutic substance (vitamin C). The suggestion that hexuronic acid and vitamin C were actually one and the same substance appeared in print in 1932 in papers by both J. L. Svirbely and Szent-Györgyi and by Waugh and King, but there can be little doubt that the idea had been mooted some years previously. Who first made the suggestion is, however, unclear, and even the main participants in the drama later appeared uncertain and confused. King (1953) claimed that it was E. C. Kendall in 1929, but according to Hopkins (reported by King) it was Harris in 1928 (King 1953) – and he had, in any case, already attributed the idea to Tillmans and Hirsch (Harris 1937: 95). But E. L. Hirst (a member of the team later involved in chemical studies on the structure of vitamin C) named Waugh and King (Hirst 1953: 413).

Hopkins had already, in 1928, sent a sample of Szent-Györgyi's hexuronic acid to Zilva for comments on its vitamin C potency. According to King, Hopkins was disturbed because Zilva (who, naturally perhaps, was reluctant to admit that his "antiscorbutic preparations" were in reality identical with hexuronic acid) had replied that the sample was not vitamin C, but did so without reporting the evidence of his tests (King 1953).

By 1932, however, evidence in favor of the identity of hexuronic acid as vitamin C was substantial. Waugh and King had shown that their "crystalline vitamin C" cured scurvy in guinea pigs (Waugh and King 1932), and earlier the same year, Svirbely and Szent-Györgyi (now working in his native Hungary) had described the antiscorbutic potency of a sample of "hexuronic acid" isolated from adrenal glands (Svirbely and Szent-Györgyi 1932).

In 1933, in a single-sentence letter in *Nature,* Szent-Györgyi and W. N. Haworth drew attention to the chemical inaptness of the term "hexuronic acid" and suggested the term "ascorbic acid," thus formally acknowledging the antiscorbutic nature of the compound. Harris and his colleagues at Cambridge demonstrated the positive correlation between the hexuronic acid content and the antiscorbutic potency in a wide range of foodstuffs and published a highly convincing "eight-point" proof of the identity of the two substances.

Their three most important points were as follows: (1) Hexuronic acid paralleled antiscorbutic potency; (2) destruction of hexuronic acid by heat or by aeration was accompanied by a corresponding fall in the antiscorbutic activity; and (3) hexuronic acid disappeared from the organs of scorbutic guinea pigs (Birch, Harris, and Ray 1933). There could now be little doubt that hexuronic acid (Tillmans and Hirsch's reducing compound) and vitamin C were one and the same substance.

The situation was not without its human aspects, and even today the question of priority in the discovery of vitamin C still elicits discussion. "The identification of vitamin C is one of the strangest episodes in the history of vitamins," wrote T. H. Jukes in commenting on the appearance in 1987 of a book by R. W. Moss that placed, in Jukes's opinion, too great an emphasis on Szent-Györgyi's contribution (Moss 1987; Jukes 1988: 1290). Moss had implied that King had rushed off his claim for the identity of vitamin C and hexuronic acid after it became clear to him that Szent-Györgyi intended making the same point in a note to *Nature* – a situation curiously reminiscent of the suggestion that Charles Darwin behaved similarly on learning in 1858 that Alfred Russel Wallace was about to publish his theory of evolution.

The emphasis now shifted to the elucidation of the structure of vitamin C. Haworth, a Birmingham (U.K.) chemist, had received from Szent-Györgyi a sample of his "hexuronic acid," and in 1933, in a series of impressive papers, the Birmingham chemist, using both degradative and synthetic procedures, described the structure of the molecule (Hughes 1983). The molecule was synthesized simultaneously, but independently, by T. Reichstein in Switzerland and by Haworth and his colleagues in Birmingham, both groups using essentially the same method.

The synthesis – which, as it later emerged, was quite different from the biosynthetic pathway – was based on the production of xylosone from xylose and its conversion with cyanide to an imino intermediate that, on hydrolysis, gave ascorbic acid. The Swiss group published their results just ahead of the Birmingham workers (Ault et al. 1933, Reichstein, Grussner, and Oppenheimer 1933). The picture was completed the following year when the Birmingham workers joined forces with Zilva to demonstrate that synthetic ascorbic acid produced at Birmingham had exactly the same antiscorbutic potency as a highly purified "natural" sample from the Lister Institute (Haworth, Hirst, and Zilva 1934).

The annual report of the Chemical Society for 1933, with perhaps unnecessary caution, stated that "although it seems extremely probable that ascorbic acid is vitamin C . . . it cannot be said that this is a certainty." Other were less circumspect. A. L. Bacharach and E. L. Smith, addressing the Society of Public Analysts and Other Chemists in November 1933, said that "Vitamin C can now be identified with a sugar acid known as ascorbic acid. . . . Contrary to expectation, it is the first vitamin not merely to have assigned to it a definite molecular formula, but actually to be synthesised by purely chemical means" (Hughes 1983). Budd was correct in his 1840 prophecy that both physiologists and chemists could contribute to the identification of the "antiscorbutic factor." But his "not too distant future" proved to be a period of 93 years!

Biosynthesis and Metabolism of Vitamin C

By the end of the 1930s, serious research had commenced on the biological role of vitamin C. In particular, biochemical reductionists sought to explain the nature of the relationship between the clinical manifestations of scurvy and the biochemical involvements of vitamin C. It was recognized that vitamin C was a powerful biological reductant, and there were early attempts to explain its nutritional significance in terms of its involvement in oxidation-reduction systems – a major theme in prewar biochemistry. But the first clear advance in the biochemistry of vitamin C came from studies of its biosynthesis, and by the early 1950s, the pathway for its formation from simple sugars had been worked out. L. W. Mapson and a colleague at the Low Temperature Research Station at Cambridge (U.K.) fed different possible precursor molecules to cress seedlings and measured the formation of vitamin C. And in the United States, King and co-workers used labeled glucose to chart the biosynthetic pathway in rats (Mapson 1967: 369–80).

The biosynthetic pathway proved to be a comparatively simple one. D-glucuronate (formed from glucose) is converted to L-gluconate and then to L-gulono-gamma-lactone, which in turn is further reduced (via L-xylo-hexulonolactone) to L-ascorbic acid (2-oxo-L-gulono-gamm-lactone). The final enzymatic step is catalyzed by L-gulonolactone oxidase (EC 1.1.3.8.) – in the liver in evolutionarily "advanced" species such as the cow, goat, rat, rabbit, and sheep and in the kidney in other species such as the frog, snake, toad, and tortoise – and it is this enzyme that is lacking in those species unable to synthesize vitamin C.

To date, this biochemical "lesion" has been detected in a small, and disparate, number of species – higher primates (including, of course, humans), guinea pigs, certain bats, birds, insects, and fish (Chatterjee 1973; Sato and Uderfriend 1978). Whether all these species are necessarily scurvy-prone is not quite so clear. A survey of 34 species of New World microchiropteran bats showed that L-gulonolactone oxidase was apparently absent from the livers of all of them (and from the kidneys of at least some of them), but nevertheless, the tissue levels of ascorbic acid (even in species that were fish-eaters or insect-eaters) were similar to those in species that could biosynthesize the vitamin (Birney, Jenness, and Ayaz 1976).

This finding would suggest that the vitamin was being synthesized in organs other than the liver and kidney; or that the metabolic requirement for it was remarkably low; or that there were extremely efficient mechanism(s) for its protection against degradative changes. The whole question of the evolutionary significance of vitamin C – in plants as well as in animals – remains a largely uncharted area.

The rate of endogenous biosynthesis of vitamin C in those species capable of producing the vitamin shows considerable interspecies variation, ranging from 40 milligrams (mg) per kilogram (kg) body weight daily for the dog to 275 for the mouse (Levine and Morita 1985). These values are well in excess of the amounts of the vitamin required to prevent the appearance of scurvy in species unable to synthesize it – a finding that has frequently been used to buttress the claim that vitamin C has a number of "extra-antiscorbutic" roles requiring daily intakes well in excess of the recommended daily amounts.

The total body pool of ascorbic acid in a 70 kg man has been estimated at about 1.5 grams (g) (but according to Emil Ginter it could be three times as great as this [Ginter 1980]), which is attainable in most people by the sustained daily intake of 60 to 100 mg. A daily intake of 10 mg vitamin C results in a body pool of about 350 mg. Scorbutic signs do not appear until the pool falls to below 300 mg (Kallner 1981; "Experimental Scurvy" 1986).

Plasma (and less conveniently, leucocyte) concentrations of ascorbic acid are often taken as an index of the body status of the vitamin. The normal concentration range in the plasma of healthy persons on an adequate plane of nutrition is 30 to 90 micromoles per liter (µmol/L) (0.5–1.6 mg/100 ml). The Nutrition Canada Interpretive Guidelines are often referred to in this respect; these guidelines suggest that values between 11 and 23 µmol/L are indicative of marginal deficiency and that values below 11 µmol/L point to frank severe deficiency – but differences of sex, race, metabolism, smoking habits, and, particularly, of age (factors known to influence plasma ascorbic acid concentrations) reduce the validity of such a generalization (Basu and Schorah 1981; Hughes 1981b).

During a period of vitamin C depletion there is a comparatively rapid loss of vitamin C (a reduction of about 3 percent in the body pool daily) resulting from the continued catabolism of the vitamin and the excretion of its breakdown products in the urine. In humans, the main pathway identified involves the conversion of the ascorbic acid to dehydroascorbic acid, diketogulonic acid, and oxalic acid (in that order), with the two latter compounds accounting for the bulk of the urinary excretion of breakdown products. Smaller amounts of other metabolites, such as ascorbic acid-2-sulphate also occur, and in the guinea pig there is substantial conversion of part of the ascorbic acid to respiratory CO_2. It has sometimes been argued that the excess formation of these catabolites (particularly oxalic acid) should signify caution in the intake of amounts of vitamin C substantially in excess of the amount required to prevent scurvy.

Biochemical Role of Vitamin C

It was noted in the early experiments of Holst and Fröhlich, and confirmed by many subsequent workers, that defective formation of connective tissue was a primary pathological feature of experimental scurvy, and at one time it was believed that this lesion could account for most of the known pathological sequelae of the disease – the petechial hemorrhages, the breakdown of gum tissue, and the impairment of wound repair tissue. Attempts to characterize the biochemical modus operandi of vitamin C in preventing scurvy, therefore, centered initially on the metabolism of collagen – the essential glycoprotein component responsible for imparting strength to connective tissue.

By the 1970s, there was suggestive evidence that the biochemical lesion was located in the hydroxylation of the proline and lysine components of the collagen polypeptide and that vitamin C had an essential role in the process (Barnes and Kodicek 1972). The hydroxylases involved in collagen biosynthesis (prolyl 4-hydroxylase, prolyl 3-hydroxylase, and lysyl hydroxylase) require ferrous iron as a cofactor, and it appears that vitamin C, a powerful biological reductant, has an almost obligatory role in maintaining the ferrous iron in the reduced form. Thus emerged a simplistic and reductionist explanation for the role of vitamin C in preventing the emergence of the main clinical features of scurvy.

Yet although there can be little doubt that vitamin C plays a critical role in the biosynthesis of collagen, recent studies have suggested that the simple "defective hydroxylation" theory is, perhaps, not the complete story. Studies have indicated that the activity of prolyl hydroxylase and the formation of collagens by fibroblast cultures is not influenced by ascorbic acid; furthermore, ascorbic acid deficiency does not always result in severe underhydroxylation of collagen in scorbutic guinea pigs (Englard and Seifter 1986).

There is increasing evidence that vitamin C may also influence the formation of connective tissue by modifying the nature and formation of the extracellular matrix molecules (Vitamin C Regulation 1990). B. Peterkofsky (1991) has recently suggested that the role of vitamin C in collagen biosynthesis is a dual one – a direct influence on collagen synthesis and an indirect one (mediated perhaps via appetite) on proteoglycan formation.

The complement component Clq, which has a central role in disease resistance, contains a collagen-like segment that is rich in hydroxyproline, and it has been suggested that this segment could offer a link with the putative anti-infective powers widely suggested for vitamin C (Pauling 1976; see also the section on megatherapy). Studies over the last 15 years, however, have failed to demonstrate that the complement system, unlike connective tissue collagen, reflects vitamin C availability (Thomas and Holt 1978; Johnston 1991). Indeed, the belief that vitamin C had anti-infection powers probably stemmed from reports by Harris in 1937 of lowered vitamin C in persons suffering from certain diseases, particularly tuberculosis.

During the 1960s and the 1970s, however, some 25 epidemiological studies were completed in different parts of the world to assess the validity of claims that vitamin C had anti-infection powers, particularly with respect to the common cold. The general conclusion drawn from the results of these studies was that the evidence for a protective/curative role for vitamin C in the common cold was far from convincing (Hughes 1981b: 22–6; Carpenter 1986: 213–16).

There is accumulating evidence, however, that vitamin C may have additional involvements in a range of enzymatic changes unrelated to the formation of collagen. There are three systems of considerable physiological significance in which vitamin C plays an important, and possibly obligatory, role: (1) as the immediate donor for dopamine B-hydroxylase, a key reaction in the conversion of tyrosine to norepinephrine (Englard and Seifter 1986; Fleming and Kent 1991); (2) in the peptidylglycine alpha-amidating monooxygenase system, whereby peptidyl carboxyl-terminal residues are amidated, a process that requires molecular oxygen, copper, and ascorbate and is important in the biosynthesis of a number of neuroendocrine peptides (Englard and Seifter 1986; Eipper and Mains 1991); (3)

in the hydroxylation reactions in the biosynthesis of carnitine from lysine and methionine (Englard and Seifter 1986; Rebouche 1991).

The exact physiological significance of these and other reactions vis-à-vis the clinical manifestations of scurvy is unclear. The first two, having obvious involvements in the endocrine and nervous systems, could well be causally related to various functional derangements of scurvy; and as carnitine has an important role in the transport of fatty acids into the mitochondria, where they may be oxidized to provide energy, it has been suggested that the carnitine involvement could account for the lassitude and fatigue that have been invariably noted as an early feature of scurvy (Hughes 1981a).

Should such involvements require an availability of ascorbic acid greater than that required to prevent the emergence of "classical" scurvy – and there is some evidence that this is so, at least in the case of carnitine biosynthesis – then a revision of the currently accepted Recommended Dietary Allowance/Reference Value would be called for (Hughes 1981a). The current recommended daily intake of vitamin C (60 mg in the United States and recently raised from 30 to 40 in the United Kingdom) is, after all, the amount estimated to prevent the emergence of the classic ("collagen") features of scurvy – and in the United Kingdom, it is based, essentially, on a single experiment completed almost half a century ago on a nonrepresentative population sample.

Source of Vitamin C

Vitamin C is a heat-labile, water-soluble, and readily oxidizable molecule, and its distribution among foodstuffs and the losses resulting from processing and food preparation have been well documented. Studying the losses induced in the vitamin C content of various foodstuffs by simple culinary procedures must be one of the commonest and oft-repeated projects in basic college and university courses, and the amount of unpublished data resulting from these studies must be immense.

The mean daily intake of vitamin C in the United Kingdom (based on noncooked purchases) is about 60 mg daily with potatoes, citrus fruits, and cabbage accounting for 20, 12, and 6 percent, respectively, of the intake. The losses resulting from cooking are substantial, and these are further increased if the cooked food is allowed to stand around before being eaten. Nevertheless, because of the comparatively widespread distribution of the vitamin in plant foodstuffs, and the role of technology in increasing the availability of uncooked plant and vegetable material during the whole year, very few persons today appear to suffer from clinically defined hypovitaminosis C; consequently, frank scurvy is an almost unknown condition.

A recent survey of vitamin C intakes in European countries revealed an interesting, and almost providential, reciprocity between the consumption of two important sources of vitamin C. Of 27 countries studied, Iceland, Switzerland, and France had the lowest annual consumption of cabbage (less than 5 kg per capita) but a high consumption of citrus fruit (over 20 kg); Romania, Poland, and the former Soviet Union, in contrast, had the lowest consumption of citrus fruit (less than 4 kg) but the highest consumption of cabbage (more than 30 kg) (Kohlmeier and Dortschy 1991). Only where a person, for ideological, economic, or supposed "health" reasons subsists on a diet devoid of fruit and vegetables (such as one based on nuts, grain, and/or cooked meat/fish) is scurvy likely to emerge.

The foliage of many flowering plants has an unexpectedly high concentration of vitamin C, with concentrations of up to 1 percent wet weight being attained in some members of the Primulaceae family. The mean concentration for 213 species examined (162 mg per 100 g) was some three times that of those culinary vegetables usually regarded as good sources of the vitamin; and the mean value for the leaves of 41 woody shrubs and trees examined was 293 mg per 100 g – significantly higher than black currants, which are usually cited as the dietary source par excellence of vitamin C (Jones and Hughes 1983, 1984; see also Table IV.A.3.1).

Table IV.A.3.1. *Ascorbic acid content of some plants (mg/100 g fresh weight)*

Culinary vegetables and fruits		
Cabbage	55	(11)
Carrots (roots)	8	(2)
Cauliflower	70	(14)
Peas (seed)	25	(4)
Potatoes (tubers)	28	(4)
Apples (fruit)	10	
Black currants (fruit)	180	
Oranges (fruit)	55	
The antiscorbutics (leaves)		
Cochlearia officinalis (scurvy grass)	63	
Nasturtium officinale (watercress)	83	
Veronica beccabunga (brooklime)	46	
Less widely used antiscorbutics		
Galium aparine (goosegrass)	84	
Menyanthes trifoliata (bog bean)	74	
Urtica dioica (stinging nettle)	169	
Vitamin C–rich leaves		
Primula vulgaris (primrose)	805	
Malus domestica (apple tree)	496	
Erica tetralix (bog heather)	394	
Vicia cracca (tufted vetch)	349	

Note: Values in parentheses are for cooked meals taken by elderly patients in hospitals (Jones, Hughes, and Davies 1988 and additional unpublished material).

Source: Based on Jones and Hughes (1983, 1984) and Hughes (1990).

The historically important "antiscorbutic herbs" are among the poorest sources of vitamin C (Hughes 1990). William Perry, who stowed boxes of mustard greens and cress on board his ship in an attempt to fend off scurvy during his Arctic expedition of 1818 (Lloyd and Coulter 1963: 108), would have done better to adorn his stateroom with primrose plants, a single leaf of which, chewed in the mouth daily, would have sufficed to offer complete protection. The exact reason, if any, for these high (and often disparate) concentrations of ascorbic acid in angiosperms is not known; nor is the role of ascorbic acid in plant biochemistry understood. It has been suggested that there is a positive correlation between the concentration of ascorbic acid in plants and corresponding concentrations of phenolic compounds, but the extent to which this reflects a biochemical relationship is a matter of conjecture (E. C. Bate-Smith, personal communication).

Vitamin C Megatherapy

The practice of ingesting daily doses of vitamin C grossly in excess of the amount believed to protect against scurvy and even in excess of the amount known to produce tissue saturation is one of the more controversial aspects of current nutritional thought. The arguments for vitamin C "megatherapy" were initially outlined in the United States by Irwin Stone and later elaborated by Linus Pauling, winner of two Nobel Prizes (Hughes 1981b: 47–53). Stone disputed the adequacy of current recommended daily intakes, basing his case primarily on the rate of biosynthesis of the vitamin by animals producing their own supply and on G. H. Bourne's estimate that the natural diet of the gorilla provides it with a daily intake of some 4.5 g ascorbic acid (Bourne 1949). His arguments for daily intakes of grams rather than milligrams were enthusiastically embraced and extended by Pauling.

Closely interwoven with the megatherapy theory is the claim that vitamin C has a number of extra-antiscorbutic functions (protection against infection and, particularly, the common cold, detoxication, cerebral function, lipid metabolism, longevity, and so forth) that might require significantly raised amounts of the vitamin (Hughes 1981b: 14–34). For example, E. Ginter has for many years carefully presented the thesis that vitamin C plays a part in lipid metabolism, particularly by enhancing the conversion of cholesterol to bile salts, and that it would, therefore, have a hypocholesterogenic function (Ginter and Bobek 1981).

To date, however, there is little evidence that these putative relationships are reflected by a specific and increased demand for vitamin C. And as indicated earlier, some of these supposed secondary roles have now been subsumed in enzymatic terms by the advances of reductionist biochemistry. Secondary (or extra-antiscorbutic) roles for vitamin C could, conceivably, require intakes greater than those necessary for the prevention of classical scurvy, but such increased requirements would, in biochemical terms, scarcely justify the massive intakes recommended by the megatherapists.

Apart from the lack of satisfactory evidence, there are other arguments against vitamin C megatherapy (Jukes 1974; Hughes 1981b: 47–53). Adverse reactions elicited by massive doses of vitamin C and the possibly toxic influence of its breakdown products could well disadvantage the body. Moreover, the ingestion of large amounts of ascorbic acid is a self-defeating exercise as the absorption of large doses is a relatively inefficient process, with less than one-half of a 1 g megadose being absorbed from the gastrointestinal tract and only one-fourth of a 5 g dose (Davies et al. 1984; "Experimental Scurvy" 1986). And, in any case, it is generally accepted that tissue saturation in humans may be satisfactorily attained by a daily intake of 100 to 150 mg or even less. The faith of the megatherapists would have appeared to blind them to the normal canons of scientific assessment.

In the mid-1970s, Pauling espoused perhaps the most controversial of all his vitamin C beliefs. In collaboration with a Scottish surgeon, Ewan Cameron, he began to write extensively on the supposed antitumor activity of vitamin C; more specifically, Cameron and Pauling published the results of a clinical trial in which it was claimed that a megadose (10 g daily) of vitamin C quadrupled the survival time of terminally ill cancer patients (Cameron and Pauling 1976). The methodology of this trial was widely criticized, and a carefully controlled attempt to repeat it at the Mayo Clinic in the United States failed to confirm the Cameron–Pauling claims. For the next 15 years, and in the face of growing reluctance on the part of the scientific press to publish his papers, Pauling continued to present his arguments for the efficacy of vitamin C in the treatment of cancer. An account of this drawn-out battle between Pauling and the American scientific establishment has recently appeared (Richards 1991).

In more general and theoretical terms, it has been suggested that the antioxidant and free-radical scavenger roles of vitamin C support its possible function in the prevention (as contrasted with the cure) of cancer. G. Block has assessed some 90 studies of cancer and vitamin C/fruit intake relationships and has concluded that there is evidence that in the majority of cancers vitamin C may have a significant prophylactic role (Block 1991). In this respect, the possible relationship between vitamin C and nitrosamine-induced cancers has attracted some attention.

It has been speculated that endogenously produced N-nitroso compounds may be important initiators of human cancers. Significant in this respect is the formation of N-nitrosamines and related compounds. Nitrosamines may be formed when nitrate, a suitable "nitrosable" amine, and bacteria coexist – as in the gastrointestinal tract. Nitrate (the main dietary sources of which are fish and root vegetables) is converted by bacterial action to nitrite, which then reacts with amines to produce carcinogenic nitrosamines. Some foods, particularly cured meat products, contain nitrosamines formed during processing.

There is evidence that vitamin C may prevent the formation of carcinogenic nitrosamines from nitrate and may even reduce the carcinogenicity of preformed nitrosamines (Hughes 1981b: 27–9; MAFF 1987). It has been suggested, for example, that a reduction in nitrosamine formation, attributable to citrus fruit vitamin C, may be a contributory factor in determining the comparatively low incidence of large bowel cancer in the "citrus belt" of the United States (Lyko and Hartmann 1980). Sodium nitrite is used in the large-scale preparation of cured meats, bacon, and sausages (primarily to prevent the activity of the highly toxic *Clostridium botulinum*), and these products, consequently, contain a range of preformed nitroso compounds. There may, therefore, be good scientific reasons for regarding orange juice as a useful dietary accompaniment to a fried breakfast!

Vitamin C and Industry

Many tens of thousands of tons of vitamin C are produced synthetically each year from glucose; the initial stages in conversion involve reduction to sorbitol followed by bacterial oxidation to sorbose. Much of this vitamin C finds its way into health-food stores for sale to megatherapy enthusiasts as a putative dietary adjuvant. A substantial proportion is used industrially as a "technological aid"; some is used in meat-curing processes to promote pigment conversion (in this application, it also has an adventitious and unintended role in reducing the formation of volatile N-nitrosamines).

Vitamin C is also widely employed as a permitted antioxidant (sometimes as ascorbyl palmitate) to prevent the formation of rancidity in stored fat products and the phenolic browning of commodities such as dehydrated potatoes. It is used as a flour improver in the Chorleywood Bread Process, where its oxidation product (dehydroascorbic acid) modifies the availability of glutathione in dough development, thereby shortening the period of fermentation.

The use of vitamin C in these technological processes finds general approval on the grounds that one is, after all, adding a beneficial vitamin rather than some untried additive of unknown toxicity. It should be pointed out, though, that little of this additive vitamin C is recoverable from the marketed product, which will, however, contain substantial amounts of vitamin C breakdown products – many of them unidentified and almost all of them of unknown toxicity. Bread is vitamin C–free despite the substantial amounts that may have been added during the Chorleywood process. It has been estimated that the average consumer may ingest up to 200 mg a week of vitamin C breakdown products from additive sources (Thomas and Hughes 1985).

Epilogue

Why vitamin C should have attracted so much attention in nutritional circles – orthodox and otherwise – is difficult to understand. Its almost limitless appeal to health enthusiasts and pseudonutritionists is matched only by the time and attention devoted to it by academic nutritionists. The annual global publication of some 2,000 papers bearing on vitamin C implies an annual research expenditure of some £40,000,000 (about 60 to 70 million U.S. dollars) – a not inconsiderable sum for studying a molecule whose nutritional significance is, at the most, marginal. Vitamin C deficiency is today a rare occurrence, and the evidence for extra-antiscorbutic requirements in excess of the mean daily intake is slender. Perhaps the biochemical versatility of the vitamin C molecule makes it attractive to biochemists who feel that it deserves a much more significant role than that of a somewhat prosaic involvement in the biosynthesis of collagen.

There are some questions that remain unanswered. For example, the apparent negative correlation between blood and tissue concentrations of vitamin C and age is puzzling. Many very elderly subjects – particularly if institutionalized – have virtually no ascorbic acid in their blood, a situation that would almost certainly be associated with the emergence of clinical scurvy in a younger age group. Yet these octogenarians and nonagenarians seem to be in no way disadvantaged by the apparent absence of the vitamin. Is there, then, a negative correlation between aging and dependency upon vitamin C? Such a relationship, if true, would be a remarkably fortuitous one as a substantial proportion of the institutionalized elderly have intakes of vitamin C well below the recommended daily amount. It is a somewhat sobering thought that in these days of scientifically attuned dietetics the mean intake of vitamin C by the institutionalized elderly in the United Kingdom is no greater than it was in hospitals a century and a half ago (Jones, Hughes, and Davies 1988).

In the more rarefied atmosphere of academic biochemistry, however, it is possible to point to real advances in our knowledge of vitamin C over the past 40 years. Today, modern high-performance liquid chromatographic techniques are replacing the classical indophenol dye method for the determination of vitamin C, with an increase in sensitivity and specificity. Our knowledge of possible biochemical involvements of the vitamin has advanced substantially. Sadly, however, one cannot point with equal certainty to any corresponding expansion of our knowledge of the nutritional significance of vitamin C beyond its role in the prevention of classical scurvy.
