McNamara, Damian. "Obesity Behind Rise in Incidence of Primary Hypertension." *Family Practice News* (April 1, 2003): 45–51.

KEY TERMS

Aneurysm—A weakened area in the wall of a blood vessel which causes an outpouching or bulge. Aneurysms may be fatal if these weak areas burst, resulting in uncontrollable bleeding.

Aorta—The main artery located above the heart that pumps oxygenated blood out into the body. The aorta is the largest artery in the body.

Arteriosclerosis—A chronic condition characterized by thickening, loss of leasticity, and hardening of the arteries and the build-up of plaque on the arterial walls. Arteriosclerosis can slow or impair blood circulation. It includes atherosclerosis, but the two terms are often used synonymously.

Artery—A blood vessel that carries blood away from the heart to the cells, tissues, and organs of the body.

Atrial—Referring to the upper chambers of the heart.

Claudication—Cramping or pain in a leg caused by poor blood circulation. This condition is frequently caused by hardening of the arteries (atherosclerosis). Intermittent claudication occurs only at certain times, usually after exercise, and is relieved by rest.

Coarctation of the aorta—A congenital defect in which severe narrowing or constriction of the aorta obstructs the flow of blood.

Dialysis—A process of filtering and removing waste products from the bloodstream, it is used as a treatment for patients whose kidneys do not function properly. Two main types are hemodialysis and peritoneal dialysis. In hemodialysis, the blood flows out of the body into a machine that filters out the waste products and routes the cleansed blood back into the body. In peritoneal dialysis, the cleansing occurs inside the body. Dialysis fluid is injected into the peritoneal cavity and wastes are filtered through the peritoneum, the thin membrane that surrounds the abdominal organs.

Diastolic blood pressure—Diastole is the period in which the left ventricle relaxes so it can refill with blood; diastolic pressure is therefore measured during diastole.

Heart attack—Damage that occurs to the heart when one of the coronary arteries becomes narrowed or blocked.

Obesity—An abnormal accumulation of body fat, usually 20% or more over an individual's ideal body weight.

Overweight—Being 25 to 29 percent over the recommended healthy body weight for a specific age and height, as established by calculating body mass index.

Retinopathy—Any disorder of the retina.

Sphygmomanometer—An instrument used to measure blood pressure.

Stroke—Interruption of blood flow to a part of the brain with consequent brain damage. A stroke may be caused by a blood clot or by hemorrhage due to a burst blood vessel. Also known as a cerebrovascular accident.

Systolic blood pressure—Blood pressure when the heart contracts (beats).

Ventricles—The lower pumping chambers of the heart. The ventricles push blood to the lungs and the rest of the body.

Hyperthyroidism

Definition

Hyperthyroidism is the overproduction of thyroid hormones by an overactive thyroid.

Description

The term hyperthyroidism covers any disease which results in overabundance of thyroid hormone. Other names for hyperthyroidism, or specific diseases within the category, include Graves' disease, diffuse toxic goiter, Basedow's disease, Parry's disease, and thyrotoxicosis.

Located in the front of the neck, the thyroid gland produces the hormones thyroxin (T4) and triiodothyronine (T3), which regulate the body's metabolic rate by helping to form protein ribonucleic acid (RNA) and increasing oxygen absorption in every cell. In turn, the production of these hormones is controlled by thyroid-stimulating hormone (TSH) that is produced by the pituitary gland. When production of the thyroid hormones increases despite the level of TSH being produced, hyperthyroidism occurs. The excessive amount of thyroid hormones in the blood increases the body's metabolism, creating both mental and physical symptoms.

Demographics

Only about 5 percent of all individuals with hyperthyroidism are younger than 15 years of age. About five times as many girls as boys develop hyperthyroidism. Almost all cases of pediatric hyperthyroidism are the form called Graves' disease. There is a form of hyperthyroidism called neonatal Graves' disease, which occurs in infants born of mothers with Graves' disease. Children with other conditions, such as trisomy 21, Addison's disease, diabetes, systemic lupus erythematosus, rheumatoid arthritis, myasthenia gravis, vitiligo, pernicious anemia, and immune thrombocytopenic purpura are more likely to develop Graves' disease.

Causes and symptoms

Hyperthyroidism is often associated with the body's production of autoantibodies in the blood which causes the thyroid to grow and secrete excess thyroid hormone. This condition, as well as other forms of hyperthyroidism, may be inherited. Regardless of the cause, hyperthyroidism produces the same symptoms, including weight loss with increased appetite, shortness of breath and fatigue, intolerance to heat, heart palpitations, increased frequency of bowel movements, weak muscles, tremors, **anxiety**, and difficulty sleeping. Adolescent girls may also notice decreased menstrual flow and irregular menstrual cycles.

Patients with Graves' disease often have a goiter (visible enlargement of the thyroid gland), although as many as 10 percent do not. These patients may also have bulging eyes. Thyroid storm, a serious form of hyperthyroidism, may show up as sudden and acute symptoms, some of which mimic typical hyperthyroidism, as well as the addition of **fever**, substantial weakness, extreme restlessness, confusion, emotional swings or psychosis, or coma. Fortunately, such a fulminant course of Graves' disease is rare in children and adolescents.

Babies with neonatal Graves' disease may suffer from **prematurity**, airway obstruction, and heart failure. Death occurs in as many as 16 percent of these babies, and other complications from which survivors may suffer include **craniosynostosis** (early closure of the sutures of the skull, which can result in compression of the growing brain), and **developmental delay**.

When to call the doctor

Parents should contact a child's pediatrician if the child shows the following symptoms: rapid weight loss, shortness of breath, intolerance to heat, heart palpitations, increased frequency of bowel movements, weak muscles, tremors, anxiety, and difficulty sleeping. An enlarged thyroid gland, seen as a bulge in the neck, should be examined by a doctor.

Diagnosis

Physicians will look for physical signs and symptoms indicated by patient history. On inspection, the physician may note symptoms such as a goiter or eye bulging. Other symptoms or **family** history may be clues to a diagnosis of hyperthyroidism. An elevated body temperature (basal body temperature) above 98.6°F (37°C) may be an indication of a heightened metabolic rate (basal metabolic rate) and hyperthyroidism. A simple blood test can be performed to determine the amount of thyroid hormone in the patient's blood. The diagnosis is usually straightforward with this combination of clinical history, physical examination, and routine blood hormone tests. Radioimmunoassay (a test to show concentrations of thyroid hormones with the use of a radioisotope mixed with fluid samples) helps confirm the diagnosis. A thyroid scan is a nuclear medicine procedure involving injection of a radioisotope dye, which tags the thyroid and helps produce a clear image of

A symptom of hyperthyroidism is the enlargement of the thyroid gland, as seen in this youngster's neck. *(Photograph by Lester V. Bergman. Corbis)*

inflammation or involvement of the entire thyroid. Other tests can determine thyroid function and thyroid-stimulating hormone levels. Ultrasonography, **computed tomography** scans (CT scan), and **magnetic resonance imaging** (MRI) may provide visual confirmation of a diagnosis or help to determine the extent of involvement.

Treatment

Treatment depends on the specific disease and individual circumstances such as age, severity of disease, and other conditions affecting a patient's health.

Antithyroid drugs

Antithyroid drugs are often administered to help the patient's body cease overproduction of thyroid hormones. This medication may work for young adults, pregnant women, and others. Women who are pregnant should be treated with the lowest dose required to maintain thyroid function in order to minimize the risk of **hypothyroidism** in the infant.

Radioactive iodine

Radioactive iodine is often prescribed to damage cells that make thyroid hormone. The cells need iodine to make the hormone, so they absorb any iodine found in the body. The patient may take an iodine capsule daily for several weeks, resulting in the eventual shrinkage of the thyroid, reduced hormone production, and a return to normal blood levels. Some patients may receive a single larger oral dose of radioactive iodine to treat the disease more quickly. This should only be done for patients who are not of reproductive age or are not planning to have children, since a large amount can concentrate in the reproductive organs (gonads).

Surgery

Some patients may undergo surgery to treat hyperthyroidism. Most commonly, patients treated with thyroidectomy, in the form of partial or total removal of the thyroid, suffer from large goiter and have suffered relapses, even after repeated attempts to address the disease through drug therapy. Some patients may be candidates for surgery because they were not good candidates for iodine therapy or refused iodine administration. Patients receiving thyroidectomy or iodine therapy must be carefully monitored for years to watch for signs of hypothyroidism (insufficient production of thyroid hormones), which can occur as a complication of thyroid production suppression.

Prognosis

Hyperthyroidism is generally treatable and carries a good prognosis. Most patients lead normal lives with proper treatment. Thyroid storm, however, can be life-threatening and can lead to heart, liver, or kidney failure. Luckily, this form of fulminant hyperthyroidism is rare in children and adolescents.

KEY TERMS

Goiter—Chronic enlargement of the thyroid gland.

Gonads—Organs that produce gametes (eggs or sperm), i.e. the ovaries and testes.

Palpitations—Rapid and forceful heartbeat.

Radioisotope—One of two or more atoms with the same number of protons but a different number of neutrons with a nuclear composition. In nuclear scanning, radioactive isotopes are used as a diagnostic agent.

Thyroidectomy—Surgical removal of all or part of the thyroid gland.

Prevention

As of 2004 there are no known prevention methods for hyperthyroidism; its causes are either inherited or not completely understood. The best prevention tactic is knowledge of family history and close attention to symptoms and signs of the disease. Careful attention to prescribed therapy can prevent complications of the disease.

Parental concerns

Parents should be aware that hyperthyroidism is very rare in young children. However, once diagnosed, the condition needs short- and long-term treatment, with regular follow-up visits to the doctor.

Hypoglycemia

Definition

Hypoglycemia is a condition characterized by low blood sugar, or abnormally low levels of glucose in the blood.

Description

Hypoglycemia (also known as a hypo, insulin shock, and a low) is brought on by abnormally low levels of glucose in the blood (i.e., 70 mg/dl or less). The condition is common among children with type 1 diabetes, but may also occur less frequently in children or teens with type 2 diabetes who are taking a sulfonylurea drug. An inadequate diet, improperly calculated insulin dose, minor illnesses, or excessive activity without adequate sustenance can contribute to the condition. If unchecked, hypoglycemia can lead to unconsciousness. In very rare cases, the victim may suffer a seizure.

A hypoglycemic child will appear irritable, sweaty, shaky, and confused and may complain of being very hungry. In most cases, a snack of quick-acting carbohydrates (e.g., juice or hard candy) will remedy the situation. Glucose tablets or gel can also be taken. A child who has lost consciousness due to hypoglycemia may require a glucagon shot to return blood sugar levels to normal.

Newborns of women with gestational, type 1, or type 2 diabetes during pregnancy may also experience hypoglycemia at birth, particularly if the mother's blood glucose levels were not well controlled in late pregnancy. High levels of maternal glucose cause the fetus to generate equally high levels of insulin to handle the overload, and when the maternal glucose source is disconnected at birth with the cutting of the umbilical cord, all of that insulin causes the newborn's blood sugar levels to plummet. Intravenous administration of a glucose solution to the newborn can help re-establish normal blood sugar levels.

A rare type of hypoglycemia, known as reactive hypoglycemia, may occur in children and teens without diabetes. In reactive hypoglycemia, blood glucose levels drop to 70 mg/dl approximately four hours after a meal is eaten, causing the same symptoms of low blood sugars that can occur in people with diabetes.

Also rare is fasting hypoglycemia, a condition in which blood sugars are 50 mg/dl or lower after an overnight fast or between meals. Certain medications and medical conditions can cause this problem in children who do not have diabetes.

Demographics

Among children with diabetes, hypoglycemia is much more common in those with type 1 diabetes (also known as insulin-dependent diabetes or juvenile diabetes) than in those with type 2 diabetes (formerly known as adult-onset diabetes).

Causes and symptoms

Hypoglycemia in children and teens with diabetes can be triggered by too much insulin, excessive **exercise** without proper food intake, certain oral medications, skipping meals, and drinking alcoholic beverages.

Symptoms of hypoglycemia include:

- shakiness
- nervousness
- irritability
- dizziness
- sweating
- confusion
- fatigue
- hunger
- feelings of anxiety

Reactive hypoglycemia can be triggered by enzyme disorders and by gastric bypass surgery. Causes of fasting hypoglycemia in children without diabetes may include insulin-producing tumors, certain hormonal deficiencies, medications (including sulfa drugs and large doses of aspirin), and critical illnesses. Fasting hypoglycemia is more likely to occur in children under the age of 10.

When to call the doctor

Children who are experiencing frequent episodes of hypoglycemia should see their diabetes care doctor as soon as possible as they may require an insulin adjustment, medication change, or another change in their treatment regimen.

If a child or teen with diabetes starts experiencing low blood sugars without any symptoms, he or she may be developing hypoglycemic unawareness and the child's physician should be notified immediately. In hypoglycemic unawareness, the body stops sending its normal warning signs of hypoglycemia, and a child may not realize that blood glucose levels are dangerously low until he or she loses consciousness.

Diagnosis

Episodes of hypoglycemia in children and adolescents with diabetes can be confirmed with a blood test on a home blood glucose monitor. A small needle or lancet is used to prick the finger or an alternate site and a small drop of blood is collected on a test strip that is inserted into the monitor. The monitor then calculates and displays the blood glucose reading on a screen. Although individual blood glucose targets should be determined by a medical professional in light of a child's medical history, the general goal is to keep them as close to normal (i.e., 90 to 130 mg/dl or 5 to 7.2 mmol/L before meals) as possible. Glucose levels that are below 70 mg/dl (3.9 mmol/L) are typically considered hypoglycemic.

In order to diagnose reactive hypoglycemia in those without diabetes, a blood sample must be drawn while a child is experiencing symptoms. If the blood glucose levels are 70 mg/dl or lower and the symptoms subside after food or drink is provided, reactive hypoglycemia is diagnosed.

Treatment

Children with diabetes who exhibit symptoms of hypoglycemia should check their blood glucose levels on a home glucose meter immediately. If levels are 70 mg/dl (3.9 mmol/L) or lower, they should take 15 grams of a fast-acting carbohydrate (e.g., glucose tablets, Life Savers, regular cola), wait 15 minutes, and test their blood sugars again. If levels are still too low, repeating the procedure is necessary until blood glucose is within a safe range.

Giving an unconscious child or teen food or drink by mouth can be potentially dangerous due to the possibility of **choking**. A glucagon injection should be used on a child that has lost consciousness due to hypoglycemia. Glucagon is a hormone manufactured by the pancreas that triggers the release of blood glucose by the liver. The synthetic version of the hormone is used to rapidly raise blood glucose levels in people with diabetes experiencing a severe low. A glucagon injection kit contains a syringe of sterile water and a vial of powdered glucagon. The water is injected into the glucagon vial and then mixed, and the resulting solution is drawn back into the syringe for injection into any muscular area (e.g., arm, buttock, thigh). Glucagon can cause **vomiting**, so a child that is given a glucagons injection should be monitored carefully to prevent aspiration.

Episodes of reactive and fasting hypoglycemia in children without diabetes can also be treated with a fast-acting carbohydrate.

Nutritional concerns

For children with diabetes, eating or drinking large quantities of carbohydrates in an attempt to push blood glucose levels back to normal can result in **hyperglycemia**, or blood sugars that are too high. The 15 grams/15 minutes rule is important to follow to avoid dramatic blood sugar swings.

Eating small, frequent meals and spreading carbohydrate intake throughout the day may help keep blood glucose levels from bouncing too high or too low.

Prognosis

With early detection and immediate and appropriate treatment, children will recover quickly from hypoglycemia.

Prevention

The best way to prevent hypoglycemia is to check blood glucose levels frequently and treat falling blood sugars before they become dangerously low. However, even the most dedicated child or parent may be faced with situations that trigger lows, such as a delay in restaurant service after an insulin injection has been taken or a broken hotel elevator that requires one to climb 20 flights of stairs after a vigorous workout in the pool. Because hypoglycemia can be predictable, children with diabetes and their parents should always have a source of fast-acting carbohydrate on hand for treatment.

A child diagnosed with reactive hypoglycemia can alleviate the problem by consuming small, frequent meals (about every three hours) that are heavy in high-fiber, low-sugar foods. Some physicians may also recommend a high-protein, low-carbohydrate diet.

Parental concerns

Parents of children with diabetes must work with their child's teachers and school administrators to ensure that their child is able to test his or her blood sugars regularly, take insulin as needed, and have access to food or drink to treat hypoglycemia when necessary. Someone at school should also be trained in how to administer a glucagon injection, an emergency treatment for a hypoglycemic episode when a child loses consciousness. Caregivers of children with type 1 diabetes should have access to an emergency glucagon kit and be trained in its use. This should include a responsible adult at the child's school and at any **extracurricular activities** where parents are not present.

Section 504 of the Rehabilitation Act of 1973 enables parents to develop both a Section 504 plan (which describes a child's medical needs) and an individualized education plan, or IEP (which describes what special accommodations a child requires to address those needs). An IEP should cover issues surrounding hypoglycemia detection and treatment, and should outline how these episodes should be handled.

Because children who are self-conscious about their differences may not comply with their treatment routines as well as they should when their peers are around, parents should work with schools and caregivers to ensure that their child has a clean and private place to test blood glucose levels and take injections.

KEY TERMS

Fast-acting carbohydrate—A carbohydrate that causes blood sugar levels to rise quickly rather than slowly and steadily. Also called simple sugars. Examples include glucose tablets, honey, fructose, hard candy, and cake frosting.

Glucagon—A hormone produced in the pancreas that changes glycogen, a carbohydrate stored in muscles and the liver, into glucose. It can be used to relax muscles for a procedure such as duodenography. An injectable form of glucagon is sometimes used to treat insulin shock.

Hypoglycemic unawareness—A condition in which normal warning signals of a blood sugar low, such as shakiness, sweating, or rapid heartbeat, are no longer felt.

Reactive hypoglycemia—A rare condition in which blood sugars drop below normal levels approximately four hours after eating.

Sulfonylurea drug—A medication for type 2 diabetes that causes the pancreas to produce more insulin, and may trigger hypoglycemia in some people.

Teens who drive and have type 1 diabetes should always test their blood glucose levels before getting behind the wheel, and should have a snack before driving if their levels have fallen below the low range of normal (i.e., 90 mg/dl or 5 mmol/L or lower). Keeping the glove compartment stocked with a roll of glucose tablets can help in the case of an unexpected low on the road.

Because alcohol can also trigger hypoglycemia, adolescents should be informed of the risks of drinking. Parents should let their children know that alcohol is both illegal for minors and potentially dangerous to their health, but they should also ensure that teens know what to do to avoid a dangerous low if they do choose to drink. Food should always accompany alcohol, and anyone who drinks in the evening should consider setting an alarm to test blood sugar levels during the night. Many of the symptoms of hypoglycemia can mimic intoxication, so even those teens who do not drink but do attend parties where alcohol is available should always make sure they are with someone whom they can trust who knows what to do in case of hypoglycemia.

Hypogonadism

Definition

Hypogonadism is the condition in which the production of sex hormones and germ cells (sperm and eggs) is inadequate.

Description

Gonads are the organs of sexual differentiation: in the female, they are ovaries; in the male, the testes. Along with producing eggs and sperm, they produce sex hormones that generate all the differences between men and women. If they produce too little sex hormone, then either the growth of the sexual organs or their function is impaired.

The gonads are not independent in their function, however. They are closely controlled by the pituitary gland. The pituitary hormones are the same for males and females, but the gonadal hormones are different. Men produce mostly androgens, and women produce mostly estrogens and progesterone. Androgens regulate the development of the embryo, determining whether it is a male or a female (male in the presence of androgens and female in the absence of androgens). They also direct the adolescent maturation of sex organs into their adult form. Further, they sustain other sexual organs and their function throughout the reproductive years. Estrogen and testosterone help to maintain bone mass and strength and may protect the cardiovascular system.

Hormones can be inadequate during or after each stage of development—embryonic and adolescent. During each stage, inadequate hormone stimulation will prevent normal development. After each stage, a decrease in hormone stimulation will result in failed function and perhaps some shrinkage. The organs affected principally by sex hormones are the male and female genitals, both internal and external, and the female breasts. Body hair, fat deposition, bone and muscle growth, and some brain functions are also influenced.

Demographics

Hypogonadism may occur at any age; however, consequences differ according to the age at onset. If hypogonadism occurs prenatally (even if incomplete), sexual ambiguity may result. If hypogonadism occurs before **puberty**, puberty does not progress. If hypogonadism occurs after puberty, infertility and sexual dysfunction result. The demographics of hypogonadism vary depending on the cause. XYY syndrome has an incidence of one in 1,000 newborn males. However, since many males with XYY syndrome look like other males without XYY syndrome, they may never be identified.

Kallman's syndrome (KS) is the most frequent cause of hypogonadotropic hypogonadism and affects approximately one in 10,000 males and one in 50,000 females. Kallman's syndrome is found in all ethnic backgrounds. The incidence of KS in males is about five times greater than KS in females; the reason is not known. Turner's syndrome occurs in approximately one out of every 2,500 live births. However, all but 2 percent of fetuses affected by the disorder are miscarried. Of all the chromosomal abnormalities that result in spontaneous abortion or miscarriage, Turner's syndrome is the most common, accounting for about 20 percent of all miscarriages.

Causes and symptoms

There are a number of causes of hypogonadism, including stress, elevated prolactin levels, and several genetic disorders. Sex is determined at the moment of conception by sex chromosomes. Females have two X chromosomes, while males have one X and one Y chromosome. Male sperm cells contain either an X or a Y; if the sperm with the Y chromosome fertilizes an egg, the baby will be male. Genetic defects sometimes result in

changes in the chromosomes. If sex chromosomes are involved, there is a change in the development of sexual characteristics. Female is the default sex of the embryo, so most of the sex organ deficits at birth occur in boys. Some, but not all, are due to inadequate androgen stimulation. The penis may be small, the testicles undescended (cryptorchidism) or various degrees of "feminization" of the genitals may be present.

After birth, sexual development does not occur until puberty. Hypogonadism most often shows up as an abnormality in boys during puberty. Again, not every defect is due to inadequate hormones. Some are due to too much of the wrong ones. Female problems in puberty are usually not caused by too little estrogen. Turner's syndrome leads to failure of puberty in some girls due to the lack of estrogen and progesterone production. Female reproductive problems are usually related to complex cycling rhythms gone wrong. The most common problems with too little hormone happen during menopause, which is normal hypogonadism.

A number of adverse events can damage the gonads and result in decreased hormone levels. The childhood disease **mumps**, if acquired after puberty, can infect and destroy the testicles—a disease called viral orchitis. Ionizing radiation and **chemotherapy**, trauma, several drugs (spironolactone, a diuretic, and ketoconazole, an antifungal agent), alcohol, marijuana, heroin, methadone, and environmental toxins can all damage testicles and decrease their hormone production. Severe diseases in the liver or kidneys, certain infections, **sickle cell anemia**, and some cancers also affect gonads. To treat some male cancers, it is necessary to remove the testicles, thereby preventing the androgens from stimulating **cancer** growth. This procedure, called castration or orchiectomy, removes androgen stimulation from the whole body.

For several reasons, the pituitary gland can fail to produce hormones. It happens rarely after pregnancy. The pituitary used to be removed to treat advanced breast or prostate cancer. Sometimes the pituitary develops a tumor that destroys it. Failure of the pituitary is called hypopituitarism and, of course, leaves the gonads with no stimulation to produce hormones. Besides the tissue changes generated by hormone stimulation, the only other symptoms relate to sexual desire and function. Libido is enhanced by testosterone, and male sexual performance requires androgens. The role of female hormones in female sexual activity is less clear, although hormones strengthen tissues and promote healthy secretions, facilitating sexual activity.

XYY syndrome

XYY syndrome is a chromosome disorder that affects males. Males with this disorder have an extra Y chromosome. The error that causes the extra Y chromosome can occur in the fertilizing sperm or in the developing embryo. There are no physical abnormalities in most males with XYY syndrome. However, some males can have one or more of the following characteristics. Males who have XYY syndrome are usually normal in length at birth but have rapid growth in childhood, typically averaging in the seventy-fifth percentile (taller than 75 percent of males their same age). Many males with XYY syndrome are not overly muscular, particularly in the chest and shoulders. Individuals with XYY syndrome often have difficulties with their coordination. As a result, they can appear to be awkward or clumsy. During their teenage years, males with XYY syndrome may develop severe **acne** that may need to be treated by a dermatologist.

Men with XYY syndrome have normal, heterosexual function, and most are fertile. However, numerous cases of men with XYY syndrome presenting with infertility have been reported. Most males with XYY syndrome have normal hormones involved in their sperm production. However, a minority of males with XYY syndrome may have increased amounts of some hormones involved in sperm production. This may result in infertility due to inadequate sperm production. The actual incidence of infertility in males with XYY syndrome is unknown.

Kallman's syndrome

Kallman's syndrome is a disorder of hypogonadotropic hypogonadism, delayed puberty, and anosmia (the inability to smell). Kallman's syndrome is a birth defect in the brain that prevents release of hormones and appears as failure of male puberty. Some boys have adequate amounts of androgen in their system but fail to respond to them, a condition known as androgen resistance. Hypogonadotropic hypogonadism (HH) occurs when the body does not produce enough of two important hormones, luteinizing hormone (LH) and follicle stimulating hormone (FSH). This results in underdeveloped gonads and often infertility. Anosmia, the inability to smell, was first described with hypogonadotropic hypogonadism in 1856, but it was not until 1944 that an instance of Kallman's reported the inheritance of the two symptoms together in three separate families. Hence, the syndrome of hypogonadotropic hypogonadism and anosmia was named Kallman's syndrome (KS). Affected people usually are detected in **adolescence** when they do not undergo puberty. The most common features are

HH and anosmia, though a wide range of features can present in an affected person. Other features of KS may include a small penis or undescended testicles in males, kidney abnormalities, **cleft lip** and/or palate, **clubfoot**, hearing problems, and central nervous system problems such as synkinesia (the performance of an unintended movement when making a voluntary one), eye movement abnormalities, and visual and hearing defects.

Diabetes mellitus

Type 1 diabetes (**diabetes mellitus**) occasionally has been associated with hypogonadism. Most cases seem to be due to the hypogonadism of **malnutrition** and respond to improved control. Some specific conditions associated with diabetes mellitus, such as hemachromatosis, and the Laurence-Moon Biedl, Alstrom, and Cushing syndromes, also typically produce hypogonadism. Normal gonadal function is required for normal male development of the genital tract and for maintenance of some elements of male sexual behavior. The most clearly androgen-dependent aspects include libido, sexual activity, and spontaneous erections. In normal, young males with hypogonadism, sexual acts, fantasies, and desire are significantly diminished. Spontaneous erections also decrease by approximately 40 percent. Replacement with testosterone prevents these changes, suggesting that an intact male gonadal system is required to maintain sexual function. However, visual and possibly tactile stimulus-bound erections are not impaired in males with hypogonadism after infancy. This implies that androgen action is not required to maintain the capacity for erection.

Turner's syndrome

Turner's syndrome is a genetic disorder caused by a missing X chromosome that occurs only in females. Women with Turner's syndrome are characterized by short stature, absence of secondary sexual characteristics, infertility, and a number of other physical abnormalities. Women with Turner's syndrome are born with underdeveloped ovaries that are eventually replaced by connective tissue. Because of the resulting lack of sex hormones, these individuals do not have menstrual periods and their breasts remain undeveloped, although they may develop underarm and pubic hair. Turner's syndrome does not affect **intelligence**, although persons with the condition have poor spatial perception and mathematical aptitude, often accompanied by learning disabilities.

In girls, hypogonadism during childhood will result in lack of **menstruation** and **breast development** and short height. If hypogonadism occurs after puberty, symptoms include loss of menstruation, low libido, hot flashes, and loss of body hair. In boys, hypogonadism in childhood results in lack of muscle and beard development and growth problems. In males the usual complaints are sexual dysfunction, decreased beard and body hair, breast enlargement, and muscle loss. If a brain tumor is present (central hypogonadism) there may be headaches or visual loss or symptoms of other hormonal deficiencies (such as **hypothyroidism**). In the case of the most common pituitary tumor, prolactinoma, there may be a milky breast discharge. People with **anorexia nervosa** (excessive dieting to the point of starvation) also may have central hypogonadism.

When to call the doctor

Parents should consult a **family** physician or pediatrician if their child has any signs or symptoms of hypogonadism. Establishing the cause of hypogonadism is an important first step to getting appropriate treatment. Children may require a consultation with an endocrinologist, a physician who specializes in the hormone-producing (endocrine) glands. If the primary care physician suspects the condition is present, he or she may refer the child to an endocrinologist. Parents may also consider taking the child directly to an endocrinologist without a referral.

Diagnosis

As of the early 2000s, there are accurate blood tests for most of the hormones in the body, including those from the pituitary and even some from the hypothalamus. Chromosomes can be analyzed, and gonads can be, but rarely are, biopsied. Tests may be done that check estrogen levels (women) and testosterone levels (men) as well as FSH levels and LH levels, the pituitary hormones that stimulate the gonads. Other tests may include a thyroid level; sperm count; prolactin level (milk hormone); blood tests for anemia, chemistries, and iron; and genetic analysis. Sometimes imaging is necessary, such as a sonogram of the ovaries. If pituitary disease is suspected, a **magnetic resonance imaging** (MRI) or computerized tomography (CT) scan of the brain may be done.

Treatment

Replacement of missing body chemicals is much easier than suppressing excesses. Estrogen is recommended only to control hot flashes and sweats after menopause but is used in young women who do not produce hormones on their own. Estrogen can be taken by mouth, injection, or skin patch. It is strongly recommended that the other female hormone, progesterone, be

taken by women who have an intact uterus as well, because doing so prevents overgrowth of uterine lining and uterine cancer. Testosterone replacement is available for males who are deficient. Testosterone comes in the form of an injection, patch, or gel.

Alternative treatment

Ethinyl estradiol, an estrogen derivative, is sometimes used for the treatment of hypogonadism.

Prognosis

Many forms of hypogonadism are potentially treatable and have a good prognosis.

Prevention

People should maintain normal body weight and have healthy eating habits to prevent anorexia nervosa. Other causes may not be preventable.

Parental concerns

Adolescents with hypogonadism may have problems fitting in socially due to delayed sexual development. Testosterone replacement therapy can induce puberty, and at a slow pace in order to allow time for adjustment to body changes and new feelings. In girls with hypogonadism, complications include the social implication of failing to go through puberty with peers (if hypogonadism occurs before puberty). A supportive family that understands the diagnosis of hypogonadism is important. Adolescents may need psychological or family counseling. Support groups can help people with hypogonadism and related conditions cope with similar situations and challenges.

PERIODICALS

Carlson, Robert H. "Panel: Here are Twenty-Five Recommendations on Hypogonadism." *Urology Times* 31 (November 2003): 22.

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes or to follow the course of a disease. Most commonly the term refers to the collection and analysis of tissue from a suspected tumor to establish malignancy.

Diabetes mellitus—The clinical name for common diabetes. It is a chronic disease characterized by the inability of the body to produce or respond properly to insulin, a hormone required by the body to convert glucose to energy.

Embryo—In humans, the developing individual from the time of implantation to about the end of the second month after conception. From the third month to the point of delivery, the individual is called a fetus.

Endocrinologist—A physician who specializes in treating patients who have diseases of the thyroid, parathyroid, adrenal glands, and/or the pancreas.

Fetus—In humans, the developing organism from the end of the eighth week to the moment of birth. Until the end of the eighth week the developing organism is called an embryo.

Hypothalamus—A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Ionizing radiation—Radiation that can damage living tissue by disrupting and destroying individual cells at the molecular level. All types of nuclear radiation–x rays, gamma rays, and beta rays–are potentially ionizing. Sound waves physically vibrate the material through which they pass, but do not ionize it.

Kallman's syndrome—A disorder of hypogonadotropic hypogonadism, delayed puberty, and anosmia. Kallman's syndrome is a birth defect in the brain that prevents release of hormones and appears as failure of male puberty.

Turner syndrome—A chromosome abnormality characterized by short stature and ovarian failure caused by an absent X chromosome. It occurs only in females.

Undescended testicle—A testicle that is still in the groin and has not made its way into the scrotum.

XYY syndrome—A chromosome disorder that affects males.

Hypospadias

Definition

Hypospadias is a congenital defect of the penis in which the urinary tract opening, or urethral meatus, is abnormally located away from the tip of the penis.

Description

In males with hypospadias, the urinary opening is located on the underside of the penis. Often there is an accompanying underdevelopment of the foreskin in which the penis has a hooded appearance. Most of the foreskin is located on the top and sides of the tip of the penis. The urethral meatus may be located at any point along the penile shaft from just below the tip of the penis to closer to the body and/or near the scrotum. It may appear as a small hole in the penis or, in more severe cases, may be a longer slit-like opening. Some cases may involve chordee, a condition in which the penis bends down or away from the body during erection.

Demographics

Hypospadias is the most common anomaly of the penis affecting approximately one in 250 males born. Research has shown a doubling of the number of babies born with this anomaly. The reason for this increase is as of 2004 unknown.

Causes and symptoms

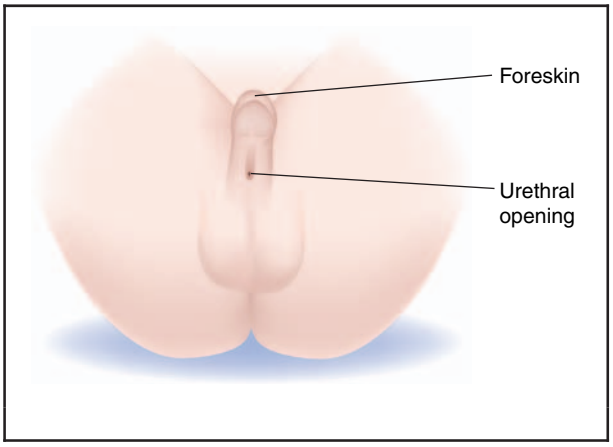
Hypospadias is a congenital anomaly resulting from incomplete closure of the tissue of the penis that forms the urethra (the tube that carries urine from the bladder to the outside of the body). The potential symptoms of hypospadias if left untreated include an abnormal direction of the urine stream, abnormal appearance of the penis, infertility if the defect is located far enough away from the tip of the penis, and an inability to have sexual intercourse in cases involving chordee.

Diagnosis

Hypospadias is diagnosed most often during the initial newborn physical examination and is classified based on where the urethral meatus is located. In rare cases infants with hypospadias occurring closer to the body and who also have undescended testicles, a karyotype or genetic screen may be performed to determine gender. Males who have hypospadias located within or near the scrotum should also have a procedure called a voiding cystogram to rule out additional urinary tract anomalies. In general, very few babies with hypospadias have other birth defects. Many males with multiple congenital anomalies, however, may also have hypospadias.

Prognosis

The prognosis for boys who have undergone hypospadias repair is excellent. Very few children experience complications. In most cases, the penis appears normal and functions normally. Less than 5 percent of children with mild hypospadias experience postoperative complications. Complications include wound infections, unexpected opening near the repair



Hypospadias, a condition in which the urethral opening is not at the tip of the penis, but rather along the penile shaft. *(Illustration by Argosy, Inc.)*

site, and rarely, meatul stenosis, a narrowing of the urinary tract opening.

Prevention

There was as of 2004 no known prevention of hypospadias.

Parental concerns

Most hypospadias cases are minor and involve few complications. Initially, parents should be sure their son is not circumcised because the foreskin is often essential in hypospadias repair surgery. Should the parents decide to allow corrective surgery, they should find a pediatric urologic surgeon with experience in performing hypospadias repairs. After surgery, care must be taken to follow all postoperative instructions and to obtain follow-up care from both the pediatrician and pediatric urologist. Parents may be concerned about the appearance and function of the penis. In most cases, following hypospadias repair surgery, the penis functions normally and is normal in appearance as well. Most males who have had a hypospadias repair are able to stand to urinate, experience normal sexual function, and normal fertility. Parents may be concerned about the physical and emotional **pain** of genital surgery. The recommended age of surgical repair is between four and 12 months. This age is ideal for many reasons including the size of the penis and the slow rate of growth of the penis at this age, the relatively low risk from anesthesia, and the fact that children at this age have not formed long-term memory and will not remember the surgery.

KEY TERMS

Anesthesia—Treatment with medicine that causes a loss of feeling, especially pain. Local anesthesia numbs only part of the body; general anesthesia causes loss of consciousness.

Chordee—An abnormal curvature of the penis.

Circumcision—A surgical procedure, usually with religious or cultural significance, where the prepuce or skin covering the tip of the penis on a boy, or the clitoris on a girl, is cut away.

Congenital—Present at birth.

Foreskin—A covering fold of skin over the tip of the penis.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Scrotum—The external pouch containing the male reproductive glands (testes) and part of the spermatic cord.

Urethra—A passageway from the bladder to the outside of the body for the discharge of urine. In the female this tube lies between the vagina and clitoris; in the male the urethra travels through the penis and opens at the tip. In males, seminal fluid and sperm also pass through the urethra.

Urethral meatus—The opening of the urethra on the body surface through which urine is discharged.

Voiding cystogram—A radiographic image of the mechanics of urination.

Deborah L. Nurmi, MS

Hypothyroidism

Definition

Hypothyroidism, or underactive thyroid, develops when the thyroid gland fails to produce or secrete as much thyroxine (T_4) and triiodothyonine (T_3) as the body needs. Because these thyroid hormones regulate such essential functions as heart rate, digestion, physical growth, and mental development, an insufficient supply of this hormone can slow metabolic processes, damage organs and tissues in every part of the body, and lead to life-threatening complications.

Description

Hypothyroidism is one of the most common chronic diseases in the United States. Symptoms may not appear until years after the thyroid has stopped functioning and often are mistaken for signs of other illnesses. Although this condition is believed to affect up to 11 million adults and children, as many as two out of every three people with hypothyroidism may not know they have the disease.

Nicknamed "Gland Central" because it influences almost every organ, tissue, and cell in the body, the thyroid is shaped like a butterfly and located just below the larynx, or Adam's apple, and in front of the trachea, or windpipe. The thyroid stores iodine that the body obtains from food, and uses this mineral to create the thyroid hormones. Low thyroid hormone levels can alter weight, appetite, **sleep** patterns, body temperature, and a variety of other physical, mental, and emotional characteristics.

Although hypothyroidism is most common in women who are middle-aged or older, the disease can occur at any age. In addition, an infant can be born with congenital hypothyroidism, i.e., without a functioning thyroid. In older children, the development of hypothyroidism may progress slowly and it may be several years before the disease is diagnosed.

Demographics

The most common cause of hypothyroidism in mid- to late-childhood and **adolescence** is Hashimoto's thyroiditis, which occurs in up to 1.2 percent of the school age population. Congenital hypothyroidism is less common. One out of every 4,000–5,000 infants is born without a properly functioning thyroid gland. Congenital hypothyroidism is twice as common in girls as in boys and about five times more common in whites than in blacks.

Causes and symptoms

Congenital hypothyroidism is a disorder that affects infants from birth, resulting from the loss of thyroid function due to the failure of the thyroid gland to develop correctly. Sometimes the thyroid gland is absent or is ectopic, i.e., in an abnormal location. This congenital defect means that the infant does not produce sufficient thyroid hormones, resulting in abnormal growth and development as well as slower mental function.

Hypothyroidism may also be caused by an abnormality of the immune system that results in damage and destruction of the thyroid gland (Hashimoto's thyroiditis). This process can result in either loss of thyroid tissue or enlargement of the thyroid. In most cases, there is no **pain** or tenderness associated with this disease, although sometimes persons affected complain of difficulty in swallowing, as if they had a lump in the throat.

Less often, hypothyroidism develops when the pituitary gland fails and does not release enough thyroid-stimulating hormone (TSH), which stimulates the thyroid to produce and secrete normal amounts of T_4 and T_3. TSH may be deficient for several reasons:

- disease of the pituitary gland (occurs rarely)
- disease of the hypothalamus (located about the pituitary), which stimulates the pituitary gland
- tumor, cyst, or other abnormal structure between the hypothalamus and pituitary gland that prevents the pituitary from receiving the stimulus to secrete TSH

Other causes of hypothyroidism include:

- Radiation. Radioactive iodine used to treat **hyperthyroidism** (overactive thyroid) or radiation treatments for head or neck cancers can destroy the thyroid gland.
- Surgery. Removal of the thyroid gland because of **cancer** or other thyroid disorders can result in hypothyroidism.
- Viruses and bacteria. Infections that depress thyroid hormone production usually cause permanent hypothyroidism.
- Medication. Nitroprusside, lithium, or iodides can induce hypothyroidism. Because patients who use these medications are closely monitored by their doctors, this side effect is very rare.
- Environmental contaminants. Certain man-made chemicals such as PCBs, found in the local environment at high levels, may also cause hypothyroidism.

Often babies with congenital hypothyroidism will appear normal at birth, which is why screening is vital.

However, some infants may have one of more of the following symptoms:

- large size (despite poor feeding habits) and increased birth weight
- puffy face and swollen tongue
- hoarse cry
- low muscle tone
- cold extremities
- persistent **constipation**, with distended abdomen
- lack of energy, sleeping most of the time and appearing tired when awake
- little or no growth

Children born with symptoms have a greater risk of **developmental delay** than children born without symptoms. The longer a child with hypothyroidism remains untreated, the greater is the loss of intellectual capacity, as measured by the standard **intelligence** testing (IQ). The ultimate IQ has been shown to be significantly higher in children whose hypothyroidism was detected and treated prior to six weeks of age, compared to those children whose hypothyroidism went untreated for six to 12 weeks.

Hypothyroidism that develops after birth is sometimes referred to as a silent disease because early symptoms may be so mild that no one realizes anything is wrong. Untreated symptoms become more noticeable and severe, and can lead to confusion and mental disorders, breathing difficulties, heart problems, fluctuations in body temperature, and death.

A child or adolescent who has hypothyroidism may have one or more of the following symptoms:

- fatigue
- decreased heart rate
- progressive hearing loss
- weight gain
- problems with memory and concentration
- depression
- goiter (enlarged thyroid gland)
- muscle pain or weakness
- numb, tingling hands
- dry skin
- swollen eyelids
- dryness or loss of hair
- extreme sensitivity to cold
- constipation
- delayed (common) or early (rare) onset of sexual development at adolescence
- irregular menstrual periods
- elevated cholesterol levels in the blood
- hoarse voice

Although hypothyroidism usually develops gradually, when the disease results from surgery or other treatment for hyperthyroidism, symptoms may appear suddenly and include severe **muscle cramps** in the arms, legs, neck, shoulders, and back.

People whose hypothyroidism remains undiagnosed and untreated may eventually develop myxedema. Symptoms of this rare, but potentially deadly, complication include enlarged tongue, swollen facial features, hoarseness, and physical and mental sluggishness. Myxedema coma can cause unresponsiveness; irregular, shallow breathing; low blood sugar; and drops in blood pressure and body temperature. The onset of this medical emergency can be sudden in children with undiagnosed hypothyroidism; it can be brought on by illness, injury, surgery, use of sedatives or anti-depressants, or exposure to very cold temperatures. Without immediate medical attention, myxedema coma can be fatal.

When to call the doctor

The doctor should be called if signs of hypothyroidism or myxedema are present. Every child who has a decrease in rate of growth in height during childhood and adolescence should be tested to determine if the growth problem is caused by hypothyroidism.

Diagnosis

In the United States, newborn infants between 24 and 72 hours old are tested for congenital thyroid deficiency (cretinism) using a test that measures the levels of thyroxine in the infant's blood. If the levels are low, the physician will likely repeat the blood test to confirm the diagnosis. The physician may take an x ray of the infant's legs. In an infant with hypothyroidism, the ends of the bones have an immature appearance. Treatment within the first few months of life can prevent **mental retardation** and physical abnormalities.

Older children who develop hypothyroidism may suddenly stop growing. If the child was above average height before the disease occurred, he or she may now be short compared to other children of the same age. Therefore, the most important feature of hypothyroidism in a child is a decrease in the rate of growth in height. If the disease is recognized early and adequately treated, the child will grow at an accelerated rate until

reaching the same growth percentile where the child measured before the onset of hypothyroidism. Diagnosis of hypothyroidism is based on the patient's observations, medical history, physical examination, and thyroid function tests. Doctors who specialize in treating thyroid disorders (endocrinologists) are most likely to recognize subtle symptoms and physical indications of hypothyroidism. A diagnostic evaluation may include a blood test known as a thyroid-stimulating hormone (TSH) assay, thyroid nuclear medicine scan, thyroid ultrasound, or needle aspiration biopsy (which is also used to provide information on thyroid masses). All patients should be sure their doctors are aware of any recent procedures involving radioactive materials or contrast media.

The blood test is extremely accurate, but some doctors doubt its ability to detect mild hypothyroidism. They advise patients to monitor their basal (resting) body temperature for below-normal readings that could indicate the presence of hypothyroidism.

Alternative treatment

Alternative treatments are primarily aimed at strengthening the thyroid but will not eliminate the need for thyroid hormone medications. Herbal remedies to improve thyroid function and relieve symptoms of hypothyroidism include bladder wrack (*Fucus vesiculosus*), which can be taken in capsule form or as a tea. The shoulder stand **yoga** position (done at least once daily for 20 minutes) is believed to improve thyroid function.

Nutritional concerns

Because the thyroid makes T_4 from iodine in food, an iodine-deficient diet can cause hypothyroidism. Adding iodine to table salt and other common foods has eliminated iodine deficiency in the United States. Some foods, including cabbage, rutabagas, radishes, peanuts, peaches, soybeans, and spinach, can interfere with thyroid hormone production. Anyone with hypothyroidism may want to avoid these foods. A high-fiber diet along with regular **exercise** is recommended to help maintain thyroid function and prevent constipation.

Prognosis

Thyroid hormone replacement therapy generally maintains normal thyroid hormone levels unless treatment is interrupted or discontinued.

KEY TERMS

Cretinism—Severe hypothyroidism that is present at birth and characterized by severe mental retardation.

Endocrine system—A group of ductless glands and parts of glands that secrete hormones directly into the bloodstream or lymphatic system to control metabolic activity. Pituitary, thyroid, adrenals, ovaries, and testes are all part of the endocrine system.

Goiter—Chronic enlargement of the thyroid gland.

Hyperthyroidism—A condition characterized by abnormal over-functioning of the thyroid glands. Patients are hypermetabolic, lose weight, are nervous, have muscular weakness and fatigue, sweat more, and have increased urination and bowel movements. Also called thyrotoxicosis.

Hypothalamus—A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Myxedema—Severe hypothyroidism, characterized by swelling of the face, hands, and feet, an enlarged tongue, horseness, and physical and mental sluggishness.

Pituitary gland—The most important of the endocrine glands (glands that release hormones directly into the bloodstream), the pituitary is located at the base of the brain. Sometimes referred to as the "master gland," it regulates and controls the activities of other endocrine glands and many body processes including growth and reproductive function. Also called the hypophysis.

Thyroid-stimulating hormone (TSH)—A hormone produce by the pituitary gland that stimulates the thyroid gland to produce the hormones that regulate metabolism. Also called thyrotropin.

Thyroxine (T_4)—The thyroid hormone that regulates many essential body processes.

Triiodothyronine (T_3)—A thyroid hormone similar to thyroxine but more powerful. Preparations of triiodothyronine are used in treating hypothyroidism.

Prevention

Hypothyroidism usually cannot be prevented, but the symptoms and effects of the disease can be controlled by prompt diagnosis and treatment.

Parental concerns

Parents must ensure that medication is taken on a routine basis by making the process a part of the family's lifestyle. Taking the medication as prescribed helps assure the child's optimal growth and development.

Hypotonia

Definition

Hypotonia, or severely decreased muscle tone, is seen primarily in children. Low-toned muscles contract very slowly in response to a stimulus and cannot maintain a contraction for as long as a normal muscle. Hypotonia is a symptom that can be caused by many different conditions.

Description

Hypotonia, also called floppy infant syndrome or infantile hypotonia, is a condition of decreased muscle tone. The low muscle tone can be caused by a variety of conditions and is often indicative of the presence of an underlying central nervous system disorder, genetic disorder, or muscle disorder. Muscle tone is the amount of tension or resistance to movement in a muscle. It is not the same as muscle weakness, which is a reduction in the strength of a muscle, but it can co-exist with muscle weakness. Muscle tone indicates the ability of a muscle to respond to a stretch. For example, if the flexed arm of a child with normal tone is quickly straightened, the flexor muscle of the arm (biceps) will quickly contract in response. Once the stimulus is removed, the muscle then relaxes and returns to its normal resting state. A child with low muscle tone has muscles that are slow to start a muscle contraction. Muscles contract very slowly in response to a stimulus and cannot maintain a contraction for as long as a normal muscle. Because low-toned muscles do not fully contract before they again relax, they remain loose and very stretchy, never achieving their full potential of sustaining a muscle contraction over time.

Hypotonic infants, therefore, have a typical "floppy" appearance. They rest with their elbows and knees loosely extended, while infants with normal muscle tone tend to have flexed elbows and knees. Head control is usually poor or absent in the floppy infant with the head falling to the side, backward, or forward. Infants with normal tone can be lifted by placing hands under their armpits, but hypotonic infants tend to slip between the hands as their arms rise unresistingly upward. While most children tend to flex their elbows and knees when resting, hypotonic children hang their arms and legs limply by their sides. Infants with this condition often lag behind in reaching the fine and gross motor developmental milestones that enable infants to hold their heads up when placed on the stomach, balance themselves, or get into a sitting position and remain seated without falling over. Hypotonia is also characterized by problems with mobility and posture, lethargy, weak ligaments and joints, and poor reflexes. Since the muscles that support the bone joints are so soft, there is a tendency for hip, jaw, and neck dislocations to occur. Some hypotonic children also have trouble feeding and are unable to suck or chew for long periods. Others may also have problems with speech or exhibit shallow breathing. Hypotonia does not, however, affect intellect.

Demographics

No demographic information as of 2004 was available for hypotonia, since it is a symptom of an underlying disorder. However, a study conducted in year 2000 by the University of Illinois provides some insights. The study followed 243 infants with hypotonia for three to seven years. By the age of three, about 30 percent had minimal problems and 46 percent had significant impairments, while 24 percent of the infants were normal. Hypotonic infants who matured into children with minimal disabilities were highly likely to have poor motor coordination at age three (78%). About 25 percent had learning problems or **language delay**; 20 percent had borderline cognition or attention deficits; and 66 percent had two or more of these characteristics.

Causes and symptoms

Hypotonias are often of unknown origin. Scientists believe that they may be caused by trauma; environmental factors; or by other genetic, muscle, or central nervous system disorders. The National Institutes of Health list the following common causes of hypotonia:

- Down syndrome: a chromosome abnormality, usually due to an extra copy of the twenty-first chromosome.
- Myasthenia gravis: a neuromuscular disorder characterized by variable weakness of voluntary muscles, which often improves with rest and worsens with activity. The condition is caused by an abnormal immune response.
- Prader-Willi syndrome: a congenital disease characterized by **obesity**, severe hypotonia, and decreased mental capacity
- Kernicterus: also called Rh incompatibility, a condition that develops when there is a difference in Rh blood type between that of the mother (Rh negative) and that of the fetus (Rh positive).
- Cerebellar ataxia: a movement disorder which with its sudden onset, often following an infectious viral disease, causes hypotonia.
- Infant **botulism**: a type of botulism, in which *Clostridium botulinum* bacteria grow within an infant's digestive tract, producing a toxin which is potentially life-threatening.
- Familial dysautonomia: also called Riley-Day syndrome, an inherited disorder that affects the function of nerves throughout the body.
- Marfan syndrome: an inherited disorder of connective tissue (tissue that adds strength to the body's structures), affecting the skeletal system, cardiovascular system, eyes, and skin.
- Muscular dystrophy: a group of disorders characterized by progressive muscle weakness and loss of muscle tissue.
- Achondroplasia: a disorder of bone growth that causes the most common type of dwarfism.
- Trisomy 13: a syndrome associated with the presence of a third number 13 chromosome.
- Sepsis: a severe, life-threatening illness caused by overwhelming infection of the bloodstream by toxin-producing bacteria.
- Aicardi syndrome: a rare genetic disorder characterized by infantile spasms (jerking), absence of the corpus callosum (the connection between the two hemispheres of the brain), **mental retardation**, and lesions of the retina of the eye or optic nerve.
- Canavan disease: an inherited metabolic disorder characterized by degeneration of the white matter of the brain.
- Congenital **hypothyroidism**: a disorder that results from decreased thyroid hormone production.
- Hypervitaminosis D: a condition that appears several months after excessive doses of vitamin D are administered.
- Krabbe disease: an inherited disorder characterized by a deficiency of the enzyme galactosylcereamidase, resulting in destruction of myelin, the fatty material that surrounds and insulates many of the nerves.
- Metachromatic leukodystrophy: an inherited disease characterized by the absence of the enzyme arylsulfatase A, which causes a material called cerebroside sulfate to accumulate in cells, which is toxic to cells, especially to the cells of the nervous system.
- Methylmalonic academia: an inherited metabolic disorder, usually diagnosed in infancy, which causes the accumulation of methylmalonic acid in the body and can lead to severe metabolic disturbances.
- Rickets: a childhood disorder involving softening and weakening of the bones, primarily caused by lack of vitamin D, calcium, or phosphate.
- Spinal muscular atrophy type 1 (Werdnig-Hoffman): a group of inherited diseases causing progressive muscle degeneration and weakness, eventually leading to death.
- Tay-Sachs disease: a genetic disorder found predominantly in Ashkenazi Jewish families results in early death.
- Vaccine reaction: any injury or condition that occurs as a result of a vaccination.

The following are common symptoms associated with hypotonia. Each child may experience different

symptoms, depending on the underlying cause of the hypotonia:

- decreased muscle tone; muscles feel soft and doughy
- ability to extend limb beyond its normal limit
- failure to acquire motor skill developmental milestones (such as holding head up without support from parent, rolling over, sitting up without support, walking)
- feeding problems (inability to suck or chew for prolonged periods)
- shallow breathing
- mouth hangs open with tongue protruding (underactive gag reflex)

When to call the doctor

Normally developing children tend to develop motor skills, posture control, and movement skills by a given age. Motor skills are divided into two categories. **Gross motor skills** include the ability of an infant to lift its head while lying on the stomach, to roll over from its back to its stomach. Normally, by a given age, a child develops the gross motor skills required to get into a sitting position and remain seated without falling over, crawl, walk, run, and jump. **Fine motor skills** include the ability to grasp, transfer an object from one hand to another, point out an object, follow a toy or a person with the eyes, or to feed oneself. Hypotonic children are slow to develop these skills, and parents should contact their pediatrician if they notice such delays or if their child appears to lack muscle control, especially if the child previously seemed to have normal muscle control.

Diagnosis

Hypotonia is normally discovered within the first few months of life. Since it is associated with many different underlying disorders, the doctor will accordingly seek to establish a **family** history as well as the child's medical history. A physical examination will be performed, usually including a detailed nervous system and muscle function examination. The latter may be performed with instruments, such as lights and reflex hammers, and usually does not cause any **pain** to the child. Most of the disorders associated with hypotonia also cause other symptoms that, when taken together, suggest a specific disorder and cause for the hypotonia. Specific diagnostic tests used will vary depending on the suspected cause of the hypotonia. Typical medical history questions include:

- When was the hypotonia first noticed?
- Was it present at birth?
- Did it start suddenly or gradually?
- Is the hypotonia always the same or does it seem worse at certain times?
- Is the child limp all over or only in certain areas?
- What other symptoms are present?

The following diagnostic tests may also be used:

- Blood tests.
- Creatine kinase (CK) test: elevated CK level in blood indicating muscles are damaged or degenerating.
- Computerized tomography scan (CT scan): a diagnostic imaging procedure that uses a combination of x-rays and computer technology to produce cross-sectional images. CT scans help physicians evaluate bone and muscle structures.
- Magnetic resonance imaging (MRI): a diagnostic procedure that uses a combination of large magnets, radio frequencies, and a computer to produce detailed images of organs and structures within the body.
- Electromyogram (EMG): a test used to evaluate nerve and muscle function.
- Electroencephalogram (EEG): a test that measures the electrical activity in the brain. An EEG measures brain waves through small button electrodes that are placed on the child's scalp.
- Spinal tap: also called lumbar puncture, measures the amount of pressure in the spinal canal and/or to remove a small amount of cerebral spinal fluid (**CSF**) for testing. Cerebral spinal fluid bathes the brain and spinal cord.
- Karyotype: a test that performs a chromosomal analysis from a blood test, used to determine whether the hypotonia is the result of a genetic disorder.
- Muscle biopsy: a sample of muscle tissue removed and examined under a microscope. Hypotonia can be assessed because muscle fibers have a smaller diameter than that of normal muscle.

Treatment

When hypotonia is caused by an underlying condition, that condition is treated first, followed by symptomatic and supportive therapy for the hypotonia. Physical therapy can improve fine motor control and overall body strength. Occupational and speech-language therapy can help breathing, speech, and swallowing difficulties. Therapy for infants and young children may also include sensory stimulation programs. Specific treatment for hypotonia is determined by the child's physician based on the following:

- the child's age, overall health, and medical history
- the extent of the condition
- the underlying cause of the condition
- the child's tolerance for specific medications, procedures, or therapies
- expectations for the course of the condition
- parent opinion or preference

No specific treatment is required to treat mild congenital hypotonia, but children with this problem may periodically need treatment for common conditions associated with hypotonia, such as recurrent joint dislocations. Treatment programs to help increase muscle strength and sensory stimulation programs are developed once the cause of the child's hypotonia is established. Such programs usually involve physical therapy through an early intervention or school-based program among other forms of therapy.

Hypotonic children are often treated by one or more of the following specialists:

- Developmental pediatrician: a pediatrician with specialized training in children's social, emotional, and intellectual development as well as health and physical growth. He or she may conduct a developmental **assessment** which will determine any delays the child has and to what extent the delay is present.
- Neurologist: a physician who has trained in the diagnosis and treatment of nervous system disorders, including diseases of the brain, spinal cord, nerves, and muscles. Neurologists perform neurological examinations of the nerves of the head and neck; muscle strength and movement; balance, ambulation, and reflexes; and sensation, memory, speech, language, and other cognitive abilities.
- Geneticist: a specialist in genetic disorders. He or she starts with the detailed history of the family's background, looks at the child's features and orders blood tests to look at the 46 chromosomes and possibly at specific genes on those chromosomes.
- Occupational therapist (OT): a professional who has specialized training in helping to develop mental or physical skills that help accomplish daily living activities, with careful attention to enhancing fine motor skills. In a developmental assessment, the occupational therapist assesses the child's fine motor skills, coordination, and age-appropriate self-help skills (eating with utensils, dressing, etc.).
- Physical therapist (PT): a professional trained in assessing and providing therapy to treat developmental delays using methods such as **exercise**, heat, light, and massage. In a developmental assessment, the physical therapist assesses the ability and quality of the child's use of legs, arms, and complete body by observing the display of specific gross motor skills as well as observing the child in play.
- Speech/language pathologist (SLP): a professional who is trained in assessing and treating problems in communication. Some SLPs are also trained to work with oral/motor problems, such as swallowing, and other feeding difficulties resulting from hypotonia.

Nutritional concerns

In some hypotonic infants, sucking is weak and in some cases not present at all. They do not act hungry or show interest in feeding. Special techniques and procedures are then required to provide adequate **nutrition**, such as special nipples, manipulation of mouth and jaw, and on rare occasions, insertion of a gastrostomy tube.

Prognosis

The outcome in any particular case depends largely on the nature of the underlying disease. Hypotonia can be life long, but in some cases, muscle tone improves over time. Children with mild hypotonia may not experience **developmental delay**, although some children acquire gross motor skills (sitting, walking, running, jumping) more slowly than most. Most hypotonic children eventually improve with therapy and time. By age five, they may not be the fastest child on the playground, but many will be there with their peers and will be holding their own. Some children are more severely affected, requiring walkers and wheelchairs and other adaptive and assistive equipment.

Prevention

As of 2004 there was no prevention for hypotonia. However, measures of prevention are increasingly possible in the early 2000s for several underlying disorders.

Parental concerns

Parents of an hypotonic child must follow the treating physician's orders for treatment of the underlying cause. They must exercise special care when lifting and carrying the hypotonic infant to avoid causing an injury to the child. If lifted under the armpits, the hypotonic infant's arms will raise with no resistance and easily slip between the hands.

A six-week-old baby girl is held horizontally by the trunk in a test for hypotonia, sometimes called "floppy infant syndrome." The girl is normal. *(Saturn Stills/ Science Photo Library/Photo Researchers, Inc.)*

Another source of concern that parents face is addressing the special needs of their hypotonic child. The world of typical children can be a difficult place for a hypotonic child, and it is tempting to isolate the child. It is not easy to go to a playgroup of toddlers when a child's latest milestone is getting from the floor into a sitting position while the other children are running across the room. There are resources for parents to help their child become as able and independent as he or she can possibly be, and the family physician is a good resource for advice.

KEY TERMS

Ataxia—A condition marked by impaired muscular coordination, most frequently resulting from disorders in the brain or spinal cord.

Biceps—The muscle in the front of the upper arm.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes or to follow the course of a disease. Most commonly the term refers to the collection and analysis of tissue from a suspected tumor to establish malignancy.

Central nervous system—Part of the nervous system consisting of the brain, cranial nerves, and spinal cord. The brain is the center of higher processes, such as thought and emotion and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system, that is the nerves present in the rest of body.

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Fine motor skill—The abilities required to control the smaller muscles of the body for writing, playing an instrument, artistic expression and craft work. The muscles required to perform fine motor skills are generally found in the hands, feet and head.

Flexor muscle—A muscle that serves to flex or bend a part of the body.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genetic disease—A disease that is (partly or completely) the result of the abnormal function or expression of a gene; a disease caused by the inheritance and expression of a genetic mutation.

Gross motor skills—The abilities required to control the large muscles of the body for walking, running, sitting, crawling, and other activities. The muscles required to perform gross motor skills are generally found in the arms, legs, back, abdomen and torso.

Immune response—A physiological response of the body controlled by the immune system that involves the production of antibodies to fight off specific foreign substances or agents (antigens).

Immune system—The system of specialized organs, lymph nodes, and blood cells throughout the body that work together to defend the body against foreign invaders (bacteria, viruses, fungi, etc.).

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct detailed images of internal body structures and organs, including the brain.

Motor control—The control of movement and posture.

Motor neuron—A nerve cell that specifically controls and stimulates voluntary muscles.

Muscle tone—Also termed tonus; the normal state of balanced tension in the tissues of the body, especially the muscles.

Muscle weakness—Reduction in the strength of one or more muscles.

Neurons—Any of the conducting cells of the nervous system that transmit signals.

Recessive disorder—Disorder that requires two copies of the predisposing gene one from each parent for the child to have the disease.

Spinal cord—The elongated nerve bundles that lie in the spinal canal and from which the spinal nerves emerge.

Underlying condition—Disorder or disease that causes the appearance of another medical disorder or condition.

Idiopathic thrombocytopenia purpura

Definition

Idiopathic thrombocytopenic purpura (ITP) is a bleeding disorder caused by an abnormally low level of blood platelets, small disc-shaped cells essential to blood clotting (coagulation). ITP describes both the cause and symptoms of the condition: idiopathic means that the disorder has no apparent cause; thrombocytopenia refers to a decreased number of blood platelets; and purpura refers to a purplish or reddish-brown skin rash caused by the leakage into the skin of blood from broken capillaries. ITP is as of 2004 often called immune thrombocytopenic purpura rather than idiopathic because studies in the early 2000s have shown the presence of autoimmune antibodies in the blood. Other names for ITP include purpura hemorrhagica and essential thrombocytopenia.

Description

Coagulation, or clotting, is a complex process in which specific proteins found in blood plasma combine with other blood components, including platelets, to form clots and prevent blood loss. Platelets are tiny colorless disc-shaped cells in the blood that collect (aggregate) in blood vessels to form a plug when a vessel is injured. The platelet plug then binds coagulation proteins to form a clot that stops bleeding. A deficiency in platelets or a disorder that affects platelet production can disrupt clotting and severely complicate blood loss from accidental injury, surgery, and specific diseases or conditions in which bleeding can occur. ITP affects the overall number of blood platelets rather than their function. The normal platelet level in adults is between 150,000 and 450,000/mm^3. Platelet counts below 50,000/mm^3 increase the risk of dangerous bleeding from trauma; counts below 20,000/mm^3 increase the risk of spontaneous bleeding.

ITP may be either acute or chronic. The acute form occurs in children between ages two and six. Although chronic ITP is most common in adult females, 10 to 20 percent of children with ITP have the chronic form.

Demographics

Acute ITP affects children of both sexes between the ages of two and six years. The chronic form, although most common in adult females between the ages of 20 and 40, is found in 10 to 20 percent of children with ITP. ITP does not appear to be related to race, lifestyle, climate, or environmental factors.

Causes and symptoms

In children, ITP is usually triggered by a virus infection, most often **rubella**, **chickenpox**, **measles**, cytomegalovirus (CMV), or Epstein-Barr virus (EBV). ITP usually begins about two or three weeks after the infection.

Acute ITP is characterized by bleeding into the skin or from the nose, mouth, digestive tract, or urinary tract. The onset is usually sudden. Bleeding into the skin takes the form of purpura or petechiae. Purpura, a purplish or reddish-brown rash or discoloration of the skin, and petechiae, small round pinpoint hemorrhages, are both caused by the leakage of blood from tiny capillaries under the skin. In addition to purpura and petechiae, spontaneous **bruises** may occur. In extreme cases, ITP may cause bleeding into the lungs, brain, or other vital organs.

Chronic ITP has a gradual onset and may have minimal or no external symptoms. The low **platelet count** may be discovered in the course of a routine blood test. Most parents consult a pediatrician or primary care doctor after noticing their child has the typical purpuric skin rash, frequent nosebleeds, or bleeding from the digestive or urinary tract.

In adults, ITP is considered an autoimmune disorder, which means that the body produces antibodies that damage some of its own products—in this case, blood platelets. Some adults with chronic ITP may have other autoimmune diseases such as lupus (systemic lupus erythematosus or SLE), rheumatoid arthritis, or scleroderma. Women with ITP may experience unusually heavy or lengthy menstrual periods. Risk factors for the development of chronic ITP in adults include being female, age over 10 years at onset of symptoms, bruising, and having another known autoimmune disease.

When to call the doctor

When a child bruises easily, has frequent nosebleeds, bloody stools, or develops a purplish or reddish-brown rash or tiny spots of hemorrhage, the symptoms should be reported to the pediatrician or **family** doctor, especially if they are noticed in the weeks following measles or chickenpox or a virus infection such as mononucleosis.

Diagnosis

ITP is usually considered a diagnosis of exclusion, which means that the doctor makes a diagnosis by ruling out other possible causes for the symptoms and physical findings. The presence of **fever**, for example, does not indicate ITP, whereas fever may occur in lupus and some other types of thrombocytopenia. Likewise, the doctor will look for an enlarged spleen by pressing on (palpating) the abdomen; if the spleen is noticeably enlarged, ITP is not absolutely ruled out but is a less likely diagnosis. If ITP is suspected, the doctor will examine the child's skin for bruises, purpuric areas, or petechiae. If nosebleeds or bleeding from the mouth or other parts of the body have been reported, the doctor will examine these areas for other possible causes of bleeding. Individuals with ITP usually look and feel healthy except for the bleeding. If the child has had a recent childhood illness (measles, chickenpox) or a virus, the risk for ITP is greater, and this fact will be considered along with diagnostic testing results.

Diagnostic tests will begin with a complete blood count (CBC), including a platelet count. A blood test for autoantibodies may be performed early in the diagnostic process as well as a test for antiplatelet antibodies. Specific diagnostic tests for autoimmune diseases and viruses (CMV, EBV, and rheumatoid factor or RF) may be performed. Coagulation tests, including clotting time, will be performed to determine the ability of the child's blood to form a clot. Platelet aggregation tests may be performed to evaluate platelet function, particularly if the platelet count is low.

KEY TERMS

Autoimmune disorder—One of a group of disorders, like rheumatoid arthritis and systemic lupus erythematosus, in which the immune system is overactive and has lost the ability to distinguish between self and non-self. The body's immune cells turn on the body, attacking various tissues and organs.

Clotting factors—Substances in the blood, also known as coagulation factors, that act in sequence to stop bleeding by triggering the formation of a clot. Each clotting factor is designated with a Roman numeral I through XIII.

Idiopathic—Refers to a disease or condition of unknown origin.

Petechia—Plural, petechiae. A tiny purple or red spot on the skin resulting from a hemorrhage under the skin's surface.

Platelet—A cell-like particle in the blood that plays an important role in blood clotting. Platelets are activated when an injury causes a blood vessel to break. They change shape from round to spiny, "sticking" to the broken vessel wall and to each other to begin the clotting process. In addition to physically plugging breaks in blood vessel walls, platelets also release chemicals that promote clotting.

Prednisone—A corticosteroid medication often used to treat inflammation.

Purpura—A group of disorders characterized by purplish or reddish brown areas of discoloration visible through the skin. These areas of discoloration are caused by bleeding from broken capillaries.

Splenectomy—Surgical removal of the spleen.

Thrombocytopenia—A persistent decrease in the number of blood platelets usually associated with hemorrhaging.

Children with ITP will usually have platelet counts below 20,000/mm^3 and a prolonged clotting time. The size and appearance of the platelets may be abnormal, which is observed microscopically. The red blood cell count (RBC) and white blood cell count (WBC) are usually normal, although about 10 percent of individuals with ITP are also anemic (have reduced RBCs and hemoglobin). The bone marrow test yields normal results. Detection of antiplatelet antibodies in the blood usually confirms a diagnosis of ITP.

Treatment

There is no specific treatment for ITP except to manage symptoms. In most cases, the disorder will resolve within two to six weeks without medications or surgery. Nosebleeds can be treated with ice packs when necessary. General care may include asking parents to watch for bruising, petechiae, or other signs of recurrence. Parents are also advised to avoid giving the child aspirin, ibuprofen, or other over-the-counter **pain** medications because these drugs are known to lengthen the clotting time of blood.

Children with acute ITP who are losing large amounts of blood or bleeding into their central nervous system require emergency treatment. This may include transfusions of platelets, intravenous immunoglobulins, or prednisone. Prednisone is a steroid medication that decreases the effects of antibodies on platelets and eventually lowers antibody production. If the child has been treated before for ITP and has not responded to prednisone or immunoglobulins, surgery may be required to remove the spleen (splenectomy), an organ that sometimes stores platelets and keeps them out of the general blood circulation. Splenectomy is usually avoided in children younger than five years because of the increased risk of a severe postoperative infection. In older children, however, splenectomy is recommended if the child has been treated for 12 months without improvement, if the ITP is very severe or is getting worse, or if the child begins to bleed into the head or brain.

Children with chronic ITP can be treated with prednisone, immune globulin, or large doses of intravenous gamma globulin. Although 90 percent of those with ITP respond to immunoglobulin treatment, it is an expensive treatment. Response to prednisone therapy is about 80 percent. Platelet transfusions are not recommended for routine treatment of ITP. If platelet levels do not improve within one to four months, or high doses of prednisone are required, splenectomy may be recommended. If the patient is an adolescent female with extremely heavy periods, splenectomy may also be recommended. Adults treated with splenectomy usually experience remission of chronic ITP. All medications for ITP are given either orally or intravenously; intramuscular injection is avoided because of the possibility of causing bleeding into the skin.

Prognosis

The prognosis for recovery from acute ITP is good; 80 percent of those affected recover without special treatment. The prognosis for chronic ITP is also good; most individuals experience long-term remission. In rare instances, however, ITP can cause life-threatening hemorrhage or bleeding into the central nervous system.

Prevention

Because as of 2004 the exact cause for ITP is unknown, no specific preventive measures are recommended. However, episodes of bleeding can be prevented in children with ITP by discouraging rough contact **sports** or other activities that increase the risk of trauma. To reduce the risk of ITP associated with other illnesses, children can be immunized against childhood diseases and kept away as much as possible from other children or adults with known or unidentified viruses.

Parental concerns

The sudden onset of ITP-like symptoms can be a concern, but the presence of a rash or bruising is not a signal for alarm because there are so many possible causes of these symptoms in childhood. Parents can be generally watchful, but not fearful. The symptoms to be alert for are frequent nosebleeds or frequent bruising with no specific cause, particularly if the child has had a recent illness or virus. It is helpful to remember that ITP, whether acute or chronic, has an excellent prognosis and may cause bleeding but not life-threatening hemorrhage in most cases. Parents can ask the pediatrician when in doubt and understand that simple blood and coagulation tests can be performed to rule out ITP.

Ileus

Definition

Ileus is a partial or complete non-mechanical blockage of the small and/or large intestine.

Description

There are two types of **intestinal obstructions**, mechanical and non-mechanical. Mechanical obstructions occur because the bowel is physically blocked and its contents cannot pass the point of the obstruction. This happens when the bowel twists on itself (volvulus) or as the result of hernias, impacted feces, abnormal tissue growth, or the presence of foreign bodies in the intestines. By contrast, non-mechanical obstruction, called ileus, occurs because the rhythmic contractions that move material through the bowel (called peristalsis) stop.

Demographics

The total rate of bowel obstruction due both to mechanical and non-mechanical causes is one in 1,000 people. Meconium ileus accounts for 9–33 percent of bowel obstructions in newborns.

Causes and symptoms

Ileus is most often associated with an infection of the peritoneum (the membrane lining the abdomen) or other intra-abdominal infections such as **appendicitis**. It is one of the major causes of bowel obstruction in infants and children. Another common cause of ileus is a disruption or reduction of the blood supply to the abdomen. Handling the bowel during abdominal surgery can also cause peristalsis to stop, so people who have had abdominal surgery are more likely to experience ileus.

Ileus can also be caused by kidney diseases, especially when potassium levels are decreased (a condition called hypokalemia). Narcotics and certain **chemotherapy** drugs, such as vinblastine (Velban, Velsar) and vincristine (Oncovin, Vincasar PES, Vincrex) can also cause ileus. Infants with **cystic fibrosis** are more likely to experience meconium ileus (obstruction of a dark green material in the intestine in newborns).

When the bowel stops functioning, the following symptoms occur:

- abdominal cramping
- abdominal distention (**pain** often increases as distention increases)
- nausea, **vomiting**, and/or **diarrhea**
- failure to pass gas or stool

When to call the doctor

A healthcare professional should be contacted if a child experiences persistent abdominal distention, is unable to have normal bowel movements, or exhibits other symptoms of ileus. Persistent abdominal pain and chronic or prolonged **constipation** are also reasons to call the doctor.

Diagnosis

When a doctor listens with a stethoscope to the abdomen of a child suffering from ileus, there will be few or no bowel sounds, indicating that the intestine has stopped functioning. Ileus can be confirmed by **x rays** of the abdomen, **computed tomography** scans (CT scans), or ultrasound. It may be necessary to do more invasive tests, such as a barium enema or upper GI series, if the obstruction is mechanical. Blood tests may also be useful in diagnosing ileus.

Barium studies are used in cases of mechanical obstruction but may cause problems by increasing pressure or intestinal contents if used in ileus. Also, in cases of suspected mechanical obstruction involving the gastrointestinal tract (from the small intestine downward) use of barium x rays are contraindicated, since they may contribute to the obstruction. In such cases a barium enema should always be done first.

Treatment

Patients may be treated with supervised bed rest in a hospital and bowel rest, where nothing is taken by mouth, and patients are fed intravenously or through the use of a nasogastric tube, a tube inserted through the nose, down the throat, and into the stomach. A similar tube can be inserted in the intestine. The contents are then suctioned out. In some cases, especially where there is a mechanical obstruction or death (necrosis) of intestinal tissue, surgery may be necessary.

Drug therapies that promote intestinal motility (ability of the intestine to move spontaneously), such as cisapride and vasopressin (Pitressin), are sometimes prescribed.

Alternative treatment

Alternative practitioners offer few treatment suggestions but focus on prevention by keeping the bowels healthy through eating a good diet, high in fiber and low

in fat. If the case is not a medical emergency, homeopaths and practitioners of traditional Chinese medicine can recommend therapies that may help to reinstate peristalsis.

Nutritional concerns

Following abdominal surgery, uncomplicated cases of ileus can be managed by minimizing the amount of food the patient consumes, ensuring adequate fluid intake, and correcting any electrolyte disturbances such as low potassium.

Prognosis

The outcome varies depending on the cause of ileus. When ileus results from abdominal surgery, the condition is usually temporary and lasts approximately 24–72 hours. The prognosis is less certain in cases in which death of intestinal tissue occurs; surgery becomes necessary to remove the necrotic tissue. In children with cystic fibrosis in which meconium ileus becomes evident soon after birth, the prognosis is linked with the primary disease; the median age of survival for cystic fibrosis patients is 30 years. However, new interventions in the treatment of CF are increasing the age span of people with CF every year.

Prevention

Most cases of ileus are not preventable. Surgery to remove a tumor or other mechanical obstruction may help to prevent a recurrence.

Nutritional concerns

In cases in which electrolyte imbalance is the cause of ileus, it is important to treat the underlying cause of the imbalance, which in many cases is related to chronic vomiting and/or diarrhea, poor fluid and/or food intake, or abuse of **laxatives** and diuretics (such as in individuals with **bulimia nervosa**).

Parental concerns

When their child is diagnosed with ileus, parents may be concerned about the necessity of surgery to correct the problem. Surgery, however, is considered only in medical emergencies and for patients for whom more conservative treatments have failed.

KEY TERMS

Bulimia nervosa—An eating disorder characterized by binge eating and inappropriate compensatory behavior, such as vomiting, misusing laxatives, or excessive exercise.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Meconium—A greenish fecal material that forms the first bowel movement of an infant.

Peritoneum—The transparent membrane lining the abdominal and pelvic cavities (parietal peritoneum) and the membrane forming the outer layer of the stomach and interstines (visceral peritoneum). Between the visceral and parietal peritoneums is a potential space called the peritoneal cavity.

Immobilization

Definition

Immobilization refers to the process of holding a joint or bone in place with a splint, cast, or brace. This is done to prevent an injured area from moving while it heals.

Purpose

Splints, casts, and braces support and protect broken bones, dislocated joints, and injured soft tissues such as tendons and ligaments. Immobilization restricts motion to allow the injured area to heal. It can help reduce **pain**, swelling, and **muscle spasms**. In some cases, splints and casts are applied after surgical procedures that repair bones, tendons, or ligaments. This allows for protection and proper alignment early in the healing process.

Description

When an arm, hand, leg, or foot requires immobilization, the cast, splint, or brace will generally extend from the joint above the injury to the joint below the injury. For example, an injury to the mid-calf requires immobilization from the knee to the ankle and foot. Injuries of the hip and upper thigh or shoulder and upper arm require a cast that encircles the body and extends down the injured leg or arm.

Casts and splints

Casts are generally used to immobilize a broken bone. Once the doctor makes sure the two broken ends of the bone are aligned, a cast is put on to keep them in place until they are rejoined through natural healing. Casts are applied by a physician, a nurse, or an assistant. They are custom-made to fit each person, and are usually made of plaster or fiberglass. Fiberglass weighs less than plaster, is more durable, and allows the skin more adequate airflow than plaster. A layer of cotton or synthetic padding is first wrapped around the skin to cover the injured area and protect the skin. The plaster or fiberglass is then applied over this and is then allowed to dry. It can take up to 24 hours for a cast to dry completely.

Most casts should be kept dry. However, some types of fiberglass casts use Gore-tex padding that is waterproof, allowing the cast to be completely immersed in water when taking a shower or bath. There are some circumstances when this type of cast material cannot be used.

A splint is often used to immobilize a dislocated joint while it heals. Splints are also often used for finger injuries, such as **fractures** or baseball finger. Baseball finger is an injury in which the tendon at the end of the finger is separated from the bone as a result of trauma. Splinting is also used to immobilize an injured arm or leg immediately after an injury. Before moving a child who has injured an arm or leg, some type of temporary splint should be applied to prevent further injury to the area. Splints may be made of acrylic, polyethylene foam, plaster of paris, or aluminum. In an emergency, a splint can be made from a piece of wood or rolled magazine.

Slings

Slings are often used to support the arm after a fracture or other injury. They are generally used along with a cast or splint, but are sometimes used alone as a means of immobilization. They can be used in an emergency to immobilize the arm until a doctor can see the child. A triangular bandage is placed under the injured arm and then tied around the neck.

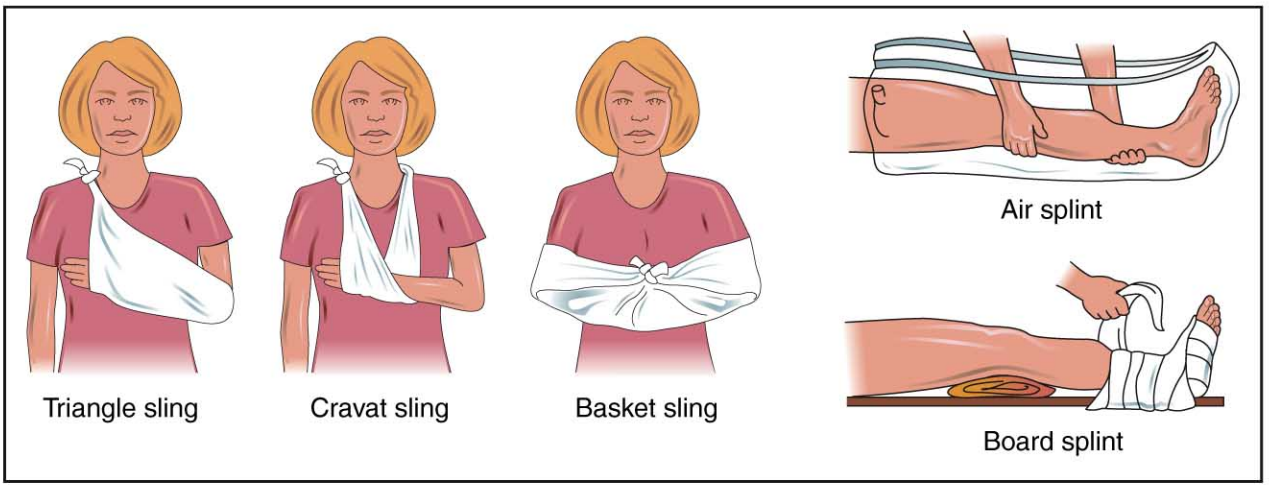
Braces

Braces are used to support, align, or hold a body part in the correct position. Braces are sometimes used after a surgical procedure is performed on an arm or a leg. They may also be used when an injury has occurred. Since some braces can be easily taken off and put back on, they are often used when the child needs physical therapy or must **exercise** the limb during the healing process. Many braces can also be adjusted to allow for a certain amount of movement.

Either a custom-made or a ready-made brace can be used. The off-the-shelf braces are made in a variety of shapes and sizes. They generally have Velcro straps that make the brace easy to adjust and to put on and take off. Both braces and splints offer less support and protection than a cast and may not be a treatment option in all circumstances.

Collars

A collar is generally used for neck injuries. A soft collar can relieve pain by restricting movement of the



These illustrations feature several types of immobilization techniques, including slings and splints. *(Illustration by Electronic Illustrators Group.)*

head and neck. Collars also transfer some of the weight of the head from the neck to the chest. Stiff collars are generally used to support the neck when there has been a fracture in one of the neck bones. Cervical collars are widely used by emergency personnel at the scene of injuries when there is a potential neck or **head injury**. The collar helps to ensure that the neck and head do not move, which could make the injury worse.

Traction

Immobilization may also be secured by traction. Traction involves using a method for applying tension to correct the alignment of two structures (e.g., two bones) and hold them in the correct position. For example, if the bone in the thigh breaks, the broken ends may have a tendency to overlap. Use of traction will hold them in the correct position for healing to occur. The strongest form of traction involves inserting a stainless steel pin through a bony prominence attached by a horseshoe-shaped bow and rope to a pulley and weights suspended over the end of the patient's bed.

Traction must be balanced by countertraction. This may be obtained by tilting the bed and allowing the patient's body to act as a counterweight. Another technique involves applying weights pulling in the opposite direction.

Traction for neck injuries may be in the form of a leather or cotton cloth halter placed around the chin and lower back of the head. For very severe neck injuries that require maximum traction, tongs that resemble ice tongs are inserted into small holes drilled in the outer skull. All traction requires careful observation and adjustment by doctors and nurses to maintain proper balance and alignment of the traction with free suspension of the weights.

Immobilization can also be secured by a form of traction called skin traction. This is a combination of a splint and traction that is applied to the arms or legs by strips of adhesive tape placed over the skin of the arm or leg. Adhesive strips, moleskin, or foam rubber traction strips are applied on the skin. This method is effective only if a moderate amount of traction is required.

Precautions

It is important to ensure that the cast is not too tight, such that blood flow is cut off and swelling is not restricted.

Preparation

There are many reasons for immobilization using splints, casts, and braces. It can be helpful if the child understands why immobilization is being done, as it may help with compliance.

Aftercare

After a cast or splint has been put on, the injured arm or leg should be elevated for 24 to 72 hours. It is recommended that the child lie or sit with the injured arm or leg raised above the level of the heart. Rest, combined with elevation, will reduce pain and speed the healing process by minimizing swelling.

Fingers or toes can be exercised as much as can be tolerated after casting. This has been found to decrease swelling and prevent stiffness. If excessive swelling is noted, the application of ice to the splint or cast may be helpful.

After the cast, splint, or brace is removed, gradual exercise is usually performed to regain muscle strength

KEY TERMS

Decubitus ulcer—A pressure sore resulting from ulceration of the skin occurring in persons confined to bed for long periods of time

Ligament—A type of tough, fibrous tissue that connects bones or cartilage and provides support and strength to joints.

Pneumonia—An infection in which the lungs become inflamed. It can be caused by nearly any class of organism known to cause human infections, including bacteria, viruses, fungi, and parasites.

Tendon—A tough cord of dense white fibrous connective tissue that connects a muscle with some other part, especially a bone, and transmits the force which the muscle exerts.

and motion. The doctor may also recommend hydrotherapy, heat treatments, and other forms of physical therapy.

Risks

For some children, such as those in traction, immobilization will require long periods of bed rest. Lying in one position in bed for an extended period can result in sores on the skin (decubitus ulcers) and skin infection. Long periods of bed rest can also cause a buildup of fluid in the lungs or an infection in the lungs (**pneumonia**). Urinary infection can also be a result of extended bed rest. Occasionally, blood clots can develop in the injured area.

People who have casts, splints, or braces on their arms or legs will generally spend several weeks not using the injured arm or leg. This lack of use can result in decreased muscle tone and shrinkage of the muscle (atrophy). This loss can usually be regained, however, through rehabilitation after the injury has healed.

Immobility can also cause psychological stress. A child restricted to a bed with a traction device may become frustrated and bored, and perhaps even depressed, irritable, and withdrawn. It may be helpful to have a bed that can be moved more easily than a traditional bed, so that the child can participate in as many **family** activities (such as dinner time and movie nights) as possible.

There is the possibility of decreased circulation if the cast, splint, or brace fits too tightly. If swelling occurs but the cast is tight enough that the swelling cannot be accommodated, serious complications can occur. Excessive pressure over a nerve can cause irritation or possible damage if not corrected. If the cast, splint, or brace breaks or malfunctions, the healing process of the bone or soft tissue can be disrupted and lead to deformity.

Parental concerns

Children can find immobilization very frustrating. Being restricted from participating in normal activities with friends because of a broken an arm or leg, or having to sit in bed for weeks if significant traction is required can be stressful. Children can be helped if parents try to provide alternate activities and engage the child in as many activities as possible with the family.

Immune system development

Definition

The child's immune system is an intricate network of interdependent cell types, substances, and organs that collectively protect the body from bacterial, parasitic, fungal, viral infections, and tumor cells.

Description

The immune system was not recognized as a functional unit of the body until the late twentieth century,

probably because its parts are not directly connected to each other and are spread in different parts of the body.

Organs of the immune system

The immune system contains the following organs and cells: tonsils and adenoids; the thymus gland; lymph nodes; bone marrow; and white blood cells that leave blood vessels and migrate through tissues and lymphatic circulation. The spleen, appendix, and patches of lymphoid tissue in the intestinal tract are also parts of the immune system.

The essential job of this system is to distinguish self-cells from foreign substances and to recognize and take protective action against any materials that ought not to be in the body, including abnormal and damaged cells. The immune system can seek out and destroy disease germs, infected cells, and tumor cells. The immune system includes the following cells:

- T lymphocytes (T cells)
- B lymphocytes (B cells)
- natural killer cells (NK cells)
- dendritic cells
- phagocytic cells
- complement proteins

These cells develop from ''pluripotential hematopoietic stem cells'' starting from a gestational age of about five weeks. They circulate through various organs in the lymphatic system as the fetus develops. T and B lymphocytes are the only units of the immune system that have antigen-specific recognition powers; they are responsible for adaptive immunity. In other words, the T and B cells are important in the immunity that **vaccination** promotes.

How immunity works

The lymphatic system is a key participant in the body's immune actions. It is a network of vessels and nodes unified by the circulatory system. Lymph nodes occur along the course of the lymphatic vessels and filter lymph fluid before it returns to the bloodstream. The system removes tissue fluids from intercellular spaces and protects the body from bacterial invasions.

Types of immunity

Immunity is the ability of the body to resist the infecting agent. When an infectious agent enters the body, the immune system develops antibodies which can weaken or destroy the disease-producing agent or neutralize its toxins. If the body is re-introduced to the same agent at a later time, it is capable of developing antibodies at a much faster pace. As a result, the individual would likely not become sick, and immunity has developed.

Natural immunity is present when a person is immune to a disease despite not having either the disease itself nor any vaccination against it. Acquired immunity may be either active or passive. Active immunity comes from having the disease or by inoculation with antigens, such as dead organisms, weakened organisms, or toxins of organisms. The antigens introduced during vaccination produce antibodies that protect the body against the infecting agent, despite the fact that the person does not become sick. Passive immunity is relatively short lived and is acquired by transferring antibodies from mother to child in the uterus or by inoculation with serum that contains antibodies from immune persons or animals. Passive immunization is used to help a person who has been exposed or is already infected to fight off disease. Although various types of serums may be used to produce passive immunization, gamma globulin is the most frequently used source of human antibodies.

Development of the immune response

Normal infants have the capability to develop responses to antigens at birth. Infants also start life with some immunoglobulin antibodies acquired from the mother. These antibodies cross the placental barrier, but not all types are transmitted equally. In particular, infants start with antibodies to viruses and gram-positive organisms, but not to gram-negative organisms. Gram is the name of a stain that distinguishes broad classes of bacteria. Gram-negative organisms are responsible for many diseases, including gonorrhea, pertussis (whooping cough), salmonella poisoning, and cholera. *Escherichia coli (E. coli)* is another common gram-negative organism.

Immunoglobulin antibodies are divided into five classes. The capacity of the body to produce each immunoglobulin varies with age. Newborn babies (premature and full-term) begin to synthesize antibodies at an increased rate soon after birth in response to antigenic stimulation of their new environment. At about six days after birth the serum concentration of specific antibodies rises sharply, and this rise continues until adult levels are achieved by approximately the end of the first year. Maternal immunity gradually disappears during the first six to eight months of life. A concentrated level of antibodies is reached and maintained by seven to eight years of age.

Common problems

Persistent infections

One of the greatest strains on the immune system is an infection it cannot remove. Parents should pay attention to unexplained fevers; night sweats; or tender, swollen lymph nodes. These symptoms can signify a hidden infection or **cancer**. Infections of the mouth and gums as well as sexually transferred infections often go unnoticed while they drain the vitality of the immune system.

Indiscriminate use of antibiotics

When the immune system successfully controls an infection on its own, it becomes stronger and better able to handle future threats. **Antibiotics** are powerful medicines that should be given only when the immune system cannot contain a bacterial infection. Overuse of antibiotics may cause the body to breed new strains of antibiotic-resistant or more dangerous bacteria. In the long run, overuse of antibiotics weakens the immune system.

Misuse of immunosuppressive drugs

Immunosuppressive drugs used in cancer **chemotherapy** or to suppress rejection of organ transplants are necessary. Of greater concern is the widespread use of corticosteroids or steroid derivatives used to treat **allergies**, autoimmune diseases, and inflammatory conditions. Though sometimes necessary, these drugs cripple the immune response and are often misunderstood, abused, and over-prescribed.

Radiation and hazardous chemicals

Exposure to radiation and hazardous chemicals may also damage the immune system. Excessive radiation of diagnostic **x rays** of the neck and chest may damage the thymus gland behind the breastbone. The thymus gland is an integral part of the immune system.

Blood transfusions and injections of blood products

Blood transfusions and injections of blood products may broadcast viral diseases like hepatitis that stress the immune system by flooding it with foreign proteins. In an emergency it may not be possible to do without blood transfusions. Sources of blood and blood products are regulated and screened for infectious substances and were as of 2004 much safer.

Other factors

Certain factors have damaging effects on the immune system of infants. Excessive consumption of alcohol during pregnancy leads to depressive levels of vitamin B and zinc, which are essential to immune competence. **Alcoholism** can also reduce the uptake of several other important nutrients needed for neonatal immune systems. Prolonged stress during pregnant and in breastfeeding mothers reduces the effectiveness of the immune system as well as the quality of immunologic factors in breast milk.

Cigarette **smoking** raises the white blood cells count, activating the immune system; however, smoking causes low-grade chronic **bronchitis**, low birth weight infants, and weakened natural immunity in newborns. Infants and children constantly exposed to cigarette smoke have weakened immune systems.

Toxic points—areas of localized infections such as dental abscesses or infected tonsils—may disturb the normal neutralization and weaken the cellular defenses in pregnant mothers and in children.

Deficiencies of many nutrients, especially certain **vitamins** and **minerals**, may weaken the immune system. Excessive **exercise** may depress the immune system temporarily.

Autoimmunity

Autoimmunity occurs when the immune system mistakenly attacks the body's own tissues, resulting in disease that can be mild or severe. Common autoimmune disorders are rheumatoid arthritis, glomerulonephritis, **rheumatic fever**, and systemic lupus erythematosus (SLE). Autoimmune reactions may be set off by infection, tissue injury, or emotional trauma in people with a genetic tendency to them.

Parental concerns

Parents may be concerned that children with acute illnesses have compromised immune systems and are less likely to have a positive response to vaccines or may be more likely to develop adverse reaction to the vaccine than healthy children. Parents may also believe that children who are ill should not further burden an immune system already committed to fighting an infection.

Most pediatricians would agree that there should be a delay in vaccinations for children with severe illnesses until the symptoms of illness are gone. The reason for deferring immunization is to avoid superimposing a reaction to the vaccine on the underlying illness or attributing symptoms of the underlying illness to the vaccine by mistake. However, a low-grade **fever** or cold is not a contraindication for routine vaccinations.

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's immune response.

Corticosteroids—A group of hormones produced naturally by the adrenal gland or manufactured synthetically. They are often used to treat inflammation. Examples include cortisone and prednisone.

Immune system—The system of specialized organs, lymph nodes, and blood cells throughout the body that work together to defend the body against foreign invaders (bacteria, viruses, fungi, etc.).

Immunization—A process or procedure that protects the body against an infectious disease by stimulating the production of antibodies. A vaccination is a type of immunization.

Lymphocyte—A type of white blood cell that participates in the immune response. The two main groups are the B cells that have antibody molecules on their surface and T cells that destroy antigens.

Phagocytosis—A process by which certain cells envelope and digest debris and microorganisms to remove them from the blood.

Parents may also be concerned that the many different vaccines that infants are given may overwhelm a child's immune system. However, infants have the capacity to respond to large numbers of antigens. Parents who worry about the increasing number of recommended vaccines may take comfort in knowing that children are exposed to fewer antigens in vaccines as of the early 2000s than in previous decades. Two reasons account for this decline: the worldwide elimination of smallpox and advances in protein chemistry in vaccines with fewer antigens.

Vaccines may cause temporary suppression of delayed-type hypersensitivity skin reactions or alter certain lymphocyte function tests. However, the short-lived immunosuppression caused by certain vaccines does not result in an increased risk of infections from other pathogens soon after vaccination.

Immunodeficiency

Definition

Immunodeficiency disorders are a group of disorders in which part of the immune system is missing or defective. The body's ability to fight infections is, therefore, impaired. As a result, a child with an immunodeficiency disorder has frequent infections that are generally more severe and last longer than in a healthy child.

Description

The immune system is the body's main defense against infections. Any defect in the immune system decreases a person's ability to fight infections. A person with an immunodeficiency disorder may get more frequent infections, heal more slowly, and have a higher incidence of some cancers.

The normal immune system involves a complex interaction of certain types of cells that can recognize and attack foreign invaders, such as bacteria, viruses, and fungi. It also plays a role in fighting **cancer**. The immune system has both innate and adaptive components. Innate immunity is made up of immune protections people are born with. Adaptive immunity develops

throughout life. It adapts to fight off specific invading organisms. Adaptive immunity is divided into two components: humoral immunity and cellular immunity.

The innate immune system is made up of the skin (which acts as a barrier to prevent organisms from entering the body); white blood cells called phagocytes; a system of proteins called the complement system; and chemicals called interferons. When phagocytes encounter an invading organism, they surround and engulf it in order to destroy it. The complement system also attacks bacteria. The elements in the complement system create a hole in the outer layer of the target cell, which leads to the death of the cell.

The adaptive component of the immune system is extremely complex and is as of the early 2000s still not entirely understood. Basically, it has the ability to recognize an organism or tumor cell as not being a normal part of the body and to develop a response to attempt to eliminate it.

The humoral response of adaptive immunity involves a type of cell called B lymphocytes. B lymphocytes manufacture proteins called antibodies (which are sometimes also called immunoglobulins). The terms antibody and immunoglobulin are often used interchangeably, although immunoglobulin refers to the larger classification system for antibodies. There are five types or classes of immunoglobulin that antibodies fit into, and each has a slightly different role in response against bacteria and viruses. Antibodies attach themselves to the invading foreign substance. This allows the phagocytes to begin engulfing and destroying the organism. The action of antibodies also activates the complement system. The humoral response is particularly useful for attacking bacteria.

The cellular response of adaptive immunity is useful for attacking viruses, some parasites, and possibly cancer cells. The main type of cell in the cellular response is the T lymphocyte. There are helper T lymphocytes and killer T lymphocytes. The helper T lymphocytes play a role in recognizing invading organisms, and they also help killer T lymphocytes to multiply. As the name suggests, killer T lymphocytes act to destroy the target organism.

Defects can occur in any component of the immune system or in more than one component (combined immunodeficiency). Different immunodeficiency diseases involve different components of the immune system. The defects can be inherited (congenital) or acquired.

Congenital immunodeficiency disorders

Congenital immunodeficiency is present at the time of birth and is the result of genetic defects. These immunodeficiency disorders are also called primary immunodeficiencies. Even though more than 70 different types of congenital immunodeficiency disorders have been identified, they rarely occur. Congenital immunodeficiencies may occur as a result of defects in B lymphocytes, T lymphocytes, or both. They also can occur in the innate immune system.

HUMORAL IMMUNITY DISORDERS The congenital immunodeficiency disorder, **Bruton's agammaglobulinemia**, also known as X-linked agammaglobulinemia, results in a decrease or absence of B lymphocytes and, therefore, a decreased ability to make antibodies. People with this disorder are particularly susceptible to infections of the throat, skin, middle ear, and lungs. It is seen only in males because it is caused by a genetic defect on the X chromosome. Since males have only one X chromosome, they always have the defect if the gene is present. Females can have the defective gene, but since they have two X chromosomes, there will be a normal gene on the other X chromosome to counter it. Women may pass the defective gene on to their sons.

B LYMPHOCYTE DEFICIENCIES If there is an abnormality in either the development or function of B lymphocytes, the ability to make antibodies will be impaired. This deficit makes the body susceptible to recurrent infections.

A type of B lymphocyte deficiency involves a group of disorders called selective **immunoglobulin deficiency syndromes**. The five different types of immunoglobulins are called IgA, IgG, IgM, IgD, and IgE. The most common type of immunoglobulin deficiency is selective IgA deficiency, occurring in about one in every 500 white persons. The amounts of the other antibody types are normal. Some patients with selective IgA deficiency experience no symptoms, while others have occasional lung infections and **diarrhea**. In another immunoglobulin disorder, IgG and IgA antibodies are deficient, and there is increased IgM. People with this disorder tend to get severe bacterial infections.

Common variable immunodeficiency (CVID) is another type of B lymphocyte deficiency. In this disorder, the production of one or more of the immunoglobulin types is decreased, and the antibody response to infections is impaired. It generally develops in people between the ages of ten and 20. The symptoms vary among affected people. Most people with this disorder have frequent infections, and some also experience autoimmune phenomena, such as autoimmune hemolytic

anemia or rheumatoid arthritis. Persons with CVID develop cancer at a higher rate than the general population, particularly lymphomas.

T LYMPHOCYTE DEFICIENCIES Severe defects in the ability of T lymphocytes to mature result in impaired immune responses to infections with viruses, fungi, and certain types of bacteria. These infections are usually severe and can be fatal.

DiGeorge syndrome is a genetic syndrome most frequently associated with a chromosomal deletion (22q11.2). This syndrome is often associated with T lymphocyte deficiencies. Children with DiGeorge syndrome either do not have a thymus or have an underdeveloped thymus. Since the thymus is a major organ that directs the production of T lymphocytes, these patients have low numbers of T lymphocytes. If the T cell count is very low the patients are susceptible to recurrent infections. The syndrome can be associated with other physical abnormalities. For example, these individuals may have distinctive facial features such as thin upper lip and flattened nasal bridge, and they may have low calcium from hypoparathyroidism or cardiac defects. If the entire syndrome is not present (as is the usual case), the syndrome is called incomplete DiGeorge, and if all elements are present and the thymus is absent, the syndrome is called complete. Children with complete DiGeorge are particularly susceptible to viral and fungal infections.

In some cases, no treatment is required for DiGeorge syndrome because T lymphocyte production improves. Either an underdeveloped thymus begins to produce more T lymphocytes, or organ sites other than the thymus compensate by producing more T lymphocytes.

COMBINED IMMUNODEFICIENCIES Some types of immunodeficiency disorders affect both B lymphocytes and T lymphocytes. For example, **severe combined immunodeficiency** disease (SCID) is caused by the defective development or function of these two types of lymphocytes. It results in impaired humoral and cellular immune responses. SCID usually is recognized during the first year of life. It tends to cause fungal infections, including severe thrush that does not respond to usual treatment; severe diarrhea; and serious bacterial infections. If the deficiency is not treated (usually by bone marrow transplant), a person with SCID usually dies from infection before the age of two years. The most common form of SCID is X-linked, i.e. the defect is on the X chromosome and, therefore, occurs only in boys. In the early 2000s new genetic defects leading to SCID are being identified each year.

DISORDERS OF INNATE IMMUNITY Disorders of innate immunity affect phagocytes or the complement system. These disorders also result in recurrent infections.

Acquired immunodeficiency disorders

Acquired immunodeficiency is more common than congenital immunodeficiency. It is the result of an infectious process or other disease. For example, the human immunodeficiency virus (HIV) is the virus that causes acquired immunodeficiency syndrome (**AIDS**). HIV, however, is not the most common cause of acquired immunodeficiency.

Acquired immunodeficiency often occurs as a complication of other conditions and diseases. For example, the most common causes of acquired immunodeficiency are **malnutrition**, some types of cancer, and infections. People who weigh less than 70 percent of the average weight of persons of the same age and gender are considered to be malnourished. Examples of types of infections that can lead to immunodeficiency are **chickenpox**, cytomegalovirus, German **measles** (**rubella**), measles, **tuberculosis**, **infectious mononucleosis** (Epstein-Barr virus), chronic hepatitis, lupus, and bacterial and fungal infections.

In some cases, acquired immunodeficiency is brought on by drugs used to treat another condition. For example, patients who have an organ transplant are given drugs to suppress the immune system so the body will not reject the organ. Also, some **chemotherapy** drugs that are given to treat cancer have the side effect of killing cells of the immune system. During the period of time that these drugs are being taken, the risk of infection increases. It usually returns to normal after the person stops taking the drugs.

Demographics

About 50,000 new cases of congenital immunodeficiencies are diagnosed in the United States each year. The frequency of severe combined immunodeficiency is estimated to be one out of every 50,000 to 500,000 births, and of combined variable immunodeficiency, one out of every 10,000 to 50,000 births. As of 2004 HIV is estimated to affect approximately 4.4 million children worldwide.

Causes and symptoms

Congenital immunodeficiency is caused by genetic defects that generally occur while the fetus is developing in the uterus. These defects affect the development and/or function of one or more of the components of the immune system. Acquired immunodeficiency is the

result of a disease process, and it occurs later in life. The causes can be diseases, infections, or the side effects of drugs given to treat other conditions.

People with an immunodeficiency disorder tend to become infected by organisms that do not usually cause disease in healthy persons. The major symptoms of most immunodeficiency disorders are repeated infections that heal slowly. These chronic infections cause symptoms that persist for long periods of time. People with chronic infection tend to be pale and thin. They may have skin **rashes**. Their lymph nodes may be absent or larger than usual, and in some types of immune deficiency the spleen and liver may be enlarged. (The lymph nodes are small organs that house antibodies and lymphocytes.) This can result in black-and-blue marks in the skin. The person may lose hair from their head. Sometimes, a red inflammation of the lining of the eye (**conjunctivitis**) is present. They may have a crusty appearance in and on the nose from chronic nasal dripping.

When to call the doctor

In an undiagnosed child, parents should inquire about immune deficiency if there are frequent infections, prolonged infections, unusual infections, unusual complications of usual infections, or if there is a **family** history of immune deficiency. If a child is known to have an immunodeficiency disorder, a healthcare provider should be contacted if the child shows signs of having an infection, such as **fever**, **vomiting**, diarrhea, swelling of the lymph nodes, or unusual fatigue.

Diagnosis

Usually, the first sign that individuals may have an immunodeficiency disorder is that they do not improve rapidly when given **antibiotics** to treat an infection. An immunodeficiency disorder is likely to be present when rare diseases occur or the patient gets ill from organisms that do not normally cause diseases, especially if the patient gets repeatedly infected. When this happens in very young children, a genetic defect may be causing an immunodeficiency disorder. When this situation occurs in older children or young adults, their medical history may indicate that childhood diseases may have caused an immunodeficiency disorder. Other possibilities also exist, such as recently acquired infections (e.g. HIV, hepatitis, tuberculosis, etc.).

Laboratory tests are used to determine the exact nature of the immunodeficiency. Most tests are performed on blood samples. Blood contains antibodies, lymphocytes, phagocytes, and complement components, all of the major immune components that might cause immunodeficiency. A blood cell count determines if the number of phagocytic cells or lymphocytes is below normal. Lower than normal counts of either of these two cell types correlates with immunodeficiency. The blood cells also are checked for their appearance. Sometimes a person may have normal cell counts, but the cells are structurally defective. If the lymphocyte cell count is low, further testing is usually done to determine whether any particular type of lymphocyte is lower than normal. A lymphocyte proliferation test is done to determine if the lymphocytes can respond to stimuli. The failure to respond to stimulants correlates with immunodeficiency. Antibody levels can be measured. Complement levels can be determined by immunodiagnostic tests.

Treatment

There is no cure for congenital immunodeficiency disorders. Therapy is aimed at controlling infections (such as with antibiotics) and, for some disorders, replacing defective or absent components.

Patients with Bruton's agammaglobulinemia must be given periodic infusions of pooled immunoglobulin from multiple donors. The product is called intravenous immunoglobulin (IVIG). The infusions are given approximately once a month for life to compensate for the patients' inability to make these proteins.

Common variable immunodeficiency also is treated with periodic infusions of IVIG throughout life. Additionally, antibiotics are given when necessary to treat infections.

Patients with selective IgA deficiency usually do not require any treatment. Antibiotics can be given for frequent infections.

In some cases, no treatment is required for DiGeorge syndrome because T lymphocyte production improves on its own. In some severe cases, a bone marrow transplant or thymus transplant can be performed to correct the problem.

For most patients with SCID, bone marrow transplantation is necessary. In this procedure, healthy bone marrow from a donor who has a similar type of tissue (usually a relative, such as a brother or sister) is removed. The bone marrow, a substance that is found in the cavity of bones, is the factory that produces blood cells, including some of the white blood cells that make up the immune system. The bone marrow of the person receiving the transplant is destroyed and is then replaced with marrow from the donor. One type of SCID called adenosine deaminase (ADA) deficiency is treated with infusion of the deficient enzyme on a regular basis, and

another type of SCID due to an absence of an interleukin, a protein that is important in directing the immune response, is also treated by infusions of the missing protein.

Treatment of the **HIV infection** that causes AIDS consists of drugs called antiretrovirals. These drugs interrupt the virus replication cycle and, therefore, spare the T cells. Several of these drugs used in various combinations with one another can treat but not cure the disease. Decreasing the viral in the blood to very low levels allows the immune system to remain in tact. Other treatments for people with AIDS are aimed at the particular infections and conditions that arise as a result of the impaired immune system.

For people being treated for cancer, periodic relief from chemotherapy drugs can restore the function of the immune system. In some cases, IVIG is utilized to boost the immune system.

Alternative treatment

For some individuals, alternative treatments such as acupuncture therapy to ease infection-related symptoms or homeopathic medicines to boost immunity may be used in conjunction with traditional medicine as part of a patient's treatment plan.

Nutritional concerns

In most cases, immunodeficiency caused by malnutrition is reversible. The health of the immune system is directly linked to the nutritional status of the patient. Among the essential nutrients required by the immune system are proteins, **vitamins**, iron, and zinc.

Prognosis

The prognosis depends on the type of immunodeficiency disorder. People with Bruton's agammaglobulinemia who are given IVIG infusions generally live into their 30s or 40s. They often die from chronic infections, usually of the lung. People with selective IgA deficiency generally live normal lives. They may experience problems if given a blood transfusion, and therefore they should wear a Medic Alert bracelet or have some other way of alerting any physician who treats them that they have this disorder.

SCID is the most serious of the immunodeficiency disorders. If a bone marrow transplant is not successfully performed, the child usually may not live beyond two years of age.

People with HIV/AIDS are living longer than in the past because of the antiretroviral drugs that became available in the mid-1990s. In the early 2000s HIV is still a potentially fatal illness, but medications have changed the face of the disease for those who have access to them. If medical treatment is timely and successful, T cells do not become depleted and opportunistic infections do not occur.

Prevention

Primary or congenital immunodeficiencies are genetic and are not preventable by avoidance of exposures or by dietary measures. However, someone with a congenital immunodeficiency disorder might want to consider getting genetic counseling before having children in order to find out if there is a chance they will pass the defect on to their children.

Some of the infections associated with acquired immunodeficiency can be prevented or treated before they cause problems. For example, there are effective treatments for tuberculosis and most bacterial and fungal infections. HIV infection can be prevented by practicing safe sex (e.g. using a **condom**) and by not using illegal intravenous drugs. These are the primary routes of transmitting the virus.

Nutritional concerns

In general, people with immunodeficiency disorders should maintain a healthy diet because malnutrition can aggravate immunodeficiencies. People can prevent malnutrition by getting adequate **nutrition**. They also should avoid being near others who have colds or are sick because they can easily acquire new infections. For the same reason, they should practice good personal hygiene, especially dental care. People with immunodeficiency disorders also should avoid eating undercooked food because it might contain bacteria that could cause infection. While this food might not cause infection in others, it is a potential source of infectious organisms for someone with an immunodeficiency.

Parental concerns

If a child has been diagnosed with an immunodeficiency disorder, the parents may be instructed to refrain from having normal childhood vaccinations that contain live viruses, since even weakened versions of the virus may cause serious disease. In some cases, the immunodeficient child needs to be encouraged to wear a mask when in public or around family members who are sick in order to reduce the risk of developing an infection.

KEY TERMS

Agammaglobulinemia—The lack of gamma globulins in the blood, associated with an increased susceptibility to infection.

B lymphocytes—Specialized blood cells that manufacture proteins called antibodies that attach themselves to invading foreign substances.

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

T lymphocytes—Specialized blood cells that recognize invading organisms (helper T lymphocytes) and destroy them (killer T lymphocytes).

Immunoglobulin deficiency syndromes

Definition

Immunoglobulin deficiency syndromes are a group of disorders that involve defects of any component of the immune system or a defect of another system that affects the immune system, leading to an increased incidence or severity of infection. In these disorders, specific disease-fighting antibodies (immunoglobulins such as IgG, IgA, and IgM) are either missing or are present in reduced levels. Children who have **immunodeficiency** syndromes may be subject to infection, diseases, disorders, or allergic reactions to a greater extent than individuals with fully functioning immune systems.

Description

Immunodeficiency is a defect of any component of the immune system or a defect of another system that affects the immune system leading to an increased incidence or severity of infection. Immunoglobulin deficiencies refer to missing or reduced levels of immunoglobulin (IgG, IgA, IgM) associated with an inability to make adequate specific antibody. These antibodies are specific proteins (immunoglobulins) produced by the immune system to respond to bacteria, viruses, fungi, parasites, or toxins that invade the body. Each class of antibody binds to corresponding molecules (antigens) on the cell surfaces of certain foreign organisms or substances, attempting to protect the body against reactions or illness. When the immune system is challenged by invading organisms, the antibodies may each play a protective role:

- Immunoglobulin G (IgG) is the most abundant class of immunoglobulins, directed toward viruses, bacterial organisms, and toxins. It is found in most tissues and in plasma, the clear portion of blood.
- Immunoglobulin M (IgM) is the first antibody produced in an immune response to any invading organism or toxic substance.
- Immunoglobulin A (IgA) is activated early in response to invasion by bacteria and viruses. It is found in saliva, tears, and all other mucus secretions.
- As of the early 2000s, IgD activity is not well understood.
- Immunoglobulin E (IgE) is found in respiratory secretions and is directed toward invasion of the body by parasites and in allergic reactions such as hay fever, **atopic dermatitis**, and allergic **asthma**.

Immunoglobulins are made by white blood cells known as B cells (B lymphocytes). Any disease that harms the development or function of B cells will, therefore, affect the production of immunoglobulin antibodies. T cells, another type of white blood cell, may also be involved in immunodeficiency disorders. About 70 percent of immunoglobulin deficiencies involve B lymphocytes and 20–30 percent involve T lymphocytes. Another 10 percent may involve both B and T lymphocytes.

Many of the infections that occur in children with immunoglobulin deficiency syndromes are caused by bacterial organisms or microbes. Certain of these invasive organisms form capsules when they enter the body, a mechanism used to confuse the immune system. In a healthy body with an adequately functioning immune system, immunoglobulin antibodies bind to the capsule and overcome the bacteria's defenses. Streptococci, meningococci, and *Haemophilus influenzae*, organisms that cause diseases such as **otitis media**, **sinusitis**, **pneumonia**, **meningitis**, osteomyelitis, septic arthritis, and sepsis, all make capsules. Children with immunoglobulin deficiencies are also prone to viral infections, including echovirus, enterovirus, and **hepatitis B**. They may also develop infection after receiving live (attenuated) **polio vaccine**. This is one of the reasons that live **polio** vaccine is no longer used routinely in the United States.

There are two types of immunodeficiency diseases: primary and secondary. Immunoglobulin deficiency syndromes are primary immunodeficiency diseases. They account for 50 percent of all primary immunodeficiencies and are the largest group of immunodeficiency disorders. Some are well defined and some are not fully understood. Secondary disorders occur in normally healthy people who are suffering from an underlying disease that weakens the immune system. Successful treatment of the disease usually reverses the immunodeficiency.

Examples of well defined immunoglobulin deficiency disorders include the following:

- X-linked agammaglobulinemia is an inherited disease stemming from a defect on the X chromosome, consequently affecting more males than females. Defect results in absence or reduced numbers of B cells that do not mature and perform normal function. Mature B cells are capable of making antibodies and developing memory, a feature in which the B cell will rapidly recognize and respond to an infectious agent the next time it is encountered. All classes of immunoglobulin antibodies are decreased in agammaglobulinemia.
- Immunoglobulin heavy chain deletion, a form of agammaglobulinemia, is a genetic disorder in which part of the antibody molecule is absent. This condition results in the loss of several antibody classes and subclasses, including most IgG antibodies and all IgA and IgE antibodies. The disease occurs because part of the gene for the heavy chain has been lost.
- X-linked hypogammaglobulinemia can occur in combination with growth hormone (GH) deficiency, producing short stature and delayed **puberty**, primarily in boys but also occurring in girls.
- Transient hypogammaglobulinemia of infancy is a temporary disease of unknown cause. It is believed to be caused by a defect in the development of T helper cells (cells that recognize foreign antigens and activate T and B cells in an immune response). As the child ages, the number and condition of T helper cells improves, and this situation corrects itself.

Hypogammaglobulinemia is characterized by low levels of gammaglobulin antibodies in the blood. During the disease period, children may have decreased levels of IgG and IgA antibodies. In some infants with this disorder, laboratory tests are able to show that the antibodies present do not react properly with infectious bacteria.

- IgG subclass deficiency is a disorder associated with a poor ability to respond and make antibody against polysaccharide antigens, primarily pneumococcus.
- Selective IgA deficiency is an inherited disease characterized by a failure of B cells to switch from making IgM to IgA antibodies. The amount of IgA produced is limited in either serum or the mucosal linings of organs. This condition may result in more infections of mucosal surfaces, such as the nose, throat, lungs, and intestines. However, most persons with this abnormality are asymptomatic.
- IgM deficiency is characterized by the absence or low level of total IgM antibodies, the body's first defense against infection. This condition results in slow response to infective organisms and slow response to treatment.
- IgG deficiency with hyper-IgM is a disorder that results when B-cells fail to switch from making IgM to IgG. This condition produces an increase in the amount of IgM antibodies present and a decrease in the amount of IgG and IgA antibodies. This disorder is the result of a genetic mutation.
- **Severe combined immunodeficiency** (SVID) is not precisely an immunoglobulin deficiency, but a combined deficiency resulting from a T-cell disorder. The T-cell dysfunction can either be X-linked, affecting more males than females and characterized by the absence of T lymphocytes, or it can occur through autosomal inheritance (not sex linked), resulting in an absence of both T and B lymphocytes and a deficient thymus gland, the lymphoid organ that produces T-cell lymphocytes.
- **Common variable immunodeficiency** (CVID) is a primary immunodeficiency with onset of symptoms typically occurring in the second or third decade of life. It is never diagnosed before two years of age and is diagnosed only after drug toxicity and other primary immune deficiencies have been ruled out. IgG and IgA and/or IgM will be measured at about two standard deviations below normal. The individual will typically not make antibodies against protein or polysaccharide antigens and will not make IgM antibodies against incompatible blood group antigens (hemagluttinins). T-cell dysfunction is the variable in this disorder. Children who have this disorder are subject to recurring infections and may not respond appropriately to immunization.

Demographics

Primary immunoglobulin deficiency syndromes occur only rarely. Those that are X-linked occur more in males than females; other immunoglobulin deficiencies occur equally in both sexes. Detection of the syndromes usually occurs in childhood. Numbers of new cases of specific syndromes are difficult to estimate because many deficiencies go undiagnosed. Among the syndromes for which incidence rates are available are IgA deficiency (one in 500–700), agammaglobulinemia (one in 50,000–100,000), severe combined immunodeficiency or SCID (one in 100,000–500,000), and common variable immunodeficiency or CVID (one in 50,000–200,000).

Causes and symptoms

Primary immunoglobulin deficiencies are primarily the result of congenital defects that affect the development and function of B lymphocytes (B cells), the white cells that fight infection and disease. Defects can occur at two main points in the development of B-cells. First, B cells can fail to develop into antibody-producing cells. X-linked agammaglobulinemia is an example of this disease. Secondly, B cells can fail to make a particular type of antibody or fail to switch classes during maturation. Initially, when B cells start making antibodies for the first time, they make IgM. As they mature and develop memory, they switch to one of the other immunoglobulin classes. Failure to switch or failure to make a subclass can lead to immunoglobulin deficiency diseases. Defects in the thymus gland that manufactures T lymphocytes or defects in the T lymphocytes themselves can also result in reduced production of immunoglobulins.

Symptoms are frequent and so are persistent infections, particularly of the respiratory system. Frequent digestive disturbances and **diarrhea** may lead to malabsorption of essential nutrients and **failure to thrive**. Children with primary immunoglobulin deficiency syndromes will exhibit some of the following characteristics:

- signs of infection in the first days or weeks of life
- a slow response to treatment
- infection suppressed by appropriate treatment but not cured
- common bacterial or viral organisms causing increasingly acute recurring infections

- uncommon bacterial or viral organisms causing infection
- multiple simultaneous infections at more than one site
- delays in growth and development
- development of unexpected complications such as **anemias** and chronic diseases

When to call the doctor

Parents should seek medical care from a pediatrician or **family** practitioner if their young child or teenager has frequent or persistent infections such as upper respiratory infections, or chronic **cough**, ear infections, sinusitis, asthma, or pneumonia. Sores that do not heal or recurring or long-lasting skin irritations may also be signs of reduced immune system functioning.

Diagnosis

An immunodeficiency disease is suspected when children become ill frequently, especially repeat illness caused by the same organisms. Diagnosis will begin with a detailed history of the child's illnesses (dates, duration, and infection site) and review of all prior medications and immunizations and results of diagnostic tests performed. Determining which immunoglobulins are present and which are absent or present in reduced amounts is critical for diagnosis. Diagnostic testing may include routine blood tests such as a complete blood count (CBC) and differential (peripheral blood smear) to evaluate overall health and determine the type and number of red cells, white cells, and platelets present in the blood. Tests or cultures may be performed to determine the type of bacteria or virus causing recurring infections. B lymphocytes and T lymphocytes may be quantified. When immunodeficiency is suspected, levels of the classes of immunoglobulins are measured in blood serum by using a clinical laboratory procedure called electrophoresis. This procedure both quantifies the amount of each antibody present and identifies the various classes and subclasses of antibodies. Deficiencies may be noted in one class or subclass or in combinations of antibodies. Genetic testing may be done to help identify the type of immunodeficiency disease.

Treatment

Immunoglobulin deficiency diseases cannot be cured, but treatment that replaces or boosts specific immunoglobulins can help support immune function in affected children. Immune serum, obtained from donated blood that contains adequate levels of IgG antibodies, may sometimes be transfused as a source of antibodies to boost the immune response, even though it may not contain all antibodies needed and may lack antibodies specific for some of the recurring infections. The preferred treatment is to give specific immunoglobulins intravenously (immunoglobulin intravenous therapy or IVIG) or subcutaneously. No replacement therapy is available for treating IgA deficiencies.

Treatment will also focus on controlling infections in immunodeficient children. Immunization against frequent infection can be achieved in some children by administering polysaccaride-protein conjugate vaccines shown to improve immune response in certain types of infection. **Antibiotics** are used routinely at the first sign of an infection to help eliminate infectious organisms. Antifungal drug therapy may be administered to treat fungus infections. Few drugs are effective against viral diseases, and each viral illness will be evaluated and treated differently, depending on the virus and the overall health of the child. Bone marrow transplantation may correct immunodefiency in some cases.

Alternative treatment

Several nutritional supplements are reported to help build the immune system. These include garlic (contains the essential trace element germanium), essential fatty acids (found in flax seed oil, evening primrose oil, and fish oils), sea vegetables such as kelp, acidophilus to supply natural bacteria in the digestive tract, and **vitamins** A and C, both powerful antioxidants that improve immune function and increase resistance to infection. Zinc is another nutrient essential to immune system functioning. Green drinks made with young barley are believed to cleanse the blood and supply chlorophyll and nutrients for tissue repair. Alcohol, certain prescription and over-the-counter drugs, and coffee and other **caffeine** drinks should be avoided. Stress is known to produce biochemicals that reduce white blood cell functioning, making it important to get sufficient **sleep** and reduce stress to help keep the immune system functioning. Therapeutic massage, **yoga**, and other types of stress reduction programs are available in most communities.

Nutritional concerns

Immune system function requires having certain essential nutrients and avoiding things that depress immunity. A diet that improves immune system functioning includes nutrients obtained as much as possible from whole foods such as fresh fruits and vegetables, whole grain breads and cereals, and brown rice and whole grain pasta for essential vitamins, **minerals**, and fiber. Such a diet also limits or eliminates refined foods.

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's immune response.

Autosomal inheritance—Inheritance involving any of the autosomes (22 pairs) and not involving sex-linked chromosomes X and Y.

Bacteria—Singular, bacterium; tiny, one-celled forms of life that cause many diseases and infections.

Immunization—A process or procedure that protects the body against an infectious disease by stimulating the production of antibodies. A vaccination is a type of immunization.

Immunoglobulin G (IgG)—Immunoglobulin type gamma, the most common type found in the blood and tissue fluids.

Thymus gland—An endocrine gland located in the upper chest just below the neck that functions as part of the lymphatic system. It coordinates the development of the immune system.

Virus—A small infectious agent consisting of a core of genetic material (DNA or RNA) surrounded by a shell of protein. A virus needs a living cell to reproduce.

Fish, fowl, and lean meats can be consumed in moderation. Sweets should be reduced or avoided.

Prognosis

Regular medical observation, treatment of symptoms, and appropriate immune system boosting usually produces a good result in children with immunodeficiencies. Prognosis is related to the immune system's ability to produce the specific antibodies that are missing or present in reduced amounts. Individuals with immunodeficiency syndromes may have a normal life span although a variety of complications can occur, including autoimmune, gastrointestinal, granulomatous, and malignant conditions as a result of progressive immune deficiency disorders and/or repeat infections.

Prevention

Immunodeficiency cannot be prevented; however, challenges to the immune system can be reduced and infections avoided in immunodeficient individuals. Immunoglobulin deficiencies require impeccable health maintenance and care, paying particular attention to good hygiene, balanced **nutrition**, sufficient rest, regular check ups and immunizations, and optimal dental care, as well as avoiding crowds and contact with other children or relatives with bacterial or virus infections.

Nutritional concerns

A healthy immune system can be maintained by providing essential nutrients through a good diet and regular supplementation. Parents can help assure that their children and teens have three nutritious, low-fat, high-fiber, whole-food meals a day (limiting or eliminating altogether refined or prepared foods and fast foods) and healthy snacks in between, such as nuts, fresh fruit, popcorn, raw veggies, and whole grain crackers with nut butters (if no **allergies** to peanuts or other nuts), naturally sweetened jellies, and low-fat cheeses. Vitamin supplements should include vitamins A, C, and E, valuable parts of the body's defense system that help to increase production of healthy white blood cells and to fight infection.

Parental concerns

Parents with immunoglobulin deficient children and teenagers will likely be concerned that their children are in frequent contact with schoolmates and friends, the common route to infection. When infection occurs frequently, it is important to remember that the pediatrician or family practitioner will have specific criteria and diagnostic tests for evaluating the child, identifying the immunodeficiency, and determining appropriate therapy. Meanwhile, parents can help keep their children away from crowds and avoid contact with other children or relatives with bacterial or virus infections.

Impetigo

Definition

Impetigo refers to a very localized bacterial infection of the skin. There are two types, bullous and epidemic.

Description

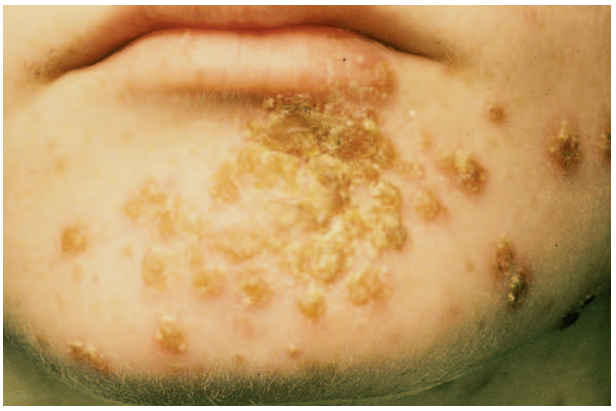
Impetigo is a skin infection that tends primarily to afflict children. Impetigo caused by the bacterium *Staphylococcus aureus* (also known as staph) affects children of all ages. Impetigo caused by the bacteria called group A streptococci (also known as strep) are most common in children ages two to five.

The bacteria that cause impetigo are very contagious. They can be spread by a child from one part of his or her body to another by scratching or contact with a towel, clothing, or stuffed animal. These same methods can pass the bacteria on from one person to another.

Impetigo tends to develop in areas of the skin that have already been damaged through some other mechanism (a cut or scrape, burn, insect bite, or vesicle from **chickenpox**).

Demographics

About 10 percent of all skin problems in children are ultimately diagnosed as impetigo.



Impetigo is a contagious bacterial skin infection that has affected the area around this patient's nose and mouth. *(© NMSB/Custom Stock Medical Photo, Inc.)*

Causes and symptoms

The first sign of bullous impetigo is a large bump on the skin with a clear, fluid-filled top (a vesicle). The bump develops a scab-like, honey-colored crust. There is usually no redness or **pain**, although the area may be quite itchy. Ultimately, the skin in this area will become dry and flake away. Bullous impetigo is usually caused by staph bacteria.

Epidemic impetigo can be caused by staph or strep bacteria and (as the name implies) is very easily passed among children. Certain factors, such as heat and humidity, crowded conditions, and poor hygiene increase the chance that this type of impetigo will spread rapidly among large groups of children. This type of impetigo involves the formation of a small vesicle surrounded by a circle of reddened skin. The vesicles appear first on the face and legs. When a child has several of these vesicles close together, they may spread to one another. The skin surface may become eaten away (ulcerated), leaving irritated pits. When there are many of these deep, pitting ulcers, with pus in the center and brownish-black scabs, the condition is called ecthyma. If left untreated, the type of bacteria causing this type of impetigo has the potential to cause a serious kidney disease (glomerulonephritis). Even when impetigo is initially caused by strep bacteria, the vesicles are frequently secondarily infected with staph bacteria.

Impetigo is usually an uncomplicated skin condition. Left untreated, however, it may develop into a serious disease, including osteomyelitis (bone infection), septic arthritis (joint infection), or **pneumonia**. If large quantities of bacteria are present and begin circulating in the bloodstream, the child is in danger of developing an overwhelming systemic infection known as sepsis.

KEY TERMS

Systemic—Relating to an entire body system or the body in general.

Ulcer—A site of damage to the skin or mucous membrane that is characterized by the formation of pus, death of tissue, and is frequently accompanied by an inflammatory reaction.

Vesicle—A bump on the skin filled with fluid.

Diagnosis

Characteristic appearance of the skin is the usual method of diagnosis, although fluid from the vesicles can be cultured and then examined in an attempt to identify the causative bacteria.

Treatment

Uncomplicated impetigo is usually treated with a topical antibiotic cream called mupirocin. In more serious, widespread cases of impetigo, or when the child has a **fever** or swollen glands, **antibiotics** may be given by mouth or even through a needle placed in a vein (intravenously).

Prognosis

Prognosis for a child with impetigo is excellent. The vast majority of children recover quickly, completely, and uneventfully.

Prevention

Prevention involves good hygiene. Hand washing; never sharing towels, clothing, or stuffed animals; and keeping fingernails well-trimmed are easy precautions to take to avoid spreading the infection from one person to another.

Impulse control disorders

Definition

Impulse control disorders are a relatively new class of **personality disorders** characterized by an ongoing inability to resist impulses to perform actions that are harmful to oneself or others. The most common of these are **intermittent explosive disorder**, kleptomania, pyromania, compulsive gambling disorder, and **trichotillomania**.

Description

Impulse control disorders include five conditions that involve a recurrent failure to resist impulsive behaviors that harm one's self or others: intermittent explosive disorder, pyromania, kleptomania, trichotillomania, and compulsive gambling disorder. Intermittent explosive disorder involves unusually aggressive and violent outbursts. Pyromania is characterized by repetitive and purposeful fire-setting. Kleptomania involves urges to steal and repetitive acts of unnecessary theft. Trichotillomania is recurrent pulling out of hair. Compulsive gambling disorder is maladaptive, repetitive gambling.

Repetitive **self-mutilation** is considered by some experts to be a type of impulse control disorder. In this condition, people cause intentional harm to themselves through burning, cutting, or scratching.

Demographics

The incidence of impulse control disorders in children and adolescents is difficult to determine. In general, intermittent explosive disorder, pyromania, and compulsive gambling disorder are more common in boys, while kleptomania is more common in girls.

Causes and symptoms

Exact causes of impulse control disorders are unknown, but may be linked to genetics, **family** environment, and/or neurological factors. Some research suggests that impulse control disorders are linked to certain hormones, abnormal nerve impulses, and variations in brain chemistry and function. Children and adolescents who have had a severe **head injury** and who have epilepsy may be at greater risk of developing these disorders. In children and adolescents, impulse control disorders often occur along with other psychological conditions, such as attention-deficit hyperactivity disorder (ADHD).

Intermittent explosive disorder is characterized by episodes of aggressive and violent outbursts and loss and lack of control of anger. Often, explosive episodes result in destruction of property, domestic violence, and physical assault, which, in turn, have legal ramifications. The degree of aggressiveness during each episode is grossly out of proportion to any stresses.

Pyromania is the repetitive, deliberate, and purposeful setting of fires. Children and adolescents with pyromania are often aroused by fire-setting, and/or feel pleasure, relief, or gratification when setting fires or witnessing the consequences of fire. In addition, pyromaniacs are fascinated and attracted to fire and related accessories (e.g., matches, lighters), and are unnaturally curious about its use and consequences. Fire-setting is not performed for any other reasons, such as for financial gain, to express anger, to conceal a criminal act, or to express sociopolitical views.

Kleptomania is an inability to resist impulses to repetitively steal objects that are not necessary for personal use or monetary value. Children and adolescents with kleptomania experience a growing sense of tension just before **stealing**, followed by pleasure, relief, or gratification during or just after stealing. Career thieves, those who steal out of need or to support substance abuse, and those who steal because they have no regard for society's laws, are not considered to have kleptomania. Individuals with kleptomania do not want to steal and feel guilty about it.

Trichotillomania is characterized by recurrent pulling out of one's hair to produce noticeable hair loss. Children and adolescents with trichotillomania experience a growing sense of tension or stress just before pulling hair out or when trying to resist hair pulling. They experience pleasure, relief, or gratification when pulling out the hair.

Compulsive gambling disorder, also called pathological gambling, is recurrent and persistent gambling behavior characterized by five or more of the following:

- having a preoccupation with gambling
- needing to gamble with increasingly larger amounts of money to achieve the same excitement
- having repeated unsuccessful efforts to control gambling
- telling lies to family members, therapists, and others to conceal extent of gambling involvement
- committing forgery, fraud, or theft to finance gambling
- being restless or irritable when trying to stop gambling
- gambling to escape problems or to relieve tension or other feelings
- jeopardizing or losing a significant job, relationship, or other opportunity due to gambling
- relying on others to provide financial support due to financial difficulties caused by gambling

When to call the doctor

Parents of children and adolescents who exhibit problems with impulse control should see a physician as soon as possible. Usually, a referral to a psychologist, psychiatrist, or therapist will be given.

Diagnosis

Impulse control disorders are diagnosed by psychological and psychiatric evaluations, interviews with family members, teachers, and caregivers, and observation and interviews with the child or adolescent. Diagnosis is based on clinical criteria defined in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision C (DSM-IV-TR)*.

Impulse control disorders often have characteristics in common with other psychological disorders and often occur in conjunction with other conditions, such as ADHD or **conduct disorder**. Therefore, diagnosis of impulse control disorders may be difficult, and they are usually diagnosed after exclusion of other disorders. For example, intermittent explosive disorder is diagnosed if the aggressive episodes cannot be better explained by another psychological disorder, such as **antisocial personality disorder**; a manic episode; ADHD; or by substance abuse or medical conditions such as head trauma. Pyromania is diagnosed when fire-setting is not better explained by conduct disorder, antisocial personality disorder, mental impairment, delusions or hallucinations, or intoxication. Kleptomania is diagnosed when repetitive

stealing is not better explained by anger or vengeance, **peer pressure**, delusions or hallucinations, conduct disorder, a manic episode, or antisocial personality disorder. Trichotillomania is diagnosed when pulling out of hair is not better explained by another mental disorder or a dermatological or medical condition, and when this practice causes clinically significant social or occupational dysfunction or impairment. Compulsive gambling disorder is diagnosed when the behavior cannot be better explained by a manic episode, conduct disorder, or peer pressure.

Treatment

Impulse control disorders are treated with medication, psychotherapy, and behavior modification. If these disorders are occurring in conjunction with another condition, such as ADHD, medication and therapy for that condition often helps alleviate the impulse control disorder. Depression is often an underlying factor in some impulse control disorders, particularly compulsive gambling disorder and trichotillomania. Therefore, treatment with **antidepressants** may be helpful.

Long-term counseling and psychotherapy is usually necessary as well. Therapy methods to help with impulse control generally involve behavior modification, anger and stress management, and psychoanalysis. Therapy can occur in residential or day treatment facilities, or on an outpatient basis. Support groups, such as Gamblers Anonymous, may also help.

Prognosis

Prognosis depends on the severity of the disorder and the commitment of the individual to seek therapy. Impulse control disorders can affect social, academic, and occupational functioning, as well as result in legal problems. Long-term participation in individual counseling and group therapy can improve prognosis.

Prevention

Impulse control disorders cannot be prevented.

Parental concerns

Children and adolescents with impulse control disorders may have difficulties in school and at home. In some cases, impulse control disorders can result in expulsion from school. Parents should investigate **alternative school** settings that may be able to provide counseling and group therapy integrated with academics. **Family therapy** may help alleviate stressful family situations and help other family members understand the impulse control disorder.

KEY TERMS

Alternative school—An educational setting designed to accommodate educational, behavioral, and/or medical needs of children and adolescents that cannot be adequately addressed in a traditional school environment.

Antisocial personality disorder—A disorder characterized by a behavior pattern that disregards for the rights of others. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy or psychopathy.

Attention deficit hyperactivity disorder (ADHD)—A condition in which a person (usually a child) has an unusually high activity level and a short attention span. People with the disorder may act impulsively and may have learning and behavioral problems.

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence. Children with a conduct disorder act inappropriately, infringe on the rights of others, and violate societal norms.

Manic episode—A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least one week, characterized by inflated sense of self-importance, decreased need for sleep, extreme talkativeness, racing thoughts, and excessive participation in pleasure-seeking activities.

Inclusion conjunctivitis

Definition

Inclusion **conjunctivitis** is an inflammation of the conjunctiva, or white of the eye. In the neonate this condition is part of a larger group of eye diseases called neonatal conjunctivitis. Inclusion conjunctivitis is also called a chlamydial conjunctivitis.

Description

Chlamydiae are similar to bacteria but cannot produce their own energy and thus live in the cells of other organisms. Once inside the host cell, chlamydiae replicate and form inclusion bodies. They then replace and finally destroy the cell membrane of the host, releasing more chlamydiae to continue the infection process. The life cycle of chlamydia is 72 hours. Chlamydiae are found in parts of the body with a mucosal membrane, which are the eye, the respiratory tract, and the genitourinary tract.

Transmission

Neonatal inclusion conjunctivitis develops within five to 12 days after birth and is contracted as the child passes through the mother's cervix. Two-thirds of those females with a chlamydial infection pass the infection on to the child during **childbirth**.

Adult inclusion conjunctivitis, which can affect sexually active adolescents, is usually transmitted sexually and develops when the eye is infected by the urogenital secretions of an individual infected with chlamydia, but it can be transmitted by eye-to-eye contact. Symptoms do not always exist with chlamydial infections, and thus it is often transmitted unknowingly. Up to 80 percent of female adults and adolescents with inclusion conjunctivitis are asymptomatic, and almost half of those with adult inclusion conjunctivitis do not have a systemic infection of chlamydia.

Demographics

The exact number of individuals with adult inclusion conjunctivitis is not known. But adult inclusion conjunctivitis, which is seen only if one is infected with chlamydia, affects 3 million annually in the United States. It is seen most often in sexually active 15 to 30 years olds, and most of these infections are reported in women 15 to 19. Forty-six percent of new cases of chlamydia fall within this group. Up to 10 percent of pregnant women harbor the chlamydial parasite. Twenty-five percent of those men with chlamydia infections are not aware of their infection.

Up to 6 percent of newborns develop neonatal inclusion conjunctivitis. Forty percent of neonatal conjunctivitis is due to chlamydia. Between 35 and 50 percent of newborns infected with chlamydia develop neonatal inclusion conjunctivitis. Neonatal chlamydial or inclusion conjunctivitis is 10 times more common than neonatal gonorrheal conjunctivitis.

Causes and symptoms

Inclusion conjunctivitis is caused by an intracellular organism called *Chlamydia trachomatis*.

The signs and symptoms of adult inclusion conjunctivitis appear two to 19 days after contact with an individual who harbors the chlamydia parasite. The symptoms of adult inclusion conjunctivitis are a foreign body sensation, watery eyes, and eyelids that stick together upon awakening. Large follicles may be seen if the lower lid is pulled down. The lymph nodes near the ears, called the preauricular nodes, may be swollen. Because the symptoms of chlamydia wax and wane and because the

adolescent or adult may be asymptomatic, proper diagnosis may be delayed.

The signs of neonatal inclusion conjunctivitis appear five to 14 days after birth. Since the lymphatic system of the newborn is not well developed, follicles will not usually be present, and the lymph nodes will not be enlarged, but the eye of the neonate with chlamydia will be red and inflamed. The infant will be tearing and have a purulent ocular discharge, and the eyelids will be swollen. Other accompanying symptoms in the infant include a **cough** and **rhinitis**.

When to call the doctor

Any red eye, with or without discharge, should be examined by an appropriate healthcare practitioner. There are many causes of eye problems, and appropriate treatment should be instituted as soon as possible if inclusion conjunctivitis is the cause of the ocular problem.

The children of mothers who give birth outside the traditional hospital setting should contact their healthcare provider regarding the necessity of prophylactic antibiotic drops. A healthcare provider should be informed if the mother or father of a newborn has an untreated sexually transmitted disease.

Diagnosis

The diagnosis of inclusion conjunctivitis cannot be made definitively without laboratory testing, but the signs of inclusion conjunctivitis can be seen by the eye care provider, even if a patient is not symptomatic. Follicles can seen on the inside inferior eyelids and occasionally under the superior eyelid of the patient with adult inclusion conjunctivitis, and if treatment has been delayed, scarring of the interior of the eyelids may be present as well as kerititis, an inflammation of the cornea, and neovascularization, or new blood vessel formation of the cornea. Upon questioning the individual may report a history of a genitourinary infection.

The laboratory testing for inclusion conjunctivitis begins with swabbing a sample from the inside of the eyelids to test for the presence of the characteristic inclusion bodies made only by chlamydia. The Giemsa stain is used often to diagnose neonatal inclusion conjunctivitis. This technique has a high rate of false positives for the adult with inclusion conjunctivitis. Immunofluorescence monoclonal antibody testing is very sensitive technique that gives a rapid diagnosis of inclusion conjunctivitis. Other techniques used to diagnose a chlamydial infection are enzyme immunoassays, serum antibody tests, and DNA probes.

Since inclusion conjunctivitis can mimic other diseases, it is important to rule out other types of conjunctivitis, such as those of viral etiology or allergy or those caused by gonorrhea.

Treatment

Neonatal inclusion conjunctivitis may resolve spontaneously within nine months without treatment. But the standard treatment for an infant younger than four months of age is oral erythromycin, four times a day for two weeks. The eye may be irrigated with saline to help remove the mucus discharge. The parents of the infant are treated as well.

Doxycycline, tetracycline, ocufloxacin, and erythromycin are sometimes prescribed. Tetracycline is not given to children under eight years of age, and ocufloxacin is not given to those under 18 years of age. Neither drug is given to pregnant or nursing women because of side effects. **Topical antibiotics** are not required if systemic or oral medication is prescribed, but if there is a co-existing inflammation in the eye, then topical steroids may be given. Finally, the sexual partners of individuals with inclusion conjunctivitis must also be receive antibiotic treatment.

Prognosis

Usually adult inclusion conjunctivitis resolves within two to four weeks with treatment. Rarely does inclusion conjunctivitis lead to blindness, unless it has been left untreated for months or longer. If untreated, a chlamydial infection can lead to pelvic inflammatory disease and scarring of fallopian tubes in women, causing infertility or ectopic pregnancies. In males, urethritis may result.

Ten to 20 percent of infants infected with chlamydia develop **pneumonia** during the first six months of life. In the infant, inclusion conjunctivitis may persist for several years.

Prevention

Since in the United States adult inclusion conjunctivitis is primarily a sexually transmitted disease, the incidence of inclusion conjunctivitis can be decreased either through abstinence or through the use of condoms. Pregnant women with a chlamydial infection should talk to their doctor about treatment of the infection. Antibiotic eye drops only may not be sufficient to prevent inclusion conjunctivitis in the newborn if the mother is infected with chlamydia.

KEY TERMS

Chlamydia—The most common bacterial sexually transmitted disease in the United States. It often accompanies gonorrhea and is known for its lack of evident symptoms in the majority of women.

Conjunctiva—Plural, conjunctivae. The mucous membrane that covers the white part of the eyes (sclera) and lines the eyelids.

Cornea—The clear, dome-shaped outer covering of the eye that lies in front of the iris and pupil. The cornea lets light into the eye.

Gonorrhea—A sexually transmitted disease that causes infection in the genital organs and may cause disease in other parts of the body.

Trachoma—A type of chlamydia that causes blindness.

The incidence of neonatal conjunctivitis can be reduced by applying erythromycin ointment to the newborn's eyes shortly after delivery. Silver nitrate, which may be instilled at some institutions at birth (instead of erythromycin), is not effective against chlamydia.

Parental concerns

In the newborn, inclusion conjunctivitis may resolve spontaneously, but there are chlamydial infections which can cause blindness if not treated. So, any eye problem in the newborn needs to be diagnosed properly and treated as indicated by the pediatrician or eye-care provider.

When inclusion conjunctivitis is diagnosed in an adolescent, it is almost always has been contracted through sexual activity. Sixty-five percent of adolescents have had sexual intercourse by age 16. Only 40 percent of young adults between 18 and 21 years of age used a **condom** during their most recent sexual encounter, and 45 percent of these individuals have already had more than three sexual partners. Because **peer pressure** makes it difficult to resist sex and because adolescents have difficulty understanding they are risks of contracting **sexually transmitted diseases**, including chlamydial infections, parents should be involved in helping the adolescent understand these risks.

Infant massage

Definition

Infant massage is the process of rubbing an infant's muscles and stroking the infant in a manner specifically designed for them. Although there are professionally trained and certified infant massage therapists, the obvious first choice to massage the baby is the mother, father, grandparent, or guardian. Equally important are the people who care for children outside the home such as, nurses on neonatal intensive care units (NICU) that work with premature babies and those who work with the disabled. The benefits derived from massage are applicable and advantageous for all of these groups.

Purpose

Infant massage provides many benefits for the infant. A caring touch is good for everyone, but especially for infants who are new to the world and need the reassurance of someone special being there for them. However, there are some major benefits for the massage givers as well. They gain an increased awareness of the baby and his or her needs while enhancing the **bonding** process between care giver and baby. Research from experiments conducted at the Touch Research Institutes at the University of Miami School of Medicine and Nova Southeastern University has been cited for the clinical benefits massage has on infants and children. Touch therapy triggers many physiological changes that help infants and children grow and develop.

Studies have shown that infant massage alleviates the stress that newborns experience as a result of the enormous change that birth creates. They have just spent nine months in a home that fed them; kept them warm; brought them the oxygen they needed; took care of waste products; and provided a gentle rocking motion to soothe them. Now, the outside world has taken over, and things are not as simple as they were. Massage enables a smoother transition from the comfortable womb to that of humankind. The benefits of massage for the infant include:

- It helps baby learn to relax.
- It improves immune system.
- It promotes bonding and communication.
- It promotes positive body image.
- It decreases the production of stress hormones.
- It promotes sounder and longer sleep.
- It helps to regulate digestive, respiratory, and circulatory systems.
- It helps relieve discomfort from gas and **colic**, congestion, and teething.

The benefits of massage for parents include:

- It improves parent-infant communication.
- It helps parents to understand and respond appropriately to baby's nonverbal cues.
- It eases stress of parent who must be separated from child during the day.
- It promotes feelings of competence and confidence in caring for baby.
- It provides a special focused time that helps deepen bonding.
- It increases parents' ability to help child relax in times of stress.
- It is fun and relaxing for parents to massage their children.

There are additional benefits that can be derived from infant massage to elicit positive outcomes for premature infants and disadvantaged mothers. They include:

- Cross-cultural studies show that babies who are held, massaged, carried, rocked, and breast fed grow into less aggressive and violent adults who demonstrate a greater degree of compassion and cooperation.
- Recent research demonstrates benefits for premature infants, children with **asthma**, diabetes, and certain skin disorders.
- Mothers with postpartum depression have shown improvement after starting infant massage.
- Teenage mothers have shown improved bonding behavior and interactions with their infants.

Description

Origins

Infant massage is an ancient practice used primarily in Asian and Pacific Island cultures because touch in these cultures is considered healthful both physically and spiritually. For example, the inclusion of infant massage into regular bath time is typical of the Maoris and Hawaiians. With the introduction of infant massage in the West in the late 1970s, it was tested to prove or disprove its efficacy. Dr. Frederick Leboyer, a French physician who advocated natural **childbirth**, supported the interest in infant massage with the publication of his photojournalistic book on the Indian art of baby massage. He believed that touch is the child's first language and that understanding spoken language comes long after understanding touch.

Infant massage was introduced formally into the United States in 1978 when Vimala Schneider McClure, a **yoga** practitioner who served in an orphanage in Northern India, developed a training program for instructors at the request of childbirth educators. An early research study by R. Rice in 1976 had shown that premature babies who were massaged surged ahead in weight gain and neurological development over those who were not massaged. McClure's practice in India, her knowledge of Swedish massage and reflexology along with her knowledge of yoga postures, which she had already adapted for babies, served to make her the foremost authority on infant massage. The International Association of Infant Massage (IAIM) had its origins in 1980 and was incorporated in 1986 by McClure and her original seven trainers. As of 2004, there were over 30 countries that have chapters of IAIM and over 15,000 certified instructors have been trained in the United States.

Various techniques are used in infant massage, with the different strokes specific to a particular therapy. Special handling is used for treating a baby with gas and colic. Some of the strokes are known as Indian milking, which is a gentle stroking of the child's legs; and the twist and squeeze stroke, a gentle squeeze of the muscles in the thigh and calf. The light strokes often employed in regular Swedish massage are applied at the end of a massage. The procedure is not unlike certain forms of adult massage, but with extra care taken for the fragility of the infant.

Infant receiving a massage. *(© Photo Researchers, Inc.)*

There are also specific Chinese techniques of pediatric massage, including massage of children with special needs. In China, these forms of massage can be given by medical professionals, but parents are often taught how to do the simpler forms for home treatment of their children.

Preparation

It is good to get a baby into a routine for massage. The time can be early in the morning, after a bath, or just before bedtime—the caregiver and baby know what is best and the time can be determined by the response. The room needs to be warm because the baby's clothes will be removed and infants have a difficult time regulating their body temperature. This is especially true for premature babies. It is preferable to have the room not be too bright with electrical light or sunlight shining on the baby's face. Research has shown that babies prefer to be massaged with oil such as a vegetable or plant oil. Traditional baby oils are mineral based, which are not readily absorbed. The two oils preferred by most massage therapists are grape seed oil and sweet almond oil. A caregiver can try both and see which is the most desirable. Generally, removing the diaper permits greater freedom of movement for the baby. For protection, the baby can by placed on a thick towel.

Precautions

It is necessary to use caution when performing infant massage in order not to injure the infant. Strokes are made with the greatest delicacy, and appropriate techniques are taught by licensed massage therapists to ensure that the infant is treated with accepted physical touch. Anyone who is unfamiliar with handling a baby should receive appropriate instruction before beginning infant massage.

Risks

No adverse side effects have been reported when infant massage is done properly after careful instruction, or by a licensed massage therapist who specializes in infant care.

Normal results

Many studies have been mentioned relating to the benefits of massage and there has been research published as early as 1969 relating to the topic. Hundreds of individual projects have been conducted throughout the world focusing on infant massage. Many of the studies are related to the benefits of massage and touch for premature infants and others born with such risk factors as drug dependence or **cerebral palsy**. Needless to say, the benefits are overwhelmingly positive and the research indicates that infant massage is increasingly recognized as a legitimate health care treatment.

Infant mortality

Definition

The infant mortality rate is the number of deaths of infants under one year of age per 1,000 live births in a given population. In 2002, the United States' infant mortality rate varied widely by race of the mother from 14.3 for infants of black mothers to 5.9 for infants of Hispanic mothers to 5.8 for infants of white mothers. As can be noted, the mortality rate for black infants is more than twice that of white infants. The overall infant mortality rate in 2002 for all races was 7.0 per 1,000 live births, which was a slight increase over the previous year.

Description

Infant mortality rate is one of the key indicators of a nation's health status. When the rate increases, as it did from 2001 to 2002, the factors that precipitated this change need to be assessed and scrutinized. The U.S. infant mortality rate is of great concern because the United States has fallen to the twenty-second nd place among industrialized nations in infant mortality rankings. Therefore, healthcare professionals and the public have stressed the need for better prenatal care, coordination of health services, and the provision of comprehensive maternal-child services.

Infant mortality rates have typically been the highest for the babies of adolescent mothers and lowest for women in their late 20s and early 30s. The rates have also been high for women in their forties and older. In general, infant mortality rates decrease with increasing maternal educational levels. Similarly the infant mortality rate for unmarried mothers is often more than 83 percent higher than the mortality rate for married women. Likewise, the infant mortality rate is characteristically higher for the infants of mothers who smoke than for those of nonsmokers.

The leading cause of infant mortality is congenital malformations, deformations and chromosomal abnormalities with a rate of 20.2 percent. Disorders related to short gestation and low birth weight was the second leading cause of death for all infants at 16.4 percent of all deaths. **Sudden infant death syndrome** (SIDS) is the third leading cause of infant death. Its incidence decreased by about

KEY TERMS

Perinatal mortality—The number of late fetal deaths, 28 weeks or more gestation, and neonatal deaths that occur in the first seven days.

9 percent, which it has been doing since 1988. The fourth leading cause of death comes under the heading of newborn affected by maternal complications of pregnancy. This rate actually increased from 2001 to 2002 from 37.2 per 100,000 live births to 42.9 per 100,000 in 2002.

An analysis of the data established that the rise in the infant mortality rate was concentrated in the neonatal period (less than 28 days) and primarily in the first week of life where more than half of all infants' deaths occur. Final birth data for 2002 made it apparent that two key predictors of infant health, the percentage of infants born preterm (less than 37 weeks gestation) and low birth weight (less than 2,500 grams) rose during this time frame. This has been a continuing long-term upward trend. The **cesarean section** rate for 2002 rose to 26.1, which is the highest ever recorded in the US. The primary cesarean rate was 7 percent higher than the previous year, and the rate of vaginal birth after cesarean (VBAC) experienced a sharp decline. The cesarean rate increase could be due to nonmedical factors as demographics, physician practice patterns, and maternal choice. Other contributing factors may be the use of continuous **electronic fetal monitoring** and inductions before 41 weeks gestation. Unnecessary interventions can contribute to a rise in cesarean rates. On the other hand, the perinatal mortality rate (the number of late fetal deaths [28 weeks or more gestation] and early neonatal deaths [less than 7 days] per 1,000 live births) remain unchanged.

Common problems

The infant mortality rate increased in the United States in 2002 for the first time since 1958, which indicates a need to examine what factors contributed to this raise. Is there a difference in mortality rates among racial groups? That is obvious—the rate for blacks is 14.2 and the rate for whites is 5.8. Experts associate this difference with the availability of prenatal care to minorities. It is expensive, and over 40 million Americans do not have health insurance. The mother's socioeconomic status is a possible contributing factor because the leading cause of death was related to congenital malformations, which in some cases can be eliminated with appropriate nutritional intake and prenatal **vitamins**. Lack of prenatal care could also contribute to the fourth largest cause of infant death, which is maternal complications. Many other industrialized countries have a socialized system of health care, which offers universal access to prenatal care and helps lower country-wide infant mortality rates.

Parental concerns

Recent data showed good news for parents of teenagers. The teen birth rate declined by 30 percent over the past decade to a historic low and the rate for black teens was down by more than 40 percent. For young black teens (15 to 17 years) the results were even more striking—the rate was cut in half since 1991. The average age at first birth was 25.1 years in 2002, an all-time high in the United States. Birth rates for women 35–39 (41 births per 1,000 women) and 40–44 (eight per 1,000) were the highest in more than three decades. The rate for women ages 20–24 (104 births per 1,000 women) was on the decline and the rate for those 25–29 was stable, but still the highest of all age groups, at 114 per 1,000 women. In contrast, the rate for teens was 43 per 1,000. In addition, just over one in 10 women smoked during pregnancy in 2002, a decline of 42 percent since 1989.

Infectious mononucleosis

Definition

Infectious mononucleosis is a contagious illness caused by the Epstein-Barr virus that can affect the liver, lymph nodes, and oral cavity. While mononucleosis is not usually a serious disease, its primary symptoms of fatigue and lack of energy can linger for several months.

Description

Infectious mononucleosis, frequently called "mono" or the "kissing disease," is caused by the Epstein-Barr virus (EBV) found in saliva and mucus. The virus affects a type of white blood cell called the B lymphocyte, producing characteristic atypical lymphocytes that may be useful in the diagnosis of the disease.

The disease typically runs its course in four to six weeks in people with normally functioning immune systems. People with weakened or suppressed immune systems, such as **AIDS** patients or those who have had organ transplants, are particularly vulnerable to the potentially serious complications of infectious mononucleosis.

Demographics

While anyone, even young children, can develop mononucleosis, it occurs most often in young adults between the ages of 15 and 35 and is especially common in teenagers. The mononucleosis infection rate among college students who have not previously been exposed to EBV has been estimated to be about 15 percent. In younger children, the illness may not be recognized.

Causes and symptoms

The EBV that causes mononucleosis is related to a group of herpes viruses, including those that cause cold sores, **chickenpox**, and shingles. Most people are exposed to EBV at some point during their lives. Mononucleosis is most commonly spread by contact with virus-infected saliva through coughing, sneezing, kissing, or sharing drinking glasses or eating utensils.

In addition to general weakness and fatigue, symptoms of mononucleosis may include any or all of the following:

- **sore throat** and/or swollen tonsils
- fever and chills
- nausea and **vomiting**, or decreased appetite
- swollen lymph nodes in the neck and armpits

Sore throat and swollen tonsils caused by infectious mononucleosis, frequently called mono or the kissing disease. *(Photograph by Dr. P. Marazzi. Science Photo Library/Photo Researchers, Inc.)*

- headaches or joint **pain**
- enlarged spleen
- jaundice
- skin rash

Complications that can occur with mononucleosis include a temporarily enlarged spleen or inflamed liver. In rare instances, the spleen may rupture, producing sharp pain on the left side of the abdomen, a symptom that warrants immediate medical attention. Additional symptoms of a ruptured spleen include light-headedness, rapidly beating heart, and difficulty breathing. Other rare, but potentially life-threatening, complications may involve the heart or brain. The infection may also cause significant destruction of the body's red blood cells or platelets.

Symptoms do not usually appear until four to seven weeks after exposure to EBV. An infected person can be contagious during this incubation time period and for as many as five months after the disappearance of symptoms. Also, the virus will be excreted in the saliva intermittently for the rest of their lives, although the individual will experience no symptoms. Contrary to popular belief, the EBV is not highly contagious. As a result, individuals living in a household or college dormitory with someone who has mononucleosis have a very small risk of being infected unless they have direct contact with the person's saliva.

Diagnosis

If symptoms associated with a cold persist longer than two weeks, mononucleosis is a possibility; however, a variety of other conditions can produce similar symptoms. If mononucleosis is suspected, a physician will

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Herpes virus—A family of viruses including herpes simplex types 1 and 2, and herpes zoster (also called varicella zoster). Herpes viruses cause several infections, all characterized by blisters and ulcers, including chickenpox, shingles, genital herpes, and cold sores or fever blisters.

Reye's syndrome—A serious, life-threatening illness in children, usually developing after a bout of flu or chickenpox, and often associated with the use of aspirin. Symptoms include uncontrollable vomiting, often with lethargy, memory loss, disorientation, or delirium. Swelling of the brain may cause seizures, coma, and in severe cases, death.

typically conduct a physical examination, including a "Monospot" antibody blood test that can indicate the presence of proteins or antibodies produced in response to infection with the EBV. These antibodies may not be detectable, however, until the second or third weeks of the illness. Occasionally, when this test is inconclusive, other blood tests may be conducted.

Treatment

The most effective treatment for infectious mononucleosis is rest and a gradual return to regular activities. Individuals with mild cases may not require bed rest but should limit their activities. Any strenuous activity, athletic endeavors, or heavy lifting should be avoided until the symptoms completely subside, since excessive activity may cause the spleen to rupture.

The sore throat and **dehydration** that usually accompany mononucleosis may be relieved by drinking water and fruit juices. Gargling salt water or taking throat lozenges may also relieve discomfort. In addition, taking over-the-counter medications, such as **acetaminophen** or ibuprofen, may relieve symptoms, but aspirin should be avoided because mononucleosis has been associated with **Reye's syndrome**, a serious illness aggravated by aspirin.

While **antibiotics** do not affect EBV, the sore throat accompanying mononucleosis can be complicated by a streptococcal infection, which can be treated with antibiotics. Cortisone anti-inflammatory medications are also occasionally prescribed for the treatment of severely swollen tonsils or throat tissues.

Prognosis

While the severity and length of illness varies, most people diagnosed with mononucleosis are able to return to their normal daily routines within two to three weeks, particularly if they rest during this time period. It may take two to three months before a person's usual energy levels return. One of the most common problems in treating mononucleosis, particularly in teenagers, is that people return to their usual activities too quickly and then experience a relapse of symptoms. Once the disease has completely run its course, the person cannot be reinfected.

Prevention

Although there is no way to avoid becoming infected with EBV, paying general attention to good hygiene and avoiding sharing beverage glasses or having close contact with people who have mononucleosis or cold symptoms can help prevent infection.

Parental concerns

The main concern for parents of children with mononucleosis is to keep the child resting until he or she fully recovers from the illness. Parents should also be aware of the symptoms of more serious complications of the liver and spleen, and should seek medical attention for a child who complains of severe abdominal pain, light-headedness, rapid heartbeat, or difficulty breathing.

Influenza

Definition

Usually referred to as the flu or grippe, influenza is a highly infectious respiratory disease. The disease is caused by certain strains of the influenza virus. When the virus is inhaled, it attacks cells in the upper respiratory tract, causing typical flu symptoms such as fatigue, **fever** and chills, a hacking **cough**, and body aches. Influenza victims are also susceptible to potentially life-threatening secondary infections. Although the stomach or intestinal "flu" is commonly blamed for stomach upsets and **diarrhea**, the influenza virus rarely causes gastrointestinal symptoms. Such symptoms are most likely due to other organisms such as rotavirus, *Salmonella*, *Shigella*, or *Escherichia coli*.

Description

The flu is considerably more debilitating than the **common cold**. Influenza outbreaks occur suddenly, and infection spreads rapidly. In the 1918–19 Spanish flu pandemic, the death toll reached a staggering 20 to 40 million worldwide. Approximately 500,000 of these fatalities occurred in the United States.

Influenza outbreaks occur on a regular basis. The most serious outbreaks are pandemics, which affect millions of people worldwide and last for several months. The 1918–19 influenza outbreak serves as the primary example of an influenza pandemic. Pandemics also occurred in 1957 and 1968 with the Asian flu and Hong Kong flu, respectively. The Asian flu was responsible for 70,000 deaths in the United States, while the Hong Kong flu killed 34,000.

Epidemics are widespread regional outbreaks that occur every two to three years and affect 5–10 percent of the population. The Russian flu in the winter of 1977 is an example of an epidemic. A regional epidemic is shorter lived than a pandemic, lasting only several weeks. Finally, there are smaller outbreaks each winter that are confined to specific locales.

The earliest existing descriptions of influenza were written nearly 2,500 years ago by the ancient Greek physician Hippocrates. Historically, influenza was ascribed to a number of different agents, including "bad air" and several different bacteria. In fact, its name comes from the Italian word for "influence," because people in eighteenth-century Europe thought that the disease was caused by the influence of bad weather. It was not until 1933 that the causative agent was identified as a virus.

There are three types of influenza viruses, identified as A, B, and C. Influenza A can infect a range of animal species, including humans, pigs, horses, and birds, but only humans are infected by types B and C. Influenza A is responsible for most flu cases, while infection with types B and C virus are less common and cause a milder illness.

Demographics

The annual death toll attributable to influenza and its complications averages 20,000 in the United States alone. In the United States, 90 percent of all deaths from influenza occur among persons older than 65. Flu-related deaths have increased substantially in the United States since the 1970s, largely because of the aging of the American population. In addition, elderly persons are vulnerable because they are often reluctant to be vaccinated against flu.

Hospitalization due to complications of influenza are common in children. Among children with chronic illnesses, about 500 children per every 100,000 between the ages of birth and age four are hospitalized annually due to influenza, while about 100 children per 100,000 without chronic illnesses are hospitalized annually. Among those with underlying high-risk conditions, infants younger than six months have the highest hospitalization rates (approximately 10–40 per 100,000 population).

Causes and symptoms

Approximately one to four days after infection with the influenza virus, the victim is hit with an array of symptoms. "Hit" is an appropriate term, because symptoms are sudden, harsh, and unmistakable. Typical influenza symptoms include the abrupt onset of a **headache**, dry cough, and chills, rapidly followed by overall achiness and a fever that may run as high as 104°F (40°C). As the fever subsides, nasal congestion and a **sore throat** become noticeable. Flu victims feel extremely tired and weak and may not return to their normal energy levels for several days or even a couple of weeks.

Influenza complications usually arise from bacterial infections of the lower respiratory tract. Signs of a

secondary respiratory infection often appear just as the victim seems to be recovering. These signs include high fever, intense chills, chest pains associated with breathing, and a productive cough with thick yellowish green sputum. If these symptoms appear, medical treatment is necessary. Other secondary infections, such as sinus or ear infections may also require medical intervention. Children with heart and lung problems, as well as other chronic diseases, are at higher risk for complications from influenza.

With children and teenagers, it is advisable to be alert for symptoms of **Reye's syndrome**, a rare, but serious complication. Symptoms of Reye's syndrome are **nausea and vomiting**, and more seriously, neurological problems such as confusion or delirium. The syndrome has been associated with the use of aspirin to relieve flu symptoms.

Diagnosis

Although there are specific viral culture tests available to identify the flu virus strain from respiratory samples, results can take several days. Therefore, doctors typically rely on a set of symptoms and the presence of influenza in the community for diagnosis. Specific tests are useful to determine the type of flu in the community, but they do little for individual treatment. Doctors may administer tests, such as throat cultures, to identify secondary infections.

Several rapid (30-minute) diagnostic tests for flu have become commercially available. These tests appear to be especially useful in diagnosing flu in children, allowing doctors to make more accurate treatment decisions in less time.

Treatment

Essentially, a bout of influenza must be allowed to run its course. Symptoms can be relieved with bed rest and by keeping well hydrated. A steam vaporizer may make breathing easier, and **pain** relievers can mask the aches and pain. Food may not seem very appetizing, but an effort should be made to consume nourishing food. Recovery should not be pushed. Returning to normal activities too quickly invites a possible relapse or complications.

Drugs

Since influenza is a viral infection, **antibiotics** are useless in treating it. However, antibiotics are frequently used to treat secondary infections.

Over-the-counter medications are used to treat flu symptoms, but it is not necessary to purchase a medication marketed specifically for flu symptoms. Any medication that is designed to relieve symptoms, such as pain and coughing, will provide some relief. Medications containing alcohol, however, should be avoided because of the dehydrating effects of alcohol. The best medicine for symptoms is simply an analgesic, such as **acetaminophen** or naproxen. (Without a doctor's approval, aspirin is generally not recommended for people under 18 owing to its association with Reye's syndrome, a rare aspirin-associated complication seen in children recovering from the flu. To be on the safe side, children should receive acetaminophen or ibuprofen to treat their symptoms.)

As of 2004, there were a number of **antiviral drugs** marketed for treating influenza. To be effective, treatment should begin no later than two days after symptoms appear. These medications are useful for decreasing the severity and duration of symptoms. Antivirals may be useful in treating patients who have weakened immune systems or who are at risk for developing serious complications. They include amantadine (Symmetrel, Symadine) and rimantadine (Flumandine), which work against Type A influenza, and zanamavir (Relenza) and oseltamavir phosphate (Tamiflu), which work against both Types A and B influenza. Amantadine and rimantadine can cause side effects such as nervousness, **anxiety**, lightheadedness, and **nausea**. Severe side effects include seizures, delirium, and hallucination, but are rare and are nearly always limited to people who have kidney problems, seizure disorders, or psychiatric disorders. Zanamavir and oseltamavir phosphate can cause **dizziness**, jitters, and insomnia.

KEY TERMS

Common cold—A mild illness caused by upper respiratory viruses. Usual symptoms include nasal congestion, coughing, sneezing, throat irritation, and a low-grade fever.

Epidemic—Refers to a situation in which a particular disease rapidly spreads among many people in the same geographical region in a relatively short period of time.

Guillain-Barré syndrome—Progressive and usually reversible paralysis or weakness of multiple muscles usually starting in the lower extremities and often ascending to the muscles involved in respiration. The syndrome is due to inflammation and loss of the myelin covering of the nerve fibers, often associated with an acute infection. Also called acute idiopathic polyneuritis.

Pandemic—A disease that occurs throughout a regional group, the population of a country, or the world.

Prognosis

Following proper treatment guidelines, healthy people under the age of 65 usually suffer no long-term consequences associated with flu infection. The elderly and the chronically ill are at greater risk for secondary infection and other complications, but they can also enjoy a complete recovery.

Most people recover fully from an influenza infection, but it should not be viewed complacently. Influenza is a serious disease, and approximately one in 1,000 cases proves fatal.

Prevention

The Centers for Disease Control and Prevention recommends that people get an influenza vaccine injection each year before flu season starts. In the United States, flu season typically runs from late December to early March. Vaccines should be received two to six weeks prior to the onset of flu season to allow the body enough time to establish immunity. Adults only need one dose of the yearly vaccine, but children under nine years of age who have not previously been immunized should receive two doses with a month between each dose.

Each season's **flu vaccine** contains three virus strains that are the most likely to be encountered in the coming flu season. When there is a good match between the anticipated flu strains and the strains used in the vaccine, the vaccine is 70–90 percent effective in people under 65. Because immune response diminishes somewhat with age, people over 65 may not receive the same level of protection from the vaccine, but even if they do contract the flu, the vaccine diminishes the severity and helps prevent complications.

The virus strains used to make the vaccine are inactivated and will not cause the flu. In the second half of the twentieth century, flu symptoms were associated with vaccine preparations that were not as highly purified as modern vaccines, not to the virus itself. In 1976, there was a slightly increased risk of developing Guillain-Barré syndrome, a very rare disorder, associated with the swine flu vaccine. This association occurred only with the 1976 swine flu vaccine preparation and as of 2004 had not recurred.

Serious side effects with modern vaccines are extremely unusual. Some people experience a slight soreness at the point of injection, which resolves within a day or two. People who have never been exposed to influenza, particularly children, may experience one to two days of a slight fever, tiredness, and muscle aches. These symptoms start within six to 12 hours after the **vaccination**.

It should be noted that certain people should not receive an influenza vaccine. Infants six months and younger have immature immune systems and will not benefit from the vaccine. Since the vaccines are prepared using hen eggs, people who have severe **allergies** to eggs or other vaccine components should not receive the influenza vaccine. As an alternative, they may receive a course of amantadine or rimantadine, which are also used as a protective measure against influenza. Other people who might receive these drugs are those that have been immunized after the flu season has started or who are immunocompromised, such as people with advanced HIV disease. Amantadine and rimantadine are 70–90 percent effective in preventing influenza.

Certain groups are strongly advised to be vaccinated because they are at increased risk for influenza-related complications. These groups are:

- children under age two
- all people 65 years and older
- residents of nursing homes and chronic-care facilities, regardless of age
- adults and children who have chronic heart or lung problems, such as asthma
- adults and children who have chronic metabolic diseases, such as diabetes and renal dysfunction, as well as severe anemia or inherited hemoglobin disorders

- children and teenagers who are on long-term aspirin therapy
- women who will be in their second or third trimester during flu season or women who are nursing
- anyone who is immunocompromised, including HIV-infected persons, **cancer** patients, organ transplant recipients, and patients receiving steroids, and those receiving **chemotherapy** or radiation therapy
- anyone in contact with the above groups, such as teachers, care givers, healthcare personnel, and **family** members
- travelers to foreign countries

A person need not be in one of the at-risk categories listed above, however, to receive a flu vaccination. Anyone who wants to forego the discomfort and inconvenience of an influenza attack may receive the vaccine.

Parental concerns

Parents should make sure that their children who fall into any of the risk categories should be vaccinated against the flu. Pregnant women in the second or third trimesters should also be vaccinated. Flu vaccines are available through pediatricians or local public health departments. Parents should also make sure kids follow good hygiene practices, including regular hand washing, and covering the mouth when sneezing or coughing. Children may acquire secondary infections, such as ear infections or sinus infections, so parents should call the pediatrician if a child develops a high fever, sudden pain in the ears or sinuses, or develops a productive cough with thick yellow-green phlegm.

Insect sting allergy

Definition

Many children experience insect **stings** every year. For most of them, these stings only cause mild **pain** and discomfort lasting for just a period of hours. Symptoms might include swelling, **itching**, and redness at the sting site. However, some children are allergic to insect stings. When they are stung by an insect to which they are allergic, their bodies produce an antibody called immunoglobulin E (IgE), which reacts with the insect venom and triggers the release of various chemicals, including histamine, that cause the allergic reaction. Stings may be life threatening for a small number of children. These severe allergic reactions may develop quickly and can involve several body organs. This type of reaction is called **anaphylaxis** and can be fatal.

Description

The majority of insect stings in the United States are from wasps, hornets, bees, yellow jackets, and fire ants. The class of insects capable of injecting venom into a person is called Hymenoptera. With the exception of fire ants, all of these insects are found throughout the United States. Fire ants are found primarily in the southeastern region of the country but have also been noted in some western states.

Insect venom is made up of proteins and other substances that usually only cause itching, pain, and swelling in those who are stung. This local reaction is usually confined to the site of the sting. Sometimes the redness and swelling may extend from the sting site and cover a larger area of the body. These large, local, non-allergic reactions can persist for days. Occasionally the site may become infected, requiring antibiotic treatment. Although most local reactions are not serious, if they are near the face or neck, swelling can block the airway and cause serious problems.

Some children may have a venom allergy, and more serious reactions can result if they are stung. It is important to note that allergic reactions to stings normally do not occur after the initial sting. A reaction may take place after two or more stings that have happened over an extended period of time. Therefore, it is essential to be aware of the possibility for allergic symptoms in children, even if they have been stung previously and had no reaction.

Demographics

It is estimated that over 2 million Americans are allergic to stinging insects. Up to one million hospital emergency room visits occur annually because of insect stings. Between 50 and 150 Americans die each year as a result of insect sting-induced anaphylaxis. It is possible that this number may be markedly underestimated. Bee, wasp, and insect stings cause more deaths in the United States than any other kind of injection of venom. Most deaths occur in people 35 to 45 years of age. About one out of 100 children has a systemic allergic reaction from the sting of an insect. Fifty percent of deaths occur within 30 minutes of the sting.

Causes and symptoms

Allergic reactions to insect stings result from an overreaction of a child's immune system to the venom injected by the insect. After the first sting, the child's body produces an allergic substance called immunoglobulin E (IgE) antibody, which reacts with the insect venom. If the child is stung again by the same type of insect or by one from a similar species, the insect venom will interact with the IgE antibody produced in response to the previous sting. This in turn causes the release of histamine and several other chemicals that cause allergic symptoms.

The sting of an insect may only cause a local response, where pain, redness, itching, and swelling are confined to the site of the sting. This type of reaction is considered normal. The normal reaction to fire ant stings is different. Clear blisters usually form within several hours then become cloudy within 24 hours. (The reaction usually presents in a ring or cluster, since a fire ant pivots and repeatedly stings. Also, fire ants travel in groups and a child may receive multiple stings from many ants.)

Larger allergic reactions often affect almost the entire arm, leg, foot, hand, or other area of the sting. Swelling occurs, and may last as long as seven to 10 days. The child may also experience a low-grade **fever**, fatigue, and **nausea**.

Some children experience a more severe allergic reaction. For a small percentage of these individuals, the stings may be life threatening. Severe allergic reactions can involve multiple body organs and may progress rapidly. This reaction is called anaphylaxis. Anaphylaxis is considered a medical emergency and may be fatal. The symptoms of anaphylaxis include the following:

- wheezing
- difficulty breathing
- itching and **hives** over large areas of the body
- swelling in the tongue or throat
- **dizziness**, chest pain, racing heartbeat, or fainting
- stomach cramps, nausea, or **diarrhea**

In severe cases, a rapid fall in blood pressure may result in shock and loss of consciousness. (This is less common in children than adults.) The progression of these symptoms may only take a few minutes.

When to call the doctor

For the majority of insect stings, home care is all that is necessary. However, in many cases medical attention is warranted. If any of the following are true, parents should seek professional assistance promptly.

- Symptoms progress beyond the site of the sting.
- Swelling becomes extensive and painful.
- The sting is located on the head or neck area.
- The child has had severe large reactions in the past.
- There is evidence of infection, such as increased pain, redness, warmth, and swelling at the sting site.

If a child develops hives, has difficulty breathing or swallowing, swelling of the lips or face, fainting, or dizziness, he or she should be transported to an emergency department immediately.

Diagnosis

An allergy to insect stings is determined by the doctor, who takes a thorough history from the patient and his or her parents. The history will usually show that the child has been stung previously. The doctor will also note the presence of the various symptoms common to insect sting allergic reactions. Skin testing may be performed by an allergist to determine the specific sensitivities the child may have.

Treatment

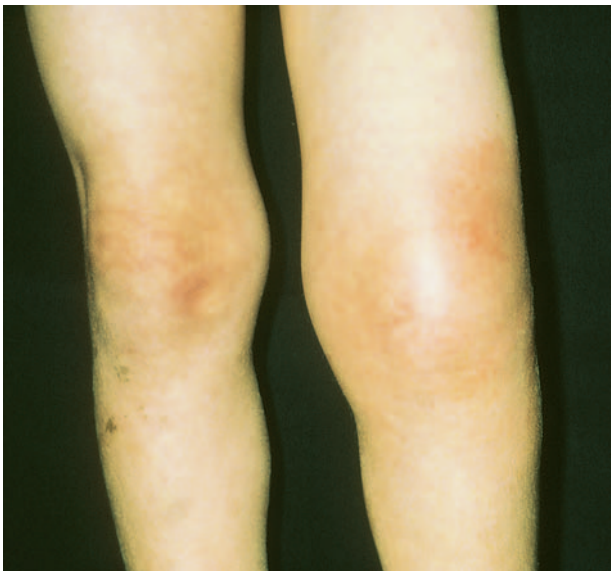
If a child has been stung by an insect that has left its stinger, it should be removed by flicking the fingers at it. Avoid squeezing the venom sac, as this can force more venom into the skin. If fire ants have stung the child, they should be carefully brushed off to prevent repeated stings.

Local treatment is normally all that is needed for small skin reactions. The affected arm or leg should be elevated and an ice pack applied to the area to reduce swelling and pain. Over-the-counter products can also be used to decrease the pain and itching. These include the following:

- products with a numbing effect, including topical anesthetics like benzocaine and phenol
- hydrocortisone products, which may decrease inflammation and swelling
- skin protectants, such as calamine lotion and zinc oxide, which have astringent, cooling, and antibacterial affects
- diphenhydramine, an antihistamine, which will help to control itching, and will counter some of the substances produced as part of the reaction
- ibuprofen or **acetaminophen** for pain relief

It is important to keep the area of the sting clean. The site should be gently cleansed with mild soap and water. Avoid breaking any blisters, as this can increase the chances of a secondary infection.

Any symptoms that progress beyond the local area of the sting require immediate attention. Allergic reactions to insect stings are considered medical emergencies. The physician will treat the child with epinephrine (adrenaline), which is usually given as an injection into the arm. An antihistamine such as diphenhydramine is usually given by mouth or injection to diminish the histamine reaction. Gluococorticoids, such as prednisone or methylprednisolone, are often given to decrease any swelling and to suppress the immune response. The physician may write prescriptions for both **antihistamines** and steroids to take after the child leaves the hospital.



Swelling in the patient's left knee from an allergic reaction to a wasp sting. *(© Dr. P. Marazzi/Photo Researchers, Inc.)*

After a child has experienced a severe allergic reaction and received emergency treatment, the doctor may write a prescription for a self-injecting epinephrine device. This device should be carried by the parent or child at all times, especially when the child is out of reach of medical care, such as on an airplane or in the woods. However, sometimes epinephrine is not enough, and other treatment may be needed. Whenever children with a known severe insect sting allergy are stung, they should receive prompt medical attention, even if they have received an epinephrine injection.

Prognosis

Prompt treatment normally prevents immediate complications, but a delay in the treatment of a severe allergic reaction can result in rapid deterioration and even death. The long-term prognosis is usually good, with the rare exception of possible local infections. If a child develops anaphylaxis after an insect sting, that child is at an increased risk of developing anaphylaxis if stung again.

Prevention

Obviously the best way to avoid an allergic reaction from an insect sting is to avoid getting stung in the first

KEY TERMS

Allergy shots—Injections given by an allergy specialist to desensitize an allergic person. Also known as immunotherapy treatment.

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

place. One way to do this is to be able to identify stinging insects and where they live.

- Honeybees have a fuzzy, rounded body with dark brown coloring and yellow markings. After stinging, the honeybee normally leaves its barbed stinger in its victim, and then the bee dies. Honeybees are usually not aggressive and will only sting if provoked. However, the so-called "killer bees," or Africanized honeybees, are far more aggressive and may sting in swarms. Wild honeybees live in honeycombs or colonies in cavities of buildings or in hollow trees. Africanized honeybees may nest in old tires or holes in the ground, in house frames, or between fence posts.
- Yellow jackets are black with yellow markings. Their nests have a papier-mâché appearance and are usually located underground. However, they can also be found in woodpiles, in the walls of frame buildings, or in masonry cracks.
- Paper wasps have slender, elongated bodies and are black, red, or brown with yellow markings. Their nests are also made of a paper-like substance that opens downward, in a circular comb of cells. Their nests are often located behind shutters, in shrubs or woodpiles, or under eaves.
- Fire ants are reddish brown to black stinging insects. They build nests of dirt in the ground that may be quite tall. Fire ants attack with little warning.

A variety of precautionary measures will decrease the chances of a child getting stung.

- Avoid walking barefoot on lawns and wear closed-toe shoes. The majority of honeybee stings occur on the bottom of the foot when a child steps on the bee.
- Hire an exterminator to destroy nests and hives around the home.
- The smell of food attracts insects, so be careful when eating, drinking, or cooking outdoors. Keep food covered.
- Remain calm and quiet if flying insects are noted and move away slowly. Do not attempt to swat them.
- Avoid using highly scented perfumes, colognes, or hair sprays.
- Avoid wearing brightly colored clothing.
- Do not wear loose fitting garments that can trap insects between the material and skin.
- Keep the areas around trash containers clean and at some distance away from where children are playing.

Allergy shots

Allergy shots for insect stings, also known as venom immunotherapy, can be an effective treatment for children who experience a severe reaction to insect stings. Any child who has had a significant reaction to an insect sting should be evaluated by an allergy specialist. Not all children who have had a reaction will get allergy shots, but many should. It was once believed that most children would outgrow insect sting **allergies** and that allergy shots were not needed. However, as of 2004, it is known that about one in five will remain allergic into adulthood. Because of this pattern, it is recommended that immunotherapy should be used for the approximately 40 percent of children who experience moderate-to-severe systemic reactions to insect stings.

Venom immunotherapy is a highly effective **vaccination** program that actually prevents future sting reactions in most patients who receive them. The child is initially tested to determine their individual sensitivities. The treatment normally involves twice weekly injections of venom in dosages that are gradually increased over about 10 to 20 weeks. At this point, a maintenance dosage is administered about every one to two months. Allergy shots given in childhood can protect the child for 10 to 20 years.

Nutritional concerns

For children who have a known allergy to the venom of honeybees, parents need to use caution (and consult with a physician) before using any honeybee products.

Parental concerns

Parents should be aware of the potential risks of insect stings and should teach their children to take measures to avoid being stung. If their child does get stung, parents need to begin treatment immediately and watch the child closely for any signs of allergic reaction. If these do occur, parents should transport their child immediately to a hospital emergency department.

Intelligence

Definition

Intelligence is an abstract concept whose definition continually evolves and often depends upon current social values as much as scientific ideas. Modern definitions refer to a variety of mental capabilities, including the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly, and learn from experience, as well as the potential to do these things.

Description

Several theories about intelligence emerged in the twentieth century and with them debate about the nature of intelligence and whether it determined by hereditary factors, the environment, or both. As methods developed to assess intelligence, experts theorized about the measurability of intelligence, its accuracy, and the field known as psychometrics, a branch of psychology dealing with the measurement of mental traits, capacities, and processes. Publication in 1994 of *The Bell Curve: Intelligence and Class Structure in American Life* by Richard J. Herrnstein and Charles Murray stirred the controversy. Their findings pointed to links between social class, race, and intelligence quotient (IQ) scores, despite questions by many about the validity of IQ tests as a measurement of intelligence or a predictor of achievement and success.

Part of the problem regarding intelligence stems from the fact that nobody has adequately defined what intelligence really means. In everyday life, people have a general understanding that some people are "smart," but when they try to define "smart" precisely, they often have difficulty because a person can be gifted in one area and average or below in another. To explain this phenomenon, some psychologists have developed theories to include multiple components of intelligence.

Since about 1970, psychologists have expanded the notion of what constitutes intelligence. Newer definitions of intelligence encompass more diverse aspects of thought and reasoning. For example, American psychologist Robert Sternberg developed a three-part theory of intelligence which states that behaviors must be viewed within the context of a particular culture; that a person's experiences impact the expression of intelligence; and that certain cognitive processes control all intelligent behavior. When all these aspects of intelligence are viewed together, the importance of how people use their intelligence becomes more important than the question of "how much" intelligence a person has. Sternberg has suggested that some intelligence tests focus too much on what a person has already learned rather than on how well a person acquires new skills or knowledge.

Another multifaceted approach to intelligence is Howard Gardner's proposal that people have eight intelligences:

- Musical: Children with musical intelligence are always singing or tapping out a beat. They are aware of sounds others miss. Musical children are discriminating listeners.
- Linguistic: Children with linguistic intelligence excel at reading, writing, telling stories, and doing crossword or other word puzzles.
- Logical-Mathematical: Children with this type of intelligence are interested in patterns, categories, and

relationships. They are good at mathematic problems, science, strategy games, and experiments.

- Bodily-Kinesthetic: These children process knowledge through their senses. They usually excel at athletics and **sports**, dance, and crafts.
- Spatial: These children think in images and pictures. They are generally good at mazes and jigsaw puzzles. They often spend lots of time drawing, building (with blocks, Legos, or erector sets), and daydreaming.
- Interpersonal: This type of intelligence fosters children who are leaders among their peers, are good communicators, and understand the feelings and motives of others.
- Intrapersonal: These children are shy, very aware of their own feelings, and are self-motivated.
- Naturalist: This type of intelligence allows children to distinguish among, classify, and use features of the environment. These children are likely to make good farmers, gardeners, botanists, geologists, florists, and archaeologists. Naturalist adolescents can often name and describe the features of every make of car around them.

Intelligence tests

There are many different types of intelligence tests, and they all do not measure the same abilities. Although the tests often have aspects that are related with each other, one should not expect that scores from one intelligence test that measures a single factor will be similar to scores on another intelligence test that measures a variety of factors. Many people are under the false assumption that intelligence tests measure a person's inborn or biological intelligence. Intelligence tests are based on an individual's interaction with the environment and never exclusively measure inborn intelligence. Intelligence tests have been associated with categorizing and stereotyping people. Additionally, knowledge of one's performance on an intelligence test may affect a person's aspirations and motivation to obtain goals. Intelligence tests can be culturally biased against certain groups.

STANFORD-BINET INTELLIGENCE SCALES Consisting of questions and short tasks arranged from easy to difficult, the Stanford-Binet measures a wide variety of verbal and nonverbal skills. Its fifteen tests are divided into the following four cognitive areas: verbal reasoning (vocabulary, comprehension, absurdities, verbal relations); quantitative reasoning (math, number series, equation building); abstract/visual reasoning (pattern analysis, matrices, paper folding and cutting, copying); and short-term memory (memory for sentences, digits, and objects, and bead memory). A formula is used to arrive at the intelligence quotient, or IQ. An IQ of 100 means that the child's chronological and mental ages match. Traditionally, IQ scores of 90–109 are considered average; scores below 70 indicate **mental retardation**. Gifted children achieve scores of 140 or above. Revised in 1986, the Stanford-Binet intelligence test can be used with children starting at age two. The test is widely used to assess **cognitive development** and often to determine placement in **special education** classes.

WECHSLER INTELLIGENCE SCALES The Wechsler intelligence scales are divided into two sections: verbal and nonverbal, with separate scores for each. Verbal intelligence, the component most often associated with academic success, implies the ability to think in abstract terms using either words or mathematical symbols. Performance intelligence suggests the ability to perceive relationships and fit separate parts together logically into a whole. The inclusion of the performance section in the Wechsler scales is especially helpful in assessing the cognitive ability of children with speech and **language disorders** or whose first language is not English. The test can be of particular value to school psychologists screening for specific learning disabilities because of the number of specific subtests that make up each section.

KAUFMAN ASSESSMENT BATTERY FOR CHILDREN The Kaufman **Assessment** Battery for Children (KABC) is an intelligence and achievement test for children ages 2.5–12.5 years. It consists of 16 subtests, not all of which are used for every age group. A distinctive feature of the KABC is that it defines intelligence as problem-solving ability rather than knowledge of facts, which it considers achievement. This distinction is evident in the test's division into two parts—intelligence and achievement—which are scored separately and together. The test's strong emphasis on memory and lesser attention to verbal expression are intended to offset cultural disparities between black and white children. In addition, the test may be given to non-native speakers in their first language and to hearing impaired children using American Sign Language.

Infancy

Babies were once thought to enter the world with minds that were blank slates that developed through a lifetime of experiences. It is as of the early 2000s known that newborns have brains as sophisticated as the most powerful supercomputers, pre-wired with a large capacity for learning and knowledge. In the first few months of life, a baby's brain develops at an amazing rate. At birth, infants have the senses of sight, sound, and touch. At about three or four months, infants begin to develop memory, and it expands quickly. Modern brain imaging

techniques have confirmed that children's intelligence is not just hereditary but is also affected greatly by environment. Babies' brains develop faster during their first year than at any other time. By three months, babies can follow moving objects with their eyes, are extremely interested in their surroundings, and can recognize familiar sounds, especially their parents' voices. At six months, infants begin to remember familiar objects, react to unfamiliar people or situations, and realize that objects are permanent. At seven months, babies can recognize their own name. Parents can help their infants develop their intelligence by talking and reading to them, playing with them, and encouraging them to **play** with a variety of age-appropriate **toys**.

Toddlerhood

Toddlers' lives generally revolve around experimenting with and exploring the environment around them. The primary source of learning for toddlers is their families. During their third year, toddlers should be able to sort and group similar objects by their appearance, shape, and function. They also start to understand how some things work, and their memory continues to improve rapidly. They are able to remember and seek out objects that are hidden or moved to a different location. Toddlers should be able to follow two-step instructions and understand contrasting ideas, such as large and small, inside and outside, opened and closed, and more and less. Toddlers also develop a basic understanding of time in relation to their regular activities, such as meals and bedtime.

Preschool

At age three, preschoolers can say short sentences, have a vocabulary of about 900 words, show great growth in communication, tell simple stories, use words as tools of thought, want to understand their environment, and answer questions. At age four, children can use complete sentences, have a 1,500-word vocabulary, frequently ask questions, and learn to generalize. They are highly imaginative, dramatic, and can draw recognizable simple objects. Preschoolers also should be able to understand basics concepts such as size, numbers, days of the week, and time. They should have an attention span of at least 20 minutes. Children this age are still learning the difference between reality and fantasy. Their curiosity about themselves and the world around them continues to increase.

School age

At age five, children should have a vocabulary of more than 2,000 words. They should be able to tell long stories, carry out directions well, read their own name, count to ten, ask the meaning of words, know colors, begin to know the difference between fact and fiction, and become interested in their surrounding environment, neighborhood, and community. Between the ages of seven and 12, children begin to reason logically and organize their thoughts coherently. However, generally, they can only think about actual physical objects; they cannot handle abstract reasoning. They also begin to lose their self-centered way of thinking. During this age range, children can master most types of conservation experiments and begin to understand that some things can be changed or undone. Early school-age children can coordinate two dimensions of an object simultaneously, arrange structures in sequence, change places or reverse the normal order of items in a series, and take something such as a story, incident, or play out of its usual setting or time and relocate it in another.

Gifted 11-year-old jazz pianist Matt Savage. Many gifted musicians have above-average intelligence. *(© Rick Friedman/Corbis.)*

Starting at about age 12, adolescents can formulate hypotheses and systematically test them to arrive at an answer to a problem. For example, they can formulate hypotheses based on the phrase "what if." They can think abstractly and understand the form or structure of a mathematical problem. Another characteristic of the later school-age years is the ability to reason contrary to fact. That is, if they are given a statement and asked to use it as the basis of an argument, they are capable of accomplishing the task. Until they reach the age of 15 or 16, adolescents are generally not capable of reasoning as an adult. High school-age adolescents continue to gain

KEY TERMS

Autism—A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

Down syndrome—A chromosomal disorder caused by an extra copy or a rearrangement of chromosome 21. Children with Down syndrome have varying degrees of mental retardation and may have heart defects.

Fragile X syndrome—A genetic condition related to the X chromosome that affects mental, physical, and sensory development. It is the most common form of inherited mental retardation.

Intelligence quotient (IQ)—A measure of somebody's intelligence, obtained through a series of aptitude tests concentrating on different aspects of intellectual functioning.

Kaufman Assessment Battery for Children—An intelligence and achievement test for children ages 2.5 to 12.5 years.

Psychometrics—The development, administration, and interpretation of tests to measure mental or psychological abilities. Psychometric tests convert an individual's psychological traits and attributes into a numerical estimation or evaluation.

Stanford-Binet intelligence scales—A device designed to measure somebody's intelligence, obtained through a series of aptitude tests concentrating on different aspects of intellectual functioning. An IQ score of 100 represents "average" intelligence.

Wechsler intelligence scales—A test that measures verbal and non-verbal intelligence.

cognitive and study skills. They can adapt language to different contexts, master abstract thinking, explore and prepare for future careers and roles, set goals based on feelings of personal needs and priorities, and are likely to reject goals set by others.

Common problems

Autism

Autism is a profound mental disorder marked by an inability to communicate and interact with others. The condition's characteristics include language abnormalities, restricted and repetitive interests, and the appearance of these characteristics in early childhood. As many as two-thirds of children with autistic symptoms are mentally deficient. However, individuals with autism can also be highly intelligent. Autistic individuals typically are limited in their ability to communicate nonverbally and verbally. About half of all autistic people never learn to speak. They are likely to fail in developing social relationships with peers, have limited ability to initiate conversation if they do learn how to talk, and show a need for routine and ritual. Various abnormalities in the autistic brain have been documented. These include variations in the frontal lobes of the brain that focus on control and planning and in the limbic system, a group of structures in the brain that are linked to emotion, behavior, smell, and other functions. Autistic individuals may suffer from a limited development of the limbic system. This would explain some of the difficulties faced by autistic individuals in processing information.

Mental retardation

Mental retardation usually refers to people with an IQ below 70. According to the American Psychiatric Association, a mentally retarded person is significantly limited in at least two of the following areas: self-care, communication, home living, social-interpersonal skills, self-direction, use of community resources, functional academic skills, work, leisure, health, and **safety**. Mental retardation affects roughly 1 percent of the U.S. population. According to the U.S. Department of Education, about 11 percent of school-aged children were enrolled in special education programs for students with mental retardation. There are four categories of mental retardation: mild, moderate, severe, and profound. There are many different causes of mental retardation, both biological and environmental. In about 5 percent of cases, retardation is transmitted genetically, usually through abnormalities in chromosomes, such as **Down syndrome** or **fragile X syndrome**. Children with Down syndrome have both mental and motor retardation. Most are severely retarded, with IQs between 20 and 49. Fragile X syndrome, in which a segment of the chromosome that determines gender is abnormal, primarily affects males.

Parental concerns

Autism symptoms begins in infancy, but typically the condition is diagnosed between the ages of two to five. The symptoms of mental retardation are usually evident by a child's first or second year. In the case of Down syndrome, which involves distinctive physical characteristics, a diagnosis can usually be made shortly after birth. Mentally retarded children lag behind their peers in developmental milestones such as sitting up,

smiling, walking, and talking. They often demonstrate lower than normal levels of interest in their environment and less responsiveness to others, and they are slower than other children in reacting to visual or auditory stimulation. By the time a child reaches the age of two or three, retardation can be determined using physical and **psychological tests**. Testing is important at this age if a child shows signs of possible retardation because alternate causes, such as impaired hearing, may be found and treated. There is no cure for autism or mental retardation.

When to call the doctor

Parents should consult a healthcare professional if their child's intellectual development appears to be significantly slower than their peers. Children suspected of having intelligence development problems should undergo a comprehensive evaluation to identify their difficulties as well as their strengths. Since no specialist has all the necessary skills, many professionals might be involved. General medical tests as well as tests in areas such as neurology (the nervous system), psychology, psychiatry, special education, hearing, speech and vision, and physical therapy may be needed. A pediatrician or a child and adolescent psychiatrist often coordinates these tests.

Parents should pay close attention to possible symptoms in their children. Autism is diagnosed by observing the child's behavior, **communication skills**, and social interactions. Medical tests should rule out other possible causes of autistic symptoms. Criteria that mental health experts use to diagnose autism include problems developing friendships, problems with make-believe or social play, endless repetition of words or phrases, difficulty in carrying on a conversation, obsessions with rituals or restricted patterns, and preoccupation with parts of objects. A diagnosis of mental retardation is made if an individual has an intellectual functioning level well below average and significant limitations in two or more adaptive skill areas. If mental retardation is suspected, a comprehensive physical examination and medical history should be done immediately to discover any organic cause of symptoms. If a neurological cause such as brain injury is suspected, the child may be referred to a neurologist or neuropsychologist for testing.

Intermittent explosive disorder

Definition

Intermittent explosive disorder (IED) is a mental disturbance that is characterized by specific episodes of

violent and **aggressive behavior** that may involve harm to others or destruction of property. IED is discussed in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition *(DSM-IV)* under the heading of "Impulse-Control Disorders Not Elsewhere Classified." As such, it is grouped together with kleptomania, pyromania, and pathological gambling.

A person must meet certain specific criteria to be diagnosed with IED:

- There must be several separate episodes of failure to restrain aggressive impulses that result in serious assaults against others or property destruction.
- The degree of aggression expressed must be out of proportion to any provocation or other stressor prior to the incidents.
- The behavior cannot be accounted for by another mental disorder, substance abuse, medication side effects, or such general medical conditions as epilepsy or head injuries.

Description

People diagnosed with IED sometimes describe strong impulses to act aggressively prior to the specific incidents reported to the doctor and/or the police. They may experience racing thoughts or a heightened energy level during the aggressive episode, with fatigue and depression developing shortly afterward. Some report various physical sensations, including tightness in the chest, **tingling** sensations, tremor, hearing echoes, or a feeling of pressure inside the head.

Many people diagnosed with IED appear to have general problems with anger or other impulsive behaviors between explosive episodes. Some are able to control aggressive impulses without acting on them while others act out in less destructive ways, such as screaming at someone rather than attacking them physically.

DSM-IV's classification of IED is not universally accepted. Many psychiatrists do not place intermittent explosive disorder into a separate clinical category but consider it a symptom of other psychiatric and mental disorders. In many cases individuals diagnosed with IED do in fact have a dual psychiatric diagnosis. IED is frequently associated with mood and **anxiety** disorders; substance abuse; eating disorders; and narcissistic, paranoid, and antisocial **personality disorders**.

One culturally specific psychiatric syndrome resembling IED is amok, which was first reported in Malaysia. As the English phrase "running amok" implies, the syndrome is characterized by sudden outbursts of indiscriminate aggression or murderous rage that are completely unprovoked or that are triggered by trivial slights.

Demographics

Although the editors of *DSM-IV* stated in 2000 that IED "is apparently rare," a group of researchers in Chicago reported in 2004 that it is more common than previously thought. They estimate that 1.4 million persons in the United States meet the criteria for IED, with a total of 10 million meeting the lifetime criteria for the disorder.

The symptoms of IED can appear at any time from late childhood through the early 20s, although the disorder is not usually diagnosed in children. The onset may be abrupt, without any warning in the form of a period of gradual change in the child or adolescent's behavior. IED appears to be more common in people from families with a history of **mood disorders** or substance abuse. The severity of the disorder appears to peak in people in their thirties and to decline rapidly in people over 50.

With regard to gender, 80 percent of individuals diagnosed with IED in the United States are adolescent and adult males; amok is a syndrome that almost always involves males. Women do experience IED, however, and have reported it as part of **premenstrual syndrome** (PMS).

Causes and symptoms

Causes

As with other impulse-control disorders, the cause of IED has not been determined. As of 2004, researchers disagreed as to whether it is learned behavior, the result of biochemical or neurological abnormalities, or a combination of factors. Some scientists have reported abnormally low levels of serotonin, a neurotransmitter that affects mood, in the cerebrospinal fluid of some anger-prone persons, but the relationship of this finding to IED is not clear. Similarly, some individuals diagnosed with IED have a medical history that includes migraine headaches, seizures, attention-deficit hyperactivity disorder, or developmental problems of various types, but it is not clear that these cause IED, as most persons with migraines, learning problems, or other neurological disorders do not develop IED.

Symptoms

Some psychiatrists who take a cognitive approach to mental disorders believe that IED results from rigid beliefs and a tendency to misinterpret other people's behavior in accordance with these beliefs. According to

Aaron Beck, a pioneer in the application of cognitive therapy to violence-prone individuals, most people diagnosed with IED believe that other people are basically hostile and untrustworthy, that physical force is the only way to obtain respect from others, and that life in general is a battlefield. Beck also identifies certain characteristic errors in thinking that go along with these beliefs:

- Personalizing: The person interprets others' behavior as directed specifically against him.
- Selective perception: The person notices only those features of situations or interactions that fit his negative view of the world rather than taking in all available information.
- Misinterpreting the motives of others: The person tends to see neutral or even friendly behavior as either malicious or manipulative.
- Denial: The person blames others for provoking his violence while denying or minimizing his own role in the fight or other outburst.

When to call the doctor

Parents should seek help for any older child or adolescent who has had more than one episode of irrationally angry or destructive behavior—if possible before the individual causes serious injury to others, has his education cut short, or gets into trouble with the law.

Diagnosis

The diagnosis of IED is basically a diagnosis of exclusion, which means that the doctor will eliminate such other possibilities as neurological disorders, mood or substance abuse disorders, anxiety syndromes, and personality disorders before deciding that the patient meets the *DSM-IV* criteria for IED. In addition to taking a history and performing a physical examination to rule out general medical conditions, the doctor may administer one or more psychiatric inventories or screening tests to determine whether the person meets the criteria for other mental disorders.

In some cases the doctor may order imaging studies or refer the person to a neurologist to rule out brain tumors, traumatic injuries of the nervous system, epilepsy, or similar physical conditions.

Treatment

Emergency room treatment

A person brought to a hospital emergency room by **family** members, police, or other emergency personnel after an explosive episode will be evaluated by a psychiatrist to see whether he can safely be released after any necessary medical treatment. If the patient appears to be a danger to self or others, he or she may be committed for further treatment. In terms of legal issues, a physician is required by law to notify the specific individuals as well as the police if the patient threatens to harm particular persons. In most states, the doctor is also required by law to report suspected abuse of children, the elderly, or other vulnerable family members.

The doctor will perform a thorough medical examination to determine whether the explosive outburst was related to substance abuse, withdrawal from drugs, head trauma, delirium, or other physical conditions. If the patient becomes violent inside the hospital, he or she may be placed in restraints or given a tranquilizer (usually either lorazepam [Ativan] or diazepam [Valium]), most often by injection. In addition to the physical examination, the doctor will obtain as detailed a history as possible from the family members or others who accompanied the patient.

Medications

Medications that have been shown to be beneficial in treating IED in nonemergency situations include lithium, carbamazepine (Tegretol), propranolol (Inderal), and such selective serotonin reuptake inhibitors as fluoxetine (Prozac) and sertraline (Zoloft). Adolescents diagnosed with IED have been reported to respond well to clozapine (Clozaril), a drug normally used to treat **schizophrenia** and other psychotic disorders.

Psychotherapy

Some persons with IED benefit from cognitive therapy in addition to medications, particularly if they are concerned about the impact of their disorder on their education, employment, or interpersonal relationships. Psychoanalytic approaches are not useful in treating IED.

Alternative treatment

Some patients diagnosed with IED have reported being helped by biofeedback, mindfulness meditation, and various forms of martial arts. Mind/body therapies appear to be helpful in gaining greater self-control, while martial arts workouts help to channel the person's physical energy or muscular tension.

Prognosis

The prognosis of IED depends on several factors that include the individual's socioeconomic status, the stability of the immediate family, the values of the

KEY TERMS

Amok—A culture-specific psychiatric syndrome first described among the Malays, in which adolescent or adult males are overcome by a sudden fit of murderous fury provoked by a perceived insult or slight. Some researchers consider amok to be a variant of intermittent explosive disorder.

Cognitive therapy—Psychological treatment aimed at changing a person's way of thinking in order to change his or her behavior and emotional state.

Delirium—Sudden confusion with a decreased or fluctuating level of consciousness.

Kleptomania—An impulse control disorder in which one steals objects that are of little or no value.

Neurotransmitter—A chemical messenger that transmits an impulse from one nerve cell to the next.

Pyromania—An impulse control disorder characterized by fire setting.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

surrounding neighborhood, and his or her motivation to change. One reason why the Chicago researchers think that IED is more common than previously thought is that most people who meet the criteria for the disorder do not seek help for the problems in their lives that result from it. The researchers found that although 88 percent of the 253 individuals with IED whom they studied were upset by the results of their explosive outbursts, only 13 percent had ever asked for treatment in dealing with it.

Prevention

Since the cause(s) of IED are not fully understood as of the early 2000s, preventive strategies should focus on treatment of young children who may be at risk for IED before they enter **adolescence**.

Parental concerns

An adolescent or young adult diagnosed with IED can cause severe disruption to family life in many different areas, ranging from the economic costs of property damage or accidents to emotional problems in other family members to serious legal penalties. It is important for the person's family to know that they do not have to tolerate violent behavior, destruction of property, harm to pets, or abuse of smaller or weaker family members. Depending on the specific situation and the pattern of previous explosive episodes, family members of adolescents or young adults may decide to leave the immediate situation, call the police or other emergency help, or take out a restraining order.

Another important dimension of IED is the damage done to the person's own life. One reason for seeking treatment for IED is to get help before the person establishes a record of school suspensions, arrests or other legal problems, hospitalizations for injuries sustained in fights or automobile accidents, or repeated firings from jobs. A history of such issues can lead to a self-fulfilling prophecy in which the person with IED continues to have episodes of uncontrolled aggression because of the belief that he or she cannot overcome the past.

Intersex states

Definition

Intersex states are conditions where a newborn's sex organs (genitals) look unusual, making it impossible to identify the gender of the baby from its outward appearance.

Description

All developing babies start out with external sex organs that look female. If the baby is male, the internal sex organs mature and begin to produce the male hormone testosterone. If the hormones reach the tissues correctly, the external genitals that looked female change into the scrotum and penis. Sometimes, the genetic sex (as indicated by chromosomes) may not match the appearance of the external sex organs.

Persons with intersex states can be classified as a true hermaphrodite, a female pseudohermaphrodite, or a male pseudohermaphrodite. This is determined by examining the internal and external structures of the child.

True hermaphrodites are born with both ovaries and testicles. They also have mixed male and female external genitals. This condition is extremely rare.

This infant was born with female and male genitalia. *(Photograph by Mike Peres. Custom Medical Stock Photo, Inc.)*

A female pseudohermaphrodite is a genetic female. However, the external sex organs have been masculinized and look like a penis. This may occur if the mother takes the hormone progesterone to prevent a miscarriage, but more often it is caused by an overproduction of certain hormones.

A male pseudohermaphrodite is a genetic male. However, the external sex organs fail to develop normally. Intersex males may have testes and a female-like vulva, or a very small penis.

Demographics

About one in every 2,000 births results in a baby whose sex organs look unusual. True hermaphrodites are extremely rare.

Any abnormality in chromosomes or sex hormones, or in the unborn baby's response to the hormones, can lead to an intersex state in a newborn. Intersex states may also be caused by a condition called **congenital adrenal hyperplasia**, which occurs in about one out of every 5,000 newborns. This disease blocks the baby's metabolism and can cause a range of symptoms, including abnormal genitals.

Common problems

When doctors are uncertain about a newborn's sex, a specialist in infant hormonal problems is consulted as soon as possible. Ultrasound can locate a uterus behind the bladder and can determine if there is a cervix or uterine canal. Blood tests can check the levels of sex hormones in the baby's blood, and chromosome analysis (called karyotyping) can determine sex. Explorative

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

surgery or a biopsy of reproductive tissue may be necessary. Only after thorough testing can a correct diagnosis and determination of gender be made.

Parental concerns

Treatment of intersex states is controversial. Traditional treatment assigns sex according to test results. Most doctors believe this gives the child the potential to identify with a sex. Treatment may then include reconstructive surgery followed by hormone therapy. Babies born with congenital adrenal hyperplasia can be treated with cortisone-type drugs and sometimes surgery.

Counseling should be given to the entire **family** of an intersex newborn. Families should explore all available medical and surgical options. Counseling should also be provided to the child when he or she is old enough.

Since the mid-1950s, doctors have typically assigned a sex to an intersex infant based on how easy reconstructive surgery would be. The American Academy of Pediatrics states that children with these types of genitals can be raised successfully as members of either sex, and recommends surgery within the first 15 months of life.

Some people are critical of this approach, including intersex adults who were operated on as children. The remolded genitals do not function sexually and can be the source of lifelong **pain**. They suggest that surgery be delayed until the individual can make informed choices about surgery and intervention.

Intestinal obstructions

Definition

Intestinal obstructions are a partial or complete blockage of the small or large intestine, resulting in failure of the contents of the intestine to pass through the bowel normally.

Description

Intestinal obstructions can occur in children as a result of congenital defects, with symptoms appearing any time between birth and adulthood. Abdominal **pain** and **vomiting** are the most frequent symptoms and a common cause of admission to emergency rooms. It is difficult for doctors to predict at birth which infants will suffer intestinal obstructions.

Intestinal obstructions can be mechanical or non-mechanical. Mechanical obstruction is the physical blockage of the intestine by a tumor, scar tissue, or another type of blockage that prevents intestinal contents from getting past the point of obstruction. One type of mechanical obstruction is caused by the bowel twisting on itself (volvulus) or telescoping into itself (intussusception). Mechanical obstruction can also result from hernias, fecal impaction, abnormal tissue growth, the presence of foreign bodies in the intestines, or inflammatory bowel disease (Crohn's disease). Non-mechanical obstruction occurs when the normal wavelike muscular contractions of the intestinal walls (peristalsis), which ordinarily move the waste products of digestion through the digestive tract, are disrupted (as in spastic **ileus**, dysmotility syndrome, or psuedo-obstruction) or stopped altogether as in paralysis of the bowel walls (paralytic ileus).

Mechanical obstruction in infants under one year of age can be caused by meconium ileus, volvulus, intussusception, and hernias. Meconium ileus is a disorder that occurs in newborns in which the meconium, the neonate's first fecal excretion after birth, is abnormally thick and stringy, rather than the collection of mucus and bile that is normally passed. The abnormal meconium blocks the intestines and must be removed with an enema or through surgery. This condition is due to a deficiency of the enzyme trypsin and other digestive enzymes produced in the pancreas. It can be an early clue that the infant may have **cystic fibrosis**. Intussusception commonly follows an infection that causes increased lymph node size in the gut, which acts as the point of folding for the intussusception.

Hirschsprung's disease (congenital megacolon), which may involve meconium ileus, is a motility disorder that is responsible for 25 percent of newborn non-mechanical intestinal obstructions, though symptoms may not develop until late in infancy or in childhood, delaying diagnosis. Children diagnosed with Hirschsprung's disease lack nerve cells (ganglia) in the large intestine, severely affecting the wavelike movements that propel material through the colon. In most affected infants, the first sign is failure to pass a stool (meconium) within 24 to 48 hours after birth. Between birth and age two, these children will likely develop other symptoms, such as chronic **constipation**, small watery stools, a distended abdomen, vomiting, poor appetite, slow weight gain, and **failure to thrive**. Most children will require surgery to remove the affected part of the colon. Surgery can be performed at age six months or as soon as diagnosed in an older infant or child. Symptoms can be removed in at least 90 percent of children born with Hirschsprung's disease. The disease is sometimes associated with other congenital conditions, such as **Down syndrome**.

Volvulus is the twisting of the small or large bowel around itself (malrotation). Volvulus of the large bowel is rare in infants and children; when it does occur it is usually in the sigmoid (sigmoid volvulus) in the lower colon. Duodenal volvulus occurs when the duodenum, the portion of small intestine that connects the stomach and jejunum, is twisted. Twisting of any portion of the intestines may cut off the supply of blood to a loop of bowel (strangulation), reducing the flow of oxygen to bowel tissue (ischemia) and leading to tissue death (gangrene). Strangulation occurs in about 25 percent of bowel obstruction cases and is a serious condition that can progress to gangrene within six to 12 hours.

Intussusception is a condition in which the bowel telescopes into itself like a radio antenna folding up. Intussusception is the most common cause of intestinal obstruction in children between the ages of three months and six years. Boys are twice as likely as girls to suffer intussusception.

Hernias are weaknesses in the abdominal wall that can trap a portion of intestine (incarceration) and cut off

the passage of food and waste through the digestive tract. In 1–5 percent of children, a **hernia** results when a feature of fetal anatomy in the inguinal area of the groin (processus vaginalis, the space through which the testis or ovaries descend) fails to close normally after birth. These inguinal hernias easily become incarcerated, trapping the bowel and causing obstruction. They are sometimes found on both sides (bilateral hernia) and they occur nine times more often in boys than girls. Parents may see a bulge in the groin area when an inguinal hernia is present. Incarceration occurs only rarely after eight years of age. In most cases, the incarcerated hernias are corrected manually rather than surgically by pushing the incarcerated bowel back up into the abdominal cavity.

Congenital adhesions or post-surgical adhesions can also cause intestinal obstruction in children. Adhesions are bands of fibrous tissue that can bind the loops of intestine to each other or to abdominal organs, narrowing the space between the intestinal walls or pulling sections of the intestines out of place, blocking the passage of food and waste. In adults, adhesions are most often caused by repeat surgery; children who have a history of abdominal surgery can also develop adhesions that can obstruct the intestines. It is not known precisely what causes the abnormal growth of fibrous tissue in congenital adhesions.

Demographics

Each year, one in 1,000 individuals of all ages are diagnosed with intestinal obstruction. Adhesions are responsible for 50–70 percent of cases. In children, 2.4 cases of intussusception are reported among 1,000 live births annually in the United States. Inguinal hernias occur in 1–5 percent of infants, with a male to female ratio of nine to one. Volvulus occurs in older children (mean age seven years) with a male to female ratio of 3.5 to one.

Causes and symptoms

The causes of small bowel obstruction in children are most often volvulus, intussusception, adhesions, or abdominal hernia, a weakness in the abdominal wall that traps a portion of intestine. The most frequent causes of large-bowel obstruction are tumors, volvulus, or small pouches that form on the intestinal wall (diverticula) that can fill with waste and expand to block the intestines. Motility disorders such as Hirschsprung's disease and psuedo-obstruction may cause blockages by retarding peristalsis, the intestinal muscle contractions that move food and waste.

Meconium ileus in newborns is caused by increased viscosity of waste products in the intestinal tract, and is sometimes secondary to cystic fibrosis. Its primary symptom will be failure of the infant to eliminate the meconium within the first two days of life.

One of the earliest signs of mechanical intestinal obstruction is abdominal pain or cramps that come and go in waves. Infants typically pull up their legs and cry in pain, then stop crying suddenly. They may behave normally for as long as 15–30 minutes between episodes, only to start crying again when the next cramp begins. The cramping results from the inability of the muscular contractions of the bowel to push the digested food past the obstruction. A classic symptom is passage of "current jelly stool" (i.e. blood) by infants after a crying fit during intussusception. Some children with intussusception may appear lethargic or have altered mental status, believed by physicians to be related to ischemia of the bowel and a decreased level of consciousness.

Vomiting is another typical symptom of intestinal obstruction. The speed of its onset is a clue to the location of the obstruction. Vomiting follows shortly after the pain if the obstruction is in the small intestine, but is delayed if it is in the large intestine. The vomited material may be green from bile or fecal in character. If the blockage is complete, the individual will not pass any gas or feces. If the blockage is only partial, however, **diarrhea** can occur. Initially there is little or no **fever**.

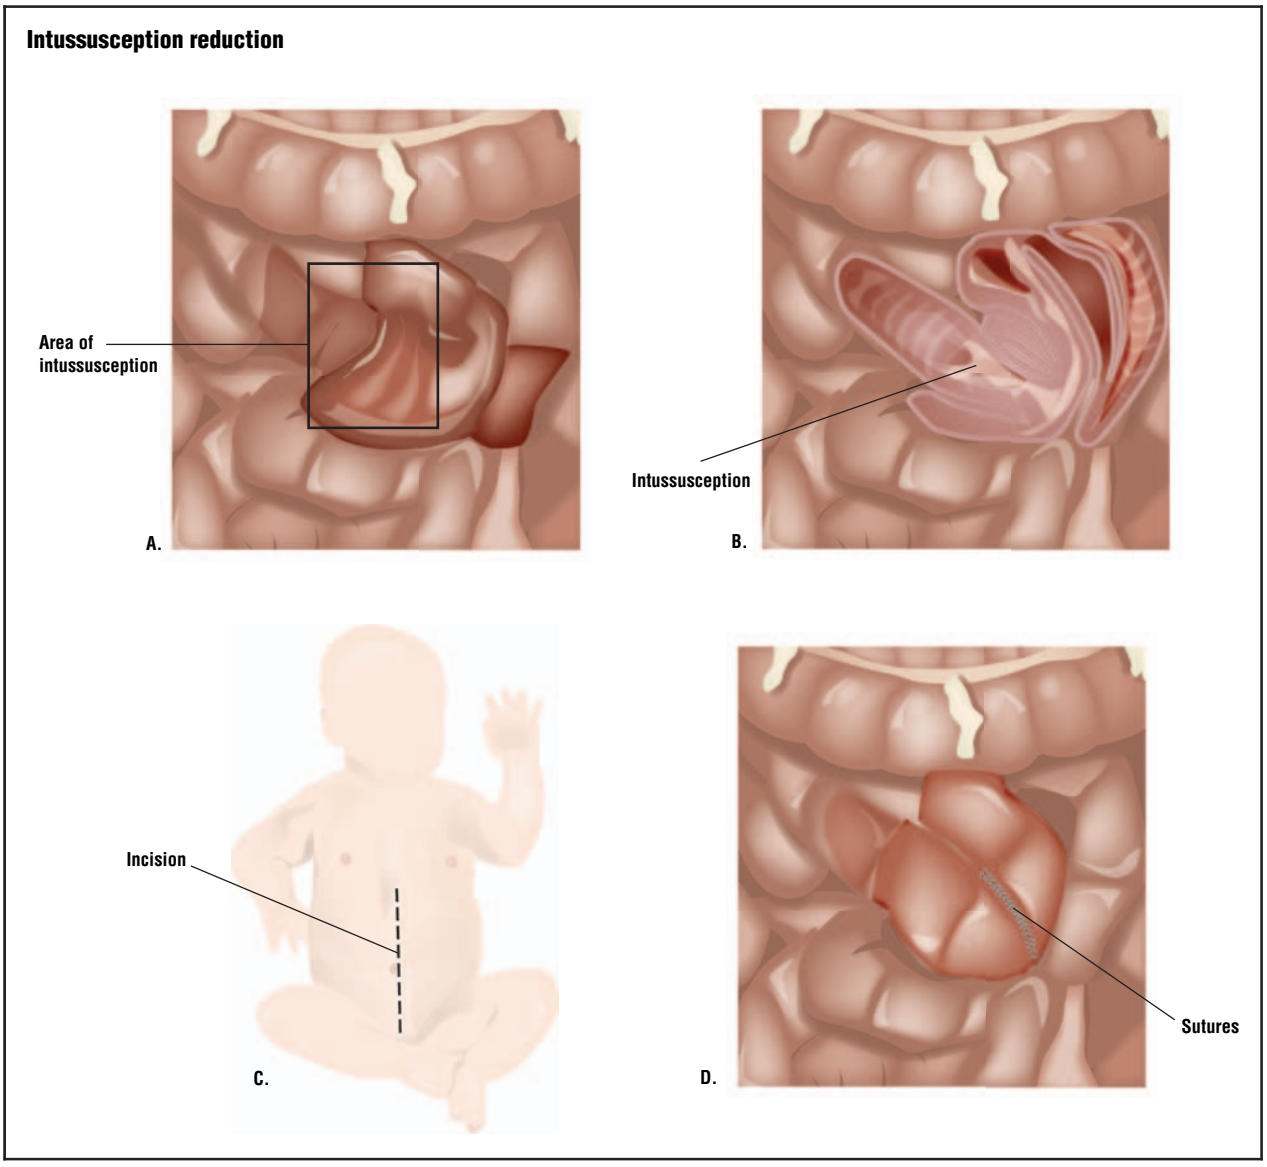
When the material in the bowel cannot move past the obstruction, the body reabsorbs large amounts of fluid and the abdomen becomes sore to the touch and swollen (distended). Persistent vomiting can result in **dehydration**. Fluid imbalances upset the balance of certain important chemicals (electrolytes) in the blood, which can cause complications such as irregular heartbeat and, without correction of the electrolyte imbalance, shock. Kidney failure is a serious complication that can occur as a result of severe dehydration and/or systemic infection from perforation of the bowel.

When to call the doctor

Medical attention is needed early in intestinal obstruction and should be sought as soon as symptoms suggest abdominal distress. Symptoms may begin with abdominal pain or cramping that may cause a toddler or older child to double over in pain. Infants will periodically cry in pain and pull their legs up to their chest. Fever may or may not be present. Vomiting may occur along with pain. If pain and crying occur every 15 or 30 minutes, it is critical to see the pediatrician or go to the emergency room so that early diagnosis can be made and treatment begun.

Diagnosis

If the doctor suspects intestinal obstruction based on the child's symptoms and the physical examination, imaging studies will be ordered that may include abdominal



Intussusception of the bowel results in the bowel telescoping onto itself (A and B). To repair it, an incision is made in the baby's abdomen to expose the bowel (C). If the surgeon cannot manipulate the bowel into a normal shape manually, the area of intussusception will be removed and remaining bowel sutured together (D). *(Illustration by GGS Information Services.)*

x rays, **computed tomography** (CT scan), or an ultrasound evaluation of the abdomen. Abdominal ultrasound is able to effectively visualize and diagnose most obstructions. The x ray images may be enhanced by giving the child a barium enema, a form of contrast or opaque media that allows more detail to be seen in x rays and MRI or CT scans. In a barium enema, barium sulfate is infused through the rectum and the intestinal area is scanned. With contrast enhancement, the exact location of the obstruction can be pinpointed in the scans or x ray film. Sometimes a lighted, flexible fiber optic instrument (sigmoidoscope) may be inserted rectally in conjunction with a barium enema to visualize the bowel. It may not possible to determine if an obstruction is simple or strangulated on scanning, and this will only be determined by performing abdominal surgery.

Diagnostic testing will include a complete blood count (CBC), electrolytes (sodium, potassium, chloride) and other blood chemistries, blood urea nitrogen (BUN), and urinalysis. Coagulation tests may be performed if the child requires surgery.

KEY TERMS

Bowel—The intestine; a tube-like structure that extends from the stomach to the anus. Some digestive processes are carried out in the bowel before food passes out of the body as waste.

Dysmotility—Abnormally slow or fast rhythmic movement of the stomach or intestine.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Gangrene—Decay or death of body tissue because the blood supply is cut off. Tissues that have died in this way must be surgically removed.

Ileus—An obstruction of the intestines usually caused by the absence of peristalsis.

Intussusception—The slipping or telescoping of one part of the intestine into the section next to it.

Ischemia—A decrease in the blood supply to an area of the body caused by obstruction or constriction of blood vessels.

Meconium—A greenish fecal material that forms the first bowel movement of an infant.

Motility—The movement or capacity for movement of an organism or body organ. Indigestion is sometimes caused by abnormal patterns in the motility of the stomach.

Peristalsis—Slow, rhythmic contractions of the muscles in a tubular organ, such as the intestines, that move the contents along.

Shock—A medical emergency in which the organs and tissues of the body are not receiving an adequate flow of blood. This deprives the organs and tissues of oxygen and allows the build-up of waste products. Shock can be caused by certain diseases, serious injury, or blood loss.

Sigmoid colon—The final portion of the large intestine that empties into the rectum.

Strangulated obstruction—An obstruction in which a loop of the intestine has its blood supply cut off.

Volvulus—A twisting of the intestine that causes an obstruction.

Treatment

Children with suspected intestinal obstruction will be hospitalized after the initial diagnostic evaluation. Treatment will likely begin immediately and proceed rapidly to avoid strangulation, which can be fatal. The first step in treatment is inserting a nasogastric tube to suction out the contents of the stomach and intestines. Intravenous fluids will be infused to prevent dehydration and to correct electrolyte imbalances that may have already occurred. Surgery can be avoided in some cases. With volvulus, for example, it may be possible to guide a rectal tube into the intestines to straighten the twisted bowels. In infants, a barium enema may reverse intussusception in 50–90 percent of cases. Another newer contrast agent, gastrografin, may be used; it is believed to have therapeutic properties as well as its ability to enhance scans. An air enema is sometimes used instead of a barium or gastrografin enema. This treatment successfully relieves partial obstruction in many infants. Children usually remain hospitalized for observation for two to three days after these procedures.

Surgical treatment will be necessary if other efforts are unsuccessful in correcting or removing the blockage. Generally, complete obstructions require surgery while partial obstructions do not. Strangulated obstructions require emergency surgery. The obstructed area is removed and part of the bowel is cut away (bowel resection). If the obstruction is caused by tumors, polyps, or scar tissue, they will be surgically removed. Hernias, if present, are repaired to correct the obstruction. **Antibiotics** may be given pre- or post-operatively to avoid the threat of infection at the site of the obstruction. Fluid replacement is given intravenously as needed.

Alternative treatment

Immediate surgery is often the only means of correcting intestinal obstruction. Alternative practitioners may recommend a high fiber diet to encourage proper stool formation; however, simple constipation is not the cause of intestinal obstruction.

Prognosis

Most intestinal obstructions can be corrected with prompt treatment and the affected child will recover without complications. Untreated intestinal obstructions can be fatal, however. The bowel either strangulates or perforates, causing massive infection. Recurrence is likely in as many as 80 percent of those in whom volvulus is treated medically rather than surgically. Recurrences in infants with intussusception are most likely to happen during the first

36 hours after the blockage has been cleared. The mortality rate for unsuccessfully treated infants is 1–2 percent.

Prevention

Most cases of intestinal obstruction are not preventable. Surgery to remove tumors or polyps in the intestines helps prevent recurrences, although adhesions can form after surgery, which can be another cause of obstruction.

Nutritional concerns

Preventing certain types of intestinal problems that may lead to intestinal obstruction may include making sure that the diet includes sufficient fiber to help encourage proper stool formation and regular elimination. High-fiber foods include whole grain breads and cereals; apples and other fresh fruits; dried fruits such as prunes; pumpkin and squash; fresh raw vegetables; beans and lentils; and nuts and seeds.

Parental concerns

Diagnosis of intestinal obstruction in a child is dependent on recognizing related symptoms. Parents may be concerned about preventing intestinal problems in their children and about missing the symptoms of possible intestinal obstruction. It is important to remember that a healthy diet with plenty of whole fruits, vegetables, and grains, and drinking a sufficient amount of water each day, will help keep the intestines healthy and elimination regular. Parents should be aware of the child's bowel habits and report constipation, diarrhea, abdominal pain, and vomiting to the pediatrician when it occurs. Diagnosed early, intestinal obstruction can be corrected without complications.

Intrauterine growth retardation

Definition

The term intrauterine growth retardation (also known as intrauterine growth restriction)(IUGR) is generically defined as a fetus who is at or below the tenth percentile in weight for its gestational age. There are two factors necessary to define an IUGR fetus: first, the fetal weight is at or below the tenth percentile for gestational age and sex; second, there is a pathological process present that prevents expression of normal growth potential. If the baby is small given its in utero age, then it is said to be small for gestational age (SGA).

Description

There are standards or averages in weight for unborn babies according to their gestational age in weeks; however, using a fetal growth curve derived from one population and applying it to another can result in over- or underestimation of the true incidence of SGA. For example, the lowest mean birth weight has been noted in Africa (New Guinea Lumi's tribe: mean birth weight = 2,400 grams); whereas the largest mean birth weight has been noted in the Caribbean (Aguilla: mean birth weight = 3,880 g). A population of smaller individuals will have smaller babies, so the difference lies in the genetic growth potential.

The normal intrauterine growth pattern occurs in three stages. In the first stage, four to 20 weeks gestation, rapid cell division and multiplication (hyperplasia) occurs as the embryo grows into a fetus. In the second stage, 20–28 weeks gestation, cell division (hyperplasia) declines and the cells increase in size (hypertrophy). In stage three, 28–40 weeks, there is a rapid increase in cell size, rapid accumulation of fat, muscle, and connective tissue. Ninety-five percent of fetal weight gain occurs during the last 20 weeks of gestation. If the delicate process of development and weight gain is disturbed or interrupted, the baby can suffer from restricted growth.

IUGR is usually classified as symmetrical or asymmetrical. Growth inhibition during the first stage produces an undersized fetus with fewer cells, but normal cell size, causing symmetric IUGR. In symmetrical

IUGR weight, head and length are all below the tenth percentile and the baby's head and body are proportionately small. Conditions associated with symmetric IUGR include: genetic (constitutional, chromosomal and single gene defects, and deletion disorders and inborn errors of metabolism), congenital anomalies, intrauterine infections, and therapeutic irradiation. Substance abuse and cigarette **smoking**, depending on dose and timing, can cause either symmetrical or asymmetrical IUGR.

Growth inhibition during stage two and three causes a decrease of cell size and fetal weight with less effect on total cell number and fetal length and head circumference, causing asymmetric IUGR. Conditions associated with asymmetric IUGR include: uteroplacental insufficiency, which is usually caused by chronic **hypertension** or preeclampsia; chronic renal disease; cyanotic heart disease; hemoglobinopathies; placental infarcts; abruptio placenta; multiple gestation; velamentous insertion of the umbilical cord and circumvallate placenta; and high altitude. In asymmetrical IUGR, weight is below the tenth percentile, and head and length are preserved. The brain can weigh five or six times more than the liver, whereas in a normal infant, the brain weighs about three times more than the liver.

Intrauterine growth retardation (IUGR)

Conditions associated with IUGR

Maternal history	Alcohol use Cocaine use Smoking Malnutrition Use of prescription drugs warfarin (Coumadin, Panwarfarin) and phenytoin (Dilantin) Prior history of IUGR pregnancy Residing at altitude over 5,000 ft (1,500 m)
Medical conditions (of mother)	Chronic hypertension Preeclampia early in gestation Diabetes mellitus Systemic lupus erythematosus Chronic kidney disease Inflammatory bowel disease Severe lung disease
Infectious diseases	Syphilis Cytomegalovirus Toxoplasmosis Rubella Hepatitis B Herpes simplex virus 1 or 2 HIV-1
Congenital disorders (of fetus)	Trisomy 21 (Down syndrome) Trisomy 18 (Edwards syndrome) Trisomy 13 (Patau syndrome) Turner's syndrome

(Table by GGS Information Services.)

Causes and symptoms

The two types of IUGR described previously contribute to IUGR according to the development at that stage. Symmetrical IUGR may occur when the unborn baby experiences a problem during early development. Asymmetrical IUGR may occur when the unborn baby experiences a problem during later development. In general, most physicians believe that IUGR is the consequence of a disease process within one or more of the three partitions that maintain and regulate fetal growth, i.e., the maternal compartment, the placenta, or the fetus.

In consideration of risk factors uteroplacental insufficiency contributes to 80 percent of IUGR due to the following maternal causes:

- deficient supply of nutrients
- smoking
- malnutrition
- anemia
- drug abuse
- vascular diseases, i.e., high blood pressure
- chronic kidney disease
- severe diabetes
- multiple gestation
- antigen/antibody reactions, i.e., lupus, antiphospholipid antibody syndrome (APA)
- primary placental causes, i.e., extensive placental infarctions, chronic placental separation, placenta previa

Primary fetal causes contribute to 20 percent of IUGR and include the following:

- exposure to an infection, i.e., **rubella** (German **measles**), cytomegalovirus, syphilis, or toxoplasmosis
- birth defects, i.e., **congenital heart disease**, genitourinary anomalies, central nervous system defects
- chromosomal abnormalities, i.e., trisomy 13, 18, or 21
- primary bone or cartilage disorder
- decreased intrinsic growth, symmetrical IUGR

Diagnosis

IUGR can be difficult to diagnose but it begins with taking an extensive maternal history. A mother with a previous IUGR is at risk of having another during a subsequent pregnancy. Maternal renal and cardiopulmonary disease and multiple gestation are factors in IUGR.

KEY TERMS

Abruptio placentae—Premature separation of the placenta from the uterine wall. It occurs late in pregnancy and results in bleeding that may or may not establish an obstetrical emergency.

Circumvallate placenta—The existence of a thick, round, white, opaque ring around the periphery of the placenta that limits the expansion of the fetal vessels.

Fundus—The inside of an organ. In the eye, fundus refers to the back area that can be seen with the ophthalmoscope.

Hemoglobinopathies—Abnormal hemoglobins in the blood, i.e., sickle cell disease, thalessemia.

Hyperplasia—A condition where cells, such as those making up the prostate gland, rapidly divide abnormally and cause the organ to become enlarged.

Hypertrophy—An increase in the size of a tissue or organ brought about by the enlargement of its cells rather than cell multiplication.

Hypoplasia—An underdeveloped or incomplete tissue or organ usually due to a decrease in the number of cells.

Placenta—The organ that provides oxygen and nutrition from the mother to the unborn baby during pregnancy. The placenta is attached to the wall of the uterus and leads to the unborn baby via the umbilical cord.

Placenta previa—A condition in which the placenta totally or partially covers the cervix, preventing vaginal delivery.

Placental infarction—An area of dead tissue in the placenta that is due to an obstruction of circulation in the area.

Preeclampsia—A condition that develops after the twentieth week of pregnancy and results in high blood pressure, fluid retention that doesn't go away, and large amounts of protein in the urine. Without treatment, it can progress to a dangerous condition called eclampsia, in which a woman goes into convulsions.

Uteroplacental insufficiency—Designates the lack of blood flow from the uterus to the placenta, resulting in decreased nourishment and oxygen to the fetus.

Velamentous insertion of the umbilical cord—The attachment of the umbilical cord close to the membranes (bag of water) or in the membranes.

A positive rollover test is predictive of IUGR and is defined as a rise in diastolic blood pressure of 20 mm Hg or more with a position change from the left lateral recumbent to supine, which is an early indication of possible pregnancy-induced hypertension. Determination of an accurate due date is essential in order for the doctor to know if development and weight gain are appropriate. Checking the mother's weight and abdominal measurements can help diagnose cases in which there are no other risk factors present. During each prenatal visit, the healthcare provider uses a tape measure to record the uterine fundal height (measured from the top of the pubic area to the top of the uterus in centimeters). As the pregnancy continues and the baby grows, the uterus stretches upward in the direction of the mother's head. Between 20 and 34 weeks gestation, the uterine fundal height, in centimeters, equals the weeks of gestation. If the uterine fundal height is more than three to four below normal, IUGR is suspected. Ultrasound is used to evaluate the growth of the baby and the ratio of the head circumference (HC) to the abdominal circumference (AC) is a good predictor of asymmetric IUGR. Decreased amniotic fluid (oligohydramnios) is associated with IUGR as the fetus may have a decreased cardiac output and thus decreased renal flow to produce less urine. The grading of the placenta indicates whether it may be inappropriately aging, but this is not as accurate as fetal measurements. Doppler flow studies of the uterine artery provide information regarding the blood flow to the uterus. Doppler studies on the umbilical cord artery and the middle cerebral artery also provide information regarding fetal growth. Biochemical tests on hormone levels of estriol and human placental lactogen provide minimal information.

Treatment

Maternal bed rest is the initial approach for the treatment of IUGR. The benefit of bed rest is that it results in increased blood flow to the uterus. Studies on the efficacy of bed rest have been inconclusive, although in the early 2000s it is still used in combination with intravenous fluid therapy and oxygen therapy. The use of baby aspirin therapy remains controversial but theoretically it serves to preserve or improve blood flow to the placenta. If the baby does not grow well in utero after conservative treatment, an obstetrician may suggest inducing labor in the mother a few weeks early, or delivering the baby by **cesarean section**.

Prognosis

Outcomes for infants with IUGR differ depending on whether the condition is symmetrical or not and

whether there are other sequelae from the underlying cause of the IUGR. Outcomes include an increased risk of long-term neurologic and behavioral handicaps, possible intrauterine demise, low blood sugar (**hypoglycemia**), and low body temperature (hypothermia). These risks increase with the severity of the growth restriction. The growth that occurs after birth cannot be predicted with certainty based on the size of the baby when it is born. Infants with asymmetrical IUGR are more likely to catch up in growth after birth than are infants who suffer from prolonged symmetrical IUGR. Delayed eruption of teeth and enamel hypoplasia and an increased incidence of postnatal infections are frequently seen. Each case is unique. Some infants who have IUGR develop normally, while others have complications of the nervous system or intellectual problems such as **learning disorders**. If IUGR is related to a disease or a genetic defect, the future of the infant is related to the severity and the nature of that disorder.

Parental concerns

Pregnant women who have been diagnosed with a fetus with IUGR should talk to their obstetrician about options for treatment. If the woman is uncomfortable with options presented by the doctor, she should seek a qualified second opinion. All pregnant women are well-advised to eat properly, get enough rest, and refrain from alcohol, drugs, and tobacco use for the health of the infant. In addition, pregnant women should be especially careful to keep themselves healthy by following good hygiene practices and receiving a **flu vaccine** if one is recommended.

Intravenous rehydration

Definition

Intravenous rehydration is the process by which sterile water solutions containing small amounts of salt or sugar are injected into the body through a tube attached to a needle which is inserted into a vein.

Purpose

Intravenous rehydration is used to restore the fluid and electrolyte balance of the body due to illness, surgery, or accident. Electrolytes are salts (sodium, potassium, chloride, calcium, magnesium, phosphate, sulfate, and bicarbonate) that become ions when mixed with fluids in the body and blood and have the ability to conduct electricity. The body uses electrolytes to carry electrical impulses from cell to cell. Moderate to severe **dehydration** can interfere with the body's normal functioning. Restoration of fluids and electrolytes through intravenous means is the swiftest means to achieve fluid balance.

Description

Fever, **vomiting**, and **diarrhea** can cause a child to become dehydrated fairly quickly. Infants and children are especially vulnerable to dehydration. Athletes who have over-exerted themselves in hot weather may also require rehydration with IV (intravenous) fluids. An IV for rehydration can be in place for several hours to several days and is generally used if a patient cannot drink fluids.

Basic IV solutions are made of sterile water with small amounts of sodium (an ingredient in table salt) or dextrose (sugar) supplied in bottles or thick plastic bags that can hang on a stand mounted next to the patient's bed. Additional mineral salts such as potassium and calcium, **vitamins**, or medications can be added to the IV solution by injecting them into the bottle or bag with a needle or injected directly into the IV line.

Precautions

Patients receiving IV therapy need to be monitored to ensure that the IV solutions are providing the correct amounts of fluids and **minerals** needed. People with kidney and heart disease are at increased risk for **overhydration**, so they must be carefully monitored when receiving IV therapy.

A child receiving fluids through an intravenous (IV) bag. *(© Tom Stewart/Corbis.)*

Preparation

The doctor orders the IV solution and any additional nutrients or medications to be added to it. The doctor also specifies the rate at which the IV will dispense the solution.

The IV solutions are prepared under the supervision of a pharmaceutical company, using sanitary techniques that prevent bacterial contamination, and come prepackaged. Additions to the IV solutions are supervised by a doctor or nurse. Just like a prescription, the IV is clearly labeled to show its contents and the amounts of any additives.

The skin around the area where the needle for the IV catheter is inserted is cleaned and disinfected. Once the IV catheter is in place, it is taped to the skin to prevent it from being dislodged. The IV line is then attached to the IV catheter. Any other IV lines can be added to the IV catheter.

Aftercare

Patients need to take fluids by mouth before an IV solution is discontinued. After the IV needle is removed, the site should be inspected for any signs of bleeding or infection.

Risks

There is a small risk of infection at the injection site that is usually treated topically. It is also possible that the IV solution may not provide all of the nutrients needed, leading to a deficiency or an imbalance, which would need to be corrected.

If the needle becomes dislodged, the solution can flow into tissues around the injection site rather than into the vein. This is called extravasation, or infiltration, and occurs in about half of pediatric IVs. In most cases, the patient reports a burning or stinging sensation at the site of the needle or IV catheter, especially when new IV fluids are started or the speed of the IV drip is increased. The tissues usually swell and become discolored, looking like a bruise. Usually, the IV catheter is removed and reinserted at another site.

If an IV has been in place for a long time or the child has had a medical condition that weakens the veins, the

KEY TERMS

Dextrose—A sugar solution used in intravenous drips.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Extravasation—To pass from a blood vessel into the surrounding tissue.

Sodium—An element; sodium is the most common electrolyte found in animal blood serum.

Thrombosis—The formation of a blood clot in a vein or artery that may obstruct local blood flow or may dislodge, travel downstream, and obstruct blood flow at a remote location. The clot or thrombus may lead to infarction, or death of tissue, due to a blocked blood supply.

child may experience vein collapse. This occurs when the vein is not able to receive anymore intravenous fluid and forces the IV solution into the surrounding tissues. It can also occur if a thrombosis, or blood clot, forms in the vein at the IV catheter site.

A collapsed vein feels and looks much like a dislodged IV catheter. This can sometimes happen when the nurse has inserted a needle or IV catheter that is too big for the size of the vein. This isn't a misjudgement on the nurse's part. Standard sized needles are used and only rarely are extremely thin needles necessary. They may be needed in adult patients as well as children. If vein collapse occurs, the IV catheter should be removed and reinserted into a different vein, usually in another part of the body. For example, if a vein in the left arm collapses, the nurse can put a new IV catheter into the right arm.

Treatment for an extravasation or a collapsed vein are similar. A warm compress is usually applied to the injection site to reduce swelling. If there is sufficient injury at the injection site, general wound care is done to prevent infection and speed healing.

Parental concerns

Usually intravenous rehydration is very effective, allowing the child's body to return to its normal fluid equilibrium. Once the child can keep fluids down orally and urine output has returned to normal, then intravenous rehydration is discontinued. Most children don't relapse once they are home if they can continue taking fluids by mouth.

Intravenous rehydration should only be used for moderate to severe dehydration. It is not recommended for mild dehydration from stomach upset or flu. Oral products that restore fluid and electrolytes balance are better for hydrating a sick child who has been vomiting during an illness or after strenuous activity in extremely hot weather. Oral rehydration also does not require a hospital stay.

To reduce the risk of displacement of the needle when the IV catheter or needle is inserted, parents should help the child keep still. The child should also be careful when moving about so as not to dislodge the IV catheter, especially at night. Parents can also look at the injection site and report any discoloration they see. They should also encourage the child to report any burning or stinging around the IV catheter to the nursing staff.

Iron deficiency anemia

Definition

Iron deficiency anemia refers to anemia that is caused by lower than normal levels of iron. This type of anemia is caused by deficient erythropoiesis, the ongoing process of the bone marrow to produce healthy red blood cells (RBCs). It is characterized by the production of small (microcytic) RBCs. When examined under a microscope, the RBCs also appear pale or light colored from the absence of heme, the major component of hemoglobin, which is the iron-bearing protein and coloring pigment in RBCs. Anemia resulting from a deficiency of iron is also called microcytic anemia.

Description

Anemia is a blood disorder characterized by abnormally low levels of healthy RBCs or reduced levels of hemoglobin (Hgb), the iron-bearing protein in RBCs that delivers oxygen to tissues throughout the body. Blood cell volume (hematocrit) may also be reduced in some **anemias**, but not necessarily in iron deficiency anemia. The reduction of any or all of these blood parameters reduces the essential delivery of oxygen through the bloodstream to the organs of the body. Iron is a mineral found in the bloodstream that is essential for growth, enzyme development and function, a healthy immune system, energy levels, and muscle strength. It is an important component of hemoglobin and myoglobin, the type of hemoglobin in muscle tissue.

Iron deficiency anemia is the most common type of anemia throughout the world, although it occurs to a lesser extent in the United States because of the higher consumption of iron-rich red meat and the practice of food fortification (addition of iron to foods by manufacturers). In developing countries in tropical climates, the most common cause of iron deficiency anemia is infestation with hookworm.

The onset of iron deficiency anemia is gradual and may not have early symptoms. The deficiency begins when the body's store of iron is depleted and more iron is being lost through bleeding or malabsorption than is derived from food and other sources. Because depleted iron stores cannot meet the red blood cells' needs, fewer red blood cells develop. In this early stage of anemia, the red blood cells look normal, but they are reduced in number. Eventually the body tries to compensate for the iron deficiency by producing more red blood cells, which are characteristically small in size (spherocytosis). Symptoms of anemia, especially weakness and fatigue, develop at this stage.

Causes and symptoms

Iron is an essential component of the production of healthy RBCs, and iron stores must be maintained for the ongoing production of RBCs by the bone marrow. Iron deficiency anemia can develop as a result of depleted iron stores from chronic blood loss, increased demands for iron as seen in periods of growth (e.g., in infancy and **adolescence**), or malabsorption of iron even when foods or supplements are supplying adequate amounts. It is accepted that iron is hard to absorb; this, in combination with diets that may not meet daily requirements, is a common route to iron deficiency and iron deficiency anemia. Iron can also be lost through strenuous **exercise** and heavy perspiration, poor digestion, frequent consumption of antacids, long-term illness, heavy menstrual cycles, and other causes.

Infancy is a period of increased risk for iron deficiency because dietary iron may not be adequate for the rapid growth of the child in the first two years of life, an example of increased demand. The human infant is born with a built-in supply of iron, which can be tapped during periods of drinking low-iron milk or formula. Both human milk and cow milk contain rather low levels of iron (0.5–1.0 mg iron/liter). However, the iron in the mother's breast milk is about 50 percent absorbed by the infant, while the iron of cow milk is only 10 percent absorbed. During the first six months of life, growth of the infant is made possible by the milk in the diet and by the infant's built-in supply of iron. However, premature infants have a lower supply of iron and, for this reason, it is recommended that pre-term infants, beginning at two months of age, be given oral supplements of 7 mg iron/day, as ferrous sulfate. Iron deficiency can be provoked where infants are fed formulas based on unfortified cow milk. For example, unfortified cow milk is given free of charge to mothers in Chile. This practice has the fortunate result of preventing general **malnutrition**, but the unfortunate result of allowing the development of mild iron deficiency.

Children have a great need for iron as they grow, and in most cases, the diet will provide replacement iron for the iron used in growth. Children seem to stay in balance unless a bleeding disorder of some kind exists, either hereditary (**hemophilia** or von Willebrand's) or related to hookworm infection or another illness. In adolescence, girls have an increased requirement for iron because of increased growth and the start of **menstruation**. Adolescent boys also experience a major growth spurt that demands more iron; iron stores are worn thin especially when healthy red cell function is needed for adequate oxygenation of exercising muscles and developing organs. Teenagers are also not noted for making

healthy food choices; often they are losing iron stores and not replenishing iron through diet.

Iron deficiency occurs most often through chronic blood loss, more often in adults than in children, although the sources of bleeding can apply to people of all ages. Blood losses from gastrointestinal bleeding, excessive menstrual bleeding, and infection with hookworm can deplete iron and lead to iron deficiency anemia. In hookworm infection, a parasitic worm that thrives in warm climates, including in the southern United States, enters the body through the skin, such as through bare feet. The hookworm then migrates to the small intestines where it attaches itself to small sausage-shaped structures in the intestines (villi) that help with the absorption of all nutrients. The hookworm damages the villi, resulting in blood loss; they simultaneously produce anti-coagulants that promote continued bleeding. Each worm can initiate losses of up to 0.25 ml of blood per day.

Chronic blood losses through gradual bleeding in the gastrointestinal tract can be provoked by other conditions such as hemorrhoids, bleeding ulcers, anal fissures, **irritable bowel syndrome**, aspirin-induced bleeding, blood clotting disorders, and diverticulosis (a condition caused by an abnormal opening from the intestine or bladder). Several genetic diseases also lead to bleeding disorders. These include the **coagulation disorders** hemophilia A and hemophilia B, and von Willebrand's disease, a bleeding disorder caused by a deficiency in von Willebrand factor, an essential component of the coagulation system. All three genetic diseases can produce symptoms and be diagnosed in childhood.

The symptoms of iron deficiency anemia appear slowly and typically include weakness and fatigue. These symptoms result because of the reduced oxygen carrying capacity of RBCs and the reduced ability of the RBCs to carry iron to working muscles. Iron deficiency can also affect other tissues, including the tongue and fingernails. Prolonged iron deficiency can result in a smooth, shiny, and reddened tongue, a condition called glossitis. The fingernails may grow abnormally and acquire a spoon-shaped appearance.

When to call the doctor

Weakness, **dizziness**, listlessness, or fatigue may be the first signs of iron deficiency anemia. A compulsion to chew on ice cubes or to eat soil is also an indication of iron deficiency. The pediatrician should be consulted if the child is extremely pale, with little or no color in the gums, nail beds, creases of the palm, or lining of the eyelids.

Demographics

In the United States, iron deficiency anemia affects thousands of toddlers between one and two years of age and more than 3 million women of childbearing age. This condition is less common in older children and in adults over 50 and rarely occurs in teenage boys and young men.

Diagnosis

Diagnosing iron deficiency anemia begins with the pediatrician taking a careful history, including the child's age, symptoms, illnesses, general state of health, and a **family** history of anemias. Symptoms noticed in children by their parents may include fatigue, weight loss, inability to concentrate, loss of appetite, and light-headedness when standing up. The physical examination may reveal paleness, and lack of color in the creases of the palms, in gums, and in the linings of the eyelids.

Diagnostic testing starts with a complete blood count (CBC) and differential, counting RBCs, white blood cells (WBCs) and measuring hemoglobin (Hgb), hematocrit (Hct), and other factors. In iron deficiency anemia, the RBC count can be normal or elevated and hemoglobin will be abnormally low. In infants, iron deficiency anemia is defined as having a hemoglobin level below 109 mg/ml when measured in whole blood, and a hematocrit of less than 33 percent. In the microscopic examination of a stained blood smear (differential), red cells may appear smaller than normal. The mean corpuscular volume (MCV) will be measured to compare the size of RBCs with normal RBCs. A reticulocyte (young RBCs) count will help determine if anemia is caused by impaired RBC production, as in iron deficiency anemia, or increased RBC destruction as in some other types of anemia. Iron, vitamin C or vitamin B_{12}, and folate levels will be measured in blood serum to identify possible deficiencies. In addition to measuring iron itself (Fe) and total iron-binding capacity (TIBC), transferrin and transferrin saturation tests may be performed to evaluate iron metabolism. Different types of hemoglobin may be measured by a diagnostic testing method called hemoglobin electrophoresis. Protoporphyrin IX, a component of hemoglobin, may be measured to help confirm a diagnosis of iron deficiency anemia. Confirmation may also be obtained by taking a bone marrow sample (bone marrow biopsy) for microscopic examination. Kidney function tests, coagulation tests, and stool examinations for occult (hidden) blood may also be performed.

The presence of occult blood found in a stool examination may indicate gastrointestinal bleeding or other causes of bleeding such as aspirin-induced or a bleeding

ulcer. The physician then needs to examine the gastrointestinal tract to determine the cause and location of bleeding. In this case, a diagnosis of iron deficiency anemia may include examination with a sigmoidoscope, a flexible, tube-like instrument with a light source that permits examination of the colon. A barium-enhanced x ray of the intestines may also be used to detect abnormalities that can cause bleeding.

The diagnosis of iron deficiency anemia may include a test for oral iron absorption, especially when evidence suggests that oral iron supplements have failed to raise hemoglobin. The oral iron absorption test is conducted by injecting 64 mg iron (325 mg ferrous sulfate) in a single dose. Blood samples are then taken after two hours and four hours. The iron content of the blood serum is then measured. The concentration of iron should rise by about 22 micromolar, when iron absorption is normal. Lesser increases in concentration mean that iron absorption is abnormal and that more effective therapy may involve injections or infusions of iron.

Treatment

The goal of treatment for iron deficiency anemia is to restore iron levels and the production of healthy RBCs and increase the essential flow of oxygen to tissues. Iron preparations may be given by injection or, in older children, as oral supplements. Taking vitamin C along with oral iron supplementation is accepted as a way to achieve better absorption of the iron. Taking iron supplements can result in **constipation**, **diarrhea**, cramps, or **vomiting** in sensitive individuals. Injections and infusions of iron can be given to individuals with poor iron absorption. Treatment of iron deficiency anemia sometimes requires more than iron supplementation. When iron deficiency is provoked by hemorrhoids or gastrointestinal bleeding, for example, surgery may be required to prevent recurrent iron deficiency anemia. When iron deficiency is provoked by bleeding due to aspirin ingestion, aspirin is discontinued. Iron deficiency caused by hookworm infection requires drug therapy to eliminate the parasite; prevention includes wearing shoes when walking in soil known to be infested with hookworms.

Alternative treatment

Vitamin C is noted for helping to absorb iron in the diet and iron supplements. Cooking in a cast iron skillet may leach small amounts of absorbable iron into the diet. Besides the iron found in eggs, fish, liver, meat, poultry, green leafy vegetables, whole grains, and enriched or whole grain breads and cereals, good food sources of iron include blackstrap molasses, brewer's yeast, and certain types of sea vegetable (e.g., hijiki, kelp, dulse). Herbal supplements that benefit individuals who have iron deficiency anemia include alfalfa, burdock root, dandelion, dong quai, mullein, nettle, raspberry leaf, shepherd's purse, and yellow dock. Herbs are available as tinctures and teas or in capsules.

Nutritional concerns

Decreased dietary iron intake is a contributing factor in iron deficiency and iron deficiency anemia. Deciding how to add enough iron to the diet, however, depends not just on which foods contain it, but in which foods iron is most available for absorption and use by the body. Bioavailability describes the percent of dietary iron that is successfully absorbed via the gastrointestinal tract to the bloodstream. Non-absorbed iron is lost in the feces. Generally, iron bioavailability in fruits, vegetables, and grains is lower than the iron availability of meat. The availability of iron in plants ranges from only 1 to 10 percent, with some exceptions, while that in meat, fish, chicken, and liver is consistently 20–30 percent. In the following list, the iron content is given parenthetically for each food.

- cabbage (1.6 mg/kg)
- spinach (33 mg/kg)
- lima beans (15 mg/kg)
- potatoes (14 mg/kg)
- tomatoes (3 mg/kg)
- apples (1.5 mg/kg)
- peanut butter (6.0 mg/kg)
- raisins (20 mg/kg)
- whole wheat bread (43 mg/kg)
- eggs (20 mg/kg)
- canned tuna (13 mg/kg)
- chicken (11 mg/kg)
- beef (28 mg/kg)

It is easy to see that apples, tomatoes, and peanut butter are relatively low in iron, while spinach, whole wheat bread, and beef are relatively high in iron. Red meat sources reliably replace the heme component of red blood cells, raising hemoglobin levels and helping to correct iron deficiency. For infants and toddlers, the most available source of iron is human milk (50% availability).

The assessment of whether a food is low or high in iron can also be made by comparing the amount of that food eaten per day with the recommended dietary allowance (RDA) for iron. The RDA for iron for the adult male is 10 mg/day, while that for the adult woman is

KEY TERMS

Erythropoiesis—The process through which new red blood cells are created; it begins in the bone marrow.

Hematocrit—A measure of the percentage of red blood cells in the total volume of blood in the human body.

Heme—The iron-containing molecule in hemoglobin that serves as the site for oxygen binding.

Hemoglobin—An iron-containing pigment of red blood cells composed of four amino acid chains (alpha, beta, gamma, delta) that delivers oxygen from the lungs to the cells of the body and carries carbon dioxide from the cells to the lungs.

Protoporphyrin IX—A protein the measurement of which is useful for the assessment of iron status. Hemoglobin consists of a complex of a protein plus heme. Heme consists of iron plus protoporphyrin IX. Normally, during the course of red blood cell formation, protoporphyrin IX acquires iron, to generate heme, and the heme becomes incorporated into hemoglobin. However, in iron deficiency, protophoryrin IX builds up.

Recommended Dietary Allowance (RDA)—The Recommended Dietary Allowances (RDAs) are quantities of nutrients in the diet that are required to maintain good health in people. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences, and may be revised every few years. A separate RDA value exists for each nutrient. The RDA values refer to the amount of nutrient expected to maintain good health in people. The actual amounts of each nutrient required to maintain good health in specific individuals differ from person to person.

15 mg/day. The RDA during pregnancy is 30 mg/day. The RDA for infants five months of age or younger is 6 mg/day, while that for infants of five months to one year of age is 10 mg/day. RDA values are based on the assumption that people eat a mixture of plant and animal foods.

Prognosis

The prognosis for treating and curing iron deficiency anemia is excellent, particularly when those affected take iron supplements as advised and are able to assimilate the iron. A number of studies have shown that iron deficiency anemia in infancy can result in reduced **intelligence**, when intelligence was measured in early childhood. It is not certain if iron supplementation of children with reduced intelligence, due to iron-deficiency anemia in infancy, has any influence in allowing a "catch-up" in intellectual development.

Prevention

In the healthy population, mineral deficiencies can be prevented by the consumption of inorganic nutrients at levels defined by the RDA. Iron deficiency anemia in infants and young children can be prevented by breastfeeding, consuming good dietary sources of iron, and using fortified foods. Liquid cow milk-based infant formulas are generally supplemented with iron (12 mg/L). The iron in liquid formulas is added as ferrous sulfate or ferrous gluconate. Commercial infant cereals are also fortified with iron, adding small particles of elemental iron. The levels used are about 0.5 gram iron/kg dry cereal. This amount of iron is about 10-fold greater than that of the iron naturally present in the cereal. Iron supplementation is not recommended for all infants, and children and pediatricians should be consulted before giving supplements. Vitamin C is recommended to improve the assimilation of iron in the body, especially when iron is obtained from non-food sources.

Nutritional concerns

The average diet in the United States contains about 6 mg of iron per calorie of food, which is sufficient for maintaining iron stores. Only 1 mg of iron, however, is absorbed for every 10 mg. consumed, which mean sources of iron must be carefully chosen. The bioavailability of iron in foods varies, influencing the amounts that can be absorbed through the intestines. Absorption is best when the food contains heme, just as in human red cells. That makes meat the best choice as a source of iron and iron-rich vegetables and fruits such as spinach and apricots the next best choice. Certain other plant foods that contain fiber, such as bran, actually reduce the absorption of non-heme iron; so do antacid medications, often taken to relieve the upset stomach associated with taking oral iron supplements. Additionally, food interactions reduce bioavailability. Ascorbic acid (vitamin C) is the only food constituent known to increase the availability of non-heme iron, such as in vegetables and also in food supplements.

Parental concerns

Understanding iron metabolism and the ways to ensure that iron deficiency anemia in infants and children can be successfully treated and prevented from

recurring may be concerns of parents. It is important to remember that although iron deficiency anemia is common in infants and toddlers, it is easily corrected by feeding infants mother's milk or iron-fortified formulas. In older children, the diet usually balances iron usage and replacement. In teenage years, when demands for iron increase for rapid growth and to compensate for menstruation in girls, parents will need to pay attention once again to providing adequate food sources. However, supplementation of iron should only be done with a doctor's recommendation.

Irritable bowel syndrome

Definition

Irritable bowel syndrome (IBS) is a common gastrointestinal condition characterized by abdominal **pain** and cramps; changes in bowel movements (**diarrhea**, **constipation**, or both); gassiness; bloating; **nausea**; and other symptoms. There is no cure for IBS; however, dietary changes, stress management, and sometimes medications are often able to eliminate or substantially reduce its symptoms.

Description

IBS is the name people use today for a condition that was once called—among other things—spastic colitis, mucous colitis, spastic colon, nervous colon, spastic bowel, and functional bowel disorder. Some of these names reflected the now outdated belief that IBS is a purely psychological disorder, a product of the patient's imagination. Although modern medicine recognizes that stress, **anxiety** and depression can trigger IBS attacks, medical specialists agree that IBS is a genuine physical disorder—or group of disorders—with specific identifiable characteristics. IBS is considered a functional disorder because it is thought to result from changes in the activity of the major part of the large intestine (the colon).

Demographics

IBS is one of the most common functional gastrointestinal disorders, affecting 10-20 percent of adults in the United States. Research has demonstrated that symptoms compatible with IBS are about as common in school-age children as in adults. IBS normally makes its first appearance during young adulthood, and symptoms usually begin at about age 20. Women with IBS represent over 70 percent of IBS sufferers. IBS is responsible for more time lost from school and work than any medical problem—other than the **common cold**. It accounts for a substantial proportion of the patients seen by specialists in diseases of the digestive system (gastroenterologists).

A community-based study of 507 middle school and high school students by Hyams, et al, found that 6-14 percent of the adolescent population had IBS symptoms. Anxiety and depression scores were significantly higher for this group. Eight percent of all the students in the study had seen a physician for abdominal pain in the previous year.

Causes and symptoms

Causes

Although the exact cause or causes of IBS are unknown, research suggests that people with IBS may have a colon that is more sensitive and reactive to certain foods and stress.

After food is digested by the stomach and small intestine, the undigested material passes in liquid form into the colon, which absorbs water, nutrients and salts. Normally, the colon is quiet during most of that period except after meals, when its muscles contract in a series of wavelike movements called peristalsis. Peristalsis helps absorption by bringing the undigested material into contact with the colon wall. It also pushes undigested material that has been converted into solid or semisolid feces toward the rectum, where it remains until a bowel movement occurs.

In IBS, however, the normal rhythm and intensity of peristalsis is disrupted. Sometimes there is too little

peristalsis, which can slow the passage of undigested material through the colon and cause constipation. Sometimes there is too much, which has the opposite effect and causes diarrhea. In other cases, peristalsis can be spasmodic, causing sudden strong muscle contractions that come and go.

DIET Some foods and beverages appear to play a key role in triggering IBS attacks. Certain foods and drinks may disrupt peristalsis in IBS patients, which may explain why IBS attacks often occur shortly after meals. Some of the chief culprits include:

- chocolate
- dairy products
- **caffeine** (in coffee, tea, colas, and other drinks)
- carbonated beverages (colas, pop, soda)
- wheat
- rye
- barley
- excess alcohol

Other foods also have been identified as problems, and the pattern of what can and cannot be tolerated is different for each person.

STRESS Stress—feeling mentally or emotionally tense, troubled, angry or overwhelmed—stimulates colon spasms in people with IBS since there is a close nervous system connection between the brain and the intestines. A large network of nerves control the normal rhythmic contractions of the colon. Although researchers do not yet understand all of the links between changes in the nervous system and IBS, they point out the similarities between mild digestive upsets and IBS. Just as healthy people can feel nauseated or have an upset stomach when under stress, people with IBS react the same way, but to a greater degree.

MENSTRUATION IBS symptoms sometimes intensify during **menstruation**, suggesting female reproductive hormones may trigger the condition.

Symptoms

The symptoms of IBS tend to rise and fall in intensity, rather than grow steadily worse over time. Symptoms always include:

- abdominal pain, which may be relieved by defecation
- diarrhea
- constipation
- diarrhea alternating with constipation

Other symptoms, which vary from person to person, include:

- cramps
- gassiness
- bloating
- nausea
- passage of mucus during bowel movements
- abnormal stool frequency—defined as greater than three bowel movements per day or less than three bowel movements per week
- abnormal stool form (lumpy, hard, loose, or watery stool)
- abnormal stool passage (straining, urgency, or feeling of incomplete bowel movement)

In general, symptoms are not present all the time and do not interfere with school and other normal activities. IBS symptoms rarely occur at night and disrupt the patient's **sleep**. Moderate IBS occasionally disrupts normal activities.

When to call the doctor

If a child has the following symptoms, the parent should contact the child's pediatrician or gastroenterologist:

- abdominal pain or diarrhea that wakes the child during the night
- persistent or severe abdominal pain
- unexplained weight loss
- rectal bleeding
- fever
- **family** history of irritable bowel disease

Diagnosis

The Rome II criteria are the accepted diagnostic criteria for IBS. These criteria were developed by an international group of pediatric gastroenterologists and include:

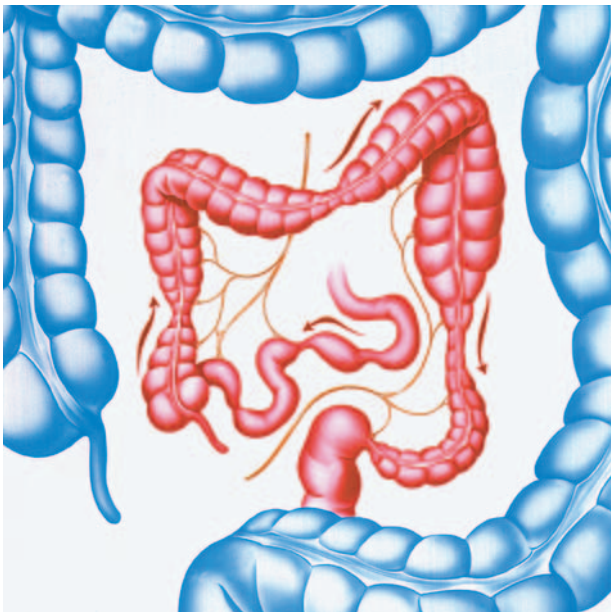
- Continuous or recurrent abdominal discomfort or pain for at least three months that is: a) Relieved with defecation and/or b) Associated with a change in frequency and/or c) Associated with a change in appearance of stool. Two or three of these features are present with an IBS diagnosis.
- No structural or metabolic abnormalities are present that may be responsible for the IBS symptoms.

The diagnosis of IBS is further supported by the presence of the symptoms listed previously. In addition, the

primary pediatrician or gastroenterologist may confirm the diagnosis of IBS after questioning the child (if old enough to provide an accurate history of symptoms) or parent about his or her physical and mental health (the medical history), performing a physical examination, and ordering laboratory tests to rule out other conditions that resemble IBS, such as Crohn's disease and ulcerative colitis.

Diagnostic tests may include stool or blood tests, hydrogen breath test, or an x ray of the bowel, called a barium enema. When symptoms continue even after treatment, endoscopic tests such as a colonoscopy or sigmoidoscopy may be performed. An endoscopic test is an internal examination of the colon using a flexible instrument (a sigmoidoscope or colonoscope) that is inserted through the anus.

A nutritional **assessment** performed by a registered dietitian may be included in the child's diagnostic evaluation. The nutritional assessment includes a review of the child's fiber intake as well as his or her usual consumption of sugars such as sorbitol and fructose—common culprits of diarrhea.



Normal and diseased (center) colons. Areas of constriction in the colon cause constipation, while areas of distention cause diarrhea. *(© 1995 John Bavosi/Science Photo Library. Custom Medical Stock Photo, Inc.)*

Treatment

Dietary changes and sometimes medications are considered the keys to successful treatment. Psychosocial difficulties are also addressed and treated with therapy or counseling as needed. Treatment requires a long-term commitment; six months or more may be needed before the child notices substantial improvement.

Alternative treatment

Alternative and complementary therapies include approaches that are considered to be outside the mainstream of traditional health care. Alternative and traditional approaches to IBS treatment overlap to a certain extent. Like traditional doctors, alternative practitioners advise a high-fiber diet to reduce digestive system irritation. They also suggest avoiding caffeine and fatty, gassy, or spicy foods, as well as alcohol. Recommended stress management techniques include **yoga**, meditation, guided imagery, hypnosis, biofeedback, and reflexology. Reflexology is a foot massage technique that is thought to relieve diarrhea, constipation, and other IBS symptoms.

The list of alternative treatments for IBS is quite long. It includes aromatherapy, homeopathy, hydrotherapy, juice therapy, acupuncture, chiropractic, osteopathy, naturopathic medicine, and Chinese traditional herbal medicine.

Before learning or practicing any particular technique, it is important for the parent/caregiver and child to learn about the therapy, its safety and effectiveness, potential side effects, and the expertise and qualifications of the practitioner. Although some practices are beneficial, others may be harmful to certain patients.

Relaxation techniques and dietary supplements should not be used as a substitute for medical therapies prescribed by a doctor. Parents should discuss these alternative treatments with the child's doctor to determine the techniques and remedies that may be beneficial for the child.

Nutritional concerns

Dietary changes, including a low-fat, high-fiber diet, may help decrease IBS symptoms. The addition of wheat bran or other fiber may be suggested to decrease symptoms. The formula for determining the recommended fiber intake for children, as advised by the American Dietetic Association, is to take the child's age plus five to equal the grams of dietary fiber the child should consume daily. Fiber should be added gradually to the child's diet.

The doctor may recommend a lactose-free diet for two or three weeks to determine if **lactose intolerance** is causing the symptoms. Lactose is the milk sugar found

KEY TERMS

Anus—The opening at the end of the intestine through which solid waste (stool) passes as it leaves the body.

Barium enema—An x ray of the bowel using a liquid called barium to enhance the image of the bowel. This test is also called a lower GI (gastrointestinal) series.

Colonoscopy—An examination of the lining of the colon performed with a colonoscope.

Constipation—Difficult bowel movements caused by the infrequent production of hard stools.

Crohn's disease—A chronic, inflammatory disease, primarily involving the small and large intestine, but which can affect other parts of the digestive system as well.

Defecation—The act of having a bowel movement or the passage of feces through the anus.

Diarrhea—A loose, watery stool.

Endoscopy—Visual examination of an organ or body cavity using an endoscope, a thin, tubular instrument containing a camera and light source. Many endoscopes also allow the retrieval of a small sample (biopsy) of the area being examined, in order to more closely view the tissue under a microscope.

Feces—The solid waste, also called stool, that is left after food is digested. Feces form in the intestines and pass out of the body through the anus.

Gastroenterologist—A physician who specializes in diseases of the digestive system.

Hydrogen breath test—A test used to determine if a person is lactose intolerant or if abnormal bacteria are present in the colon.

Lactose—A sugar found in milk and milk products.

Peristalsis—Slow, rhythmic contractions of the muscles in a tubular organ, such as the intestines, that move the contents along.

Sigmoidoscopy—A procedure in which a thin, flexible, lighted instrument, called a sigmoidoscope, is used to visually examine the lower part of the large intestine. Colonoscopy examines the entire large intestine using the same techniques.

Ulcerative colitis—A form of inflammatory bowel disease characterized by inflammation of the mucous lining of the colon, ulcerated areas of tissue, and bloody diarrhea.

in dairy products. Lactose intolerance is a common condition in up to 40% of patients with IBS. During the lactose-free period, the child should avoid all products containing lactose. The parent and child are asked to record the intake of all foods and beverages and note when symptoms occur after eating or drinking.

To identify other problem-causing foods or beverages, it is helpful for the parent and child to keep a diary of symptoms for two or three weeks, including daily activities, meals, symptoms and emotions. The doctor can then review the diary with the parent and child to identify possible problem areas.

In addition to lactose, known problem-causing substances include caffeine, beans, onions, cabbage, cucumbers, broccoli, fatty foods, alcohol, and certain medications. Once the specific substances that trigger symptoms are identified, they should be avoided. A registered dietitian can help the parent and child make specific dietary changes.

If lactose intolerance is a problem, the child may need to take calcium supplements or choose other foods high in calcium to meet the recommended daily requirement. If lactose intolerance is not a problem, the child can still have milk or milk products.

Medications

Medications affect each child differently, and no one medication works for every child with IBS. The child and parent will need to work with the doctor to find the best combination of medicine, diet, counseling and support to manage symptoms.

Stool softeners such as polyethelene glycol (Miralax) or an over-the-counter laxative may be recommended for constipation. Mineral oil also may be helpful. However, it is important not to use over-the-counter remedies without first consulting with the child's doctor.

Tricyclic **antidepressants** in low doses may be prescribed for pain relief. Antidepressants work by blocking pain transmission from the nervous system. Antispasmodic medications can slow bowel contractions and decrease diarrhea. Anticholinergics may help control intestinal cramping. Keep in mind that the effectiveness of these drugs to treat IBS has not been studied extensively in children.

Counseling and support

Psychological counseling or behavioral therapy may be recommended for some patients to reduce anxiety and stress and to learn to cope with the symptoms of IBS. Biofeedback, guided imagery, relaxation therapy, hyp-

nosis, and cognitive-behavioral therapy are examples of behavioral therapy. An ongoing and supportive doctor-patient relationship is also very important. The child and family must be reassured that although IBS causes symptoms that are uncomfortable and sometimes painful, it is not a harmful condition and does indicate a serious problem.

Prognosis

IBS is not a life-threatening condition. It is not an anatomical or structural defect, nor an identifiable physical or chemical disorder. IBS does not cause intestinal bleeding or inflammation, nor does it cause other gastrointestinal diseases or **cancer**. Although IBS can last a lifetime, in up to 30% of cases the symptoms eventually disappear. Even if the symptoms cannot be eliminated, with appropriate treatment they usually can be managed enough so IBS becomes merely an occasional inconvenience.

Prevention

Nutritional concerns

To help prevent or decrease the child's symptoms, parents can:

- help the child identify and avoid problematic foods
- work with a registered dietitian to facilitate specific dietary changes
- incorporate changes in the child's diet gradually so his or her body has time to adjust
- establish set times for meals; not allowing the child to skip a meal
- encourage the child to drink at least eight 8-ounce glasses of water per day
- serve small portions during meals
- teach the child to eat slowly, to avoid swallowing too much air that can produce excess gas
- try offering smaller, more frequent meals
- keep a regular schedule for bathroom visits

Parental concerns

Parents should reinforce with the child that IBS is not a life-threatening condition and that dietary changes and stress reduction can help reduce symptoms. Remind the child that six months or more may be needed before he or she notices substantial improvement in symptoms.

Itching

Definition

Itching is an intense, distracting irritation or tickling sensation that may be felt all over the skin's surface or confined to just one area. The medical term for itching is pruritus.

Description

Itching instinctively leads most people to scratch the affected area. Different people can tolerate different amounts of itching, and the threshold of tolerance can change due to stress, emotions, and other factors. In general, itching is more severe if the skin is warm and if there are few distractions. This is why people tend to notice itching more at night.

Demographics

It is common for children to be itchy occasionally. Prolonged itching in a specific location and generalized itching in many different areas of the body are less common.

Causes and symptoms

The reason for the sensation of itching is not well understood. While itching is the most noticeable symptom in many skin diseases, it does not necessarily mean that a person who feels itchy has a disease.

Stress and emotional upset can make itching worse, no matter what the underlying cause. Itching is often worse at night or at times when there are no distractions. If emotional problems are the primary reason for the itch, the condition is known as psychogenic itching. Some people become convinced that their itch is caused by a parasite; this conviction is often linked to burning sensations in the tongue and may be caused by a major psychiatric disorder.

Generalized itching

Itching that occurs all over the body may indicate a medical condition such as **diabetes mellitus**, liver disease, kidney failure, **jaundice**, thyroid disorders, or rarely, **cancer**. Blood disorders such as leukemia and lymphatic conditions such as Hodgkin's disease may sometimes cause itching as well.

Some children may develop an itch without a rash when they take certain drugs such as aspirin or codeine. Others may develop an itchy red drug rash or **hives** because of an allergy to a specific drug such as penicillin.

Itching also may be caused when any of the family of hookworm larvae penetrate the skin. This includes swimmer's itch and creeping eruption caused by cat or dog hookworm and ground itch caused by the true hookworm.

Many skin conditions cause an itchy rash. These include:

- atopic **dermatitis**
- **contact dermatitis**
- dermatitis herpetiformis (occasionally)
- eczema
- fungus infections (such as athlete's foot)
- hives (urticaria)
- insect **bites**
- lice
- lichen planus
- neurodermatitis (lichen simplex chronicus)
- psoriasis (occasionally)
- scabies

Itching all over the body can be caused by something as simple as bathing too often, which removes the skin's natural oils and may make the skin too dry.

Localized itching

Specific itchy areas may occur if a person comes in contact with soap, detergents, or wool or other rough-textured, scratchy material. Adults who have hemorrhoids, anal fissure, or persistent **diarrhea** may notice itching around the anus (called pruritus ani). When children itch in this area, the cause is most likely **pinworms**.

Intense itching in the external genitalia in women (pruritus vulvae) may be due to **candidiasis** (yeast), hormonal changes, or the use of certain spermicides or vaginal suppositories, ointments, or deodorants.

When to call the doctor

If the child is itchy all over or has a localized itch in combination with a rash, **fever**, infection, or is acting sick, the doctor should be contacted.

Diagnosis

Itching is a symptom that is obvious to its victim. Because itching can be caused by such a wide variety of triggers, a complete physical examination and medical history will help diagnose the underlying problem.

KEY TERMS

Atopic dermatitis—An intensely itchy inflammation often found on the face, in the bend of the elbow, and behind the knees of people prone to allergies. In infants and young children, this condition is called infantile eczema.

Creeping eruption—Itchy, irregular, wandering red lines on the foot made by burrowing larvae of the hookworm family and some roundworms.

Dermatitis herpetiformis—A chronic, very itchy skin disease with groups of red lesions that leave spots behind when they heal.

Eczema—A superficial type of inflammation of the skin that may be very itchy and weeping in the early stages; later, the affected skin becomes crusted, scaly, and thick.

Hodgkin's disease—One of two general types of lymphoma (cancers that arise in the the lymphatic system and can invade other organs), Hodgkin's disease is characterized by lymph node enlargement and the presence of a large polyploid cells called Reed-Sternberg cells.

Lichen planus—A noncancerous, chronic itchy skin disease that causes small, flat purple plaques on wrists, forearm, ankles.

Neurodermatitis—An itchy skin disease (also called lichen simplex chronicus) found in nervous, anxious people.

Psoriasis—A chronic, noncontagious skin disease that is marked by dry, scaly, and silvery patches of skin that appear in a variety of sizes and locations on the body.

Scabies—A contagious parasitic skin disease caused by a tiny mite and characterized by intense itching.

Swimmer's itch—An allergic skin inflammation caused by a sensitivity to flatworms that die under the skin, resulting in an itchy rash.

A variety of blood and stool tests may be needed to help the doctor to determine the cause of the itch.

Treatment

Antihistamines such as diphenhydramine (Benadryl) can help relieve itching caused by hives but will not relieve itching from other causes. Most antihistamines also make people sleepy, which can help children **sleep** who would otherwise be awakened by the itch.

Specific treatment of itching depends on the underlying condition that causes it. In general, itchy skin should be treated very gently. While scratching may temporarily ease the itch, in the long run scratching makes the itch worse and can lead to an endless cycle in which scratching an itch makes it more itchy.

To avoid the urge to scratch, a cooling or soothing lotion or cold compress can be applied when the urge to scratch occurs. Soaps are often irritating to the skin and can make an itch worse; they should be avoided or used only when necessary.

Creams or ointments containing cortisone may help control the itch from insect bites, contact dermatitis, or eczema. Cortisone cream should not be applied to the face unless prescribed by a doctor.

Probably the most common cause of itching is dry skin. There are a number of simple things that can be done to ease the annoying itch:

- Do not wear tight clothes.
- Avoid synthetic fabrics.
- Take shorter baths.
- Wash the area in lukewarm water with a little baking soda.
- For generalized itching, take a lukewarm shower or oatmeal (or Aveeno) bath.
- Apply bath oil or lotion (without added colors or scents) right after bathing.

Children who itch as a result of mental problems or stress may benefit from seeing a mental health expert.

Prognosis

Most cases of itching resolve successfully when the underlying cause is treated.

Prevention

There are certain things people can do to avoid itchy skin. Children who tend toward itchy skin should take the following steps:

- Avoid a daily bath.
- Use only lukewarm water when bathing.
- Use only gentle soap.
- Pat dry, not rub dry, after bathing, leaving a bit of water on the skin.

- Apply a moisture-holding ointment or cream after the bath.
- Use a humidifier in the home.

Children who are allergic to certain substances, medications, or foods can avoid the resulting itch if they avoid contact with the allergen. Avoiding insect bites, bee **stings**, **poison ivy**, and similar plants can prevent the resulting itch. Treating sensitive skin carefully, avoiding overdrying of the skin, and protecting against diseases that cause itchy **rashes** are all good ways to avoid itching.

Parental concerns

Children who are itchy should have their finger nails cut short to help ensure that they do not scratch the itchy area enough to create breaks in the skin. Scratching until the skin is broken can lead to infection. Itching can be very frustrating, and, if it is severe, it can interfere with normal activities such as studying or sleeping. Itching is a symptom of many common childhood ailments such as **chickenpox** and contact with poison ivy, as well as of some more serious conditions.

Jaundice

Definition

Jaundice is a yellowing of the skin and/or whites of the eyes caused by high levels of bilirubin—a dark yellow-green or orange-red pigment—in the blood.

Description

Jaundice, also called icterus or hyperbilirubinemia, is a very common condition in newborns. Newborn or **neonatal jaundice**, sometimes referred to as physiologic or physiological jaundice, affects more than half of all full-term newborns and 80 percent of premature newborns within the first few days of life. It commonly lasts for one to two weeks. Jaundice that is present at birth or that lasts more than a couple of weeks may be abnormal jaundice and a symptom of an underlying problem. Jaundice in older children or adults is a symptom of hepatitis (inflammation of the liver) or some other liver disorder.

Jaundice results from higher than normal levels of bilirubin in the blood. Bilirubin is a breakdown product of red blood cells. Red blood cells normally are removed and broken down in the spleen after about 120 days in circulation. Heme (component of hemoglobin in red blood cells that carries oxygen throughout the body) is broken down into bilirubin, which moves to the liver where it is processed and added to bile, a digestive fluid. The bile travels through the bile ducts to the intestine and is excreted in the stool.

Infants are born with excess red blood cells that are rapidly recycled by the spleen and liver, releasing bilirubin. This pigment gives a newborn's stools their yellow color. If more bilirubin is produced than can be processed by the liver, blood levels of bilirubin rise, and the excess is deposited in tissues causing the skin to appear yellow.

Demographics

Although jaundice affects the majority of newborns, it often is more severe in Asian or Native American children. It also is more common in infants who are not breastfeeding efficiently, resulting in low fluid intake.

In 2001 the U.S. Centers for Disease Control and Prevention (CDC) reported that cases of brain damage associated with hyperbilirubinemia (called neonatal encephalopathy, bilirubin-induced brain injury, or kernicterus) had been increasing since about 1990, perhaps due to shorter hospital stays following birth. One cause of hyperbilirubinemia in seemingly healthy full-term or near-term infants is **biliary atresia**, an obstruction or inflammation of the bile ducts. This condition occurs in about one in every 15,000 live births, and girls are slightly more at risk than boys.

Causes and symptoms

Neonatal jaundice

Prior to birth the mother's liver processes bilirubin for the fetus. At birth, particularly with preterm births, an infant's immature liver may not be able to process all of the bilirubin formed as red blood cells are removed from circulation. The excess bilirubin causes jaundice by the third or fourth day after birth. The jaundice usually appears first on the face and progresses downward to the chest, abdomen, legs, and feet. If newborn feeding is delayed for any reason, such as illness, a digestive tract problem, or low fluid intake due to inefficient breastfeeding; the infant produces fewer stools, resulting in critically high blood levels of bilirubin and severe jaundice.

Most full-term babies with neonatal jaundice have no other symptoms. However, if bilirubin levels continue to rise, other symptoms may include:

- sleepiness
- lethargy
- slow or reluctant feeding

Risk factors for hyperbilirubinemia include:

- birth more than two weeks before the due date
- jaundice within the first 24 hours after birth
- significant bruising or bleeding under the scalp caused by labor and delivery
- high bilirubin levels prior to hospital discharge
- difficulty breastfeeding, resulting in low fluid intake
- a parent or sibling who had high bilirubin levels at birth

Abnormal jaundice in newborns

Jaundice at birth or within the first 24 hours after birth can be a sign of abnormal jaundice. Abnormal jaundice can be dangerous, particularly in preterm or unhealthy newborns. Depending on the cause and extent of the jaundice, it also may be harmful in full-term infants.

The most common cause of abnormal jaundice is an ABO blood type incompatibility between mother and child. If the mother has O-type blood and the infant has either A or B blood type, or if the mother has A-type blood and the child has B-type or vice versa, the mother's antibodies circulating in the baby's blood attack the child's foreign blood type, causing damage to and destruction of the baby's red blood cells. This process, called hemolysis, is accompanied by the release of excess amounts of bilirubin.

In the past Rhesus (Rh) blood factor incompatibility between the mother and child was a major cause of kernicterus. An Rh-negative mother who was exposed to her fetus's Rh-positive blood during a previous pregnancy or delivery or who has accidentally received an Rh-positive blood transfusion has antibodies against Rh-positive blood cells. These antibodies can circulate in her Rh-positive newborn, initiating hemolysis and causing severe abnormal jaundice.

Rare causes of severe neonatal jaundice

Jaundice can result from a congenital (present at birth) malformation of the liver, bile ducts, or gall bladder. Jaundice resulting from a congenital defect usually does not appear until the baby is at least ten days old. Biliary atresia—the underdevelopment, inflammation, or obstruction of the bile ducts that carry bile from the liver to the gall bladder and small intestine—causes bile to build up in the liver and forces the bilirubin into the blood. The cause of biliary atresia was as of 2004 unknown, and jaundice may not appear until the infant is two to six weeks old. Other symptoms of biliary atresia include:

- itching
- dark brown urine due to excess bilirubin excreted in the urine
- light-gray or chalky-colored stools from lack of bilirubin excreted by the intestines

Jaundice that develops or persists after the second week of life also can be due to the following:

- breast milk jaundice (prolonged jaundice resulting from breastfeeding) that occurs when a chemical in the mother's breast milk interferes with the infant liver's ability to process bilirubin
- liver malfunction or damaged liver cells
- an enzyme deficiency
- an abnormality of the red blood cells such as anemia
- blood hemorrhaging
- a blood infection (sepsis)
- a liver infection such as hepatitis virus
- toxoplasmosis, an infection caused by an animal parasite and transmitted to the fetus via an infected mother (House cats can be carriers of toxoplasmosis.)
- an infection anywhere in the body that impairs the efficiency of the liver, including neonatal **herpes simplex** or salmonella

Such infections may be congenital, having been passed from the mother to the fetus, or may occur after birth.

Other causes of jaundice

There are numerous other causes of neonatal and childhood jaundice, including the following:

- liver cell damage resulting from a variety of conditions such as a viral infection, an adverse drug reaction, or drugs or other chemicals that damage the liver (Jaundice can be a late symptom of hepatitis in an older baby or child.)
- hemolytic jaundice caused by hemolytic anemia, in which red blood cells are turned over faster than usual
- Hodgkin's disease in teenagers

Symptoms accompanying jaundice caused by liver cell damage may include:

- nausea
- vomiting
- abdominal pain
- swollen abdomen

When to call the doctor

A doctor should be consulted any time a child develops jaundice. Infants who are discharged from the hospital before bilirubin levels begin to rise, about three days after birth, should have their bilirubin level tested within a few days, particularly if they were preterm infants. Infants who become lethargic or reluctant to feed should be examined immediately, because symptoms can be signs of severe hyperbilirubinemia that can cause brain damage.

Diagnosis

Newborns are examined under good light for signs of jaundice. A simple blood test, with a few drops of blood taken from the infant's heel, measures bilirubin levels in the blood. The test may be repeated frequently in a jaundiced newborn to assure that bilirubin levels are dropping. An instrument called a bilirubinometer can be held against the baby's skin to assess the level of jaundice. The Minolta/Hill-Rom Air-Shields Transcutaneous Jaundice Meter accurately measures bilirubin levels by shining lights of different colors through the skin and measuring the reflection, eliminating the need for blood tests via heel pricks.

If there is reason to believe that the newborn is suffering from an abnormal jaundice, additional tests must be performed. These include:

- blood cell counts to detect anemia
- tests for blood clotting function
- tests for excess destruction of red blood cells
- blood tests to assess liver function
- a liver biopsy, in which liver cells are removed and examined under a microscope to look for liver disease
- urine and stool samples to check for signs of bacterial or viral infection

Breast milk jaundice due to a reaction with a breast milk component is suspected when the more common causes of jaundice have been ruled out.

Biliary atresia must be detected before two months of age to prevent further liver damage. Diagnoses of biliary atresia and other liver conditions are made by imaging techniques, including the following:

- ultrasound scanning, which uses sound waves to obtain images of the liver, gallbladder, and biliary tract (Abdominal ultrasound can distinguish between jaundice caused by biliary atresia and jaundice caused by liver malfunction.)
- magnetic resonance imaging (MRI) of the liver
- computed tomography (CT) or computed axial tomography (CAT) scans, which use a thin, rotating x-ray beam to obtain an image
- endoscopic retrograde cholangiopancreatography (ERCP), in which a radiopaque dye that is visible on **x rays** is inserted into the upper portion of the small intestine so that it flows back up the biliary tract
- liver scans using radioactive dyes

Treatment

Neonatal jaundice usually requires only observation. The infant may stay in the hospital for an extra day or return within the next few days for an examination. However, jaundice in a preterm baby may require intensive care. As the infant's liver matures and the excess blood cells are removed, the jaundice disappears. The child may be given additional fluids, possibly intravenously, to help remove the bilirubin. Frequent feedings lead to more frequent stools, which reduces the reabsorption of bilirubin from the intestines into the blood. Breast milk usually is considered superior to water or formula for relieving jaundice because breast milk produces stool with every feeding, thereby excreting bilirubin. Breastfeeding should not be discontinued because of neonatal jaundice.

If an infant's bilirubin levels are quite high or rising rapidly, phototherapy can prevent complications. The child is undressed and placed in a lighted incubator to stay warm. A high-intensity, cool, blue-fluorescent light is absorbed by the bilirubin and converts it into a harmless form than can be excreted in the bile and urine. An eye shield protects the baby's eyes. The infant is removed from the incubator for feeding. Other phototherapy methods—such as a fiber optic bilirubin blanket—incorporate the light into a blanket so that the child can be breastfed during treatment or treated at home. Phototherapy is continued until bilirubin levels have returned to normal, usually within a few days.

Side effects of phototherapy may include:

- loose stools
- rash
- dehydration
- sleepiness
- disinterest in breastfeeding

If bilirubin approaches a dangerous level, an exchange blood transfusion is used to rapidly lower it. A catheter is placed into the umbilical vein at the cut surface of the umbilical cord, and the newborn's blood is replaced with an equal volume of new blood. Rh incompatibility also may be treated by exchange transfusion.

Antibiotics may be used to prevent or treat a suspected infection in jaundiced infants. Babies with very severe jaundice have their hearing tested and are monitored for several months.

Surgery for biliary atresia must be performed within the first few weeks of an infant's life to prevent fatal liver damage. About 40–50 percent of infants with biliary atresia are candidates for replacement bile ducts leading from the liver into the intestine. Called the Kasai procedure or hepatoportoenterostomy, the obstructed ducts are replaced with sections from the infant's intestines. Infants with a duct obstruction within the liver itself usually require a liver transplant by the age of two.

Prolonged breast-milk jaundice may require breastfeeding to be halted for a few days until bilirubin levels drop. The breasts should be pumped in the interim so that the mother does not stop producing milk and breastfeeding can be resumed.

Prognosis

Neonatal jaundice disappears after one to two weeks. It may last slightly longer in breastfed infants. The jaundice does not harm the infant in any way, and breastfeeding should not be discontinued.

Severe untreated jaundice leading to kernicterus may result in the following:

- mental retardation
- cerebral palsy
- deafness
- death

Untreated biliary atresia leads to biliary cirrhosis, a progressive, irreversible scarring of the liver, by about two months of age. About 50 percent of bile duct replacement surgeries are successful, and the jaundice usually disappears within several weeks. Despite this success, the liver damage often progresses on to cirrhosis.

Breast-milk jaundice, resulting from a reaction to a breast milk component, is not dangerous. The baby's liver soon adapts to the problem and the jaundice disappears.

Prevention

In 2004 the American Academy of Pediatrics issued revised guidelines for identifying and managing neonatal jaundice. They recommend:

- that all newborns be assessed for their risk of developing severe jaundice, including measuring bilirubin levels before hospital discharge
- a follow-up visit occur within three to five days after birth when bilirubin levels are likely to peak

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Bile—A bitter yellow-green substance produced by the liver. Bile breaks down fats in the small intestine so that they can be used by the body. It is stored in the gallbladder and passes from the gallbladder through the common bile duct to the top of the small intestine (duodenum) as needed to digest fat.

Bile ducts—Tubes that carry bile, a thick yellow-green fluid that is made by the liver, stored in the gallbladder, and helps the body digest fats.

Biliary atresia—An obstruction or inflammation of a bile duct that causes bilirubin to back up into the liver.

Bilirubin—A reddish yellow pigment formed from the breakdown of red blood cells, and metabolized by the liver. When levels are abnormally high, it causes the yellowish tint to eyes and skin known as jaundice. Levels of bilirubin in the blood increase in patients with liver disease, blockage of the bile ducts, and other conditions.

Hemolysis—The process of breaking down of red blood cells. As the cells are destroyed, hemoglobin, the component of red blood cells which carries the oxygen, is liberated.

Hyperbilirubinemia—A condition characterized by a high level of bilirubin in the blood. Bilirubin is a natural byproduct of the breakdown of red blood cells, however, a high level of bilirubin may indicate a problem with the liver.

Kernicterus—A potentially lethal disease of newborns caused by excessive accumulation of the bile pigment bilirubin in tissues of the central nervous system.

Phototherapy—Another name for light therapy in mainstream medical practice.

- breastfeeding a newborn at least eight to 12 times per day, since effective breastfeeding significantly reduces the risk of hyperbilirubinemia
- that parents be provided with written and oral information about the risks of neonatal jaundice

In cases of known Rh incompatibility, the mother is given an injection of RhoGAM, an immune globulin preparation, at about 28 weeks of pregnancy and again immediately after the child's birth. This destroys any Rh-positive fetal blood cells in the mother's circulation before her immune system can produce antibodies against them.

Parental concerns

Parents should examine their infant in natural daylight and under fluorescent lighting for signs of jaundice. Jaundice may be harder to see in infants with darker skin. However, when a child's nose and forehead are pressed gently, the skin is white in healthy babies of all races, but yellowish if jaundice is present. If the skin appears yellow, the test should be repeated on the chest or abdomen. Parents also should be aware of symptoms that may accompany jaundice, including fussiness, unusual sleepiness, or difficulty feeding.

Mothers who are having difficulty breastfeeding should seek help. Although breast milk is an effective treatment for jaundice, breastfed babies may receive fewer calories than formula-fed babies during the first days of life, causing bilirubin levels to rise.

Juvenile arthritis

Definition

Juvenile arthritis (JA) refers to a number of different conditions, all of which strike children and all of which have joint inflammation as their major manifestation. The condition is also referred to as juvenile rheumatoid arthritis.

Description

The skeletal system of the body is made up of different types of the strong, fibrous tissue known as connective tissue. Bone, cartilage, ligaments, and tendons are all forms of connective tissue which have different compositions and different characteristics.

The joints are structures that hold two or more bones together. Some joints (synovial joints) allow for movement between the bones being joined (called articulating bones). The simplest model of a synovial joint involves two bones, separated by a slight gap called the joint cavity. The ends of each articular bone are covered by a layer of cartilage. Both articular bones and the joint cavity are surrounded by a tough tissue called the articular capsule. The articular capsule has two components: the

fibrous membrane on the outside and the synovial membrane (or synovium) on the inside. The fibrous membrane may include tough bands of fibrous tissue called ligaments, which are responsible for providing support to the joints. The synovial membrane has special cells and many capillaries (tiny blood vessels). This membrane produces a supply of synovial fluid which fills the joint cavity, lubricates it, and helps the articular bones move smoothly about the joint.

In JA, the synovial membrane becomes intensely inflamed. Usually thin and delicate, the synovium becomes thick and stiff, with numerous infoldings on its surface. The membrane becomes invaded by white blood cells, which produce a variety of destructive chemicals. The cartilage along the articular surfaces of the bones may be attacked and destroyed, and the bone, articular capsule, and ligaments may begin to be worn away (eroded). These processes severely interfere with movement in the joint.

JA specifically refers to chronic arthritic conditions which affect a child under the age of 16 years and which last for a minimum of three to six months. JA is often characterized by a waxing and waning course, with flares separated by periods during which no symptoms are noted (remission). Some literature refers to JA as juvenile rheumatoid arthritis, although most types of JA differ significantly from the adult disease called rheumatoid arthritis, in terms of symptoms, progression, and prognosis.

Demographics

Between five and 18 of every 100,000 children develop juvenile rheumatoid arthritis each year; the overall prevalence is approximately 30–150 per 100,000. More than 65,000 young people in the United States develop it each year. It can affect children as young as two years of age.

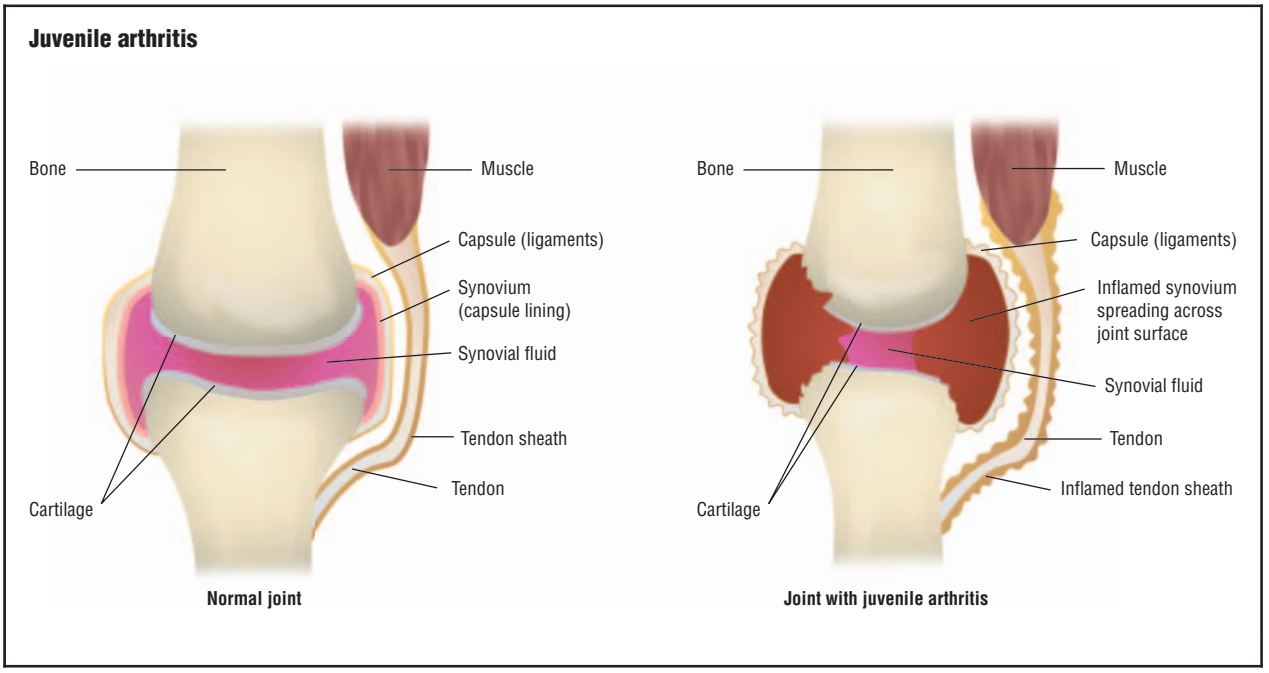
Causes and symptoms

A number of different causes have been sought to explain the onset of JA. There seems to be some genetic link, based on the fact that the tendency to develop JA sometimes runs in a particular **family** and based on the fact that certain genetic markers are more frequently found in patients with JA and other related diseases. Many researchers have looked for some infectious cause for JA, but no clear connection to a particular organism had been made as of 2004. JA is considered by some to be an autoimmune disorder. Autoimmune disorders occur when the body's immune system mistakenly identifies the body's own tissue as foreign and goes about attacking those tissues, as if trying to rid the body of an invader (such as a bacteria, virus, or fungi). While an autoimmune mechanism is strongly suspected, certain markers of such a mechanism (such as rheumatoid factor, often present in adults with such disorders) are rarely present in children with JA.

Joint symptoms of arthritis may include stiffness, **pain**, redness and warmth of the joint, and swelling. Bone in the area of an affected joint may grow too quickly or too slowly resulting in limbs which are of different lengths. When the child tries to avoid moving a painful joint, the muscle may begin to shorten from disuse. This condition is called a contracture.

Symptoms of JA depend on the particular subtype. JA is classified by the symptoms which appear within the first six months of the disorder:

- Pauciarticular JA: The most common and the least severe type of JA affects about 40–60 percent of all JA patients. This type of JA affects fewer than four joints, usually the knee, ankle, wrist, and/or elbow. Other more general (systemic) symptoms are usually absent, and the child's growth usually remains normal. Very few children (fewer than 15 percent) with pauciarticular JA end up with deformed joints. Some children with this form of JA experience painless swelling of the joint. Some children with JA have a serious inflammation of structures within the eye, which if left undiagnosed and untreated could even lead to blindness. While many children have cycles of flares and remissions, in some children the disease completely and permanently resolves within a few years of diagnosis.
- Polyarticular JA: About 40 percent of all cases of JA are of this type. More girls than boys are diagnosed with this form of JA, and it is most common in children up to age three or after the age of ten. Polyarticular JA affects five or more joints simultaneously. This type of JA usually affects the small joints of both hands and both feet, although other large joints may be affected as well. Some patients with arthritis in their knees will experience a different rate of growth in each leg. Ultimately, one leg will grow longer than the other. About half of all patients with polyarticular JA have arthritis of the spine and/or hip. Some patients with polyarticular JA will have other symptoms of a systemic illness, including anemia (low red blood cell count), decreased growth rate, low appetite, low-grade **fever**, and a slight rash. The disease is most severe in those children who are diagnosed in early **adolescence**. Some of these children test positive for a marker present in other autoimmune disorders, called rheumatoid factor (RF), which is found in adults who have rheuma-



Normal knee joint (left) and one affected by juvenile arthritis, which shows damaged cartilage and inflammation of the synovial fluid and tendon sheath. *(Illustration by GGS Information Services.)*

toid arthritis. Children who are positive for RF tend to have a more severe course, with a disabling form of arthritis that destroys and deforms the joints. This type of arthritis is thought to be the adult form of rheumatoid arthritis occurring at a very early age.

- Systemic onset JA: Sometimes called Still disease (after a physician who originally described it), this type of JA occurs in about 10–20 percent off all patients with JA. Boys and girls are equally affected, and diagnosis is usually made between the ages of five and 10 years. The initial symptoms are not usually related to the joints. Instead, these children have high fevers; a rash; decreased appetite and weight loss; severe joint and muscle pain; swollen lymph nodes, spleen, and liver; and serious anemia. Some children experience other complications, including inflammation of the sac containing the heart (pericarditis); inflammation of the tissue lining the chest cavity and lungs (pleuritis); and inflammation of the heart muscle (myocarditis). The eye inflammation often seen in pauciarticular JA is uncommon in systemic onset JA. Symptoms of actual arthritis begin later in the course of systemic onset JA, and they often involve the wrists and ankles. Many of these children continue to have periodic flares of fever and systemic symptoms throughout childhood. Some children go on to develop a polyarticular type of JA.
- Spondyloarthropathy: This type of JA most commonly affects boys older than eight years of age. The arthritis occurs in the knees and ankles, moving over time to include the hips and lower spine. Inflammation of the eye may occur occasionally but usually resolves without permanent damage.
- Psoriatic JA: This type of arthritis usually shows up in fewer than four joints but goes on to include multiple joints (appearing similar to polyarticular JA). Hips, back, fingers, and toes are frequently affected. A skin condition called **psoriasis** accompanies this type of arthritis. Children with this type of JA often have pits or ridges in their fingernails. The arthritis usually progresses to become a serious, disabling problem.

When to call the doctor

A pediatrician, family physician, or other primary care doctor frequently manages the treatment of a child with JA, often with the help of other doctors. Depending on the patient's and parents' wishes and the severity of the disease, the team of doctors may include pediatric rheumatologists (doctors specializing in childhood arthritis), ophthalmologists (eye doctors), orthopaedic surgeons (bone specialists), and physiatrists (rehabilitation specialists), as well as physical and occupational therapists. The main goals of treatment are to preserve a high level of physical and social functioning and

maintain a good quality of life. To achieve these goals, doctors recommend treatments to reduce swelling; maintain full movement in the affected joints; relieve pain; and identify, treat, and prevent complications. Most children with JA need medication and physical therapy to reach these goals.

Diagnosis

Diagnosis of JA is often made on the basis of the child's collection of symptoms. Laboratory tests often show normal results. Some nonspecific indicators of inflammation may be elevated, including white blood cell count, erythrocyte sedimentation rate, and a marker called C-reactive protein. As with any chronic disease, anemia may be noted. Children with an extraordinarily early onset of the adult type of rheumatoid arthritis have a positive test for rheumatoid factor.

Treatment

Treating JA involves efforts to decrease the amount of inflammation in order to preserve movement. Medications which can be used for this include nonsteroidal anti-inflammatory agents (such as ibuprofen and naproxen). Oral (by mouth) steroid medications are effective but have many serious side effects with long-term use. Injections of steroids into an affected joint can be helpful. Steroid eye drops are used to treat eye inflammation. Other drugs that have been used to treat JA include methotrexate, sulfasalazine, penicillamine, and hydroxychloroquine. Physical therapy and exercises are often recommended in order to improve joint mobility and to strengthen supporting muscles. Occasionally, splints are used to rest painful joints and to try to prevent or reduce deformities.

Alternative treatment

Alternative treatments that have been suggested for arthritis include juice therapy, which can work to detoxify the body, helping to reduce JA symptoms. Some recommended fruits and vegetables to include in the juice are carrots, celery, cabbage, potatoes, cherries, lemons, beets, cucumbers, radishes, and garlic. However, for children with osteoarthritis, citrus fruits and vegetables from the nightshade family, including potatoes, tomatoes, peppers, and eggplant, should be avoided since they can promote swelling. As an adjunct therapy, aromatherapy preparations use cypress, fennel, and lemon. Massage oils include rosemary, benzoin, chamomile, camphor, juniper, and lavender. Other types of therapy that have been used for JA include acupuncture, acupressure, and bodywork. Nutritional supplements that may be beneficial include large amounts of antioxidants (**vitamins** C, A, E, zinc, selenium, and flavenoids), as well as B vitamins and a full complement of **minerals** (including boron, copper, and manganese). Other nutrients that assist in detoxifying the body, including methionine, cysteine, and other amino acids, may also be helpful. A number of autoimmune disorders, including JA, seem to have a relationship to **food allergies**. Identification and elimination of reactive foods may result in a decrease in JA symptoms. Constitutional homeopathy can also work to quiet the symptoms of JA and bring about balance to the whole person.

A young girl with juvenile arthritis uses braces to help rest painful joints and prevent deformities. *(© John Moss/Photo Researchers, Inc.)*

Nutritional concerns

When female patients were compared to age-matched normals, greater than one serving per week of grilled (broiled) or baked fish (other than tuna) was

associated with a decreased risk of disease. This inverse association was stronger than that for omega-3 fatty acid intake alone. In another study, patients with active disease randomly received treatment with or without a diet in which the energy consumption was adjusted to normal standards for body-weight, and the intake of fish and antioxidants was increased. After six months, those following the diet demonstrated significant improvement in the duration of morning stiffness, the number of swollen joints, and pain status.

Several studies, some of which were controlled, have found beneficial effects from a vegetarian or vegan diet. In one study, for example, patients randomly received either an uncooked vegan diet or a control diet for three months. Those on the vegan diet experienced subjective relief of rheumatic stiffness and joint swellings and an improvement in general wellbeing. After returning to the meat diet, these symptoms worsened. The degree of tender joints remained unchanged in controls, but in the diet group their number decreased significantly.

Prognosis

The prognosis for pauciarticular JA is quite good, as is the prognosis for spondyloarthropathy. Polyarticular JA carries a slightly worse prognosis. RF-positive polyarticular JA carries a difficult prognosis, often with progressive, destructive arthritis and joint deformities. Systemic onset JA has a variable prognosis, depending on the organ systems affected and the progression to polyarticular JA. About 1–5 percent of all JA patients die of such complications as infection, inflammation of the heart, or kidney disease.

Prevention

Because so little is known about what causes JA, there are no recommendations available for ways to avoid developing it.

Parental concerns

JA affects the entire family who must cope with the special challenges of this disease. JA can strain a child's participation in social and after-school activities and make schoolwork more difficult. There are several things that family members can do to help the child do well physically and emotionally. These include the following:

- Ensure that the child receives appropriate medical care and follows the doctor's instructions. Many treatment options are available, and because JA is different in each child, what works for one may not work for another. If the medications that the doctor prescribes do not relieve symptoms or if they cause unpleasant side effects, patients and parents should discuss other choices with their doctor. A person with JA can be more active when symptoms are controlled.
- Encourage **exercise** and physical therapy for the child. For many young people, exercise and physical therapy play important roles in treating JA. Parents can arrange for children to participate in activities that the doctor recommends. During symptom-free periods, many doctors suggest playing team **sports** or doing other activities to help keep the joints strong and flexible and to provide play time with other children and encourage appropriate social development.
- Work closely with the school to develop a suitable lesson plan for the child and to educate the teacher and the child's classmates about JA. Some children with JA may be absent from school for prolonged periods and need to have the teacher send assignments home. Some minor changes such as an extra set of books or leaving class a few minutes early to get to the next class on time can be a great help. With proper attention, most children progress normally through school.
- Treat the child as normally as possible. Explain to the child that getting JA is nobody's fault. Some children believe that JA is a punishment for something they did. Consider joining a support group. The American Juvenile Arthritis Organization runs support groups for people with JA and their families. Support group meetings provide the chance to talk to other young people and parents of children with JA and may help a child and the family cope with the condition.

KEY TERMS

Articular bones—Two or more bones that are connected to each other via a joint.

Joint—The connection point where two bones meet.

Synovial joint—A fully moveable joint in which a synovial cavity is present between two articulating bones. Also called a diarthrosis.

Synovial membrane—The membrane that lines the inside of the articular capsule of a joint, and produces a lubricating fluid called synovial fluid.

K

Kawasaki syndrome

Definition

Kawasaki syndrome is a potentially fatal inflammatory disease that affects several organ systems in the body, including the heart, circulatory system, mucous membranes, skin, and immune system. As of 2004 its cause was unknown.

Description

In the 1960s, Tomisaku Kawasaki noted a characteristic cluster of symptoms in Japanese schoolchildren. Ultimately named for Kawasaki, the disorder was subsequently found worldwide. Kawasaki syndrome, also called mucocutaneous lymph node syndrome (MLNS), is an inflammatory disorder with potentially fatal complications affecting the heart and its larger arteries.

Demographics

Kawasaki syndrome occurs primarily in infants and children; about 80 percent of diagnosed patients are under the age of five. On rare occasions, the disorder has been diagnosed in teenagers or adults. Nearly twice as many males are affected as females. Although persons of Asian descent are affected more frequently than either black or white individuals, there does not appear to be a distinctive geographic pattern of occurrence. Although the disease usually appears in individuals, it sometimes affects several members of the same **family** and occasionally occurs in small epidemics. About 3,000 cases are diagnosed annually in the United States.

Causes and symptoms

The specific cause of Kawasaki syndrome was as of 2004 unknown, although the disease resembles an infectious illness in many ways. It has been suggested that Kawasaki syndrome represents an allergic reaction or other unusual response to certain types of infections. Some researchers think that the syndrome may be caused by the interaction of an immune cell, called the T cell, with certain poisons (toxins) secreted by bacteria.

Kawasaki syndrome has an abrupt onset, with **fever** as high as 104°F (40°C) and a rash that spreads over the patient's chest and genital area. The fever is followed by a characteristic peeling of the skin beginning at the fingertips and toenails. In addition to the body rash, the patient's lips become very red, with the tongue developing a "strawberry" appearance. The palms, soles, and mucous membranes that line the eyelids and cover the exposed portion of the eyeball (conjuntivae) become purplish-red and swollen. The lymph nodes in the patient's neck may also become swollen. These symptoms may last from two weeks to three months, with relapses in some patients.

In addition to the major symptoms, about 30 percent of patients develop joint **pain** or arthritis, usually in the large joints of the body. Others develop **pneumonia**, **diarrhea**, dry or cracked lips, **jaundice**, or an inflammation of the membranes covering the brain and spinal cord (**meningitis**). A few patients develop symptoms of inflammation in the liver (hepatitis), gallbladder, lungs, or tonsils.

About 20 percent of patients with Kawasaki syndrome develop complications of the cardiovascular system. These complications include inflammation of the heart tissue (myocarditis), disturbances in heartbeat rhythm (arrhythmias), and areas of blood vessel dilation (aneurysms) in the coronary arteries. Other patients may develop inflammation of an artery (arteritis) in their arms or legs. Complications of the heart or arteries begin to develop around the tenth day after the illness begins, when the fever and rash begin to subside. A few patients may develop gangrene (the death of soft tissue) in their hands and feet. The specific causes of these complications were as of 2004 not known.

Diagnosis

Because Kawasaki syndrome is primarily a disease of infants and young children, the disease is most likely to be diagnosed by a pediatrician. The physician will first consider the possible involvement of other diseases that cause fever and skin **rashes**, including **scarlet fever**, **measles**, **Rocky Mountain spotted fever**, **toxoplasmosis** (a disease carried by cats), juvenile rheumatoid arthritis, and a blistering and inflammation of the skin caused by reactions to certain medications (Stevens-Johnson syndrome).

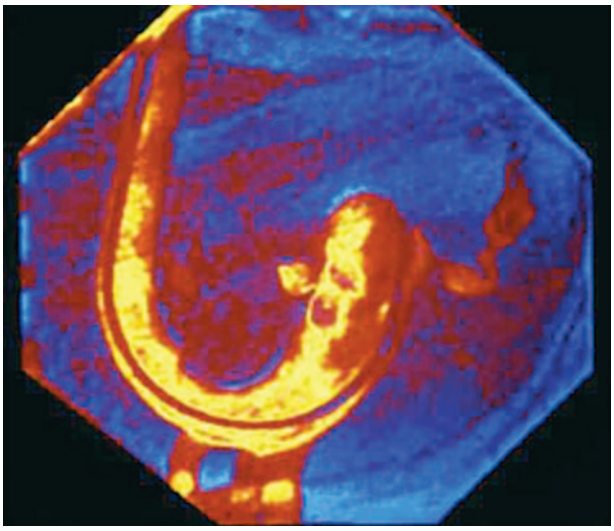
Once other diseases have been ruled out, the patient's symptoms will be compared with a set of diagnostic criteria. The patient must have a fever lasting five days or longer that does not respond to **antibiotics**, together with four of the following five symptoms:

- inflammation of the conjunctivae of both eyes with no discharge
- at least one of the following changes in the mucous membranes of the mouth and throat: "strawberry" tongue, cracked lips, or swollen throat tissues
- at least one of the following changes in the hands or feet: swelling caused by excess fluid in the tissues, peeling of the skin, or abnormal redness of the skin
- a skin eruption or rash associated with fever (exanthem) on the patient's trunk
- swelling of the lymph nodes in the neck to a size greater than 1.5 cm

Given the unknown cause of this syndrome, there are no laboratory tests that can confirm the diagnosis. The following test results, however, are associated with the disease:

- Blood tests show a high white blood cell count, high **platelet count**, a high level of protein in the blood serum, and mild anemia.
- A chest x ray may show enlargement of the heart (cardiomegaly).
- Urine may show the presence of pus or an abnormally high level of protein.
- An electrocardiogram may show changes in the heartbeat rhythm.

In addition to these tests, it is important to take a series of echocardiograms during the course of the illness because 20 percent of Kawasaki patients develop coronary aneurysms or arteritis that will not appear during the first examination.



An angiogram showing abnormal coronary arteries in a child suffering from Kawasaki's disease. The coronary arteries bulge into balloon shapes, called aneurysms, along their lengths. *(Photograph by Mehau Kulyk. Photo Researchers, Inc.)*

Treatment

Kawasaki syndrome is usually treated with a combination of aspirin, to control the patient's fever and skin inflammation, and high doses of intravenous immune globulin to reduce the possibility of coronary artery complications. Some patients with heart complications may be treated with drugs that reduce blood clotting or may receive corrective surgery.

Follow-up care includes two to three months of monitoring with chest **x rays**, electrocardiography, and echocardiography. Treatment with aspirin is often continued for several months.

Prognosis

Most patients with Kawasaki syndrome will recover completely, but about 1–2 percent die as a result of blood clots forming in the coronary arteries or as a result of a heart attack. Deaths are sudden and unpredictable. Almost 95 percent of fatalities occur within six months of infection, but some have been reported as long as 10 years afterward. Long-term follow-up of patients with aneurysms indicates that about half show some healing of the aneurysm. The remaining half has a high risk of heart complications in later life.

Parental concerns

It is important that parents of children diagnosed with Kawasaki syndrome follow recommended treatments and follow-up care for the disease, because of the

KEY TERMS

Aneurysm—A weakened area in the wall of a blood vessel which causes an outpouching or bulge. Aneurysms may be fatal if these weak areas burst, resulting in uncontrollable bleeding.

Arrhythmia—Any deviation from a normal heart beat.

Arteritis—Inflammation of an artery.

Cardiomegaly—An enlarged heart.

Conjunctiva—Plural, conjunctivae. The mucous membrane that covers the white part of the eyes (sclera) and lines the eyelids.

Exanthem—A skin eruption associated with a disease, usually one accompanied by fever as in Kawasaki syndrome.

Gangrene—Decay or death of body tissue because the blood supply is cut off. Tissues that have died in this way must be surgically removed.

Hepatitis—An inflammation of the liver, with accompanying liver cell damage or cell death, caused most frequently by viral infection, but also by certain drugs, chemicals, or poisons. May be either acute (of limited duration) or chronic (continuing). Symptoms include jaundice, nausea, vomiting, loss of appetite, tenderness in the right upper abdomen, aching muscles, and joint pain. In severe cases, liver failure may result.

Meningitis—An infection or inflammation of the membranes that cover the brain and spinal cord. It is usually caused by bacteria or a virus.

Mucocutaneous lymph node syndrome (MLNS)—Another name for Kawasaki syndrome. The name comes from the key symptoms of the disease, which involve the mucous membranes of the mouth and throat, the skin, and the lymph nodes. MLNS is a potentially fatal inflammatory disease of unknown cause.

Myocarditis—Inflammation of the heart muscle (myocardium).

Stevens-Johnson syndrome—A severe inflammatory skin eruption that occurs as a result of an allergic reaction or respiratory infection.

T cell—A type of white blood cell that is produced in the bone marrow and matured in the thymus gland. It helps to regulate the immune system's response to infections or malignancy.

risk of potentially serious complications. Any worsening or unexplained new symptoms should be reported to the treating pediatrician.

Klinefelter syndrome

Definition

Klinefelter syndrome is a chromosome disorder in males that results in **hypogonadism** (small penis and small firm testicles). People with this condition are born with at least one extra X chromosome.

Description

Klinefelter syndrome is a condition where one or more extra X-chromosomes are present in a male. Boys with this condition appear normal at birth, but the defect becomes apparent in **puberty** when secondary sexual characteristics fail to develop, or develop later. By mid-puberty, boys with Klinefelter syndrome have low levels of testosterone, resulting in small testicles and the inability to make sperm. Affected males may also have learning disabilities and behavior problems such as **shyness** and immaturity and at an increased risk for certain other health problems such as pulmonary disease, varicose veins, breast **cancer**, extragonadal germ cell tumor (a rare tumor), and osteoporosis. Some mild cases may be

undetected, with no abnormalities present except infertility.

Demographics

Klinefelter syndrome is one of the most common chromosomal abnormalities. About 1 in every 500 to 800 males is born with this disorder. Approximately 3% of the infertile male population have Klinefelter syndrome.

Causes and symptoms

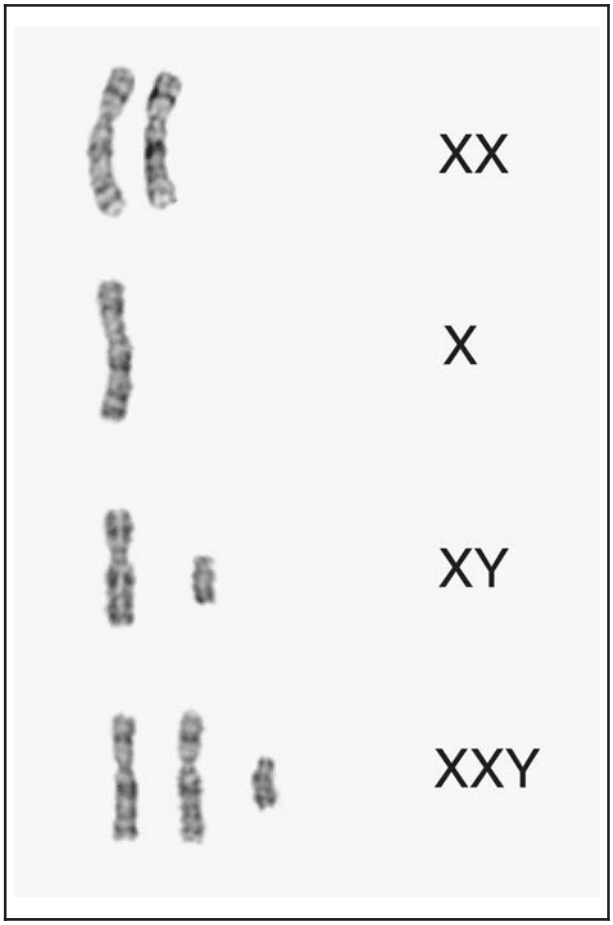
Normally, a person has a total of 46 chromosomes in each cell, two of which are responsible for determining that individual's sex. These two sex chromosomes are called X and Y. The combination of these two types of chromosomes determines the sex of a child. Females have two X chromosomes (the XX combination); males have one X and one Y chromosome (the XY combination).

In Klinefelter syndrome, a problem very early in fetal development results in an abnormal number of chromosomes. Most commonly, a male with Klinefelter syndrome will be born with 47 chromosomes in each cell, rather than the normal number of 46. The extra chromosome is an X chromosome. This means that rather than having the normal XY combination, the male has an XXY combination. Because people with Klinefelter syndrome have a Y chromosome, they are all male.

Approximately 1/3 of all males with Klinefelter syndrome have other chromosome changes involving an extra X chromosome. Mosaic Klinefelter syndrome occurs when some of the cells in the body have an extra X chromosome and the other have normal male chromosomes. These males can have the same or milder symptoms than those with non-mosaic Klinefelter syndrome. Males with more than one additional extra X chromosome, such as 48,XXXY, are usually more severely affected than males with 47,XXY.

Klinefelter syndrome is not considered an inherited condition. The risk of Klinefelter syndrome reoccurring in another pregnancy for a woman who had a son with Klinefelter syndrome is not increased above the risk of the general population.

The symptoms of Klinefelter syndrome are variable; not every affected person will have all of the features of the condition. Males with Klinefelter syndrome appear normal at birth and have normal male genitalia. From childhood, males with Klinefelter syndrome are taller than average with long limbs. Approximately 20–50% have a mild intention tremor, an uncontrolled shaking. Many males with Klinefelter syndrome have poor upper body strength and can be clumsy. Klinefelter syndrome does not cause **homosexuality**. Approximately 1/3 of males with Klinefelter syndrome have breast growth, some requiring breast reduction surgery.



Sex chromosomes showing different phenotypes: XX–normal female; X–female with Turner syndrome; XY–normal male; and XXY–male with Klinefelter. *(Lerner & Lerner, LLC.)*

Most boys enter puberty normally, though some can be delayed. The Leydig cells in the testicles usually produce testosterone. With Klinefelter syndrome, the Leydig cells fail to work properly causing the testosterone production to slow. By mid-puberty, testosterone production is decreased to approximately half of normal. This can lead to decreased facial and pubic hair growth. The decreased testosterone also causes an increase in two other hormones, follicle stimulating hormone (FSH) and luteinizing hormone (LH). Normally, FSH and LH help the immature sperm cells grown and develop. In Klinefelter syndrome, there are few or no sperm cells. The increased amount of FSH and LH cause

hyalinization and fibrosis, the growth of excess fibrous tissue, in the seminiferous tubules, where the sperm are normally located. As a result, the testicles appear smaller and firmer than normal. With rare exception, men with Klinefelter syndrome are infertile because they can not make sperm.

While it was once believed that all boys with Klinefelter syndrome were mentally retarded, doctors now know that the disorder can exist without retardation. However, children with Klinefelter syndrome frequently have difficulty with language, including learning to speak, read, and write. Approximately 50% of males with Klinefelter syndrome are dyslexic. They may also have attention deficient hyperactivity disorder.

Some people with Klinefelter syndrome have difficulty with social skills and tend to be more shy, anxious, or immature than their peers. They can also have poor judgement and do not handle stressful situations well. As a result, they often do not feel comfortable in large social gatherings. Some people with Klinefelter syndrome can also have **anxiety**, nervousness and/or depression.

Taurodontism, an enlargement of the pulp of the teeth with surface thinning, is very common in Klinefelter syndrome and can be diagnosed with dental x rays.

The greater the number of X chromosomes present, the greater the disability. Boys with several extra X chromosomes have distinctive facial features, more severe retardation, deformities of bony structures, and even more disordered development of male features.

When to call the doctor

Parents should call a doctor if their son fails to develop secondary sexual characteristics at puberty.

Diagnosis

During a physical examination, a doctor will look for a simian crease (a single crease in the palm). A rectal exam may show an enlarged prostate. A single testicle may be present in the scrotum, indicating a probable undescended testicle. A semen examination will show low sperm count, while other tests will show decreased serum testosterone levels, increased levels of serum luteining and serum follicle stimulating hormones and increased serum estradiol levels (a type of estrogen).

Diagnosis of Klinefelter syndrome is confirmed by examining chromosomes for evidence of more than one X chromosome present in a male. This can be done in pregnancy with prenatal testing such as chorionic villus sampling or **amniocentesis**. Chorionic villus sampling is a procedure done early in pregnancy (approximately 10–12 weeks) to obtain a small sample of the placenta for testing. An amniocentesis is done further along in pregnancy (from approximately 16–18 weeks) to obtain a sample of fluid surrounding the baby for testing. Both procedures have a risk of miscarriage. Usually these procedures are done for a reason other than diagnosing Klinefelter syndrome. For example, a prenatal diagnostic procedure may be done on an older woman to determine if her baby has **Down syndrome**. If the diagnosis of Klinefelter syndrome is suspected in a young boy or adult male, chromosome testing can also be on a small blood or skin sample after birth.

Treatment

There is no treatment available to change chromosomal makeup. Children with Klinefelter syndrome may benefit from a speech therapist for speech problems or other educational intervention for learning disabilities. Testosterone injections started around the time of puberty and continued for life may help to produce more normal development, including more muscle mass, hair growth and increased sex drive. Testosterone supplementation will not increase testicular size, decrease breast growth or correct infertility.

Prognosis

While many men with Klinefelter syndrome live normal lives, nearly 100 percent of these men will be sterile (unable to produce a child). However, a few men with Klinefelter syndrome have been reported who have fathered a child through the use of assisted fertility services. Males with Klinefelter syndrome have an increased risk of several conditions such as osteoporosis, pulmonary disease, varicose veins, autoimmune disorders such as lupus and arthritis, diabetes, breast cancer and extragonadal germ cell tumor (a rare tumor).

Prevention

Klinefelter syndrome usually is not inherited but occurs during fetal development, so there is no means of preventing the disease. However, one risk factor for this condition is the mother giving birth at an older age; therefore, genetic counseling and testing is recommended.

Parental concerns

Families may wish to seek counseling regarding the effects of the syndrome on relationships within the **family**. Many people respond with guilt, **fear**, or

KEY TERMS

Follicle-stimulating hormone (FSH)—A pituitary hormone that in females stimulates the ovary to mature egg capsules (follicles) and in males stimulates sperm production.

Luteinizing hormone—A hormone secreted by the pituitary gland that regulates the menstrual cycle and triggers ovulation in females. In males it stimulates the testes to produce testosterone.

Testosterone—Male hormone produced by the testes and (in small amounts) in the ovaries. Testosterone is responsible for some masculine secondary sex characteristics such as growth of body hair and deepening voice. It also is sometimes given as part of hormone replacement therapy to women whose ovaries have been removed.

blame when a genetic disorder is diagnosed in the family, or they may overprotect the affected member. Support groups are often good sources of information about Klinefelter syndrome; they can offer helpful suggestions about living with it as well as emotional support.

Labyrinthitis

Definition

Labyrinthitis is an inflammation of the inner ear that is often a complication of infection of the middle ear (**otitis media**). It is usually caused by the spread of bacterial or viral infections from the head or respiratory tract into the inner ear.

Description

The labyrinth is a group of interconnected canals chambers located in the inner ear. It is made up of the cochlea and the semicircular canals. The cochlea is involved in transmitting sounds to the brain. The semicircular canals send information to the brain about the head's position and how it is moving. The brain uses this information to maintain balance. Labyrinthitis is caused by the inflammation of the labyrinth. Its most frequent symptom is vertigo (**dizziness**), because the information that the semicircular canals send to the brain about the position of the head is affected.

Demographics

Labyrinthitis is rare and is more likely to occur after middle ear infections, **meningitis**, or upper respiratory infection. It may also occur after trauma, because of a tumor, or after the ingesting of toxic substances. It is thought to be more common in females than in males.

Causes and symptoms

When a disease agent causes labyrinthitis, the disease agent usually reaches the inner ear by one of three routes:

- Bacteria may be carried from the middle ear or the membranes that cover the brain.
- Viruses, such as those that cause **mumps**, **measles**, **influenza**, and colds may reach the inner ear following an upper respiratory infection.
- The **rubella** virus can cause labyrinthitis in infants prior to birth.

Labyrinthitis can also be caused by toxins, by a tumor in the ear, by trauma to the ear, and sometimes high doses of medications or **allergies**.

The primary symptoms of labyrinthitis are vertigo and hearing loss, along with a sensation of ringing in the ears called tinnitus. Vertigo occurs because the inner ear controls the sense of balance, as well as hearing. Some individuals also experience **nausea and vomiting** and spontaneous eye movements in the direction of the unaffected ear. Bacterial labyrinthitis may produce a discharge from the infected ear.

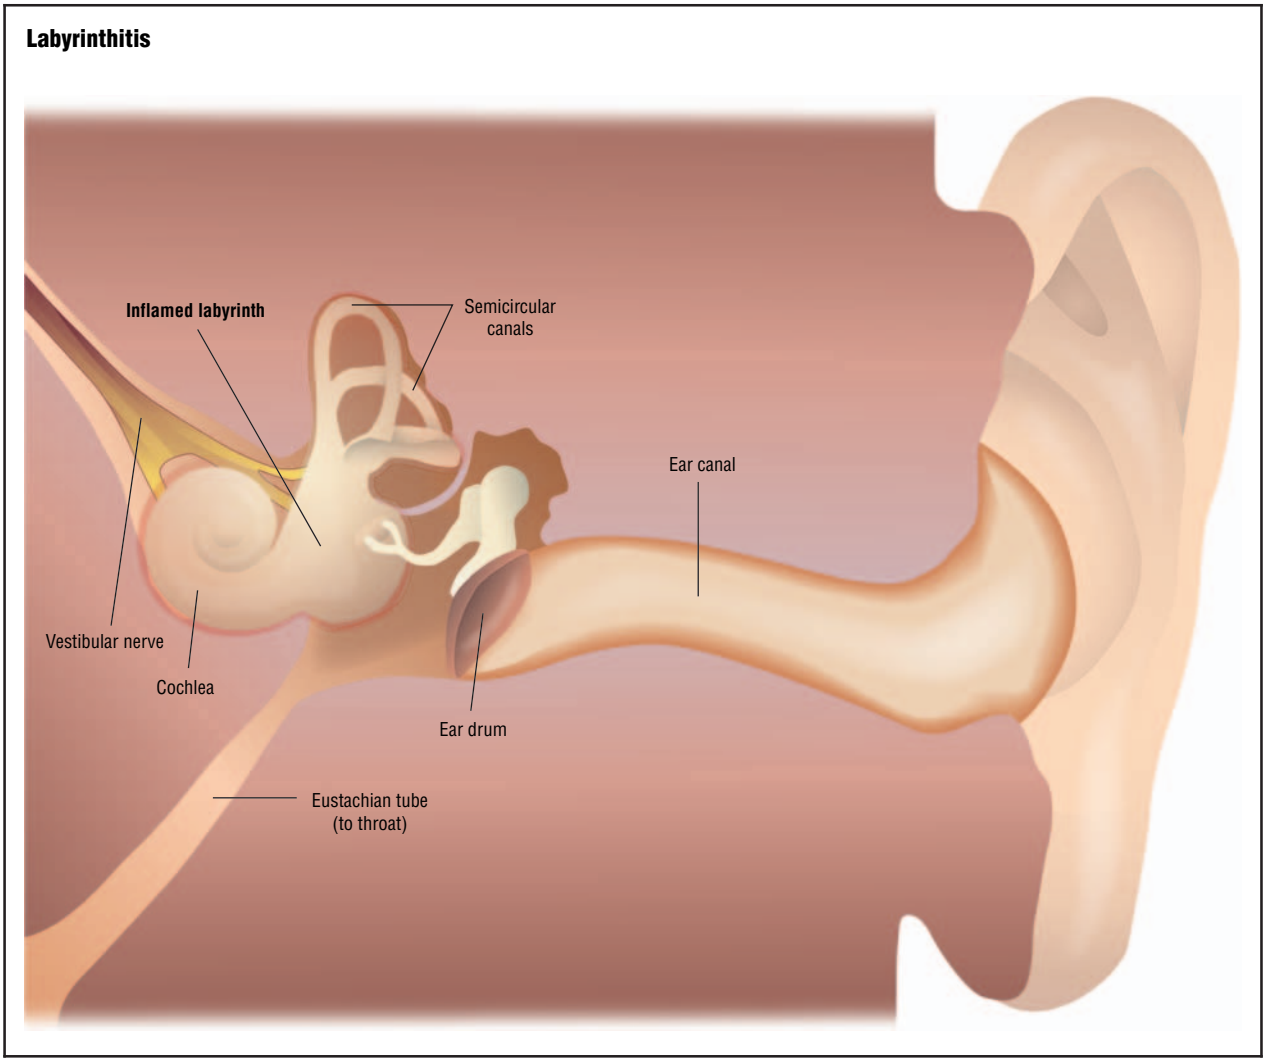
When to call the doctor

If a child has vertigo, especially along with **nausea**, **vomiting**, or hearing loss, the doctor should be called.

Diagnosis

Diagnosis of labyrinthitis is based on a combination of the individual's symptoms and history, especially a history of a recent upper respiratory infection. The doctor will test the child's hearing and order a laboratory culture to identify the organism if the patient has a discharge.

If there is no history of a recent infection, the doctor will order tests such as a commuted topography (CT) scan or a **magnetic resonance imaging** (MRI) scan to help rule out other possible causes of vertigo, such as tumors. If it is believed a bacterium is causing the labyrinthitis, blood tests may be done, or any fluid draining from the ear may be analyzed to help determine what type of bacteria is present.



Labyrinthitis, or inner ear infection, causes the labyrinth area of the ear to become inflamed. *(Illustration by GGS Information Services.)*

Treatment

If a bacterial agent is found to be the cause, the individual is given **antibiotics** to clear up the infection. Antibiotics cannot cure viral infections. Some patients may require surgery to drain the inner and middle ear. If an underlying condition such as a tumor is found to be the cause of the labyrinthitis, treatment will depend on the underlying condition.

Because most labyrinthitis resolves on its own, most treatment is focused on controlling the symptoms. Medications may be prescribed to help reduce vertigo and nausea. If vomiting cannot be controlled, so that fluids cannot be kept down, fluids may be administered intravenously to prevent **dehydration**.

Individuals with labyrinthitis should rest in bed until the acute dizziness subsides. Some experts believe that recovery is aided by moving around once the most acute symptoms are no longer present. This can be difficult, however, because moving often makes symptoms worse.

Prognosis

Most people who have labyrinthitis recover completely, although it often takes five to six weeks for the vertigo to disappear entirely and the individual's hearing to return to normal. In a few cases, the hearing loss may be permanent. Permanent hearing loss is more common in cases of labyrinthitis that are caused by bacteria. For

KEY TERMS

Labyrinth—The bony cavity of the inner ear.

Otitis media—Inflammation or infection of the middle ear space behind the eardrum. It commonly occurs in early childhood and is characterized by ear pain, fever, and hearing problems.

Vertigo—A feeling of dizziness together with a sensation of movement and a feeling of rotating in space.

some individuals, episodes of dizziness may still occur months after the main episode is over.

Prevention

The most effective preventive strategy includes prompt treatment of middle ear infections, as well as monitoring of patients with mumps, measles, influenza, or colds for signs of dizziness or hearing problems.

Parental concerns

Labyrinthitis generally resolves by itself; however, in some cases permanent hearing loss can result. Labyrinthitis may cause repeated episodes of vertigo even after the main symptoms have gone away. If the episodes occur when the head is moved suddenly, this can make it difficult for a child to engage in some physical activities or **sports**.

Lactation

Definition

Lactation refers to the formation of milk in the breasts during the period following **childbirth**. Breastfeeding is the process of the infant obtaining milk by suckling at the breast.

Description

Although **breast development** begins around **puberty**, development of mammary function is only completed in pregnancy. During the first half of pregnancy the mammary ducts proliferate and group together to form large lobules. During the second half of pregnancy, secretory activity increases and the alveoli become distended by accumulating colostrum. After 16 weeks of pregnancy, lactation occurs even if the pregnancy does not progress.

The ability of the mammary gland to secrete milk during later pregnancy is called lactogenesis, stage 1. During this time, breast size increases and fat droplets accumulate in the secretory cells. The onset of copious milk secretions after birth is lactogenesis, stage 2, and usually occurs from day two or three to eight days postpartum. During this time, the milk goes through a maturation process to match the infant's needs. Without the hormone prolactin, lactation would not occur. During pregnancy prolactin helps to increase breast mass but does not cause lactation because it is inhibited by the hormone progesterone, which is made by the placenta. The inhibiting influence of progesterone is so strong that lactation is delayed if any of the placenta is retained after birth. Prolactin levels rise and fall in direct proportion to the frequency, intensity, and duration of nipple stimulation from the infant's suckling. During the first week after birth, prolactin levels in breastfeeding women fall about 50 percent. If a mother does not breastfeed,

prolactin levels usually reach the levels of the nonpregnant state by seven days postpartum. After milk "comes in" or rapidly increases in volume, lactation is no longer driven by the hormone prolactin. It shifts control to a milk removal driven process, i.e., sucking stimulus. Thus, the initiation of lactation is not driven by breastfeeding, but breastfeeding is necessary for the continuation of lactation.

The breast is not a passive container of milk. It is an organ that actively produces milk due to the stimulus of the infant's sucking; the removal of milk from the breasts causes continued milk production. It is a supply and demand response that regulates the production of milk to match the intake of the infant. The composition of breast milk changes to meet the specific needs of the growing infant. In response to suckling, the hormone oxytocin causes the milk ejection reflex or "let-down" reflex to occur. Milk ejection is the forceful expulsion of milk from the alveoli openings. Oxytocin secretion is also nature's way of causing a woman's uterus to contract after birth to control postpartum bleeding and assist in uterine involution. These contractions can continue for up to 20 minutes after feeding and may be painful during the first few days. The benefit of this, however, is that uterine discharge diminishes faster and the uterine involution occurs more quickly.

Colostrum is thick and creamy yellow as compared with mature milk, which is thin and bluish-white. Compared with mature milk, colostrum is richer in protein and **minerals** and lower in carbohydrates, fat, and some **vitamins**. The high concentration of total protein and minerals in colostrum gradually changes to meet the infant's needs over the first two to three weeks until lactation is established. The key component in colostrum and breast milk is immunoglobulins or antibodies that serve to protect the infant against infections or viruses. Breast milk also facilitates the development of the infant's own immune system to mature faster. As a result, breast-fed babies have fewer ear infections, **diarrhea**, **rashes**, **allergies**, and other medical problems than bottle-fed babies. Human milk is rich in proteins, lipids, carbohydrates, vitamins, minerals, hormones, enzymes, growth factors, and many types of protective agents. It contains about 10 percent solids for energy and growth and the rest is water, which is essential to maintain hydration. This is also why a breastfed baby does not need additional water. Infants can digest breast milk much more rapidly than formula and, therefore, do not get constipated. On average, it takes about 30 minutes longer to digest formula as opposed to breast milk. Breastfed babies have better cheekbone development and better jaw alignment.

Besides the benefits of the contracting uterus, the process of producing milk burns calories, which helps the mother to lose excess weight gained during pregnancy. After all, that is why pregnant women put on extra fat during pregnancy—energy storage for milk production. Breastfeeding is also related to a lower risk of breast **cancer** and ovarian cancer. For every year of life spent breastfeeding, a woman's risk of developing breast cancer drops by 4.3 percent and this is on top of the 7 percent reduction she enjoys for every baby to whom she gives birth.

Additionally, there is the convenience. Breast milk is always with the mother. Mothers do not have to store it. It is always at the right temperature. It is free. It does not require sterilization. In fact, it prevents diseases and has protective factors resulting in healthier babies and decreased healthcare costs. It saves money as there is no need to buy formula, bottles, and nipples.

Procedure

It is best to begin breastfeeding immediately after birth as it is an infant's natural instinct to nurse then. Regardless of the baby's initial suckling behavior, this interaction stimulates uterine contractions, promotes colonization of harmless bacteria on the nipple, and helps to protect the infant from pathogenic bacteria. It is an important time to nuzzle. Women breastfeed for a longer duration if feedings are started early. The first several feedings have an imprinting effect. It is recommended to continue feeding about every two to three hours. It is important to remember that all babies are different; some need to nurse almost constantly at first, while others can go much longer between feedings. There are babies and mothers who have no trouble breastfeeding, while others may need some assistance. Once the baby begins to suck, the mother makes sure that the entire dark area around the nipple (areola) is in the baby's mouth. This helps stimulate milk flow and allows the baby to get enough milk. Nipple soreness can be a result of the infant not getting a good grasp of the entire areola. A newborn needs to be fed at least eight to 12 times in 24 hours. Since breast milk is so easily digested, a baby may be hungry again as soon as one and one-half hours after the last feeding.

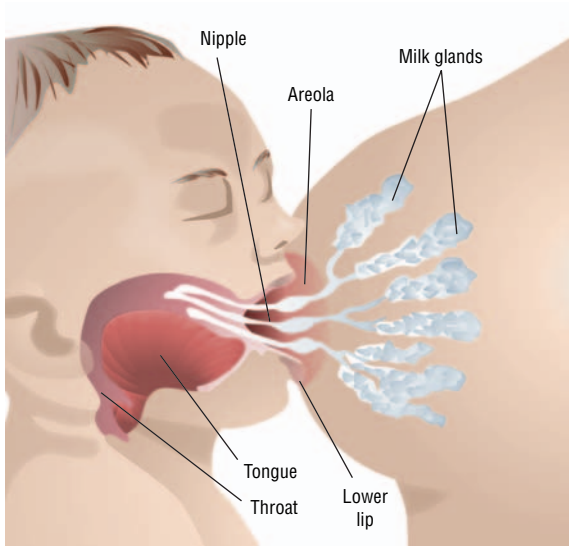
Mothers need to be comfortable when nursing; therefore, loose, front-opening clothes and a good nursing bra are essential. They need to explore different positions for breastfeeding to determine what is best for them. The cradle hold works well in bed or sitting in a comfortable chair. The football hold is excellent if the woman had a **cesarean section**. The mother can use pillows to support the baby and a footstool to flatten her

Lactation

Signs of good breastfeeding progress	Warning signs
Eight to 12 feeding per 24 hours	Fewer than eight feedings in 24 hours; baby sleeps four to six hours at time
Baby nurses every 1.5 to three hours	Baby nurses every hour or more, but never seems satisfied
Six to eight wet diapers every 24 hours after the third day	Fewer than six wet diapers after the third day
Soft yellow stools, about 1 tablespoon or larger	Dark black, green, or brown stools after the third day
After the third day, four to 10 stools per day	Fewer than three or four stools per day after the third day
Average daily weight gain of 15 to 30 g once milk comes in	Baby does not regain birth weight by 10 days of age
Milk comes in; breasts are full and warm and may leak milk	Milk does not seem to come in by the fifth day
Intermittent periods of rhythmic sucking and audible swallows	Milk comes in, but sucking or swallowing is not audible
Breasts are tender and may be slightly painful or sore	Sore and painful nipples throughout most feedings; scabbed or cracked nipples
Breasts soften after a feed	Severe engorgement; breast remain very hard after a feed

(Table by GGS Information Services.)

Lactation



When an infant is properly latched onto the breast, the baby's nose touches (or nearly touches) the breast. He or she takes the entire areola into the mouth, facilitating the intake of milk far back into the throat. *(Illustration by GGS Information Services.)*

lap. The mother can position the baby's head by snuggling it in one arm and supporting her breast with the other hand by keeping her thumb well above the areola and the rest of the fingers below and under the breast (sometimes called the C-hold). In this position, the mother can lift her breast and guide her nipple in any direction as she helps the baby to take in more of the areola.

For early feedings, the infant should be offered both breasts at each feeding as this stimulates the need-supply response. The length of the feeding is up to the mother. The general rule is to watch the baby, not the clock. If, however, it is a first time mother, 20 to 30 minutes on the first side can be suggested. If the baby falls asleep at the breast, the next feeding should begin with the breast that was not nursed. Mothers can tell if the baby is getting enough milk by checking diapers; a baby who is wetting between four to six disposable diapers (six to eight cloth) and who has three or four bowel movements in 24 hours is getting enough milk.

Common problems

New mothers may experience nursing problems, including the following:

- Engorgement: Breasts that are too full can prevent the baby from suckling because they cannot be grasped. Expressing milk manually or with a breast pump can alleviate this problem.
- Sore nipples: Transient soreness can occur during the first week postpartum and is usually temporary. Air drying the nipples and rubbing colostrum or breast milk into them provides relief. Prolonged, abnormal soreness lasts longer than a week postpartum. Discontinuing use of soap on breasts while bathing and applying purified lanolin to nipples and air drying them helps.
- Infection: Soreness and inflammation on the breast surface or a fever in the mother may be an indication of breast infection (mastitis). If it is just starting, the mother should drink lots of water and nurse frequently on the affected breast. **Antibiotics** may be necessary if the infection persists.

Lactation consultants work at almost every hospital where babies are delivered. First-time mothers can request the lactation consultant to visit her. The mother should make a note of the lactation consultant's phone number should problems be encountered after mother and infant go home.

There are no rules about when to stop breastfeeding. A baby needs breast milk for at least the first year of life and it is preferred that no solid food be given for at least

KEY TERMS

Alveoli—The tiny air sacs clustered at the ends of the bronchioles in the lungs in which oxygen-carbon dioxide exchange takes place.

Bromocriptine—Also known as Parlodel, it is a dopamine receptor agonist used to treat galactorrhea by reducing levels of the hormone prolactin and is also used to treat Parkinson's disease.

Colostrum—Milk secreted for a few days after birth and characterized by high protein and antibody content.

Ergotamine—A drug used to prevent or treat migraine headaches. It can cause vomiting, diarrhea, and convulsions in infants and should not be taken by women who are nursing.

Involution—The return of a large organ to normal size.

Lactogenesis—The initiation of milk secretion.

Lithium—A medication prescribed to treat the manic (excited) phases of bipolar disorder.

Mammary—Relating to the breast.

Methotrexate—A drug that interferes with cell growth and is used to treat rheumatoid arthritis as well as various types of cancer. Side-effects may include mouth sores, digestive upsets, skin rashes, and hair loss. Since this drug can supress an infant's immune system, it should not be taken by nursing mothers.

Placenta—The organ that provides oxygen and nutrition from the mother to the unborn baby during pregnancy. The placenta is attached to the wall of the uterus and leads to the unborn baby via the umbilical cord.

Postpartum—After childbirth.

Progesterone—The hormone produced by the ovary after ovulation that prepares the uterine lining for a fertilized egg.

Prolactin—A hormone that helps the breast prepare for milk production during pregnancy.

the first six months to prevent allergies. As long as a baby eats age-appropriate solid food, the mother may nurse for several years.

Parental concerns

The majority of illnesses are not transmitted via breast milk; in fact, breast milk prevents many illnesses. However, some viruses, including HIV (the virus that causes **AIDS** can be passed in breast milk; for this reason, women who are HIV-positive should not breastfeed unless they are living in a country that does not have clean water to make formula. A lack of clean water to make formula could result in an infant dying from diarrhea.

Many medications have not been tested in nursing women, so it is not certain what drugs can affect a breastfed child. A nursing woman should always check with her doctor or lactation consultant before taking any medications, including over-the-counter drugs. The mother can usually take antibiotics without discontinuing breastfeeding.

The following drugs are not safe for a mother to take while she is nursing:

- radioactive drugs for some diagnostic tests
- chemotherapy drugs for cancer
- bromocriptine
- ergotamine
- lithium
- methotrexate
- street drugs (including marijuana, heroin, amphetamines)
- tobacco

Linda K. Bennington

Lactose intolerance

Definition

Lactose intolerance refers to the inability of the body to digest lactose.

Description

Lactose is the predominant form of sugar present in milk. The enzyme lactase, which is normally produced by cells lining the small intestine, breaks down lactose into substances that can be absorbed into the bloodstream. When dairy products are ingested, the lactose reaches the digestive system and is broken down by lactase into the simpler sugars glucose and galactose, which can then be absorbed into the bloodstream. Lactose intolerance occurs when, due to a deficiency of lactase, lactose is not completely broken down and consequently blood sugar levels do not rise. While not usually a dangerous condition, lactose intolerance can cause severe discomfort.

Lactose intolerance is also referred to as lactase deficiency, milk intolerance, dairy product intolerance, or disaccharidase deficiency.

Demographics

From 30 to 50 million Americans suffer from the symptoms of lactose intolerance by the age of 20. People from cultures in which adult consumption of milk and milk products occurred earliest are less likely to be lactose intolerant than people from areas where dairy farming began more recently. The prevalence of deficiency in production of the lactase enzyme, therefore, varies among different ethnic groups. Among Asian populations it is almost 100 percent, with symptoms occurring around the age of five; among Native Americans it is 80 percent; among blacks it is 70 percent, with symptoms appearing by the age of 10; and among American Caucasians, the prevalence of lactose intolerance is only 20 percent. However, individuals who are mildly or moderately deficient in the production of the lactase enzyme may not exhibit symptoms of lactose intolerance.

Causes and symptoms

Lactose intolerance can be caused by some diseases of the digestive system (for example, celiac sprue and **gastroenteritis**) and by injuries to the small intestine that result in a decreased production of lactase. While rare, some children are also born unable to produce the enzyme. For most people, however, lactase deficiency develops naturally because, after about two years of age, the body produces less lactase. Before humans became dairy farmers, they usually did not continue to drink milk, so their bodies did not produce lactase after early childhood.

Symptoms of lactose intolerance include **nausea**, cramps, **diarrhea**, floating and foul-smelling stools, bloating, and intestinal gas. The symptoms usually occur between 30 minutes to two hours after eating or drinking lactose-containing foods. A child may also exhibit weight loss, slow growth, and **malnutrition**.

When to call the doctor

If a child develops symptoms of lactose intolerance, the doctor should be consulted concerning dietary substitutions.

Diagnosis

To diagnosis lactose intolerance, usually healthcare professionals measure the absorption of lactose in the digestive system by using the lactose tolerance test, the hydrogen breath test, or the stool acidity test. Each of these can be performed as an outpatient in a hospital, clinic, or doctor's office.

Children who are to take the lactose tolerance test must fast before being tested. They then drink a lactose-containing liquid for the test; medical personnel take blood samples during the next two hours to measure the children's blood glucose level. The blood glucose level, or blood sugar level, indicates how well the body is digesting the lactose. A diagnosis of lactose intolerance is confirmed when blood glucose level does not rise. This test is not administered to infants and very young children because of the risk of **dehydration** from drinking the lactose-containing liquid, which can cause diarrhea in those who are lactose intolerant, resulting in dehydration.

Hydrogen is usually detected only in small amounts in the breath. However, when undigested lactose found in the colon is fermented by bacteria, hydrogen in the breath is produced in greater quantities. The hydrogen is exhaled after being absorbed from the intestines and carried through the bloodstream to the lungs. The hydrogen breath test involves having the child drink a lactose-containing beverage. Healthcare professionals monitor the breath at regular intervals to see if the hydrogen levels rise, which indicates improper lactose digestion. Children taking the test who have had certain foods, medications, or cigarettes before the test may get inaccurate results. While the test is useful for children and adults, infants and young children should not take it because of the risk of dehydration from diarrhea in those who are lactose intolerant.

The stool acidity test measures the amount of acid in the stool. This is a safe test for newborns and young children. The test detects lactic acid and other short-chain fatty acids from undigested lactose fermented by bacteria in the colon. Glucose may also be found in the stool sample, resulting from unabsorbed lactose in the colon.

Some parents may try to self-diagnose lactose intolerance in their child by using an **elimination diet**, a diet that eliminates obvious milk and milk products. However, because there are so many food products that may contain hidden sources of milk, such a diet should be supervised by a dietician or developed by following a guide to a lactose-eliminating diet. A simpler way to self-diagnose lactose intolerance is by a milk challenge. The child fasts overnight, drinks a glass of milk in the morning, and then fasts for the next three to five hours. If the child is lactose intolerant, the child should experience symptoms within several hours. If symptoms do occur, the child should be evaluated by a healthcare professional to rule out the possibility of a milk allergy. However, milk **allergies** are rare and usually only occurs in infants and young children.

Treatment

Since there is no treatment that can improve the body's ability to produce lactase, treatment for lactose deficiency is focused on controlling the diet.

Most children affected by lactose intolerance do well if they limit their intake of lactose-containing food and drinks. Individuals differ in the amounts they can handle before experiencing symptoms. Many children may only need to eliminate major milk-containing products from their diet, while others who are intolerant to even small amounts of lactose may be required to follow severe dietary restrictions.

Foods that contain lactose include milk, low-fat milk, skim milk, chocolate milk, buttermilk, sweetened condensed milk, dried whole milk, instant nonfat dry milk, low-fat yogurts, frozen yogurt, ice cream, ice milk, sherbet, cheese, cottage cheese, low-fat cottage cheese, cream, and butter. Other foods that may contain hidden lactose are: nondairy creamers, powdered artificial sweeteners, foods containing milk power or nonfat milk solids, bread, cake, margarine, creamed soups, pancakes, waffles, processed breakfast cereals, salad dressings, lunch meats, puddings, custards, confections, and some meat products. Lactose is also used as the base for more than 20 percent of prescription drugs and 6 percent of over-the-counter drugs.

For infants younger than two years of age, soy formulas are adequate substitutes for milk. Toddlers may drink rice or soymilk, while older children who are sensitive to lactose can take lactase enzymes, which are available without a prescription. Using the liquid form of lactase enzymes, children can add a few drops in their milk, put the milk in the refrigerator and drink it after 24 hours, when the lactase enzymes have reduced the lactose content by 70 percent. If the milk is heated first and double the amount of lactase liquid enzymes is added, the milk will be 90 percent lactose-free. Supermarkets also carry lactose-reduced milk and other products, which contain nutrients found in the regular products but without the lactose.

In the early 2000s, researchers have developed a chewable lactase enzyme tablet. Taking three to six tablets just before eating helps some children digest lactose-containing solid foods.

Nutritional concerns

Eliminating milk from the diet can result in deficiencies of calcium, vitamin D, riboflavin, and protein. Milk substitutes for children are a necessity, as other sources of calcium are required. Fermented milk products such as yogurt are often tolerated. Buttermilk and cheeses have less lactose than milk. Goat's milk can sometimes be tolerated but should be consumed with meals.

Prognosis

Lactose intolerance is easy to manage and is not considered dangerous. People of all ages, but especially children, have to replace the calcium that is lost by cutting back on milk products; this can be accomplished by taking supplements and eating calcium-rich foods, such as broccoli, kale, canned salmon with bones, calcium-fortified foods, and tofu. They may also add lactase enzymes to dairy products to reduce lactose content as

KEY TERMS

Galactose—One of the two simple sugars (glucose is the other one) that makes up the protein, lactose, found in milk. Galactose can be toxic in high levels.

Glucose—A simple sugar that serves as the body's main source of energy.

Lactase—The enzyme produced by cells that line the small intestine that allows the body to break down lactose.

Lactose—A sugar found in milk and milk products.

well as use lactose-reduced dairy products. Many children who suffer with lactose intolerance are able to continue eating some milk products.

Prevention

Often lactose intolerance is a natural occurrence that cannot be avoided. However, people can prevent symptoms by managing the condition with diet and lactase supplements.

Parental concerns

Parents must guard the health of a child who is lactose intolerant by carefully managing the child's diet to avoid foods that will result in symptoms while providing foods that contain necessary nutrients for the child's health and growth.

Language delay

Definition

A language delay is **language development** that is significantly below the norm for a child of a specified age.

Description

Language delay is a communication disorder, a category that includes a wide variety of speech, language, and hearing impairments. The milestones of language development, including the onset of babbling and a child's first words and sentences, normally occur within approximate age ranges. However, individual children vary enormously regarding the exact age at which each milestone is reached. There also are different styles of language development. Most children have acquired good verbal communication by the age of three. But one child may be wordless until the age of two and a half and then immediately start talking in three-word sentences. Another child might have several words at ten months but add very few additional words over the following year. Other children start talking at about 12 months and progress steadily.

Language delay usually becomes apparent during infancy or early childhood. Any delay in general development usually causes language delay. Children with language delay may acquire language skills in the usual progression but at a much slower rate, so that their language development may be equivalent to a normally developing child of a much younger chronological age. Maturation delay, also called developmental language delay, is one of the most common types of language delay. Children with a maturation delay may be referred to as "late talkers" or "late bloomers." Maturation delays frequently run in families.

Demographics

Speech/language delay is the most common developmental disorder in children aged three to 16 years, affecting approximately 3 to 10 percent of children. It is three to four times more common in boys than in girls.

Causes and symptoms

Environmental causes

Common nonphysical causes of language delay include circumstances in which the following are the case:

- The child is concentrating on some other skill, such as walking perfectly, rather than on language.
- The child has a twin or sibling very close in age and thus may not receive as much individual attention.
- The child has older siblings who interpret so well that the child has no need to speak or whose talk is so continuous that the child lacks the opportunity to speak.
- The child is in a daycare situation with too few adults to provide individual attention.
- The child is under the care of a non-English speaker.
- The child is bilingual or multilingual, learning two or more languages simultaneously but at a slower speed; the child's combined comprehension of the languages is normal for that age.
- The child suffers from psychosocial deprivation such as poverty, **malnutrition**, poor housing, neglect, inadequate linguistic stimulation, emotional stress.
- The child is abused; abusive parents are more likely to neglect their children and less likely to communicate with them verbally.

Physical causes

Language delay may result from a variety of underlying disorders, including the following:

- **mental retardation**
- maturation delay (This delay in the maturation of the central neurological processes required to produce speech is often the cause of late talking.)
- **hearing impairment**
- **dyslexia**, a specific reading disorder which may cause language delay in preschoolers
- a learning disability
- cerebral palsy, in which numerous factors may contribute to language delay
- autism, a developmental disorder in which, among other things, children do not use language or use it abnormally
- congenital blindness, even in the absence of other neurological impairment
- brain damage
- Klinefelter syndrome, a disorder in which males are born with an extra X chromosome
- receptive aphasia or receptive language disorder, a deficit in spoken language comprehension or in the ability to respond to spoken language, resulting from brain damage
- expressive aphasia, an inability to speak or write, although comprehension is normal; caused by malnutrition, brain damage, or hereditary factors
- childhood apraxia of speech, a nervous system disorder

Mental retardation accounts for more than 50 percent of language delays. Language delay is usually more severe than other developmental delays in retarded children, and it is often the first noticeable symptom of mental retardation. Mental retardation causes global language delay, including delayed auditory comprehension and use of gestures.

Impaired hearing is one of the most common causes of language delay. Any child who does not hear speech in a clear and consistent manner will have language delay. Even a minor hearing impairment can significantly affect language development. In general the more severe the impairment, the more serious the language delay. Children with congenital (present at birth) hearing impairment or hearing loss that occurs within the first two years of life (known as prelingual hearing loss) experience serious language delay, even when the impairment is diagnosed and treated at an early age. However, deaf children born to parents who use sign language develop infant babble and a fully expressive sign language at the same rate as hearing children.

Symptoms of language delay

Symptoms of language delay include the following:

- failure to meet the developmental milestones for language development
- language development that lags behind other children of the same age by at least one year
- inability to follow directions
- slow or incomprehensible speech after three years of age
- serious difficulties with syntax (placing words in a sentence in the correct order)
- serious difficulties with articulation, including the substitution, omission, or distortion of certain sounds

Language delays resulting from underlying conditions may have symptoms specific to the condition. Nonetheless, specific symptoms of language delay may include the following:

- not babbling by 12 to 15 months of age
- not understanding simple commands by 18 months of age
- not talking by two years of age
- not using sentences by three years of age

- not being able to tell a simple story by four or five years of age

Symptoms of language delay with mental retardation

Mentally impaired children usually babble during their first year and may speak their first words within the normal age range. However, they often cannot do the following:

- put words together
- speak in complete sentences
- acquire a larger, more varied vocabulary
- develop grammatically

Mentally impaired children in conversation may be repetitive and routine, exhibiting little **creativity**. Nevertheless vocabulary and grammatical development appear to proceed by very similar processes in mentally retarded and developmentally normal children.

In general the severity of language delay depends on the severity of the mental retardation. Levels of retardation and language skill are ranked as follows:

- mild retardation (**intelligence** quotient [IQ] range of 52–68): usually eventually develop language skills
- moderate retardation (IQ range of 36–51): usually learn to talk and communicate
- severe retardation (IQ range of 20–35): have limited language but can speak a few words

Language delays among mentally retarded children vary greatly. Some severely mentally impaired children who also have **hydrocephalus** or **Williams syndrome** may acquire exceptional conversational language skills, sometimes called the "chatterbox syndrome." Some children (called savants) test as mentally retarded but learn their native language, as well as foreign languages, very easily. With **Down syndrome** and some other disorders, language delay is more severe than other mental impairments. This factor may be due to the characteristic facial abnormalities and relatively large tongues of Down-syndrome children. Children with Down syndrome also are at higher risk for hearing impairment and ear infections that cause hearing loss.

Symptoms of language delay with other disorders

Symptoms of language delay in a hearing-impaired child include the following:

- babbling at an older-than-normal age
- babbling that is less varied and less sustained
- first words at age two or older
- only two-word sentences by age four or five in a profoundly deaf child

Dyslexic children have difficulty separating parts of words and single words within a group of words. Symptoms of dyslexia may include:

- poor articulation
- difficulties identifying sounds within words, blending sounds, or rhyming
- difficulty putting sounds in the correct order
- hesitation in choosing words

A learning-disabled child usually exhibits an uneven pattern of language development. In addition, about 50 percent of autistic children never learn to speak. Those who do speak often have severe language delay and may use words in unusual ways. They rarely participate in interactive dialogue and often speak with an unusual rhythm or pitch. The speech of some autistic children has an atonic or sing-song quality.

Children with congenital blindness average about an eight-month delay in speaking words. Although blind children develop language in much the same way as sighted children, they may rely more on conversational formulas.

The speech of children with receptive aphasia is both delayed and sparse, ungrammatical, and poorly articulated. Children with expressive aphasia fail to speak at the usual age although they have normal speech comprehension and articulation. Children with defined lesions in language areas on either side of the brain have initial but quite variable language delays. Usually their language catches up by the age of two or three without noticeable deficits.

Apraxia affects the ability to sequence and vocalize sounds, syllables, and words. Children with apraxia know what they want to say, but their brains do not send the correct signals to the lips, jaw, and tongue to form the words. In addition to language delay, apraxia often causes other expressive **language disorders**.

When to call the doctor

Children who are not talking at all by the age of two should have a complete developmental **assessment**. Children who are not progressing in word-learning skills by the end of the first grade should be tested for dyslexia.

Diagnosis

Diagnosis of language delay requires a complete physical examination and a thorough developmental history, with special attention to language milestones. In young children it may be very difficult to distinguish between a late talker and a developmental expressive disorder. The diagnosis often is made by a speech/language pathologist. Language performance of bilingual children must be compared to that of other bilingual children of a similar cultural and linguistic background. Generalized delay in all developmental milestones suggests mental retardation.

Numerous tests are used to screen for language delay and assess language development. Some of these are described below:

- The Denver Developmental Screening Test is the most popular test in clinical use for children from birth to six years of age. Since language delay is the most common early symptom of global intellectual impairment, the test provides a comprehensive developmental assessment.
- The Early Language Milestone Scale is a simple tool for assessing language development in children under the age of three. It relies on parents' reports and a very short test focusing on visual, receptive, and expressive language.
- The Mullen Scales of Early Learning is a comprehensive assessment of language, motor, and perceptual abilities in children from birth to five years eight months of age.
- The Peabody Picture Vocabulary Test, for children aged two-and-a-half to 18 years, is a useful screening instrument for word comprehension.
- The Receptive One-Word Picture Vocabulary Test provides information about a child's ability to understand language.

Other tests for language delay include:

- Early Speech Perception Test
- Assessing Prelinguistic and Early Linguistic Behaviors in Developmentally Young Children
- Joliet 3-Minute **Preschool** Speech and Language Screen
- Fluharty Preschool Speech and Language Screening Test
- Assessment of Fluency in School-Age Children
- Children's Articulation Test
- Clinical Evaluation of Language Fundamentals
- Phonological Assessment of Child Speech (Initial assessment may indicate the need for additional testing to identify underlying physical conditions.)

Treatment

About 60 percent of language delays in children under age three resolve spontaneously. Early detection and intervention for language delay can help prevent social, cognitive, and emotional problems. Treatment of language delay is individualized for each child with the primary goal of teaching the child strategies for comprehending spoken language and producing appropriate linguistic or communicative behavior. Depending on the type and cause of the delay, the healthcare team may include a physician, a speech/language pathologist, an audiologist, a psychologist, an occupational therapist, and a social worker. Psychotherapy may be recommended if the language delay is accompanied by **anxiety** or depression. Speech therapy is used to help mentally impaired children develop intelligible language. Behavior therapy may help autistic children progress in speech acquisition.

Hearing-impaired children who are identified and receive early intervention before six months of age develop significantly better language skills than children identified after six months of age. Early, consistent, and conscious use of visual communication modes such as sign language, finger spelling, and cued speech, and/or hearing amplification and oral training can reduce the language delay. Since only about 10 percent of deaf children are born to deaf parents, hearing parents can promote their deaf child's language development by learning and using sign language. Many types of hearing aids are available for children as young as three months. **Cochlear implants** may be used for profoundly deaf children aged two to six. These children usually develop better language skills than those with hearing aids or other devices.

Prognosis

With appropriate intervention language-delayed children usually catch up with their peers. Children with maturation delay usually have normal language development by the time they enter school. Although a bilingual home environment can cause a temporary language delay, most children become proficient in both languages before the age of five. Nevertheless, early language delays may cause problems with behavior and social interactions. A language delay can lead to elective **mutism**, a condition in which children choose not to speak.

KEY TERMS

Apraxia—Impairment of the ability to make purposeful movements, but not paralysis or loss of sensation.

Expressive aphasia—A developmental disorder in which a child has lower-than-normal proficiency in vocabulary, production of complex sentences, and word recall, although language comprehension is normal.

Maturation delay—Developmental language delay; a language delay caused by the slow maturation of speech centers in the brain; often causes late talking.

Receptive aphasia—A developmental disorder in which a child has difficulty comprehending spoken and written language.

Such children typically speak when they are on their own, with their friends, and sometimes with their parents; however, they will not speak in school, in public situations, or with strangers.

Most mentally retarded children eventually develop at least some degree of language. But frustration and anger at their inability to communicate effectively can lead to numerous social and behavioral problems. An adolescent with Down syndrome and an IQ of about 50 may speak at the grammatical level of an unaffected three-year-old, with short, repetitive, simple sentences. Nevertheless, Down-syndrome children often are very sociable and interested in conversational language.

Children who receive early intervention for hearing impairments can develop at nearly the same rate as other children. However, depending on the severity of their hearing loss, they may continue to have difficulties with articulation and speech quality as well as with written language. Children who lose their hearing after the first few years of life have far fewer language delays than children who are deaf from birth or who lose their hearing within the first year.

Most children with receptive aphasia gradually acquire a language of their own, understood only by those close to them. Children with expressive aphasia will not develop normal language skills without intervention and are at risk for language-based learning disabilities.

Prevention

There are no known preventions for most language delays. Prenatal care and good **nutrition** during pregnancy and early childhood may help prevent some expressive language delays. Hearing-impaired children who use sign language within their families usually have no signed-language delay.

Parental concerns

A speech/language pathologist can teach parents methods for encouraging and enhancing their child's language development. Special programs also are available for helping language-delayed children and their parents. Parents, caregivers, and teachers of children with language delay should take the following steps:

- adjust their speech to the child's level
- use consistent language
- use meaningful language
- repeat words, phrases, sentences, and stories
- use small-group instruction

Language development

Definition

Language development is the process by which children come to understand and communicate language during early childhood.

Description

From birth up to the age of five, children develop language at a very rapid pace. The stages of language development are universal among humans. However, the age and the pace at which a child reaches each milestone of language development vary greatly among children. Thus, language development in an individual child must be compared with norms rather than with other individual children. In general girls develop language at a faster rate than boys. More than any other aspect of development, language development reflects the growth and maturation of the brain. After the age of five it becomes much more difficult for most children to learn language.

Receptive language development (the ability to comprehend language) usually develops faster than expressive language (the ability to communicate). Two different styles of language development are recognized. In referential language development, children first speak single words and then join words together, first into two-word sentences and then into three-word sentences. In expressive language development, children first speak in long unintelligible babbles that mimic the cadence and rhythm of adult speech. Most children use a combination these styles.

Infancy

Language development begins before birth. Towards the end of pregnancy, a fetus begins to hear sounds and speech coming from outside the mother's body. Infants are acutely attuned to the human voice and prefer it to other sounds. In particular they prefer the higher pitch characteristic of female voices. They also are very attentive to the human face, especially when the face is talking. Although crying is a child's primary means of communication at birth, language immediately begins to develop via repetition and imitation.

Between birth and three months of age, most infants acquire the following abilities:

- seem to recognize their mother's voice
- quiet down or smile when spoken to
- turn toward familiar voices and sounds
- make sounds indicating pleasure
- cry differently to express different needs
- grunt, chuckle, whimper, and gurgle
- begin to coo (repeating the same sounds frequently) in response to voices
- make vowel-like sounds such as "ooh" and "ah"

Between three and six months, most infants can do the following:

- turn their head toward a speaker
- watch a speaker's mouth movements
- respond to changes in a tone of voice
- make louder sounds including screeches
- vocalize excitement, pleasure, and displeasure
- cry differently out of **pain** or hunger
- laugh, squeal, and sigh
- sputter loudly and blow bubbles
- shape their mouths to change sounds
- vocalize different sounds for different needs
- communicate desires with gestures
- babble for attention
- mimic sounds, inflections, and gestures
- make many new sounds, including "p," "b," and "m," that may sound almost speech-like

The sounds and babblings of this stage of language development are identical in babies throughout the world, even among those who are profoundly deaf. Thus all babies are born with the capacity to learn any language. Social interaction determines which language they eventually learn.

Six to 12 months is a crucial age for receptive language development. Between six and nine months babies begin to do the following:

- search for sources of sound
- listen intently to speech and other sounds
- take an active interest in conversation even if it is not directed at them
- recognize "dada," "mama," "bye-bye"
- consistently respond to their names
- respond appropriately to friendly and angry tones
- express their moods by sound and body language
- **play** with sounds
- make long, more varied sounds
- babble random combinations of consonants and vowels
- babble in singsong with as many as 12 different sounds
- experiment with pitch, intonation, and volume
- use their tongues to change sounds
- repeat syllables
- imitate intonation and speech sounds

Between nine and 12 months babies may begin to do the following:

- listen when spoken to
- recognize words for common objects and names of **family** members
- respond to simple requests
- understand "no"
- understand gestures
- associate voices and names with people
- know their own names
- babble both short and long groups of sounds and two-to-three-syllable repeated sounds (The babble begins to have characteristic sounds of their native language.)
- use sounds other than crying to get attention
- use "mama" and "dada" for any person
- shout and scream
- repeat sounds
- use most consonant and vowel sounds
- practice inflections
- engage in much vocal play

Toddlerhood

During the second year of life language development proceeds at very different rates in different children. By the age of 12 months, most children use "mama/dada" appropriately. They add new words each month and temporarily lose words. Between 12 and 15 months children begin to do the following:

- recognize names
- understand and follow one-step directions
- laugh appropriately
- use four to six intelligible words, usually those starting with "b," "c," "d," and "g," although less than 20 percent of their language is comprehensible to outsiders
- use partial words
- gesture and speak "no"
- ask for help with gestures and sounds

At 15 to 18 months of age children usually do the following:

- understand "up," "down," "hot," "off"
- use 10 to 20 intelligible words, mostly nouns
- use complete words
- put two short words together to form sentences
- chatter and imitate, use some echolalia (repetitions of words and phrases)
- have 20 to 25 percent of their speech understood by outsiders

At 18 to 24 months of age toddlers come to understand that there are words for everything and their language development gains momentum. About 50 of a child's first words are universal: names of foods, animals, family members, **toys**, vehicles, and clothing. Usually children first learn general nouns, such as "flower" instead of "dandelion," and they may overgeneralize words, such as calling all toys "balls." Some children learn words for social situations, greetings, and expressions of love more readily than others. At this age children usually have 20 to 50 intelligible words and can do the following:

- follow two-step directions
- point to parts of the body
- attempt multi-syllable words
- speak three-word sentences

- ask two-word questions
- enjoy challenge words such as "helicopter"
- hum and sing
- express pain verbally
- have 50 to 70 percent of their speech understood by outsiders

After several months of slower development, children often have a "word spurt" (an explosion of new words). Between the ages of two and 18 years, it is estimated that children add nine new words per day. Between two and three years of age children acquire:

- a 400-word vocabulary including names
- a word for most everything
- the use of pronouns
- three to five-word sentences
- the ability to describe what they just saw or experienced
- the use of the past tense and plurals
- names for body parts, colors, toys, people, and objects
- the ability to repeat rhymes, songs, and stories
- the ability to answer "what" questions

Children constantly produce sentences that they have not heard before, creating rather than imitating. This **creativity** is based on the general principles and rules of language that they have mastered. By the time a child is three years of age, most of a child's speech can be understood. However, like adults, children vary greatly in how much they choose to talk.

Preschool

Three to four-year-olds usually can do the following:

- understand most of what they hear
- converse
- have 900 to 1,000-word vocabularies, with verbs starting to predominate
- usually talk without repeating syllables or words
- use pronouns correctly
- use three to six-word sentences
- ask questions
- relate experiences and activities
- tell stories (Occasional **stuttering** and stammering is normal in preschoolers.)

Language skills usually blossom between four and five years of age. Children of this age can do the following:

- verbalize extensively
- communicate easily with other children and adults
- articulate most English sounds correctly
- know 1,500 to 2,500 words
- use detailed six to eight-word sentences
- can repeat four-syllable words
- use at least four prepositions
- tell stories that stay on topic
- can answer questions about stories

School age

At age five most children can do the following:

- follow three consecutive commands
- talk constantly
- ask innumerable questions
- use descriptive words and compound and complex sentences
- know all the vowels and consonants
- use generally correct grammar

Six-year-olds usually can correct their own grammar and mispronunciations. Most children double their vocabularies between six and eight years of age and begin reading at about age seven. A major leap in reading comprehension occurs at about nine. Ten-year-olds begin to understand figurative word meanings.

Adolescents generally speak in an adult manner, gaining language maturity throughout high school.

Common problems

Language delay is the most common **developmental delay** in children. There are many causes for language delay, both environmental and physical. About 60 percent of language delays in children under age three resolve spontaneously. Early intervention often helps other children to catch up to their age group.

Common circumstances that can result in language delay include:

- concentration on developing skills other than language
- siblings who are very close in age or older siblings who interpret for the younger child

- inadequate language stimulation and one-on-one attention
- bilingualism, in which a child's combined comprehension of two languages usually is equivalent to other children's comprehension of one language
- psychosocial deprivation

Language delay can result from a variety of physical disorders, including the following:

- mental retardation
- maturation delay (the slower-than-usual development of the speech centers of the brain), a common cause of late talking
- a hearing impairment
- a learning disability
- cerebral palsy
- autism (a developmental disorder in which, among other things, children do not use language or use it abnormally)
- congenital blindness, even in the absence of other neurological impairment
- Klinefelter syndrome, a disorder in which males are born with an extra X chromosome

Brain damage or disorders of the central nervous system can cause the following:

- receptive aphasia or receptive language disorder, a deficit in spoken language comprehension or in the ability to respond to spoken language
- expressive aphasia, an inability to speak or write despite normal language comprehension
- childhood apraxia of speech, in which a sound is substituted for the desired syllable or word

Parental concerns

Language development is enriched by verbal interactions with other children and adults. Parents and caregivers can have a significant impact on early language development. Studies have shown that children of talkative parents have twice the vocabulary as those of quiet parents. A study from the National Institute of Child Health and Human Development (NICHD) found that children in high-quality childcare environments have larger vocabularies and more complex language skills than children in lower-quality situations. In addition language-based interactions appear to increase a child's capacity to learn. Recommendations for encouraging language development in infants include:

- talking to them as much as possible and giving them opportunities to respond, perhaps with a smile; short periods of silence help teach the give-and-take of conversation
- talking to infants in a singsong, high-pitched speech, called "parentese" or "motherese" (This is a universal method for enhancing language development.)
- using one- or two-syllable words and two to three-word sentences
- using proper words rather than baby words
- speaking slowly, drawing-out vowels, and exaggerating main syllables
- avoiding pronouns and articles
- using animated gestures along with words
- addressing the baby by name
- talking about on-going activities
- asking questions
- singing songs
- commenting on sounds in the environment
- encouraging the baby to make vowel-like and consonant-vowel sounds such as "ma," "da," and "ba"
- repeating recognizable syllables and repeating words that contain the syllable

When babies reach six to 12 months-of-age, parents should play word games with them, label objects with words, and allow the baby to listen and participate in conversations. Parents of toddlers should do the following:

- talk to the child in simple sentences and ask questions
- expand on the toddler's single words
- use gestures that reinforce words
- put words to the child's gestures
- name colors
- count items
- gently repeat correctly any words that the child has mispronounced, rather than criticizing the child

Parents of two to three-year-olds should do the following:

- talk about what the child and parent are doing each day
- encourage the child to use new words
- repeat and expand on what the child says
- ask the child yes-or-no questions and questions that require a simple choice

Language development

Age	Activity
Two months	Cries, coos, and grunts.
Four months	Begins babbling. Makes most vowel sounds and about half of consonant sounds.
Six months	Vocalizes with intonation. Responds to own name.
Eight months	Combines syllables when babbling, such "Ba-ba."
Eleven months	Says one word (or fragment of a word) with meaning.
Twelve months	Says two or three words with meaning. Practices inflection, such as raising pitch of voice at the end of a question.
Eighteen months	Has a vocabulary between five and 20 words, mostly nouns. Repeats word or phrase over and over. May start to join two words together.
Two years	Has a vocabulary of 150–300 words. Uses I, me, and you. Uses at least two prepositions (in, on, under). Combines words in short sentences. About two-thirds of what is spoken is understandable.
Three years	Has a vocabulary of 900–1000 words. Uses more verbs, some past tenses, and some plural nouns. Easily handles three-word sentences. Can give own name, sex, and age. About 90% of speech is understandable.
Four years	Can use at least four prepositions. Can usually repeat words of four syllables. Knows some colors and numbers. Has most vowels and diphthongs and consonants p, b, m, w, and n established. Talks a lot and repeats often.
Five years	Can count to ten. Speech is completely understandable, although articulation might not be perfect. Should have all vowels and consonants m, p, b, h, w, k, g, t, d, n, ng, y. Can repeat sentences as long as nine words. Speech is mostly grammatically correct.
Six years	Should have all vowels and consonants listed above, has added, f, v, sh, zh, th, l. Should be able to tell a connected story about a picture.
Seven years	Should have consonants s–z, r, voiceless th, ch, wh, and soft g. Should be able to do simple reading and print many words.
Eight years	All speech sounds established. Carries on conversation at a more adult level. Can tell complicated stories of past events. Easily uses complex and compound sentences. Reads simple stories with ease and can write simple compositions.

SOURCE: Child Development Institute. 2004. http://www.childdevelopmentinfo.com.

(Table by GGS Information Services.)

- encourage the child to ask questions
- read books about familiar things, with pictures, rhymes, repetitive lines, and few words
- read favorite books repeatedly, allowing the child to join in with familiar words
- encourage the child to pretend to read
- not interrupt children when they are speaking

Parents of four to six-year-olds should:

- not speak until the child is fully attentive
- pause after speaking to give the child a chance to respond
- acknowledge, encourage, and praise speech
- introduce new words
- talk about spatial relationships and opposites
- introduce limericks, songs, and poems
- talk about the television programs that they watch
- encourage the child to give directions
- give their full attention when the child initiates a conversation

Parents of six to 12-year-olds should talk to the children, not at them, encourage conversation by asking questions that require more than a yes-or-no answer, and listen attentively as the child recounts the day's activities.

Additional recommendations for parents and caregivers, by the American Academy of Pediatrics and others, include:

- talking at eye level with a child and supplementing words with body language, gestures, and facial expressions to enhance language comprehension
- talking in ways that catch a child's attention
- using language to comfort a child
- using correct pronunciations
- using expressive language to discuss objects, actions, and emotions
- playing with sounds and words
- labeling objects and actions with words
- providing objects and experiences to talk about
- choosing activities that promote language
- listening carefully to children and responding in ways that let them know that they have been understood, as well as encouraging further communication
- using complete sentences and adding detail to expand on what a child has said
- knowing when to remain silent
- reading to a child by six months of age at the latest

KEY TERMS

Apraxia—Impairment of the ability to make purposeful movements, but not paralysis or loss of sensation.

Expressive aphasia—A developmental disorder in which a child has lower-than-normal proficiency in vocabulary, production of complex sentences, and word recall, although language comprehension is normal.

Expressive language—Communicating with language.

Expressive language development—A style of language development in which a child's babble mimics the cadence and rhythm of adult speech.

Receptive aphasia—A developmental disorder in which a child has difficulty comprehending spoken and written language.

Receptive language—The comprehension of language.

Referential language development—A style of language development in which a child first speaks single words and then joins words together into two- and three-word sentences.

- encouraging children to ask questions and seek new information
- encouraging children to listen to and ask questions of each other

Television viewing does not promote language development.

When to call the doctor

Parents should call the pediatrician immediately if they suspect that their child may have a language delay or a hearing problem. Warning signs of language delay in toddlers include:

- avoiding eye contact
- neither understanding nor speaking words by 18 months of age
- difficulty learning nursery rhymes or simple songs
- not recognizing or labeling common objects
- inability to pay attention to a book or movie
- poor articulation, such that a parent cannot understand the child more than 50 percent of the time

Language disorders

Definition

A language disorder is a deficit or problem with any function of language and communication.

Description

Speech and language disorders are extremely common. They can range from slow acquisition of language to sound substitution or **stuttering** to the inability to understand or produce and language at all. The federal Agency for Healthcare Research and Quality estimated in 2002 that communication disorders cost the United States between $30 and $154 billion annually in lost productivity and money spent on medical care, **special education**, and remediation.

Language disorders and the brain

Speech and language pathologists and neurologists (doctors who specialize in the brain and nervous system) have known for about 100 years that certain areas in the left hemisphere of the brain—Broca's area in the posterior frontal lobe and Wernicke's area in the temporal lobe—are centrally involved in language functions. Damage to Broca's area results in problems with language fluency: shortened sentences, impaired flow of speech, poor control of rhythm and intonation, and a telegraphic style with missing inflections. Damage to Wernicke's area produces speech that is fluent and often rapid, but with relatively senseless content, many invented words, and word substitutions.

With the invention of new technologies, including **computed tomography** (CT) scans and **magnetic resonance imaging** (MRI), several studies have looked at the **language development** in very young children with lesions in the traditional language areas of the brain. There is surprising agreement among the studies in their results: all find initial delays in language development followed by remarkably similar progress after about age two to three years. Lasting deficits have not been noticed in these children. Surprisingly, there are also no dramatic effects of laterality; lesions to either side of the brain seem to produce virtually the same effects. However, most of the data comes from conversational analysis or relatively unstructured testing, and these children have not been followed until school age. Nevertheless, the findings suggest remarkable plasticity and robustness of language in spite of brain lesions that would devastate an adult's language abilities.

Language disorders and hearing loss

Children with a hearing loss, either from birth or acquired during the first year or two of life, generally have a serious delay in spoken language development. The hearing loss occurs despite very early diagnosis and fitting with appropriate hearing aids. However, in the unusual case that sign language is the medium of communication in the **family** rather than speech, the child shows no delay in learning to use that language. Hearing development is always one of the first things checked if a pediatrician or parent suspects a **language delay**. The deaf child exposed only to speech will usually begin to babble ("baba, gaga") at a slightly later point than the hearing child. Recent work suggests that the babbling is neither as varied nor as sustained as in hearing children. However, there is often a long delay until the first words are spoken, sometimes not until age two years or older.

Depending on the severity of the hearing loss, the stages of early language development are also quite delayed. It is not unusual for the profoundly deaf child at age four or five years to only have two-word spoken sentences. It is only on entering specialized training programs for oral language development that the profoundly deaf child begins to acquire more spoken language. Often, such children do not make the usual **preschool** language gains until they reach grade school. Many deaf children learning English have pronounced difficulties in articulation and speech quality, especially if they are profoundly deaf, since they get no feedback in how they sound. A child who has hearing for the first few years of life has an enormous advantage in speech quality and oral language learning over a child who is deaf from birth or within his or her first year.

Apart from speech difficulties, deaf children learning English often show considerable difficulty with the

inflection and syntax of the language, which marks their writing as well as their speech. The ramifications of this delayed language are also significant for learning to read, and reading proficiently. The average deaf high school student often only reads at fourth grade level.

Language disorders and mental retardation

Mental retardation can also affect the age at which children learn to talk. A mentally retarded child is defined as one who falls in the lower end of the range of **intelligence**, usually with an IQ (intelligence quotient) below 80 on some standardized IQ tests. There are many causes of mental retardation, including identified genetic syndromes such as **Down syndrome**, **Williams syndrome**, or **fragile X syndrome**.

Retardation can also be caused by damage to the fetus during pregnancy due to alcohol, drug abuse or toxicity, and disorders of the developing nervous system such as **hydrocephalus**. Finally, there are environmental causes following birth such as **lead poisoning**, anoxia, or **meningitis**.

Any of these situations is likely to slow down the child's rate of development in general, and thus to have effects on language development. However, most children with very low IQs develop some language, suggesting it is a relatively "buffered" system that can survive a good deal of insult to the developing brain. In cases of hydrocephalus, for example, it has been noted that children who are otherwise quite impaired intellectually can have impressive conversational language skills. Sometimes called the "chatterbox syndrome," this linguistic sophistication belies their poor ability to deal with the world. In an extreme case, a young man with a tested IQ in the retarded range has an apparent gift for acquiring foreign languages, and could learn a new one with very little exposure. For example, he could do fair translations at a rapid pace from written languages as diverse as Danish, Dutch, Hindi, Polish, French, Spanish, and Greek. He is, in fact, a savant in the area of language, and delights in comparing linguistic systems, although he does not have the mental capacity to live independently.

Adults should not consider retarded children to be a uniform class; different patterns can arise with different syndromes. For example, in hydrocephalic children and Williams syndrome, language skills may be preserved to a degree greater than their general intellectual level. In other groups, including Down syndrome, there may be more delay in language than in other mental abilities.

Most retarded children babble during the first year and develop their first words within a normal time span, but are then slow to develop sentences or a varied vocabulary. Vocabulary size is one of the primary components of standardized tests of verbal intelligence, and it grows slowly in retarded children. Nevertheless, the process of vocabulary development seems quite similar: retarded children also learn words from context and by incidental learning, not just by direct instruction.

Grammatical development, though slow, comes in the same way, and in the same order, as it does for normal IQ children. The child's conversation, however, may contain more repetition. The Down syndrome adolescent with an IQ of around 50 points does not seem to progress beyond the grammatical level of the normally intelligent child at three years, with short sentences that are restricted in variety and complexity. Children with Down syndrome are also particularly delayed in speech development. This is due in part to the facial abnormalities that characterize this syndrome, including a relatively large tongue. It is also linked to the higher risk they appear to suffer from ear infections and hearing loss.

Specific language impairment

Specific language impairment describes a condition of markedly delayed language development in the absence of any apparent handicapping conditions such as deafness, **autism**, or mental retardation. Specific language impairment (SLI) is also sometimes called childhood dysphasia, or developmental language disorder.

Children with SLI usually begin to talk at approximately the same age as normal children, but are markedly slower in their progress. They seem to have particular problems with inflection and word forms, such as leaving off endings when forming verb tenses (for example, the -ed ending when forming the past tense). This problem can persist much longer than early childhood, often into grade school and beyond, where these children encounter difficulties in reading and writing. The child with SLI often has difficulties learning language "incidentally," (picking up the meaning of a new word from context or generalizing a new syntactic form). This is in contrast to the normal child's development, where incidental learning and generalization are the hallmarks of language acquisition. Children with SLI are not cognitively impaired and are not withdrawn or socially aloof like the autistic child.

Very little is known about the cause or origin of specific language impairment, although evidence is growing that the underlying condition may be a form of brain abnormality. However, any such brain abnormality is not readily apparent with existing diagnostic technologies. When compared to other children, SLI children do not

Speech therapists help children overcome their speech and language disorders. *(© Bob Rowan; Progressive Image/Corbis.)*

have clear brain lesions or marked anatomical differences in either brain hemisphere.

Demographics

About one in six people, or 42 million individuals in the United States, have some type of communication disorder. About 28 million have speech, voice, or language problems associated with hearing loss, and about 14 million have similar problems not associated with impaired hearing. More than one million children in special education classes are categorized as having a speech or language disability.

Causes and symptoms

Language disorders can arise at many points in the language production process such as:

- from damage to the part of the brain that produces language
- from damage to the part of the brain that understands language
- from hearing loss
- from damage to the muscles and tissues of the mouth and throat needed for speech (e.g. **cleft palate**)
- from neurological disorders that interrupt the transmission of information necessary to receive and produce language
- from unknown (idiopathic) causes

Symptoms of language disorders vary widely, but include:

- slow acquisition of speech and language
- inability to make the physical sounds associated with language production (mutism)
- failure to make sense of spoken or written words
- inability to speak under certain social circumstances (selective mutism)

KEY TERMS

Speech pathologist—An individual certified by the American Speech-Language-Hearing Association (ASHA) to treat speech disorders.

- transformations of words or sounds when speaking
- inability to recall known words

When to call the doctor

Parents should talk to their pediatrician immediately if their child appears to have **hearing impairment**. They should also consult with their doctor if the child does not babble or begin to use single words within the normal time frame. Parents of older children may need a referral to a speech and language specialist if their child stutters, lisps, has difficulty forming words or producing coherent speech, or exhibits certain learning disabilities.

Diagnosis

Speech and language disorders are usually diagnosed by a speech and language pathologist, often with the help of a pediatrician, audiologist (hearing specialist), and neurologist. Many **assessment** tests are designed specifically for use in children, including the Clinical Evaluation of Language Fundamentals (also available in Spanish); the Preschool Language Scale (also available in Spanish); the Test of Language Development, Primary; and the Test of Language, Intermediate. There are assessments designed to evaluate speech production, such as the Goldman-Fristoe test of Articulation.

Treatment

Treatment varies, depending on the type and cause of the language disorder. However, in all language disorders and delays, early intervention is key to improvement. Many educators of the deaf now urge early compensatory programs in signed languages, because the deaf child shows no handicap in learning a visually based language. Deaf children born to signing parents begin to ''babble'' in sign at the same point in infancy that hearing infants babble speech, and proceed from there to learn a fully expressive language. However, only 10 percent of deaf children are born to deaf parents, so hearing parents must show a commitment and willingness to learn sign language. Furthermore, command of at least written English is still a necessity for such children to be able to function in the larger community.

Speech therapy can be a considerable aid to many children with language disorders For example, it can help to make a Down syndrome child's speech more intelligible. Despite the delay, children with Down syndrome are often quite sociable and interested in language for conversation.

Surgery, followed by speech therapy, can correct physical deformities, such as cleft palate, that interfere with speech production.

Psychotherapy can help older children whose language disorders are psychologically based.

Prognosis

Prognosis varies on an individual basis, depending on the cause, type, and severity of the language disorder. Those children who receive early intervention therapies are more likely to have a better outcome than those for whom services are delayed.

Prevention

Many language disorders are not preventable. However, those that arise from damage to the fetus due to the mother's use of drugs or alcohol during pregnancy can be prevented by avoiding these substances.

Parental concerns

Language is such a critical part of our society that parents are justly concerned when their child has a language disorder. The parents' approach to the disorder can greatly influence the child's self-image, **self-esteem**, and ultimately his or her success in reaching the fullest language potential.

Laxatives

Definition

Laxatives are products that promote bowel movements.

Description

Laxatives may be grouped by mechanism of action.

Saline cathartics include dibasic sodium phosphate (Phospo-Soda), magnesium citrate, magnesium hydroxide (milk of magnesia), magnesium sulfate (Epsom salts), sodium biphosphate, and others. They act by attracting and holding water in the intestinal lumen, and may produce a watery stool. Magnesium sulfate is the most potent of the laxatives in this group.

Stimulant and irritant laxatives increase the peristaltic movement of the intestine. Examples include cascara and bisadocyl (Dulcolax). Castor oil works in a similar fashion.

Bulk producing laxatives increase the volume of the stool, and will both soften the stool and stimulate intestinal motility. Psyillium (Metamucil, Konsil) and methylcellulose (Citrucel) are examples of this type. The overall effect is similar to that of eating high-fiber foods, and this class of laxative is most suitable for regular use.

Docusate (Colace) is the only representative example of the stool softener class. It holds water within the fecal mass, providing a larger, softer stool. Docusate has no effect on acute **constipation**, since it must be present before the fecal mass forms to have any effect, but may be useful for prevention of constipation in patients with recurrent problems, or those who are about to take a constipating drug, such as narcotic **analgesics**.

Mineral oil is an emollient laxative. It acts by retarding intestinal absorption of fecal water, thereby softening the stool.

The hyperosmotic laxatives are glycerin and lactulose (Chronulac, Duphalac), both of which act by holding water within the intestine. Lactulose may also increase peristaltic action of the intestine.

General use

Laxatives are used to treat constipation—the passage of small amounts of hard, dry stools, usually fewer than three times a week. Constipation may be caused by several conditions, some of which are potentially serious, and require medical attention:

- Neurologic—caused by failure of nerves to stimulate movement of the muscles of the intestines.
- Obstructive—failure of the muscles in the intestine to open, or presence of a mass that's blocking passage of the feces through the intestine.
- Endocrine/metabolic—caused by some diseases including hypothyroidism.
- Medicinal—caused by some drugs, including narcotic analgesics, iron, and some drugs used in **cancer** treatment.

Chronic constipation occurs in 1–4% of children between the ages of four and 10. If constipation continues, it should be treated by a physician.

A reasonable first step is to assure that there is enough fiber in the diet. This may be done by switching to a high fiber breakfast cereal. If this doesn't lead to improvement, then medical attention is necessary.

Precautions

Short term use of laxatives is generally safe except in **appendicitis**, fecal impaction, or intestinal obstruction. Lactulose is composed of two sugar molecules; galactose and fructose, and should not be administered to patients who require a low galactose diet.

Chronic use of laxatives may result in fluid and electrolyte imbalances, steatorrhea, osteomalacia, **diarrhea**, cathartic colon, and liver disease. Excessive intake of mineral oil may cause impaired absorption of oil soluble

KEY TERMS

Carbohydrates—Compounds, such as cellulose, sugar, and starch, that contain only carbon, hydrogen, and oxygen, and are a major part of the diets of people and other animals.

Cathartic colon—A poorly functioning colon, resulting from the chronic abuse of stimulant cathartics.

Colon—The part of the large intestine that extends from the cecum to the rectum. The sigmoid colon is the area of the intestine just above the rectum; linking the descending colon with the rectum. It is shaped like the letter S.

Diverticulitis—Inflammation of the diverticula (small outpouchings) along the wall of the colon, the large intestine.

Fiber—Carbohydrate material in food that cannot be digested.

Hyperosmotic—Hypertonic, containing a higher concentration of salts or other dissolved materials than normal tissues.

Osteomalacia—A bone disease that occurs in adults due to a prolonged period of vitamin D deficiency. It is characterized by softening of the bone and is sometimes referred to as adult rickets.

Steatorrhea—An excessive amount of fat in the feces due to poor fat absorption in the gastrointestinal tract.

Stool—The solid waste that is left after food is digested. Stool forms in the intestines and passes out of the body through the anus.

vitamins, particularly A and D. Excessive use of magnesium salts may cause hypermanesemia.

Side effects

Excessive use of laxatives may result in dependency on these products. This may cause a condition known as cathartic colon.

Excessive use of laxatives that contain sodium or magnesium may result in dangerously high blood levels of these elements.

Interactions

Mineral oil and docusate should not be used in combination. Docusate is an emulsifying agent which will increase the absorption of mineral oil.

Bisacodyl tablets are enteric coated, and so should not be used in combination with antacids. The antacids will cause premature rupture of the enteric coating.

Preventing side effects

Used properly, laxatives are very safe. Do not overuse or give in doses larger than those labeled. If constipation persists, obtain medical help.

Parental concerns

Laxatives should not be used too frequently. Bulk laxatives such as psyllium should be the normal first choice.

Mineral oil should not be given to infants or other children while laying down. This may result in the oil going into the lungs.

Lead poisoning

Definition

Lead **poisoning** occurs when a person swallows, absorbs, or inhales lead in any form. The result can be damaging to the brain, nerves, and many other parts of the body. Acute lead poisoning, which is somewhat rare, occurs when a relatively large amount of lead is taken into the body over a short period of time. Chronic lead poisoning is a common problem in children that occurs when small amounts of lead are ingested over a longer period. The Centers for Disease Control and Prevention (CDC) defines childhood lead poisoning as a whole-blood lead concentration equal to or greater than 10 micrograms/dL.

Description

Lead can damage almost every system in the human body, and it can also cause high blood pressure (**hypertension**). It is particularly harmful to the developing brain of fetuses and young children. The higher the level of lead in a child's blood and the longer this elevated level lasts, the greater the chance of ill effects. Over the long term, lead poisoning in a child can lead to learning disabilities, behavioral problems, and even **mental retardation**. At very high levels, lead poisoning can cause seizures, coma, and even death.

Many children with elevated blood levels are exposed to lead through peeling paint in older homes. Others are exposed through dust or soil that has been contaminated by old paint or past emissions of leaded gasoline. Since children between the ages of 12 and 36 months are apt to put things in their mouths, they are more likely than older children to take in lead. Pregnant women who come into contact with lead can pass it along to the fetus.

Over 80 percent of American homes built before 1978 have lead-based paint in them, according to the Centers for Disease Control and Prevention (CDC). The older the home, the more likely it is to contain lead paint, and the higher the concentration of lead in the paint is apt to be. Some homes also have lead in the water pipes or plumbing. Without knowing it, people may have lead in the paint, dust, or soil around their homes or in their drinking water, since lead cannot be seen, smelled, or tasted. Because lead does not break down naturally, it can continue to cause problems until it is removed.

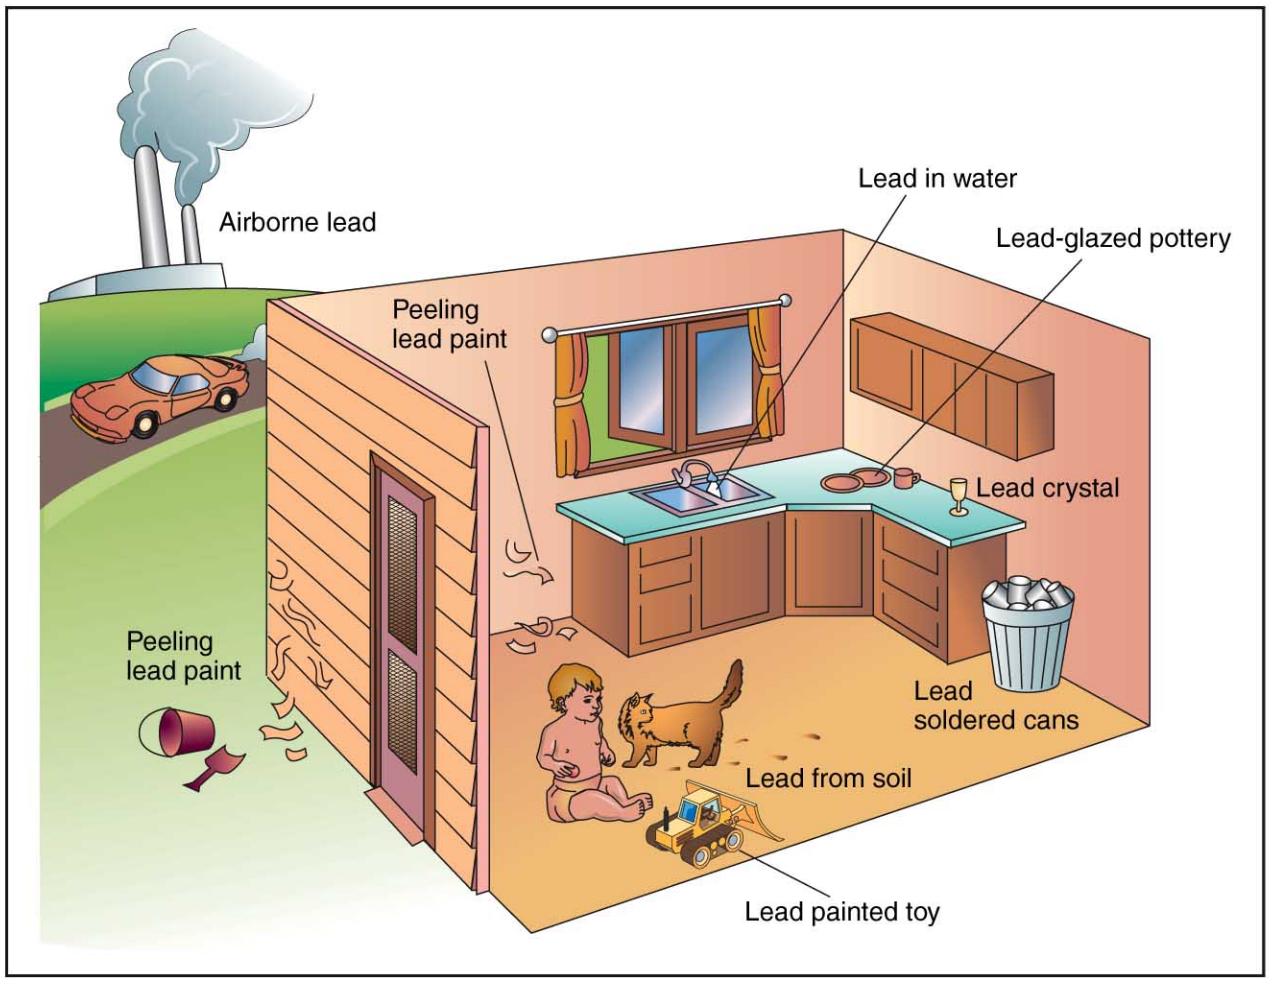
Demographics

According to the Agency for Toxic Substances and Disease Registry, approximately one out of every six children in the United States has a high level of lead in the blood. According to the National Center for Environmental Health, there were about 200 deaths from lead poisoning in the United States between 1979 and 1998. Most of the deaths were among males (74%), African Americans (67%), adults over the age of 45 (76%), and Southerners (70%).

Causes and symptoms

Before scientists knew how harmful it could be, lead was widely used in paint, gasoline, water pipes, and many other products. In the early 2000s house paint is almost lead-free, gasoline is unleaded, and household plumbing is no longer made with lead materials. Still, remnants of the old hazards remain. Following are some sources of lead exposure:

- Lead-based paint: This is the most common source of exposure to large amounts of lead among preschoolers. Children may eat paint chips from older homes that have fallen into disrepair. They may also chew on painted surfaces such as windowsills. In addition, paint may be disturbed during remodeling.
- Dust and soil: These can be contaminated with lead from old paint or past emissions of leaded gasoline. In addition, pollution from operating or abandoned industrial sites and smelters can find its way into the soil, resulting in soil contamination.
- Drinking water: Exposure may come from lead water pipes, found in many homes built before 1930. Even newer copper pipes may have lead solder. Also, some new homes have brass faucets and fittings that can leach lead.
- Jobs and hobbies: A number of activities can expose participants to lead. These include making pottery or stained glass, refinishing furniture, doing home repairs,



Continuous exposure to lead can damage nearly every system in the human body and is particularly harmful to the developing brain of fetuses and young children. Common sources of lead exposure include lead-based paint, dust and soil, drinking water, food from cans, and eating utensils, such as plates and drinking glasses, that are lead-based. *(Illustration by Electronic Illustrators Group.)*

and using indoor firing ranges. When adults take part in such activities, they may inadvertently expose children to lead residue that is on their clothing or on scrap materials.

- Food: Imported food cans often have lead solder. Lead may also be found in leaded crystal glassware and some imported ceramic or old ceramic dishes (e.g., ceramic dishes from Mexico). A 2003 study of cases of lead poisoning in pregnant women found that 70 percent of affected people were Hispanics, most of whom had absorbed the lead from their pottery. In addition, food may be contaminated by lead in the water or soil.
- Folk medicines: Certain folk medicines (for example, alarcon, alkohl, azarcon, bali goli, coral, ghasard, greta, liga, pay-loo-ah, and rueda) and traditional cosmetics (kohl, for example) contain high concentrations of lead.
- Moonshine whiskey: Lead poisoning from drinking illegally distilled liquor is still a cause of death among adults in the southern United States.
- Gunshot **wounds**: Toxic amounts of lead can be absorbed from bullets or bullet fragments that remain in the body after emergency surgery.

Evidence as of 2004 suggested that lead may be harmful to children even at low levels that were once thought to be safe, and the risk of damage rises as blood levels of lead increase. The symptoms of chronic lead poisoning take time to develop, however. Children can appear healthy despite having high levels of lead in their blood. Over time, though, problems such as the following may arise:

- learning disabilities
- hyperactivity

- mental retardation
- slowed growth
- hearing loss
- headaches

It is also known that certain genetic factors increase the harmful effects of lead poisoning in susceptible children; however, these factors are not completely understood.

Lead poisoning is also harmful to adults, in whom it can cause high blood pressure, digestive problems, nerve disorders, memory loss, and muscle and joint **pain**. In addition, it can lead to difficulties during pregnancy, as well as cause reproductive problems in both men and women.

In the early 2000s, chronic exposure to lead in the environment has been found to speed up the progression of kidney disorders in people without diabetes.

Acute lead poisoning

Acute lead poisoning, while less common, shows up more quickly and can be fatal. Symptoms such as the following may occur:

- severe abdominal pain
- diarrhea
- nausea and vomiting
- weakness of the limbs
- seizures
- coma

When to call the doctor

The CDC recommends testing all children at 12 months of age and, if possible, again at 24 months. Testing should start at six months for children at risk for lead poisoning.

Diagnosis

A high level of lead in the blood can be detected with a simple blood test. In fact, testing is the only way to know for sure if children without symptoms have been exposed to lead, since they can appear healthy even as long-term damage occurs. Based on test results and a child's risk factors, the doctor will then decide whether further testing is needed and how often. In some states, more frequent testing is required by law.

Children at risk

Children with an increased risk of lead poisoning include those for whom the following is true:

- They live in or regularly visit a house built before 1978 in which chipped or peeling paint is present.
- They live in or regularly visit a house that was built before 1978 where remodeling is planned or underway.
- They have a brother or sister, housemate, or playmate who has been diagnosed with lead poisoning.
- They have the habit of eating dirt or have been diagnosed with pica.
- They live with an adult whose job or hobby involves exposure to lead.
- They live near an active lead smelter, battery-recycling plant, or other industry that can create lead pollution.

Adults at risk

Testing is also important for adults whose job or hobby puts them at risk for lead poisoning. This need applies to people who take part in the following activities:

- glazed pottery or stained glass production
- furniture refinishing
- home renovation
- target shooting at indoor firing ranges
- battery reclamation
- precious metal refining
- radiator repair
- art restoration

Treatment

The first step in treating lead poisoning is to avoid further contact with lead. For adults, this usually means making changes at work or in hobbies. For children, it means that parents and guardians need to find and remove sources of lead in the home. In most states, the public health department can help assess the home and identify lead sources.

If the problem is lead paint, a professional with special training should remove it. Removal of lead paint is not a do-it-yourself project. Scraping or sanding lead paint creates large amounts of dust that can poison people in the home. This dust can stay around long after the work is completed. In addition, heating lead paint can release lead into the air. For these reasons, lead paint should only be removed by someone who knows how to do the job safely

KEY TERMS

Chelation therapy—A treatment using chelating agents, compounds that surround and bind to target substances allowing them to be excreted from the body.

Dimercaprol—A chemical agent used to remove excess lead from the body.

Edetate calcium disodium—A chemical chelating agent used to remove excess lead from the body.

Penicillamine (Cuprimine, Depen)—A drug used to treat medical problems (such as excess copper in the body and rheumatoid arthritis) and to prevent kidney stones. It is also sometimes prescribed to remove excess lead from the body.

Pica—A desire that sometimes arises in pregnancy to eat nonfood substances, such as dirt or clay.

Succimer—A chelating agent that is used to remove excess lead from the body. Sold under the trade name Chemet.

and has the equipment to clean up thoroughly. Occupants, especially children and pregnant women, should leave the home until the cleanup is finished.

Medical professionals should take all necessary steps to remove bullets or bullet fragments from people with gunshot injuries.

If blood levels of lead are high enough, the doctor may also prescribe chelation therapy. This refers to treatment with chemicals that bind to the lead and help the body pass it in urine at a faster rate. There are four chemical agents that may be used for this purpose, either alone or in combination. Edetate calcium disodium (EDTA calcium) and dimercaprol (BAL) are given through an intravenous line or in shots, while succimer (Chemet) and penicillamine (Cuprimine, Depen) are taken by mouth. (Although many doctors prescribe penicillamine for lead poisoning, this use of the drug has not been approved by the Food and Drug Administration.)

Changes in diet are no substitute for medical treatment. However, getting enough calcium, zinc, and protein may help reduce the amount of lead the body absorbs. Iron is also important, since people who are deficient in this nutrient absorb more lead. Garlic and thiamine, a B-complex vitamin, have been used to treat lead poisoning in animals. However, their usefulness in humans for this purpose has not as of 2004 been demonstrated. Nutritional, botanical, and homeopathic medicines can be administered once the source is removed to help correct any imbalances brought on by lead toxicity.

Prognosis

If acute lead poisoning reaches the stage of seizures and coma, there is a high risk of death. Even if the person survives, there is a good chance of permanent brain damage. The long-term effects of lower levels of lead can also be permanent and severe. However, if chronic lead poisoning is caught early, these negative effects can be limited by reducing future exposure to lead and getting proper medical treatment.

Prevention

Many cases of lead poisoning can be prevented. The following steps can help:

- Keep the areas where children **play** as clean and dust-free as possible.
- Wash pacifiers and bottles when they fall to the floor and wash stuffed animals and **toys** often.
- Make sure children wash their hands before meals and at bedtime.
- Mop floors and wipe windowsills and other chewable surfaces, such as cribs, twice a week with a solution of powdered dishwasher detergent in warm water.
- Plant bushes next to an older home with painted exterior walls to keep children at a distance.
- Plant grass or another ground cover in soil that is likely to be contaminated, such as soil around a home built before 1960 or located near a major highway.
- Have household tap water tested to find out if it contains lead.
- Use only water from the cold-water tap for drinking, cooking, and making baby formula, since hot water is likely to contain higher levels of lead.
- If the cold water has not been used for six hours or more, run it for several seconds, until it becomes as cold as it will get, before using it for drinking or cooking. The more time water has been sitting in the pipes, the more lead it may contain.
- Do not store food in open cans, especially imported cans.
- Do not store or serve food in pottery meant for decorative use.
- People who work with lead in a job or hobby should change their clothes before they go home.

Nutritional concerns

Avoid preparing or serving food in containers that have lead in their glazing. Do not consume homemade liquor that has been distilled.

Parental concerns

Lead tastes sweet. Parents living in homes built prior to 1978 should be vigilant regarding removing all flaking or peeling paint. Simply re-painting such surfaces will not resolve the problem. Parents must monitor the environments in which their children play and the objects that go into their children's mouths. Cleanliness is a must if old paint is in a child's environment. Removal (stripping paint to bare metal or bare wood) of lead is the best way to prevent lead exposure in children.

Learning disorders

Definition

Learning disorders are academic difficulties experienced by children and adults of average to above-average **intelligence**. People with learning disorders have difficulty with reading, writing, mathematics, or a combina-

tion of the three. These difficulties significantly interfere with academic achievement or daily living.

Description

Children with learning disorders, or disabilities, have specific impairments in acquiring, retaining, and processing information. Standardized tests place them well below their IQ range in their area of difficulty. The five main types of learning disorders are reading disorders, mathematics disorders, disorders of written expression, disorders of **fine motor skills**, and information processing disorders.

Reading disorders

Reading disorders are the most common type of learning disorder. Children with reading disorders have difficulty recognizing and interpreting letters and words (**dyslexia**). They are unable to recognize and decode the sounds and syllables (phonetic structure) behind written words and language in general. This condition lowers accuracy and comprehension in reading.

Mathematics disorders

Children with mathematics disorders (dyscalculia) have problems recognizing and counting numbers correctly. They have difficulty using numbers in everyday settings. Mathematics disorders are typically diagnosed in the first few years of elementary school when formal teaching of numbers and basic math concepts begins. Children with mathematics disorders usually have a coexisting reading disorder, a disorder of written expression, or both.

Disorders of written expression

Disorders of written expression typically occur in combination with reading disorders or mathematics disorders or both. The condition is characterized by difficulty with written compositions (dysgraphia). Children with this type of learning disorder have problems with spelling, punctuation, grammar, and organizing their thoughts in writing.

Disorders of fine motor skills

Children with motor skill disorders (dyspraxia) have coordination problems and may have difficulty with handwriting tasks and speech patterns. Dyspraxia tends to affect boys more than girls.

Information processing disorders

Information processing disorders often occur along with other types of learning disorders. Children with this problem have difficulty processing the sensory input they receive, specifically sight and sound information. They can see and hear adequately, but they have difficulty distinguishing between different visual cues and auditory signals, and may have problems understanding spatial relationships and sequencing the sights and sounds they observe.

Demographics

Learning disorders affect approximately two million children between the ages of six and 17 (5 percent of public school children), although some experts think the figure may be as high as 15 percent. The male to female ratio for learning disorders is about five to one.

Causes and symptoms

Learning disorders are thought to be caused by neurological abnormalities or differences that trigger impairments in the regions of the brain that control visual and language processing and attention and planning. These traits may be genetically linked. Children from families with a history of learning disorders are more likely to develop disorders themselves. In 2003, a team of Finnish researchers reported finding a candidate gene for developmental dyslexia on human chromosome 15q21.

Learning difficulties may also be caused by such medical conditions as a traumatic brain injury or brain infections such as **encephalitis** or **meningitis**.

The defining symptom of a learning disorder is academic performance that is markedly below a child's age and grade capabilities and measured IQ. Children with a reading disorder may confuse or transpose words or letters and omit or add syllables to words. The written homework of children with disorders of written expression is filled with grammatical, spelling, punctuation, and organizational errors. The child's handwriting is often extremely poor. Children with mathematical disorders are often unable to count in the correct sequence, to name numbers, and to understand numerical concepts.

When to call the doctor

A child thought to have a learning disorder should undergo a complete medical examination to rule out an organic cause of the problem. This may include an eye exam by an ophthalmologist, a psychological exam by a psychologist, and an exam by an otolaryngologist (an ear, nose, and throat doctor, or ENT).

Diagnosis

Problems with vision or hearing, mental disorders (depression, **attention-deficit/hyperactivity disorder**), **mental retardation**, cultural and language differences, and inadequate teaching may be mistaken for learning disorders or may complicate a diagnosis. A comprehensive medical, psychological, and educational **assessment** is critical to making a correct diagnosis.

A psychoeducational assessment should be performed by a psychologist, psychiatrist, neurologist, neuropsychologist, or learning specialist. A complete medical, **family**, social, and educational history is compiled from existing medical and school records and from interviews with the child and the child's parents and teachers. A series of written and verbal tests are then given to the child to evaluate his or her cognitive and intellectual functioning. Commonly used tests include the Wechsler Intelligence Scale for Children (WISC-III), the Woodcock-Johnson Psychoeducational Battery, the Peabody Individual Achievement Test-Revised (PIAT-R) and the California Verbal Learning Test (CVLT). Federal legislation mandates that this testing is free of charge within the public school system.

Treatment

Once a learning disorder has been diagnosed, an individual education plan (IEP) is developed for the child in question. IEPs are based on psychoeducational test findings. They provide for annual retesting to measure a child's progress. Learning-disordered students may receive special instruction within a regular general education class or they may be taught in a **special education** or learning center for a portion of the day.

Common strategies for the treatment of reading disorders focus first on improving a child's recognition of the sounds of letters and language through phonics training. Later strategies focus on comprehension, retention, and study skills. Students with disorders of written expression are often encouraged to keep journals and to write with a computer keyboard instead of a pencil. Instruction for students with mathematical disorders emphasizes real-world uses of arithmetic, such as balancing a checkbook or comparing prices.

Prognosis

The high school dropout rate for children with learning disabilities is almost 40 percent. Children with learning disabilities that go undiagnosed or are improperly treated may never achieve functional literacy. They often develop serious behavior problems as a result of their frustration with school. In addition, their learning problems are often stressful for other family members and may strain family relationships. The key to helping these students reach their fullest potential is early detection and the implementation of an appropriate individualized education plan (IEP). The prognosis is good for a large percentage of children with reading disorders that are identified and treated early. Learning disorders typically persist into adulthood, but with proper educational and vocational training, an individual can complete college and pursue a challenging career. Studies of the occupational choices of adults with dyslexia indicate that they do particularly well in people-oriented professions and occupations, such as nursing or sales.

Common strategies for the treatment of reading disorders focus first on improving a child's recognition of the sounds of letters and language through phonics training. *(© Robert Maass/Corbis.)*

Prevention

Some studies have indicated that one-on-one tutoring of children at risk for developing learning disorders

KEY TERMS

Dyslexia—A type of reading disorder often characterized by reversal of letters or words.

IEP—Individualized Education Plan. Under federal law governing special education, every child in public schools who is determined through assessment to have special mental disability needs has an IEP. An IEP is typically developed by a team of professionals that may include special education teachers, physical, occupational and speech therapists, psychologists, parents or guardians, and others who may be called on to provide expertise. The team meets at least once a year to set goals for the next school year and to assess progress on already established goals. Parents who are not satisfied with school-based assessments have the right to ask for independent assessments that must be paid for by the school system.

IQ—Intelligence quotient, a measure of intellectual functioning determined by performance on standardized intelligence tests. It is usually calculated by dividing an individual's mental age (determined by testing) by his/her chronological age and multiplying that result by 100.

Phonics—A system to teach reading by teaching the speech sounds associated with single letters, letter combinations, and syllables.

may be effective in preventing later reading and writing problems.

Parental concerns

Parents of children with learning disorders should stay in close contact with educators and school administrators to ensure that their child's IEP undergoes a regular review and continues to provide the maximum educational benefit for their child.

Leukemias, acute

Definition

Leukemia is a **cancer** that starts in the organs that make blood, namely the bone marrow and the lymph system. Depending on their characteristics, leukemias can be divided into two broad types. Acute leukemias are the rapidly progressing leukemias, while the **chronic leukemias** progress more slowly. The vast majority of the childhood leukemias are of the acute form.

Description

The cells that make up blood are produced in the bone marrow and the lymph system. The bone marrow is the spongy tissue found in the large bones of the body. The lymph system includes the spleen (an organ in the upper abdomen), the thymus (a small organ beneath the breastbone), and the tonsils (an organ in the throat). In addition, the lymph vessels (tiny tubes that branch like blood vessels into all parts of the body) and lymph nodes (pea-shaped organs that are found along the network of lymph vessels) are also part of the lymph system. Lymph is a milky fluid that contains cells. Clusters of lymph nodes are found in the neck, underarm, pelvis, abdomen, and chest.

Blood is made up of red blood cells (RBCs), which carry oxygen and other materials to all tissues of the body; white blood cells (WBCs), which fight infection; and platelets, which play a part in the clotting of the blood. The white blood cells can be further subdivided into three main types: granulocytes, monocytes, and lymphocytes.

The granulocytes, as their name suggests, contain particles (granules). These granules contain special proteins (enzymes) and several other substances that can break down chemicals and destroy microorganisms, such as bacteria. Monocytes are the second type of white blood cell. They are also important in defending the body against pathogens.

The lymphocytes form the third type of white blood cell. There are two main types of lymphocytes: T lymphocytes and B lymphocytes. They have different functions within the immune system. The B cells protect the body by making antibodies, which are proteins that can attach to the surfaces of bacteria and viruses. This attachment sends signals to many other cell types to come and destroy the antibody-coated organism. The T cells protect the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the infected cell. The T cells recognize these proteins and make certain chemicals that are capable of destroying the virus-infected cells. In addition, the T cells can destroy some types of cancer cells.

The bone marrow makes stem cells, which are the precursors of the different blood cells. These stem cells mature through stages into RBCs, WBCs, or platelets. In acute leukemias, the maturation process of the white blood cells is interrupted. The immature cells (blasts) proliferate rapidly and begin to accumulate in various organs and tissues, thereby affecting their normal function. This uncontrolled proliferation of the immature cells in the bone marrow affects the production of the normal red blood cells and platelets as well.

Acute leukemias are of two types: acute lymphocytic leukemia and acute myelogenous leukemia. Different types of white blood cells are involved in the two leukemias. In acute lymphocytic leukemia (ALL), it is the T or the B lymphocytes that become cancerous. The B cell leukemias are more common than T cell leukemias. Acute myelogenous leukemia, also known as acute nonlymphocytic leukemia (ANLL), is a cancer of the monocytes and/or granulocytes.

Demographics

Leukemias account for 2 percent of all cancers. Because leukemia is the most common form of childhood cancer, it is often regarded as a disease of childhood. However, leukemias affect nine times as many adults as children. Half of the cases occur in people who are 60 years of age or older. The incidence of acute and chronic leukemias is about the same.

Leukemia strikes both sexes and all ages. The human T-cell leukemia virus (HTLV-I) is believed to be the causative agent for some kinds of leukemias. However, as of 2004, the cause of most leukemias is not known. Acute lymphoid leukemia (ALL) is more common among Caucasians than among African-Americans, while acute myeloid leukemia (AML) affects both races equally. The incidence of acute leukemia is slightly higher among men than women. People with Jewish ancestry have a higher likelihood of getting leukemia. A higher incidence of leukemia has also been observed among persons with **Down syndrome** and some other genetic abnormalities.

Causes and symptoms

Exposure to ionizing radiation and to certain organic chemicals, such as benzene, is believed to increase the risk of developing leukemia. Having a history of diseases that damage the bone marrow, such as aplastic anemia, or a history of cancers of the lymphatic system puts people at a high risk for developing acute leukemias. Similarly, the use of anticancer medications, immunosuppressants, and the antibiotic chloramphenicol are also considered risk factors for developing acute leukemias.

The symptoms of leukemia are generally vague and non-specific. A patient may experience all or some of the following symptoms:

- weakness or chronic fatigue
- fever of unknown origin

- weight loss that is not due to dieting or exercise
- frequent bacterial or viral infections
- headaches
- skin rash
- non-specific bone pain
- easy bruising
- bleeding from gums or nose
- blood in urine or stools
- enlarged lymph nodes and/or spleen
- abdominal fullness

Diagnosis

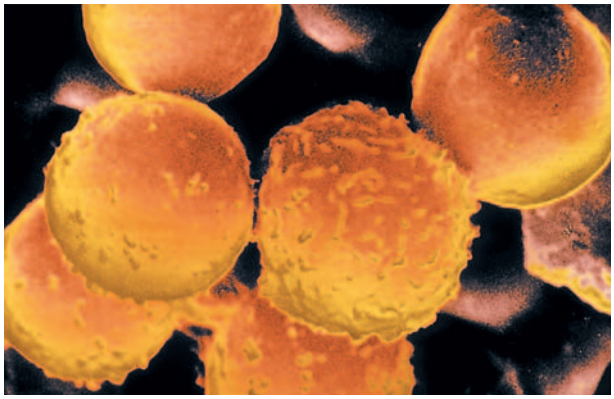
Like all cancers, acute leukemias are most successfully treated when found early. There were as of 2004 no screening tests available.

If the doctor has reason to suspect leukemia, he or she will conduct a very thorough physical examination to look for enlarged lymph nodes in the neck, underarm, and pelvic region. Swollen gums, enlarged liver or spleen, **bruises**, or pinpoint red **rashes** all over the body are some of the signs of leukemia. Urine and blood tests may be ordered to check for microscopic amounts of blood in the urine and to obtain a complete differential blood count. This count gives the numbers and percentages of the different cells found in the blood. An abnormal blood test might suggest leukemia; however, the diagnosis has to be confirmed by more specific tests.

The doctor may perform a bone marrow biopsy to confirm the diagnosis of leukemia. During the biopsy, a cylindrical piece of bone and marrow is removed. The tissue is generally taken out of the hipbone. These samples are sent to the laboratory for examination. In addition to diagnosis, the biopsy is also repeated during the treatment phase of the disease to see if the leukemia is responding to therapy.

A spinal tap (lumbar puncture) is another procedure that the doctor may order to diagnose leukemia. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw some cerebrospinal fluid and to look for leukemic cells.

Standard imaging tests, such as x rays, **computed tomography** scans (CT scans), and **magnetic resonance imaging** (MRI) may be used to check whether the leukemic cells have invaded other areas of the body, such as the bones, chest, kidneys, abdomen, or brain. A gallium scan or bone scan is a test in which a radioactive chemical is injected into the body. This chemical accumulates in the areas of cancer or infection, allowing them to be viewed with a special camera.



An enhanced transmission electron microscopy (TEM) image of white blood cells from a patient with acute myelogenous leukemia cells. *(© Professor Aaron Polliack, Science Source/Photo Researchers, Inc.)*

Treatment

There are two phases of treatment for leukemia. The first phase is called induction therapy. As the name suggests, during this phase, the main aim of the treatment is to reduce the number of leukemic cells as far as possible and induce a remission in the patient. Once the patient shows no obvious signs of leukemia (no leukemic cells are detected in blood tests and bone marrow biopsies), the patient is said to be in remission. The second phase of treatment is then initiated. This is called continuation or maintenance therapy, and the aim in this case is to kill any remaining cells and to maintain the remission for as long as possible.

Chemotherapy is the use of drugs to kill cancer cells. It is usually the treatment of choice and is used to relieve symptoms and achieve long-term remission of the disease. Generally, combination chemotherapy, in which multiple drugs are used, is more efficient than using a single drug for the treatment. Some drugs may be administered intravenously (through a vein) in the arm; others may be given by mouth in the form of pills. If the cancer cells have invaded the brain, then chemotherapeutic drugs may be put into the fluid that surrounds the brain through a needle in the brain or back. This is known as intrathecal chemotherapy.

Because leukemia cells can spread to all the organs via the blood stream and the lymph vessels, surgery is not considered an option for treating leukemias.

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes or to follow the course of a disease. Most commonly the term refers to the collection and analysis of tissue from a suspected tumor to establish malignancy.

Chemotherapy—Any treatment of an illness with chemical agents. The term is usually used to describe the treatment of cancer with drugs that inhibit cancer growth or destroy cancer cells.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Cytokines— Chemicals made by the cells that act on other cells to stimulate or inhibit their function. They are important controllers of immune functions.

Immunotherapy—A mode of cancer treatment in which the immune system is stimulated to fight the cancer.

Lumbar puncture—A procedure in which the doctor inserts a small needle into the spinal cavity in the lower back to withdraw spinal fluid for testing. Also known as a spinal tap.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct detailed images of internal body structures and organs, including the brain.

Maturation—The process by which stem cells transform from immature cells without a specific function into a particular type of blood cell with defined functions.

Radiation therapy—A cancer treatment that uses high-energy rays or particles to kill or weaken cancer cells. Radiation may be delivered externally or internally via surgically implanted pellets. Also called radiotherapy.

Remission—A disappearance of a disease and its symptoms. Complete remission means that all disease is gone. Partial remission means that the disease is significantly improved, but residual traces of the disease are still present. A remission may be due to treatment or may be spontaneous.

Radiation therapy, which involves the use of x-rays or other high-energy rays to kill cancer cells and shrink tumors, may be used in some cases. For acute leukemias, the source of radiation is usually outside the body (external radiation therapy). If the leukemic cells have spread to the brain, radiation therapy can be given to the brain.

Bone marrow transplantation is a process in which the patient's diseased bone marrow is replaced with healthy marrow. There are two ways of doing a bone marrow transplant. In an allogeneic bone marrow transplant, healthy marrow is taken from a donor whose tissue is either the same as or very closely resembles the patient's tissues. The donor may be a twin, a sibling, or a person who is not related at all. First, the patient's bone marrow is destroyed with very high doses of chemotherapy and radiation therapy. Healthy marrow from the donor is then given to the patient through a needle in a vein to replace the destroyed marrow.

In the second type of bone marrow transplant, called an autologous bone marrow transplant, some of the patient's own marrow is taken out and treated with a combination of anticancer drugs to kill all the abnormal cells. This marrow is then frozen and saved. The marrow remaining in the patient's body is destroyed with high-dose chemotherapy and radiation therapy. The marrow that was frozen is then thawed and given back to the patient through a needle in a vein. This mode of bone marrow transplant is in the early 2000s being investigated in clinical trials.

Biological therapy or immunotherapy is a mode of treatment in which the body's own immune system is harnessed to fight the cancer. Substances that are routinely made by the immune system (such as growth factors, hormones, and disease-fighting proteins) are either synthetically made in a laboratory or their effectiveness is boosted and they are then put back into the patient's body. This treatment mode is also being investigated in the early 2000s in clinical trials all over the United States at major cancer centers.

Prognosis

Like all cancers, the prognosis for leukemia depends on the patient's age and general health. According to sta-

tistics, more than 60 percent of the patients with leukemia survive for at least a year after diagnosis. Acute myelocytic leukemia (AML) has a poorer prognosis rate than acute lymphocytic leukemias (ALL) and the chronic leukemias. Between 1985 and 2004, the five-year survival rate for patients with ALL increased from 38 to 57 percent.

Interestingly enough, since most childhood leukemias are of the ALL type, chemotherapy has been highly successful in their treatment. This is because chemotherapeutic drugs are most effective against actively growing cells. Due to the new combinations of anticancer drugs being used, the survival rates among children with ALL have improved dramatically. Eighty percent of the children diagnosed with ALL as of 2004 survive for five years or more, as compared to 50 percent in the late 1970s.

Prevention

Most cancers can be prevented by changes in lifestyle or diet, which will reduce the risk factors. However, in leukemias, there are as of 2004 no such known risk factors. Therefore, as of 2004, no way is known to prevent leukemias from developing. People who are at an increased risk for developing leukemia because of proven exposure to ionizing radiation or exposure to the toxic liquid benzene, and people with Down syndrome, should undergo periodic medical checkups.

Parental concerns

Parents of a child with leukemia must balance their own fears for their child's health with the child's fears and worries. Also, given the large financial burden leukemia treatment entails, parents will want to make sure they are aware of what and what is not covered by their insurance. Parents can find a variety of sources, written and online, that will help them deal with the new circumstances of themselves and their **family**.

Leukemias, chronic

Definition

Chronic leukemia is a disease in which abnormal, cancerous white blood cells are made in the bone marrow. Depending on the type of white blood cell that is involved, chronic leukemia can be classified as chronic lymphocytic leukemia or chronic myeloid leukemia.

Description

Chronic leukemia is a **cancer** that starts in the blood cells made in the bone marrow. The bone marrow is the spongy tissue found in the large bones of the body. The bone marrow makes precursor cells called blasts or stem cells, which mature into different types of blood cells. Unlike **acute leukemias**, in which the process of maturation of the blast cells is interrupted, in chronic leukemias, the cells do mature and only a few remain as immature cells. However, even though the cells appear normal, they do not function as normal cells.

Bone marrow produces different types of cells: red blood cells (RBCs), which carry oxygen and other materials to all tissues of the body; white blood cells (WBCs), which fight infection; and platelets, which play a part in the clotting of the blood. The white blood cells can be further subdivided into three main types: the granulocytes, monocytes, and the lymphocytes.

The granulocytes, as their name suggests, contain granules (particles). These granules contain special proteins (enzymes) and several other substances that can break down chemicals and destroy microorganisms such as bacteria.

Monocytes are the second type of white blood cell. They are also important in defending the body against pathogens.

The lymphocytes form the third type of white blood cell. There are two main types of lymphocytes: T lymphocytes and B lymphocytes. They have different functions within the immune system. The B cells protect the body by making antibodies, which are proteins that can attach to the surfaces of bacteria and viruses. This attachment sends signals to many other cell types to come and destroy the antibody-coated organism. The T cell protects the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the infected cell. The T cells can recognize these proteins and produce certain chemicals (cytokines) that are capable of destroying the virus-infected cells. In addition, the T cells can destroy some types of cancer cells.

Chronic leukemias develop very gradually. The abnormal lymphocytes multiply slowly, but in a poorly regulated manner. They live much longer and thus their numbers build up in the body. The two types of chronic leukemias can be easily distinguished under the microscope. Chronic lymphocytic leukemia (CLL) involves the T or B lymphocytes. B cell abnormalities are more common than T cell abnormalities. T cells are affected in only 5 percent of the patients. The T and B lymphocytes can be differentiated from the other types of white blood cells based on their size and by the absence of granules inside them. In chronic myelogenous leukemia (CML), the cells that are affected are the granulocytes.

Chronic lymphocytic leukemia (CLL) often has no symptoms at first and may remain undetected for a long time. Chronic myelogenous leukemia (CML), by contrast, may progress to a more acute form.

Demographics

Chronic leukemias account for 1.2 percent of all cancers. Because leukemia is the most common form of childhood cancer, it is often regarded as a disease of childhood. However, leukemias affect nine times as many adults as children. In chronic lymphoid leukemia, 90 percent of the cases are seen in people who are 50 years or older, with the average age at diagnosis being 65. The incidence of the disease increases with age. It is almost never seen in children. Chronic myeloid leukemias are generally seen in people in their mid-40s. In addition, it accounts for about 4 percent of childhood leukemia cases.

Causes and symptoms

Leukemia strikes both sexes and all ages. Although the cause is unknown, chronic leukemia is linked to genetic abnormalities and environmental factors. For example, exposure to ionizing radiation and to certain organic chemicals, such as benzene, is believed to increase the risks for getting leukemia. Chronic leukemia occurs in some people who are infected with two human retroviruses (HTLV-I and HTLV-II). An abnormal chromosome known as the Philadelphia chromosome is seen in 90 percent of those with CML. The incidence of chronic leukemia is slightly higher among men than women.

The symptoms of chronic leukemia are generally vague and non-specific. In chronic lymphoid leukemia (CLL), a patient may experience all or some of the following symptoms:

- swollen lymph nodes
- an enlarged spleen, which could make the patient complain of abdominal fullness
- chronic fatigue
- a general feeling of ill-health
- fever of unknown origin
- night sweats
- weight loss that is not due to dieting or exercise
- frequent bacterial or viral infections

In the early stages of chronic myeloid leukemia (CML), the symptoms are more or less similar to CLL. In the later stages of the disease, the patient may experience the following symptoms:

- non-specific bone **pain**
- bleeding problems
- mucus membrane irritation
- frequent infections
- a pale color due to a low red blood cell count (anemia)
- swollen lymph glands
- fever
- night sweats

Diagnosis

There are no screening tests available for chronic leukemias. The detection of these diseases may occur by chance during a routine physical examination.

If the doctor has reason to suspect leukemia, he or she will conduct a very thorough physical examination

to look for enlarged lymph nodes in the neck, underarm, and pelvic region. Swollen gums, an enlarged liver or spleen, **bruises**, or pinpoint red **rashes** all over the body are some of the signs of leukemia. Urine and blood tests may be ordered to check for microscopic amounts of blood in the urine and to obtain a complete differential blood count. This count will give the numbers and percentages of the different cells found in the blood. An abnormal blood test might suggest leukemia; however, the diagnosis has to be confirmed by more specific tests.

The doctor may perform a bone marrow biopsy to confirm the diagnosis of leukemia. During the bone marrow biopsy, a cylindrical piece of bone and marrow is removed. The tissue is generally taken out of the hipbone. These samples are sent to the laboratory for examination. In addition to diagnosis, bone marrow biopsy is also done during the treatment phase of the disease to see if the leukemia is responding to therapy.

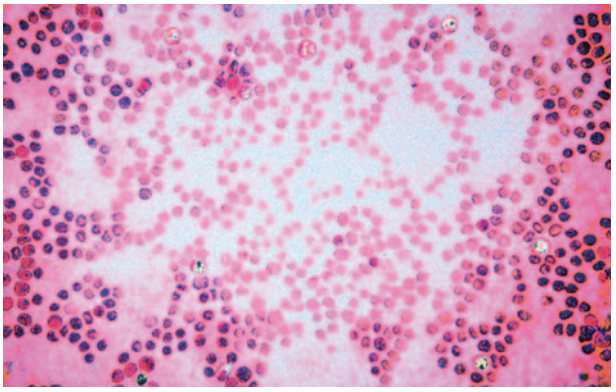
Standard imaging tests such as x-rays, **computed tomography** scans (CT scans), and **magnetic resonance imaging** (MRI) may be used to check whether the leukemic cells have invaded other organs of the body, such as the bones, chest, kidneys, abdomen, or brain.

Treatment

The treatment depends on the specific type of chronic leukemia and its stage. In general, **chemotherapy** is the standard approach to both CLL and CML. Radiation therapy is occasionally used. Because leukemia cells can spread to all the organs via the blood stream and the lymph vessels, surgery is not considered an option for treating leukemias.

Bone marrow transplantation (BMT) is in the early 2000s becoming the treatment of choice for CML because it has the possibility of curing the illness. BMT is generally not considered an option in treating CLL because CLL primarily affects older people, who are not considered to be good candidates for the procedure.

In BMT, the patient's diseased bone marrow is replaced with healthy marrow. There are two ways of doing a bone marrow transplant. In an allogeneic bone marrow transplant, healthy marrow is taken from another person (donor) whose tissue is either the same or very closely resembles the patient's tissues. The donor may be a twin, a sibling, or a person who is not related at all. First, the patient's bone marrow is destroyed with very high doses of chemotherapy and radiation therapy. To replace the destroyed marrow, healthy marrow from the donor is given to the patient through a needle in the vein.



Chronic lyphocytic leukemia cells, colorized and magnified 400 times. *(© 1999 Custom Medical Stock Photo, Inc.)*

In the second type of bone marrow transplant, called an autologous bone marrow transplant, some of the patient's own marrow is taken out and treated with a combination of anticancer drugs to kill all the abnormal cells. This marrow is then frozen to save it. The marrow remaining in the patient's body is then destroyed with high dose chemotherapy and radiation therapy. Following that, the patient's own marrow that was frozen is thawed and given back to the patient through a needle in the vein. This mode of bone marrow transplant is as of the early 2000s being investigated in clinical trials.

In chronic lymphoid leukemia (CLL), chemotherapy is generally the treatment of choice. Depending on the stage of the disease, single or multiple drugs may be given. Drugs commonly prescribed are steroids, chlorambucil, fludarabine, and cladribine. Low dose radiation therapy may be given to the whole body, or it may be used to alleviate the symptoms and discomfort due to an enlarged spleen and lymph nodes. The spleen may be removed in a procedure called a splenectomy.

In chronic myeloid leukemia (CML), the treatment of choice is bone marrow transplantation. During the slow progress (chronic phase) of the disease, chemotherapy may be given to try to improve the cell counts. Radiation therapy, which involves the use of x rays or other high-energy rays to kill cancer cells and shrink tumors, may be used in some cases to reduce the discomfort and pain due to an enlarged spleen. For chronic leukemias, the source of radiation is usually outside the body (external radiation therapy). If the leukemic cells have spread to the brain, radiation therapy can be directed at the brain. As the disease progresses, the spleen may be removed in an attempt to try to control the pain and to improve the blood counts.

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes or to follow the course of a disease. Most commonly the term refers to the collection and analysis of tissue from a suspected tumor to establish malignancy.

Chemotherapy—Any treatment of an illness with chemical agents. The term is usually used to describe the treatment of cancer with drugs that inhibit cancer growth or destroy cancer cells.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Cytokines—Chemicals made by the cells that act on other cells to stimulate or inhibit their function. They are important controllers of immune functions.

Immunotherapy—A mode of cancer treatment in which the immune system is stimulated to fight the cancer.

Lumbar puncture—A procedure in which the doctor inserts a small needle into the spinal cavity in the lower back to withdraw spinal fluid for testing. Also known as a spinal tap.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct detailed images of internal body structures and organs, including the brain.

Maturation—The process by which stem cells transform from immature cells without a specific function into a particular type of blood cell with defined functions.

Radiation therapy—A cancer treatment that uses high-energy rays or particles to kill or weaken cancer cells. Radiation may be delivered externally or internally via surgically implanted pellets. Also called radiotherapy.

Remission—A disappearance of a disease and its symptoms. Complete remission means that all disease is gone. Partial remission means that the disease is significantly improved, but residual traces of the disease are still present. A remission may be due to treatment or may be spontaneous.

In the acute phase of CML, aggressive chemotherapy is given. Combination chemotherapy, in which multiple drugs are used, is more efficient than using a single drug for the treatment. The drugs may either be administered intravenously (through a vein) in the arm or by mouth in the form of pills. If the cancer cells have invaded the central nervous system (CNS), chemotherapeutic drugs may be put into the fluid that surrounds the brain through a needle in the brain or back. This is known as intrathecal chemotherapy.

Biological therapy or immunotherapy is a mode of treatment in which the body's own immune system is harnessed to fight the cancer. Substances that are routinely made by the immune system (such as growth factors, hormones, and disease-fighting proteins) are either synthetically made in a laboratory, or their effectiveness is boosted and they are then put back into the patient's body. This treatment mode in the early 2000s is also being investigated in clinical trials all over the United States at major cancer centers.

Prognosis

The prognosis for leukemia depends on the patient's age and general health. According to statistics, in chronic lymphoid leukemia, the overall survival for all stages of the disease is nine years. Most of the deaths in people with CLL are due to infections or other illnesses that occur as a result of the leukemia.

In CML, if bone marrow transplantation is performed within one to three years of diagnosis, 50 to 60 percent of the patients survive three years or more. If the disease progresses to the acute phase, the prognosis is poor. Less than 20 percent of these patients go into remission.

Prevention

Most cancers can be prevented by changes in lifestyle or diet, which will reduce the risk factors. However, in leukemias, there were as of 2004 no known risk factors. Therefore, as of 2004, there was no way known to prevent the leukemias from developing. People who are at an increased risk for developing leukemia because of

proven exposure to ionizing radiation, the organic liquid benzene, or people who have a history of other cancers of the lymphoid system (Hodgkin's lymphoma) should undergo periodic medical checkups.

Parental concerns

Parents of a child with leukemia must balance their own fears for their child's health with the child's fears and worries. Also, given the large financial burden leukemia treatment entails, parents will want to make sure they are aware of what and what is not covered by their insurance. Parents can find a variety of sources, written and online, that will help them deal with the new circumstances of themselves and their **family**.

Lice infestation

Definition

A lice infestation, or pediculosis, is caused by parasites living on human skin. Lice are tiny, wingless insects with sucking mouthparts that feed on human blood and lay eggs on body hair or in clothing. Lice **bites** can cause intense **itching**.

Description

There are three related species of human lice:

- head lice, *Pediculus humanus capitis*
- body lice, *Pediculosis humanus corpus*
- pubic lice, *Phthirus pubis*, commonly called crab lice

Pediculosis capitis is an infestation of head lice. A body lice infestation is called pediculosis corporis. Pediculosis palpebrarum or phthiriasis palpebrarum, caused by crab lice, is an infestation of the pubic hair.

Head lice live and crawl on the scalp, sucking blood every three to six hours. Their claws are adapted for clinging to hair or clothing. Adult head lice can be silvery-white to reddish-brown. They are about the size of a sesame seed. Female lice lay their eggs in sacs called nits that are about 0.04 in (1 mm) long and are glued to shafts of hair close to the scalp. During her one-month lifespan a female louse may lay more than 100 eggs. The nymphs hatch in three to 14 days and must feed on blood within one day. Nymphs are smaller and lighter in color than adults and become sexually mature after nine to 12 days.

Body lice lay their nits in clothing or bedding. Occasionally the nits are attached to body hair. Body lice nits are oval and yellow to white in color. They may not hatch for up to 30 days. Nymphs mature in about seven days.

Pubic lice have large front legs and look like tiny crabs. Females are larger than males. Nits hatch in about one week and the nymphs mature in about seven days.

Transmission

Lice are endemic in human populations, spreading through personal contact or contact with infested clothing or other personal items. They can be transmitted when unaffected clothing is stored with infested items. Among children head lice are commonly transmitted by the sharing of hats, combs, brushes, hair accessories, headphones, pillows, and stuffed **toys**. Pubic lice are sexually transmitted, although occasionally they can be transmitted through infested bedding, towels, or clothing.

Lice do not jump, hop, or fly and they do not live on pets. Head lice cannot survive without a human host for more than a few days at most. Body lice can live without

human contact for up to 10 days. Pubic lice can survive for one to two weeks without human contact.

Demographics

Head lice infestations are extremely common among children in schools, childcare facilities, camps, and playgrounds. They are the second most common communicable health problem in children, after the **common cold**, and appear to be on the increase. Some 6 to 12 million American children get head lice every year. In developing countries more than 50 percent of the general population may be infested. Although anyone can get head lice, children aged three to ten and their families are most affected. Girls and women are more susceptible than boys and men. Although American black children are much less likely to have head lice than white or Hispanic children, the incidence is increasing, particularly in black children with thick hair, hair extensions, or wraps. In Africa head lice have adapted their claws to the curly, elliptical hair shafts of blacks. Neither frequent brushing or shampooing nor hair length affects the likelihood of a head lice infestation.

In general body lice infestations occur in crowded, unsanitary facilities, such as prisons and military or refugee camps. They usually are associated with poor personal hygiene, as may occur during war or natural disasters or in cold climates. They are common among the homeless.

Causes and symptoms

Lice infestations are characterized by intense itching caused by an allergic reaction to a toxin in lice saliva. The itching can interfere with **sleep** and concentration. Repeated bites can lead to generalized skin eruptions or inflammation. Swelling or inflammation of the neck glands are common complications of head lice.

Body lice bites first appear as small red pimples or puncture marks and may cause a generalized skin rash. Intense itching can result in deep scratches around the shoulders, flanks, or neck. If the infestation is not treated, complications may develop, including **headache**, **fever**, and skin infection with scarring.

When to call the doctor

A doctor may need to distinguish between body lice and **scabies** (a disease caused by skin mites) and between pubic lice and eczema (a skin condition). A doctor should be consulted if complications develop from a lice infestation or if a child contracts a bacterial infection from scratching the bites.

Diagnosis

Lice usually are diagnosed by the itching; however, itching may not occur until several weeks after infestation, if at all. The tickling caused by moving lice may be noticeable. Definite diagnosis requires identification of lice or their nits.

Head lice may cause irritability in children and scalp irritations or sores may be present. Head lice in children are usually confined to the scalp. An adult louse may be visible as movement on the scalp, especially around the ears, nape of the neck, and centerline of the crown, the warmest parts of the head. Since less than 20 mature lice may be present at a given time during infestation, the nits often are easier to spot. Nits vary in color from grayish-white to yellow, brown, or black. They are visible at the base or on the shaft of individual hairs. Applying about 10 oz (280 gm) of isopropyl (rubbing) alcohol to the hair and rubbing with a white towel for about 30 seconds releases lice onto the towel for identification.

Body lice appear similar to head lice; however, they burrow into the skin and are rarely seen except on clothing where they lay their nits in seams. Over time body lice infestations can lead to a thickening and discoloring of the skin around the waist, groin, and upper thighs.

Pubic lice usually appear first on genital hair, although they may spread to other body hair. In young children pubic lice usually are seen on the eyebrows or eyelashes. Pubic lice appear as brown or gray moving dots on the skin. There are usually only a few live lice present and they move very quickly away from light. Their white nits can be seen on hair shafts close to the skin. Although pubic lice sometimes produce small, bluish spots called maculae ceruleae on the trunk or thighs, usually it is easier to spot scratching marks. Small, dark-brown specks of lice excretion may be visible on underwear.

Since pediculicides (medications for treating lice) are usually strong insecticides with potential side effects, it is important to rule out other causes of scratching and skin inflammation. Oval-shaped head lice nits can be distinguished from dandruff because they are glued at an angle to the hair shaft, whereas flat, irregularly shaped flakes of dandruff shake off easily.

Treatment

Most authorities believe that head lice should be treated immediately upon discovery. Before beginning any treatment, parents should test a small scalp section for allergic reactions to the medication, use a vinegar

rinse to help loosen nits, and wash hair with regular shampoo.

Infested eyebrows should be treated with petroleum jelly for several days and the nits should be plucked off with tweezers or fingernails. Infested eyelashes are treated with a thick coating of prescription petroleum ointment, applied twice daily for ten days.

The treatment for body lice is a thorough washing of the entire body and replacement of infected clothing. Clothing and bedding should be washed at 140°F (60°C) and dried at high temperature or dry-cleaned.

Pediculicides

Head and pubic lice infestations usually are treated with insecticidal lotions, shampoos, or cream rinses. These pediculicides should not be used on children under two; near broken skin, eyes, or mucous membranes; in the bathtub or shower; by those with **allergies**, **asthma**, epilepsy, or certain other medical conditions. Itching may not subside for several days following treatment.

All U.S. Food and Drug Administration (FDA)-approved non-prescription pediculicides contain relatively safe and effective pyrethroids. Insecticidal pyrethrins (0.33%) (RID, A-200) are extracts from chrysanthemum flowers. Permethrin (1%)(Nix) is a more stable synthetic pyrethrin. Pyrethroid pediculicides also usually contain 4 percent piperonyl butoxide.

Pyrethroids are applied for a specified length of time (usually ten minutes) and then thoroughly rinsed out. The hair should not be washed for one or two days after treatment. Cream rinse, conditioner, hair spray, mousse, gel, mayonnaise, or vinegar should not be used before treatment or within one week after treatment since these products can reduce pediculicide effectiveness.

Prescription insecticides are used when other lice treatments fail or cannot be used. The following are prescription insecticides, which carry certain risks:

- Malathion (0.5% in Ovide), a neurotoxic organophosphate, was withdrawn from the U.S. market due to an increase in malathion-resistant lice. It was reintroduced in 1999. It is foul-smelling and flammable. Sometimes infested clothing is treated with a 1 percent malathion powder.
- Lindane (1% or higher) (Kwell), an organochloride neurotoxin, can induce seizures and death in susceptible people, even when used according to the directions. In 2003 the FDA required new labeling and a reduction in bottle size.
- Ivermectin (Stromectol), an oral treatment for intestinal parasites, is effective against head lice but as of 2004 had not been approved for that use by the FDA.

Experts disagree about the effectiveness and/or safety of pediculicides. Pediculicides do not kill nits, so nit removal and a second application in seven to 10 days are required. During the 1990s, as schools began requiring children to be lice- and nit-free, the use of pyrethroids rose significantly and the FDA began receiving reports of their ineffectiveness. Pediculicides can be poisonous if used improperly or too frequently and overuse can lead to the proliferation of chemically resistant lice. Pediculicide residue may remain on the hair for several weeks and can cause skin or eye irritations.

Alternative treatment

Olive oil or petroleum ointment may be used to smother head lice. After applying to the hair and scalp, the child's head is covered with a shower cap for four to six hours. The treatment is repeated daily for three or four days. Cutting the hair or shaving the head also may be effective. Other treatments for head lice include:

- olive oil (three parts) and essential oil of lavender (one part)
- herbal shampoos or pomades
- RID Pure Alternative, a nontoxic, hypoallergenic, dye- and fragrance-free product
- a spray containing phenethyl propionate, cedar oil, peppermint oil, and sodium lauryl sulfate (LiceFree)
- cocamide DEA (a lathering agent), triethanolamine (a local irritant), and disodium EDTA (a chelator) (SafeTek) are both a nontoxic pediculicide and a conditioner for combing out lice and nits.

A common herbal treatment for pubic lice consists of pennyroyal oil (25%), garlic oil (25%), distilled water (50%). The mixture is applied to the pubic hair once a day for three days.

Nit removal

Treatment does not kill all lice nits. Hair and pubic lice nits must be removed manually to prevent re-infestation as the eggs hatch. Manual removal alone may treat a lice infestation effectively.

Before removing head lice nits, one of the following procedures may be used:

- a 50 percent vinegar rinse to loosen the nits
- wiping individual locks of hair from base to tip with a cloth soaked in vinegar

- catching live lice with a comb, tweezers, fingernails, or by sticking them with double-sided tape
- an enzymatic lice-egg remover

In addition, hair should be clean, damp, and untangled; clothing should be removed and a towel placed between the hair and shoulders; the hair should be divided into square-inch sections with the use of clips or elastics to divide long hair.

Head lice nits are removed by combing through each hair section from scalp to tip. Between each passing, the comb should be dipped in water and wiped with a paper towel to remove lice and nits. The comb should be held up to the light to be sure it is clean. If necessary the comb may be cleaned with a toothbrush, fingernail brush, or dental floss. Good light and possibly a magnifying glass are required. Long, thick hair may take an hour to comb out thoroughly. Towels and clothing should be washed after combing. The process should be repeated at least twice a week for at least two weeks.

Nits also can be manually removed with any fine-toothed comb, including pet flea combs, a specialized nit comb (LiceMeister, LiceOut), a battery-powered vibrating or anti-static comb, tweezers, baby safety scissors, and fingernails.

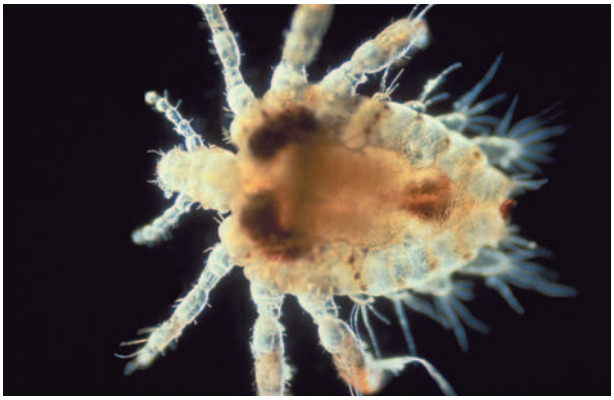
Re-infestation

Re-infestation occurs often with all types of lice due to the following:

- ineffective or incomplete treatment
- chemical-resistant lice
- failure to remove live nits
- failure to treat all infected household members and playmates
- failure to remove nits from clothing, bedding, towels, or other items
- re-infestation from another source

Head lice re-infestation can be prevented by the following:

- repeating lice checks and nit removal daily until no more are found
- notifying school, camp, or daycare, and parents of playmates
- checking and treating household members, playmates, schoolmates, school or daycare staff, and others in close contact with the child
- treating combs and brushes with rubbing alcohol, Lysol, or soapy water above 130°F (54°C)



A close-up view of a body louse. *(Custom Medical Stock Photo Inc.)*

- washing all bedding, clothing, headgear, scarves, and coats with soapy water at 130°F (54°C) and drying with high heat for at least 20 minutes
- washing or vacuuming stuffed animals and other toys
- vacuuming all helmets, carpets, rugs, mattresses, pillows, upholstery, and car seats (Permethrin sprays for treating mattresses, furniture, and other items are not recommended.)
- removing the vacuum-cleaner bag after use, sealing in a plastic bag, and placing in the outside garbage
- dry-cleaning non-washable items or sealing them in a plastic bag for up to four weeks
- repeating treatment if necessary

Re-infestation with body or pubic lice can be prevented by washing underclothes, sleepwear, bedding, and towels in hot, soapy water and drying with high heat for at least 20 minutes. Clothing infected with body lice should be ironed under high heat.

Prognosis

Lice infestations are not usually dangerous. Despite the presence of chemically-resistant lice and the thoroughness required to prevent re-infestation, all lice infestations are eradicated eventually.

Prevention

Prevention of lice infestation depends on adequate personal hygiene and consistently not sharing combs, brushes, hair accessories, hats, towels, or bedding. Hair should be checked weekly for lice and nits.

KEY TERMS

Crabs—An informal or slang term for pubic lice.

Endemic—Natural to or characteristic of a particular place, population, or climate.

Insecticide—Any substance used to kill insects.

Lindane—A benzene compound that is used to kill body and pubic lice. Lindane is absorbed into the louse's central nervous system, causing seizures and death.

Malathion—An insecticide that can be used in 1% powdered form to disinfect the clothes of patients with body lice.

Neurotoxin—A poison that acts directly on the central nervous system.

Nits—The eggs produced by head or pubic lice, usually grayish white in color and visible at the base of hair shafts.

Pediculicide—Any substance that kills lice.

Pediculosis—A lice infestation.

Permethrin—A medication used to rid the scalp of head lice. Permethrin works by paralyzing the lice, so that they cannot feed within the 24 hours after hatching required for survival.

Petroleum jelly or ointment—Petrolatum, a gelatinous substance obtained from oil that is used as a protective dressing.

Piperonyl butoxide—A liquid organic compound that enhances the activity of insecticides.

Pyrethrin, pyrethroid—A naturally occurring insecticide extracted from chrysanthemum flowers. It paralyzes lice so that they cannot feed.

Regular lice checks in schools and "no nit" reentry policies have not been shown to be effective. The American Academy of Pediatrics, the Harvard School of Public Health, and the National Association of School Nurses recommend their elimination, although many healthcare professionals disagree.

Parental concerns

Usually children are not allowed to return to daycare or school until they are lice- and nit-free. The discovery of head lice may cause distress for children and their families. Parents should stay calm and explain to the child:

- what head lice are and how they are transmitted
- that lice are very common and that many—if not most—children have them at some point
- that it is nothing to be embarrassed or ashamed about
- that the infestation is not the child's fault

Scratching or scraping at lice bites may cause **hives** or abrasions that can lead to bacterial skin infections. In developing countries head lice infestations are a significant cause of contagious bacterial infections. Body lice can carry and transmit disease-causing organisms. Although pubic lice do not carry diseases, they often are found in association with other **sexually transmitted diseases**. Crab lice in children may be an indication of sexual activity or abuse.

Lipidoses

Definition

Lipidoses are genetic disorders, passed from parents to their children, characterized by defects of the digestive system that impair the way the body uses dietary fat. When the body is unable to properly digest fats, lipids accumulate in body tissues in abnormal amounts.

Description

The digestion, storage, and use of fats (lipids) from foods are complex processes that involve hundreds of chemical reactions in the body. In most people, the body is already programmed by its genetic code to produce all of the enzymes and chemicals necessary to carry out these functions. These genetic instructions are passed from parents to their offspring.

People with lipidoses are born without the genetic codes needed to tell their bodies how to complete a particular part of the fat digestion and utilization process. In most of these disorders, the body does not produce a certain enzyme, or specialized chemical. Over 30 different disorders of fat metabolism are related to genetic defects. Some people can carry the gene for these defects, but be free of symptoms; although the defects are passed from parents to children, the parents often do not have the disorders themselves.

There is great variance in the symptoms, available treatments, and long-term consequences of these conditions. Some of the conditions become apparent shortly after the infant is born. In other lipid disorders, symptoms may not develop until adulthood. For most of the lipidoses, diagnosis is suspected based on symptoms and **family** history. Tests of blood, urine, and tissue can be used to confirm the diagnosis. Genetic testing can be used, in some cases, to identify the defective gene. Some of these disorders can be controlled with changes in the diet, medications, or enzyme supplements. However, for many of these diseases, no treatment is available. Some may cause death in childhood or contribute to a shortened life expectancy. This section focuses on some of the most common or most serious lipidoses.

Demographics

Lipidoses are very rare. The number of people affected depends on the disease, but for many diseases incidence is as little as one in 40,000 people. Some diseases have a higher prevalence in specific populations.

Fabry's disease

Causes and symptoms

Approximately one in every 40,000 males is born with Fabry's disease. This condition has an X-linked, recessive pattern of inheritance, meaning that the defective gene is carried on the X chromosome. A female who carries a defective recessive gene on one of her two X chromosomes will not have the disease because she also has one good X chromosome. However, she has a 50 percent chance of passing the defective gene to her sons. The sons inheriting one defective gene will develop the disorder because a male has only one X chromosome, which he receives from his mother and one Y chromosome from his father. The mother also has a 50 percent chance of passing the defective recessive gene to her daughters who will be carriers of the disorder (like their mother), but will not show symptoms of the disease. Some female carriers of Fabry's disease show mild signs of the disorder, especially cloudiness of the cornea.

The gene that is defective in Fabry's disease causes a deficiency of the enzyme alpha-galactosidase A. Without this enzyme, fatty compounds start to line the blood vessels. The collection of fatty deposits eventually affects blood vessels in the skin, heart, kidneys, and nervous system. The first symptoms in childhood are **pain** and discomfort in the hands and feet brought on by **exercise**, **fever**, stress, or changes in the weather. A raised rash of dark red-purple spots is common, especially on skin between the waist and the knees. Other symptoms include a decreased ability to sweat and changes in the cornea or outer layer of the eye. Although the disease begins in childhood, it progresses very slowly. Kidney and heart problems develop in adulthood.

Diagnosis

A diagnosis of Fabry's disease can be confirmed by a blood test to measure for alpha-galactosidase A. Women who are carriers of the defective gene can also be identified by a blood test.

Treatment

Treatment focuses on prevention of symptoms and long-term complications. Daily doses of diphenylhydantoin (Dilantin) or carbamazapine (Tegretol) can prevent or reduce the severity of pain in the hands and feet associated with this condition. A diet low in sodium and protein may be beneficial to those individuals who have some kidney complications. If kidney problems progress, kidney dialysis or kidney transplantation may be required. Enzyme replacement therapy is being explored.

Prognosis

Although patients with Fabry's disease usually survive to adulthood, they are at increased risk for **stroke**, heart attack, and kidney damage.

Gaucher disease

Causes and symptoms

Gaucher (pronounced go-shay) disease is the most common of the lipid storage disorders. It is found in populations all over the world (20,000–40,000 people have a type of the disease), and it occurs with equal frequency in males and females. Gaucher disease has a recessive pattern of inheritance, meaning that a person must inherit a copy of the defective gene from both parents in order to have symptoms of the disease. The genetic defect causes a deficiency of the enzyme glucocerebrosidase that is responsible for breaking down a certain type of fat and releasing it from fat cells. These fat cells begin to crowd out healthy cells in the liver, spleen, bones, and nervous system. Symptoms of Gaucher disease can start in infancy, childhood, or adulthood.

Three types of Gaucher disease have been identified, but there are many variations in how symptoms develop. Type 1 is the most common and affects both children and adults. It occurs much more often in people of Eastern European and Russian Jewish (Ashkenazi) ancestry, affecting one out of every 450 live births in this population. The first signs of the disease include an enlarged liver and spleen, causing the abdomen to swell. Children with this condition may be shorter than normal. Other symptoms include tiredness, pain, bone deterioration, broken bones, anemia, and increased bruising. Type 2 Gaucher disease is more serious, beginning within the first few months after birth. Symptoms, which are similar to those in type 1, progress rapidly, but also include nervous system damage. Symptoms of type 3 Gaucher disease begin during early childhood with symptoms like type 1. Unlike type 2, the progress of the disease is slower, although it also includes nervous system damage.

Diagnosis

Gaucher disease may be suspected, based on symptoms, and is confirmed with a blood test for levels of the deficient enzyme. Samples of tissue from an affected area may also confirm a diagnosis.

Treatment

The symptoms of Gaucher disease can be stopped and even reversed by treatment with enzyme replacement injections. Two enzyme drugs available are alglucerase (Ceredase) and imiglucerase (Cerezyme). Other treatments address specific symptoms such as anemia, broken bones, or pain.

Prognosis

The pain and deformities associated with symptoms can make coping with this illness very challenging for individuals and families. With treatment and control of symptoms, people with type 1 Gaucher disease may lead fairly long and normal lives. Most infants with type 2 die before age two. Children with type 3 Gaucher disease may survive to **adolescence** and early adulthood.

Krabbe's disease

Causes and symptoms

Krabbe's disease is caused by a deficiency of the enzyme galactoside beta- galactosidase. It has a recessive pattern of inheritance and is believed to occur in one out of 40,000 births in the United States. This condition, which is also called globoid cell leukodystrophy or Krabbe leukodystrophy, is characterized by acute nervous system degeneration. It develops in early infancy with initial symptoms of irritability, **vomiting**, and episodes of partial unconsciousness. Symptoms progress rapidly to seizures, difficulty swallowing, blindness, deafness, **mental retardation**, and paralysis.

Treatment

No treatment is available.

Prognosis

Children born with Krabbe's disease die in infancy.

Niemann-pick disease

Causes and symptoms

At least five different forms of Niemann-Pick disease (NPD) have been identified. The different types seem to be related to the activity level of the enzyme sphingomyelinase. In patients with types A and B NPD, there is a build-up of sphingomyelin in cells of the brain, liver, spleen, kidney, and lung. Type A is the most common form of NPD and the most serious, with death usually occurring by the age of 18 months. Symptoms develop within the first few months of life and include poor appetite, failure to grow, enlarged liver and spleen, and the appearance of cherry red spots in the retina of the eye. Type B develops in infancy or childhood with symptoms of mild liver or spleen enlargement and lung problems. Types C and D NPD are related to cholesterol transfer out of cells. Children with types C or D grow normally in early childhood, but eventually develop difficulty in walking and loss of muscle coordination. Ultimately, the nervous system becomes severely damaged and these patients die. Type C occurs in any population, while type D has been identified only in individuals from Nova Scotia, Canada.

Diagnosis

Diagnosis is confirmed by analyzing a sample of tissue. Prenatal diagnosis of types A and B NPD can be done with **amniocentesis** or chorionic villi sampling.

Treatment

Treatment consists of supportive care to deal with symptoms and the development of complications. Bone marrow transplantation is being investigated as a possible treatment. Low-cholesterol diets may be helpful for patients with types C and D.

Prognosis

Patients with type A NPD usually die within the first 18 months of life. Type B patients generally live to adulthood but suffer from significant liver and lung problems. With types C and D NPD, there is significant nervous system damage leading to severe **muscle spasms**, seizures, and eventually coma and death. Some patients with types C and D die in childhood, while less severely affected individuals may survive to adulthood.

Refsum's disease

Causes and symptoms

Refsum's disease has a recessive pattern of inheritance and affects populations from Northern Europe, particularly Scandinavians. It is due to a deficiency of phytanic acid hydroxylase, an enzyme that breaks down a fatty acid called phytanic acid. This condition affects the nervous system, eyes, bones, and skin. Symptoms, which usually appear by age 20, include vision problems (retinitis pigmentosa and rhythmic eye movements, or **nystagmus**), loss of muscle coordination, loss of sense of smell (anosmia), pain, **numbness**, and elevated protein in the cerebrospinal fluid.

Treatment

A diet free of phytanic acid (found in dairy products, tuna, cod, haddock, lamb, stewed beef, white bread, white rice, boiled potatoes, and egg yolk) can reduce some of the symptoms. Plasmapheresis—a process where whole blood is removed from the body, processed through a filtering system, and then returned to the body—may be used to filter phytanic acid from the blood.

Tay-Sachs disease

Causes and symptoms

Tay-Sachs disease (TSD) is a fatal condition caused by a deficiency of the enzyme hexosaminidase A (Hex-A). The defective gene that causes this disorder is found in roughly one in 250 people in the general population. However, certain populations have significantly higher rates of TSD. French-Canadians living near the St. Lawr-

ence River and in the Cajun regions of Louisiana are at higher risk of having a child with TSD. The highest risk seems to be in people of Eastern European and Russian Jewish (Ashkenazi) descent. Tay-Sachs disease has a recessive pattern of inheritance, and approximately one in every 27 people of Jewish ancestry in the United States carries the TSD gene. Symptoms develop in infancy and are due to the accumulation of a fatty acid compound in the nervous system. Early symptoms include loss of vision and physical coordination, seizures, and mental retardation. Eventually, the child develops problems with breathing and swallowing. Blindness, paralysis, and death follow.

Diagnosis

Carriers of the Tay-Sachs related gene can be identified with a blood test. Amniocentesis or chorionic villi sampling can be used to determine if the fetus has Tay-Sachs disease.

Treatment

There is no treatment for Tay-Sachs disease. Parents who are identified as carriers may want to seek genetic counseling. If a fetus is identified as having TSD, parents can then consider their options.

Prognosis

Children born with Tay-Sachs disease become increasingly debilitated; most die by about age four.

Wolman's disease

Causes and symptoms

Wolman's disease is caused by a genetic defect with a recessive pattern of inheritance that results in a deficiency of an enzyme that breaks down cholesterol. This causes large amounts of fat to accumulate in body tissues. Symptoms begin in the first few weeks of life and include an enlarged liver and spleen, adrenal calcification (hardening of adrenal tissue due to deposits of calcium salts), and fatty stools.

Treatment

No treatment is available.

Prognosis

Death generally occurs before six months of age.

KEY TERMS

Amniocentesis—A procedure performed at 16-18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby for analysis. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling—A procedure performed at 10 to 12 weeks of pregnancy in which a needle is inserted either through the mother's vagina or abdominal wall into the placenta to withdraw a small amount of chorionic membrane from around the early embryo. The amniotic fluid can be examined for signs of chromosome abnormalities or other genetic diseases.

Lipids—Organic compounds not soluble in water, but soluble in fat solvents such as alcohol. Lipids are stored in the body as energy reserves and are also important components of cell membranes. Commonly known as fats.

Recessive—Refers to an inherited trait that is outwardly obvious only when two copies of the gene for that trait are present. An individual displaying a recessive trait must have inherited one copy of the defective gene from each parent.

X-linked—A gene carried on the X chromosome, one of the two sex chromosomes.

Prevention

There is no known way to prevent lipidoses. Couples who have family histories of genetic defects can undergo genetic testing and counseling to see if they are at risk for having a child with one of the lipidoses disorders. During pregnancy, cell samples can be collected from the fetus using amniocentesis or chorionic villi sampling. The results of these tests can indicate if the developing fetus has a lipidosis disorder.

Parental concerns

Lipidoses have a variety of different symptoms and progressions. There are treatments for some—but not all—lipidoses. Treating the symptoms is always an integral part of lessening the impact of the disease. If parents have one child with a lipidoses disorder and are consider-

ing having other children, genetic counseling or in utero testing of the fetus may be beneficial.

Lisping

Definition

A lisp is a functional speech disorder that involves the inability to correctly pronounce one or more sibilant consonant sounds, usually *s* or *z*.

Description

Lisping is a speech disorder characterized by the inability to correctly pronounce the sounds of *s* or *z*, known as the sibilant consonants. Usually *th* sounds are substituted for the sibilants. The word "lisp," for example, would be pronounced "lithp" by someone with this speech disorder.

Many children lisp at certain stages of speech development, especially when they lose their front primary teeth. Lisping is, therefore, sometimes called a developmental phonetic disorder. Frontal or interdental lisp is produced when the tongue protrudes through the front teeth when teeth are missing and is the most familiar type of lisp. Sibilant production may be interfered with in a number of other ways as well. These are all classified as lisping and include excessive pressure by the tongue against the teeth, the tongue held too far back along the midline of the palate, and a "substitute hiss" produced in the throat or larynx.

Sometimes children with functional **speech disorders** have problems making other sounds, such as *sh*, *l*, *r*, and *ch*. When a child cannot produce these sounds correctly, the condition is usually not considered a true lisp, but is a functional speech disorder.

Children can have a functional speech disorder as well as a developmental phonological disorder. The latter is not a matter of being able to physically make a specific sound but is a language disorder. These children have trouble organizing the sounds of speech in common patterns and may consistently replace one sound with another. For example, a child may say "wun" instead of "sun" or "doe" instead of "so."

There are four main types of lisps.

- Interdental lisp—occurs when the tongue protrudes between the front teeth and the *s* or *z* is pronounced like *th*.
- Dentalized lisp or dentalized production—occurs when the tongue pushes against the front teeth.
- Lateral lisp—sounds wet because the air flows around the tongue, which is in the normal position to produce the *l* sound.
- Palatal lisp—the middle of the tongue touches the soft palate, or roof of the mouth, when trying to produce the *s* sound.

Demographics

According to the National Institute on Deafness and Other Communication Disorders, about one in six people in the United States (42 million adults and children) has a communication disorder. Of them, 14 million have a speech, voice, or language disorder that is not linked to hearing loss. Functional speech disorders with no known cause, such as lisping, affect 10 percent of the population; 8–9 percent serious enough to require treatment. Nearly 5 percent of first graders have functional speech disorders, and 50–70 percent of all children with functional speech disorders struggle academically throughout elementary school and high school.

Causes and symptoms

As a functional speech disorder, lisping has no clear known cause. It is often referred to as a speech delay of unknown origin. Structural irregularities of the tongue, palate, or teeth (including abnormalities in the number or position of the teeth) may be implicated in lisping, but they generally are not the main causes. Mild hearing loss involving high frequencies may also impair a child's ability to hear language correctly and be able to repeat phonetic sounds. In some cases, a child with no physical abnormality will develop a lisp. It has been thought that some of these children may be imitating another child or an adult who lisps.

Lisping is also associated with immature development. Some children will adopt a lisp as a means of gaining attention. Other children will begin to lisp after they have experienced unusual stress or trauma. This behavior is part of a regression into a more secure period and can include other types of regressive behaviors such as bed wetting or wanting to **sleep** with the light on in the bedroom.

One theory of the cause of lisping is the result of tongue thrusting, a physiological behavior that causes the tongue to flatten and thrust forward during swallowing and speaking. It is suggested that **thumb sucking**, overuse of pacifiers, bottle feeding, and recurrent upper respiratory illnesses cause tongue thrusting. Thumbs (or fingers), artificial nipples, and pacifiers keep the tongue flat and do not allow the muscles of the tongue to develop in a normal fashion. When the child speaks, the tongue shoots forward, creating a lisp.

Frequent upper respiratory illnesses often stuff the nose, forcing these children to breathe through their mouths. The sounds that they make when they speak may be thick and garbled, and may encourage lisping. Closing the mouth and teeth to make *s* or *z* sounds cuts off the breath, so children compensate by trying to speak without closing their mouths completely. Thus, a lisp develops.

When to call the doctor

The interdental lisp and the dentalized lisp are common in normal speech development. However, if they persist well past four-and-one-half years and garble the speech so that the child is not understood, he or she should be evaluated. The evaluation will determine if there is a physiological basis for the lisp and identify the type of lisp. In some cases, the child will be evaluated and observed for several months or longer to see if the condition can be outgrown. Lateral and palatal lisps are not found in typical speech development and should be evaluated by a speech-language pathologist. If untreated, lisping can persist into adulthood.

For some children, everything they say seems to be interdental. In these cases, there may be an obstruction of the nose because of infection, allergy, enlarged adenoids, or other facial problems. Excessive interdental speech can also be related to mouth breathing and sucking habits. These children should be seen by a physician to treat the health problems and then referred to a speech-language pathologist to correct the lisp.

Diagnosis

A physician can determine whether there are structural irregularities within the mouth or problems with the child's hearing, and can treat related **allergies** and nasal problems. However, true assessment of a child's ability to make speech sounds must be done by a speech-language pathologist. The child's medical history will be taken and the speech-language pathologist will examine the anatomy of the child's mouth and the movements it can make. Next, the child's speech and reading aloud is often recorded for later analysis. This speech sample will also yield information about the quality of the child's voice, how fluent speech occurs, and the child's semantic and physical sound- making skill.

Treatment

Typical treatment is called articulation therapy. The speech-language pathologist finds out whether the child can hear proper speech sounds, and proceeds to read a list of words with specific sounds that the child is having trouble articulating. Lists of contrast words are also read so that the child can hear the subtle differences in word sounds. Therapy then moves to working on the position in the word where the sound occurs; that is, at the beginning, in the middle, or at the end. Specific word exercises follow, beginning with single sounds, then syllables, and moving on to words, phrases, and sentences. Finally, the child participates in controlled conversations such as talking casually during a meal.

Prognosis

Most lisps are developmental and resolve themselves in children by the time they are about five to eight years old. If they last longer or are of a specific type, speech therapy is recommended. The outcome of speech therapy is usually quite good. Depending on the specifics of the therapy and the nature of the lisp, treatment can be relatively short term, lasting only a few months. Some cases may take a year or more.

Prevention

Parents can reduce the risk of a lisp developing because of tongue thrusting by restricting **pacifier use** or choosing to breastfeed their babies. They can also speak clearly in complete sentences around their children and not use baby talk. They should treat allergies and respiratory illnesses immediately to keep the nose open and breathing free. The child's hearing and teeth should be checked periodically to make sure he or she can hear speech clearly and form words correctly. Parents can also encourage the musculature of the mouth by showing children how to drink from straws and how to blow bubbles. In addition, playing word and naming games encourages good speech development and stimulates learning.

Parental concerns

In many families, a child's lisp goes unnoticed, especially if it does not interfere with understanding what the child is saying. These children may grow up content to keep a lisp, feeling that it is a specific part of what makes them who they are, just as some people keep a gap between their front teeth and see it as distinct characteristic. (Lauren Hutton kept the gap between her teeth even as she became a top model, and Boris Karloff had one of the most famous lisps in the world.)

Outside of the home, some children may be teased by other children or feel embarrassed to speak up in the classroom. They may have trouble spelling or even reading because they cannot make some of the sounds necessary to read and write well. These children may have serious **self-esteem** issues related to their lisps. In these cases, seeing a speech-language pathologist early in their lives and correcting their lisps could bolster self-confidence and ability to learn.

Still other families may think that a child's lisp is endearing and cute. They may even encourage the child to continue lisping because he or she receives positive regard whenever the lisping sounds are made. Sometimes, these same families suddenly decide that lisping is no longer cute and want their children to drop their lisps and grow up. These children still can benefit from speech therapy, but they may become resistant to treatment because they are confused about the abrupt change in the family's behavior. In this case, counseling is recommended in addition to sessions with a speech-language pathologist.

A lisp can be a source of distress for adolescent boys and young men who may be told that they are gay because they lisp. A functional speech disorder has no connection with a person's sexual orientation. Many young men, although they **fear** it may be too late, seek out speech-language pathologists as adults to correct their lisps because of this teasing.

KEY TERMS

Palate—The roof of the mouth.

Tongue thrusting—A physiological behavior that causes the tongue to flatten and thrust forward during swallowing and speaking.

Listeriosis

Definition

Listeriosis is an illness caused by the bacterium *Listeria monocytogenes* that is acquired by eating contaminated food. The organism can spread to the blood stream and central nervous system. In women who contract listeriosis while pregnant, the disease often causes miscarriage or stillbirth.

Description

Listeriosis is caused by an infection with the bacterium *Listeria monocytogenes*. These bacteria can be carried by many animals and birds, and they have been found in soil, water, sewage, and animal feed. Five out of every 100 people carry *Listeria monocytogenes* in their intestines. Listeriosis is considered a food-borne illness because most people are probably infected after eating food contaminated with *Listeria monocytogenes*. However, a woman can pass the bacteria to her baby during pregnancy. In addition, there have been a few cases where workers have developed *Listeria* skin infections by touching infected calves or poultry.

In the 1980s, the United States government began taking measures to decrease the occurrence of listeriosis. Subsequently, processed meats and dairy products were tested for the presence of *Listeria monocytogenes*. The Food and Drug Administration (FDA) and the Food Safety and Inspection Service (FSIS) can legally prevent food from being shipped, or order food recalls, if they detect any *Listeria* bacteria. These inspections, in combination with the public education regarding the proper handling of uncooked foods, appear to be helping. Nonetheless, as of 2004, about 2,500 individuals become seriously ill from *Listeria* annually, with about 500 deaths.

Demographics

Persons at particular risk for listeriosis include the elderly, pregnant women, newborns, and those with a weakened immune system (called immunocompromised). Risk is increased when a person suffers from diseases such as **AIDS**, **cancer**, kidney disease, **diabetes mellitus**, or by the use of certain medications. Infection is most common in babies younger than one month old and adults over 60 years of age. Pregnant women account for 27 percent of the cases, and immunocompromised persons account for almost 70 percent. Persons with AIDS are 280 times more likely to get listeriosis than others.

Causes and symptoms

As noted, persons become infected with *Listeria monocytogenes* by eating contaminated food. *Listeria* has been found on raw vegetables, fish, poultry, raw (unpasteurized) milk, fresh meat, processed meat (such as deli meat, hot dogs, and canned meat), and certain soft cheeses. Listeriosis outbreaks in the United States since the 1980s have been linked to cole slaw, milk, Mexican-style cheese, undercooked hot dogs, undercooked chicken, and delicatessen foods. Unlike most other bacteria, *Listeria monocytogenes* does not stop growing when food is in the refrigerator; its growth is merely slowed. Fortunately, typical cooking temperatures and the pasteurization process do kill this bacteria.

Listeria bacteria can pass through the wall of the intestines, and from there they can get into the blood stream. Once in the blood stream, they can be transported anywhere in the body but are commonly found the central nervous system (brain and spinal cord); and in pregnant women they are often found in the placenta (the organ which connects the baby's umbilical cord to the uterus). *Listeria monocytogenes* live inside specific white blood cells called macrophages. Inside macrophages, the bacteria can hide from immune responses and become inaccessible to certain **antibiotics**. *Listeria* bacteria are capable of multiplying within macrophages and then may spread to other macrophages.

After people consume food contaminated with this bacteria, they may see symptoms of infection 11 to 70 days later. Most people do not get any noticeable symptoms. Scientists suspect that *Listeria monocytogenes* can cause upset stomach and intestinal problems just like other food-borne illnesses. Persons with listeriosis may develop flu-like symptoms such as **fever**, **headache**, **nausea and vomiting**, tiredness, and **diarrhea**.

Pregnant women experience a mild, flu-like illness with fever, muscle aches, upset stomach, and intestinal problems. They recover, but the infection can cause miscarriage, premature labor, early rupture of the birth sac, and stillbirth. Half of the newborns infected with *Listeria* die from the illness.

There are two types of listeriosis in the newborn baby: early-onset disease and late-onset disease. Early-onset disease refers to a serious illness that is present at birth and usually causes the baby to be born prematurely. Babies infected during the pregnancy usually have a blood infection (sepsis) and may have a serious, whole body infection called granulomatosis infantisepticum. When a full-term baby becomes infected with *Listeria* during **childbirth**, that situation is called late-onset disease. Commonly, symptoms of late-onset listeriosis

appear about two weeks after birth. Babies with late-term disease typically have **meningitis** (inflammation of the brain and spinal tissues); yet they have a better chance of surviving than those with early-onset disease.

Immunocompromised adults are at risk for a serious infection of the blood stream and central nervous system (brain and spinal cord). Meningitis occurs in about half of the cases of adult listeriosis. Symptoms of listerial meningitis occur about four days after the flu-like symptoms and include fever, personality change, uncoordinated muscle movement, tremors, muscle contractions, seizures, and slipping in and out of consciousness.

Listeria monocytogenes causes endocarditis in about 7.5 percent of the cases. Endocarditis is an inflammation of heart tissue due to the bacterial infection. Listerial endocarditis causes death in about half of the patients. Diseases which have been caused by *Listeria monocytogenes* include brain abscess, eye infection, hepatitis (liver disease), peritonitis (abdominal infection), lung infection, joint infection, arthritis, heart disease, bone infection, and gallbladder infection.

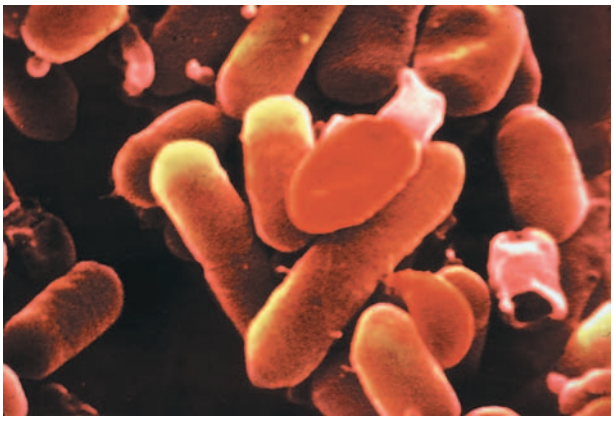
Diagnosis

Listeriosis may be diagnosed and treated by infectious disease specialists and internal medicine specialists. The diagnosis and treatment of this infection should be covered by most insurance providers.

The only way to diagnose listeriosis is to isolate *Listeria monocytogenes* from blood, cerebrospinal fluid, or stool. A sample of cerebrospinal fluid is removed from the spinal cord using a needle and syringe. This procedure is commonly called a spinal tap. The amniotic fluid (the fluid which bathes the unborn baby) may be tested in pregnant women with listeriosis. This sample is obtained by inserting a needle through the abdomen into the uterus and withdrawing fluid. *Listeria* grows well in laboratory media, and test results can be available within a few days.

Treatment

Listeriosis is treated with the antibiotics ampicillin (Omnipen) or sulfamethoxazole-trimethoprim (Bactrim, Septra). Because the bacteria live within macrophage cells, treatment may be difficult, and the treatment periods may vary. Usually, pregnant women are treated for two weeks; newborns, two to three weeks; adults with mild disease, two to four weeks; persons with meningitis, three weeks; persons with brain abscesses, six weeks; and persons with endocarditis, four to six weeks.



Scanning electron micrograph (SEM) scan of lysteria monocytogenes. *(© CNRI/Phototake.)*

Patients are often hospitalized for treatment and monitoring. Other drugs may be provided to relieve **pain** and fever and to treat other reactions to the infection.

Prognosis

The overall death rate for listeriosis is 26 percent. This high death rate is due to the serious illness suffered by newborns, the elderly, and immunocompromised persons. Healthy adults and older children have a low death rate. Complications of *Listeria* infection include: meningitis, sepsis, miscarriage, stillbirth, **pneumonia**, shock endocarditis, abscess (localized infection) formation, and eye inflammation.

Prevention

As of the early 2000s the United States government has done much to prevent listeriosis. Persons at extremely high risk (pregnant women, immunocompromised persons, etc.) must use extra caution. High risk persons should avoid soft cheeses, such as Mexican cheese, feta, Brie, Camembert, and blue cheese (cottage cheese is safe); thoroughly cook leftovers and ready-to-eat foods (such as hot-dogs); and avoid foods from the deli.

For all people, the risk of listeriosis can be reduced by taking these precautions:

- Completely cook all meats and eggs.
- Carefully wash raw vegetables before eating.
- Keep raw meat away from raw vegetables and prepared foods. After cutting raw meat, wash the cutting board with detergent before using it for vegetables.

KEY TERMS

Abscess—A localized collection of pus in the skin or other body tissue caused by infection.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Macrophage—A large white blood cell that engulfs and digests foreign invaders, such as bacteria and viruses, in an attempt to stop them from causing disease within the body.

Meningitis—An infection or inflammation of the membranes that cover the brain and spinal cord. It is usually caused by bacteria or a virus.

Sepsis—A severe systemic infection in which bacteria have entered the bloodstream or body tissues.

- Avoid drinking unpasteurized milk or foods made from such milk.
- Wash hands thoroughly after handling raw meat.
- Follow the instructions on food labels. Observe food expiration dates and storage conditions.

Lying

Definition

A lie is any deliberate deviation from the truth; it is a falsehood communicated with the intention to mislead or deceive.

Description

Lies differ in type, incidence, magnitude and consequence, with many gradations of severity, from harmless exaggeration and embellishment of stories, to intentional and habitual deceit. Behavioral scientist Wendy Gamble identified four basic types of lies for a University of Arizona study in 2000:

- Prosocial: Lying to protect someone, to benefit or help others.
- Self-enhancement: Lying to save face, to avoid embarrassment, disapproval or punishment.
- Selfish: Lying to protect the self at the expense of another, and/or to conceal a misdeed.
- Antisocial: Lying to hurt someone else intentionally.

Lying is considered by most child development specialists to be a natural developmental occurrence in childhood. Though there is no empirical data about how children learn to lie, parental honesty is recognized as a primary influence on the development of truthfulness in children.

Preschool

Making up stories is part of a normal fantasy life for young children. It is a positive sign of developing **intelligence** and of an active and healthy imagination. Preschool children who are beginning to express themselves through language are not yet able to make a clear

distinction between reality and make-believe. Storytelling at this age is seldom an intentional effort to deceive. When preschool children do engage in intentional deceit, it is usually to avoid reprimand. They are concerned with pleasing the parent, and may **fear** the punishment for admitting a mistake or misdeed.

Many children are socialized by their parents at a very early age to tell "white"; lies to avoid hurting another's feelings. "White lies" or "fibs" are commonplace in many households and social settings and are observed and imitated by children. The incidence of prosocial or "white lies," tends to increase in children as they grow older.

Dr. Kang Lee of the Department of Psychology at Queens University in Kingston, Ontario, Canada, observed young children telling so-called "white lies" to avoid disappointing the researcher. Such prosocial lying behavior occurred in children as young as age three. Dr. Lee's research found that over 60 percent of the 400 boys and girls he studied would pretend to be pleased when asked how they liked a used bar of soap, given as a prize after playing a game with researchers. When parents instructed the children to "be polite" when the researcher asked if they liked the soap, as many as 80 percent of these children, ages three to 11 years of age were dishonest.

Dr. Michael Lewis of Robert Wood Johnson Medical School, has found that as many as 65 percent of the children he studied had learned to lie by age two and one half. This research also reveals a correlation between higher IQ and the incidence of lying in children.

School-age children

Children from age five or six have learned the difference between lies and truth. The motives for lying in this age group are more complex. Prosocial lying may increase, particularly among peers, to avoid hurting another's feelings. In addition, if a parent's expectations for the child's performance are too high, the child may engage in self-enhancing lies out of fear of censure. School-age children also experiment with selfish lies to avoid punishment, or to gain advantage. They are testing the limits as they try to understand how the rules work and what the consequences may be for stepping out of bounds.

By age seven children have developed the ability to convincingly sustain a lie. This capacity has serious implications with regard to children's competency to testify in a court of law. The veracity of child witnesses and their understanding of the concept of an oath are important research issues. Children at this age recognize the difference between what they are thinking and how they can manipulate the thinking of another to serve their own ends.

The type and frequency of lies and the reasons why a child may be dishonest are also related to their stage of **moral development**.

Children progress sequentially through several stages of moral development, according to psychologist Lawrence Kohlberg:

- avoiding punishment
- doing right for self-serving reasons
- fitting in with and pleasing others
- doing one's duty
- following agreed upon rules
- acting on principles

Adolescents are developmentally involved in becoming independent persons. They are working hard to establish their own identity, one that is separate from that of their parents. Peer approval is more important than parental approval during **adolescence**. Conflicts during these years between parental control versus personal autonomy may lead to increased lying to preserve a sense of separation and power from parents, teachers, and other authority figures. Adolescents may also lie to cover up serious behavior problems. A discerning parent will attempt to discover the motive behind the lie.

Common problems

Childhood lying has many causes, including the need to maintain parental approval, to gain attention, to avoid disappointing others, to evade the consequences of misbehavior, or to avoid responsibility. Older children may lie as a means of breaking away from parental control. Issues of **self-esteem**, fear of consequences, the desire to have one's own way, the need to gain attention, or to protect oneself from harm, are also a factor. Difficult circumstances in the home and social environment of the child may increase the likelihood of problem lying.

Early intervention in the case of compulsive lying may reduce the risk of the child developing a life-time habit of deceit. Children who are chronic liars are often found to engage in other antisocial behaviors. If a child's lying is accompanied by fighting, cheating, **stealing**, cruelty, and other impulse control problems, appropriate intervention is required. Lying that is consistently self-serving with no prosocial motive is a serious issue. Lying with malice and without any sign of remorse may indicate that the child has not yet developed a moral con-

science, and may need help to move toward a higher stage of moral development, one that includes a concern for the impact of one's actions upon others.

Children become more adept liars with practice. As they grow older it may become increasingly difficult for a parent, teacher or caregiver to detect dishonesty. Close observation and familiarity with the child, as well as an understanding of their developmental stage, are critical to the diagnosis of problem lying.

Most children with the benefit of a loving **family** environment, one where honesty is valued and modeled and dishonesty is appropriately challenged, will more often than not come to recognize that lying is not an acceptable behavior. Early and appropriate intervention when problem lying persists will increase the possibility that the child will choose honesty in subsequent interactions.

Children may observe much routine dishonesty in the home, school and surrounding culture. Parental examples of honesty in interpersonal relationships are critical if a child is to develop an ethic of truthfulness. Children commonly experiment with lying in the natural course of development. They need help recognizing and understanding the distinction between prosocial and antisocial lying.

Exaggeration and embellishment when relating incidents or telling stories, and the so-called "white lies," told to avoid disappointing or hurting others feelings, do not have the negative, antisocial consequences of serious lying. Parents should intervene when the lying is of a serious nature and explain the impact of dishonesty on another's feelings. This will help the child to develop a moral sense of right and wrong and to value honesty in interpersonal relationships.

Parental concerns

Repetitive lying can develop into a serious habit leading to adjustment problems later in life. Lying that persists and worsens year after year is cause for concern. Chronic lying is often accompanied by other antisocial behaviors. Adolescents may lie to cover up illicit drug or alcohol abuse. Early parental intervention in situations of serious lying may interrupt the formation of a habit of lying in young children. Parents who model truth telling and praise honesty will encourage trust in the parent-child relationship.

When to call the doctor

Serious and repetitive lying may require the professional intervention of a school psychologist or a community mental health agency. Counseling may help to uncover any underlying conditions such as attention-deficit/hyperactivity disorder (AD/HD), **bipolar disorder**, or learning disabilities. Pathological lying often accompanies serious psychiatric problems such as **conduct disorder** or **antisocial personality disorder**, which normally have their onset during adolescence. Children who use lying as a primary means of avoiding personal responsibility, particularly in adolescence, may be attempting to cover up more serious problems with substance abuse.

KEY TERMS

Antisocial personality disorder—A disorder characterized by a behavior pattern that disregards for the rights of others. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy or psychopathy.

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence. Children with a conduct disorder act inappropriately, infringe on the rights of others, and violate societal norms.

Prosocial behaviors—Social behavior characterized by positive, cooperative, and reciprocal social exchanges.

Lyme disease

Definition

Lyme disease is an inflammatory disease transmitted through the bite of a deer tick carrying the spiral-shaped bacterium *Borrelia burgdorferi*. Symptoms can include skin rash, joint inflammation, **fever**, **headache**, fatigue, and muscle **pain**. Lyme disease is also called Lyme borreliosis.

Description

Lyme disease is an inflammatory, systemic disease, meaning that it affects multiple body systems. Although clinical signs of Lyme disease have been reported for more than 100 years, the disease was not recognized as a distinct illness until 1975, when a cluster of unusual arthritis cases in Lyme, Connecticut, led physicians to discover that town residents living near heavily wooded areas were most affected by arthritis and other symptoms. Tick **bites** were then linked to the cause of the arthritis cases. *Borrelia burgdorferi*, the spiral-shaped bacterium called a spirochete, that causes Lyme disease, was not discovered until 1981 by Willy Burgdorfer.

Although Lyme disease is easily treated, it is not easily diagnosed, since symptoms are often attributed to other conditions. If not treated early and properly with **antibiotics**, Lyme disease can have long-term and disabling effects. In its early stages, Lyme disease affects the skin and produces flu-like symptoms; the disease spreads to the joints and nervous system in its later stages.

Transmission

Lyme disease is a vector-borne disease, meaning that it is transmitted from one host to another by a carrier—called a vector—that transmits but does not become infected with the disease. In the United States, the deer tick in the genus *Ixodes* is the vector for *Borrelia burgdorferi* and Lyme disease transmission. Lyme dis-

ease is transmitted when a tick carrying the *Borrelia burgdorferi* bacterium bites a human to feed on blood. The bacterium is transferred from the intestines of the tick through the mouthparts and into the bloodstream while the tick is feeding. Ticks are most likely to transmit *Borrelia burgdorferi* after remaining attached and feeding for two or more days. In most areas, ticks are most active from April to October, but in milder climates, ticks may bite year-round.

During their two-year life cycle and three life stages (larva, nymph, and adult), deer ticks feed on a number of mammals that may carry the *Borrelia burgdorferi* bacterium in their blood, but the white-footed mouse is the most common source of infection. In the summer, the larval ticks hatch from eggs laid in the ground and feed by attaching themselves to small animals and birds. At this stage, they are not a problem for humans. It is the next stage—the nymph—that causes most cases of Lyme disease. Nymphs are very active from spring through early summer, at the height of outdoor activity for most people. Because they are still quite small (less than 2 mm), they are difficult to spot, giving them ample opportunity to transmit *Borrelia burgdorferi* while feeding. Although far more adult ticks than nymphs carry *Borrelia burgdorferi*, the adult ticks are much larger, more easily noticed, and more likely to be removed before they have fed long enough to transmit *Borrelia burgdorferi*. Neither *Borrelia burgdorferi* nor Lyme disease can be transmitted directly from one person to another or from pets to humans.

Demographics

Lyme disease is the most common vector-borne disease in the United States. In 2002 alone, 23,763 cases were reported to the Centers for Disease Control and Prevention (CDC), a 40-percent increase over the number reported in 2001. According to the CDC, the actual number of Lyme cases may exceed 200,000 due to underreporting and limitations in disease surveillance methods. CDC statistics indicate that the largest proportion of Lyme disease cases occurs in children aged five to 14 years, and more than 50 percent of Lyme disease cases involve children under age 12. Although cases of Lyme disease have been reported in 49 of the 50 states, more than 95 percent of reported cases occur in just twelve states: Connecticut, Rhode Island, New York, Pennsylvania, Delaware, New Jersey, Maryland, Maine, New Hampshire, Minnesota, Massachusetts, and Wisconsin. In the United States, the Great Lakes region and the Pacific Northwest also have a higher incidence of Lyme disease. The disease is also found in Scandinavia, continental Europe, the countries of the former Soviet Union, Japan, China, and Australia.

Causes and symptoms

Lyme disease is caused by the *Borrelia burgdorferi* bacterium. Once *Borrelia burgdorferi* gains entry to the body through a tick bite, it can move through the bloodstream quickly. Only 12 hours after entering the bloodstream, *Borrelia burgdorferi* can be found in cerebrospinal fluid (which means it can affect the nervous system). Treating Lyme disease early and thoroughly is important because Lyme disease can hide for long periods within the body in a clinically latent state. That ability explains why symptoms can recur in cycles and can flare up after months, years, or decades.

Lyme disease is usually described in terms of length of infection (time since the person was bitten by a tick infected with Lyme disease) and whether *Borrelia burgdorferi* is localized or disseminated (spread through the body by fluids and cells carrying *Borrelia burgdorferi*). Furthermore, when and how symptoms of Lyme disease appear can vary widely from patient to patient. People who experience recurrent bouts of symptoms over time are said to have chronic Lyme disease.

Early localized Lyme disease

The most recognizable indicator of Lyme disease is a rash around the site of the tick bite. Often, the tick exposure has not been recognized. The eruption might be warm or itch. The rash—erythema migrans (EM)—generally develops within three to 30 days and usually begins as a round, red patch that expands outward from the tick bite. About 80 percent of patients with Lyme disease develop EM. Clearing may take place from the center out, leaving a bull's-eye effect; in some cases, the center gets redder instead of clearing. On children with dark skin, the rash may look like a bruise. Of those who develop Lyme disease, about 50 percent notice flu-like symptoms, including fatigue, headache, chills and fever, muscle and joint pain, and lymph node swelling. Many children with Lyme disease can develop neurologic symptoms within a few weeks following a tick bite. Neurologic symptoms in children with early Lyme disease include **dizziness**, stiff neck, unilateral or bilateral facial palsy, inflammation of brain membranes (a form of **meningitis**), knee and/or wrist arthralgia, tingling/numbness, **sleep** disturbance, and difficulties with memory, concentration, and learning.

Late disseminated disease and chronic Lyme disease

Weeks, months, or even years after an untreated tick bite, symptoms can appear in several forms, including the following:

- fatigue, forgetfulness, confusion, mood swings, irritability, numbness
- neurologic problems, such as pain (unexplained and not triggered by an injury), **Bell's palsy** (facial paralysis, usually one-sided but possibly on both sides), a mimicking of the inflammation of brain membranes known as meningitis fever, and severe headache
- arthritis (short episodes of pain and swelling in joints) and other musculoskeletal complaints (Arthritis eventually develops in about 60 percent of patients with untreated Lyme disease.)

In adults, less common effects of Lyme disease are heart abnormalities (such as irregular rhythm or cardiac block) and eye abnormalities (such as swelling of the cornea, tissue, or eye muscles and nerves). However, children with Lyme disease frequently complain of chest pain and have papilledema (swelling of the optic nerve). In addition, children with late-stage Lyme disease are more likely than adults to have fever and joint swelling and pain.

When to call the doctor

A child should see a doctor if an attached tick is found that is engorged with blood (usually indicating attachment for more than six hours). Parents should remove the tick gently with tweezers. Medical laboratories can test the tick for *Borrelia burgdorferi* if the tick is alive; parents should place the tick in a tightly sealed plastic bag or small bottle with a moistened cotton ball and take it to the doctor. Most doctors will not prescribe antibiotics immediately following a tick bite but will ask parents to monitor their child for symptoms of early Lyme disease.

Less than 50 percent of children realize that they have been bitten by a tick. And, according to pediatricians specializing in Lyme disease, many children already have chronic Lyme disease when they are first diagnosed because children have difficulties effectively verbalizing their symptoms and their symptoms may be misdiagnosed. Any child that develops a round, bull's-eye skin rash, joint pain, flu-like symptoms, and/or neurologic symptoms as described above should see a doctor. Because many children do not develop a rash or the rash may not be readily visible (e.g., on the scalp under hair), children living in or visiting areas with a high incidence of Lyme disease and those participating in frequent outdoor activities during active tick months who develop joint pain and neurologic symptoms should see a doctor.

Diagnosis

In children, symptoms of Lyme disease can mimic those of other common childhood conditions, and children may not realize they have been bitten by a tick; therefore, diagnosis of Lyme disease in children can be difficult. Therefore, diagnosis of Lyme disease relies on information the patient and parents provide and the doctor's clinical judgment, particularly through elimination of other possible causes of the symptoms. Differential diagnosis (distinguishing Lyme disease from other diseases) is based on clinical evaluation with laboratory tests used for clarification when necessary. A two-test approach is common to confirm the results. Because of the potential for misleading results (false-positive and false-negative), laboratory tests alone cannot establish the diagnosis.

In February 1999 the Food and Drug Administration (FDA) approved a new blood test for Lyme disease called PreVue. The test, which searches for antigens (substances that stimulate the production of antibodies) produced by *Borrelia burgdorferi*, gives results within one hour in the doctor's office. A positive result from the PreVue test is confirmed by a second blood test known as the Western blot, which must be done in a laboratory.

Doctors generally know which disease-causing organisms are common in their geographic area. The most helpful piece of information is whether a tick bite or rash was noticed and whether it happened locally or while traveling. Doctors may not consider Lyme disease if it is rare locally but will take it into account if a patient mentions vacationing in an area where the disease is commonly found.

Treatment

The treatment for Lyme disease is antibiotic therapy. If a child has strong indications of Lyme disease (symptoms and medical history), the doctor will probably begin treatment on the presumption of this disease. The American College of Physicians recommends treatment for a patient with a rash resembling EM or who has arthritis, a history of an EM-type rash, and a previous tick bite.

The benefits of early treatment must be weighed against the risks of overtreatment. The longer a patient is ill with Lyme disease before treatment, the longer the course of therapy must be, and the more aggressive the

The first sign of lyme disease is usually an itchy bull's-eye rash around the site of the tick bite. *(© 1993 Science Photo Library. Custom Medical Stock Photo, Inc.)*

treatment. The development of opportunistic organisms may produce other symptoms. For example, after long-term antibiotic therapy, patients can become more susceptible to yeast infections. Treatment may also be associated with adverse drug reactions.

For most children, oral antibiotics (amoxicillin) are prescribed for 21 days. When symptoms indicate nervous system involvement or a severe episode of Lyme disease, an intravenous antibiotic (ceftriaxone, cefotaxime, ampicillin) may be given for four to six weeks or longer. Some physicians consider intravenous ceftriaxone the best therapy for any late manifestation of disease, but treatments for late Lyme disease are still controversial as of 2004. Corticosteroids (oral) may be prescribed if eye abnormalities occur, but they should not be used without first consulting an eye doctor. Nonsteroidal anti-inflammatory medications (ibuprofen) may be prescribed for joint pain and inflammation.

The doctor may have to adjust the treatment regimen or change medications based on the patient's response. Treatment can be difficult because *Borrelia burgdorferi* comes in several strains (some may react to different antibiotics than others) and may even have the ability to switch forms during the course of infection. Also, *Borrelia burgdorferi* can shut itself up in cell niches, allowing it to hide from antibiotics. Finally, antibiotics can kill *Borrelia burgdorferi* only while it is active rather than dormant.

Alternative treatment

Supportive therapies may minimize symptoms of Lyme disease or improve the immune response. These include vitamin and nutritional supplements, mostly for chronic fatigue and increased susceptibility to infection. For example, yogurt and *Lactobacillus acidophilus* preparations help fight yeast infections, which are common in patients on long-term antibiotic therapy. In addition, botanical medicine and homeopathy can be considered to help bring the body's systems back to a state of health and well-being. A Western herb, spilanthes (*Spilanthes* spp.), may be effective in treating diseases such as Lyme disease that are caused by spirochetes (spiral-shaped bacteria). Therapy using a low-current electrical field or magnetic pulses is also as of 2004 under research to treat bacterial infections. It is important to note that no

alternative treatments have been proven to cure Lyme disease.

Prognosis

If aggressive antibiotic therapy is given early and the patient cooperates fully and sticks to the medication schedule, recovery should be complete. Only a small percentage of Lyme disease patients fail to respond or relapse (have recurring episodes). Most long-term effects of the disease result when diagnosis and treatment is delayed or missed. Co-infection with other infectious organisms spread by ticks in the same areas as *Borrelia burgdorferi* (babesiosis and ehrlichiosis, for instance) may be responsible for treatment failures or more severe symptoms. Most fatalities reported with Lyme disease involved patients coinfected with babesiosis.

Prevention

Lyme disease can be prevented by taking the following measures to reduce exposure to tick bites:

- Avoid areas likely to be infested with ticks, especially during spring and summer, when tick nymphs are most likely to feed. Areas most likely to be infested with ticks include moist and shady areas, wooded and brushy areas, overgrown grassy areas, and areas with a high rodent and deer population.
- When outdoors, wear light-colored clothing, long-sleeved shirts, and long pants tucked into socks or boots.
- Use insect repellents according to **safety** guidelines for children.
- Perform a full-body "tick check" after outdoor activities and use tweezers to gently remove and dispose of ticks.
- Do not try to remove the tick by using petroleum jelly, alcohol, or a lit match.
- Place the tick in a closed container (for species identification later, should symptoms develop) or dispose of it by flushing or by placing the tick between scotch tape.
- Check pets frequently for ticks, since ticks can migrate to children from pets.

Update on vaccination

A vaccine for Lyme disease known as LYMErix was available from 1998 to 2002, when it was removed from the United States market. The decision was influenced by reports that LYMErix may be responsible for neurologic complications in vaccinated patients. As of late 2004, the best prevention strategy was minimizing risk of exposure to ticks and using personal protection precautions.

KEY TERMS

Babesiosis—A infection transmitted by the bite of a tick and characterized by fever, headache, nausea, and muscle pain.

Bell's palsy—Facial paralysis or weakness with a sudden onset, caused by swelling or inflammation of the seventh cranial nerve, which controls the facial muscles. Disseminated Lyme disease sometimes causes Bell's palsy.

Blood-brain barrier—An arrangement of cells within the blood vessels of the brain that prevents the passage of toxic substances, including infectious agents, from the blood and into the brain. It also makes it difficult for certain medications to pass into brain tissue.

Cerebrospinal fluid—The clear, normally colorless fluid that fills the brain cavities (ventricles), the subarachnoid space around the brain, and the spinal cord and acts as a shock absorber.

Disseminated—Spread to other tissues.

Erythema migrans—A red skin rash that is one of the first signs of Lyme disease in about 75% of patients.

Lyme borreliosis—Another name for Lyme disease.

Spirochete—A type of bacterium with a long, slender, coiled shape. Syphilis and Lyme disease are caused by spirochetes.

Vector—A carrier organism (such as a fly or mosquito) which serves to deliver a virus (or other agent of infection) to a host. Also refers to a retrovirus that had been modified and is used to introduce specific genes into the genome of an organism.

Parental concerns

Because most children do not realize they have been in tick-infested areas or been bitten by a tick and because deer ticks can be the size of a poppy seed or smaller, parents should be diligent about checking children for ticks, especially if the **family** lives in or visits an area with a high incidence of Lyme disease or an area near tick habitats. Also, because Lyme disease is difficult to diagnose in children, parents who suspect Lyme disease in their children should inform their doctor about the possibility

of the disease and be proactive in requesting further medical evaluation and treatment.

Lymphadenitis

Definition

Lymphadenitis is the inflammation of lymph nodes. It is often a complication of bacterial infections, although it can also be caused by viruses or other disease agents. Lymphadenitis may be either generalized, involving a number of lymph nodes, or limited to a few nodes in the area of a localized infection. Lymphadenitis is sometimes accompanied by lymphangitis, which is the inflammation of the lymphatic vessels that connect the lymph nodes.

Description

The lymphatic system is a network of vessels (channels), nodes (glands), and organs. It is part of the immune system, which protects against and fights infections, inflammation, and cancers. The lymphatic system also participates in the transport of fluids, fats, proteins, and other substances throughout the body. The lymph nodes are small structures that filter the lymph fluid and contain many white blood cells to fight infections. Lymphadenitis is marked by swollen lymph nodes that develop when the glands are overwhelmed by bacteria, virus, fungi, or other organisms. The nodes may be tender and hard or soft and "rubbery" if an abscess has formed. The skin over an inflamed node may be red and hot. The location of the affected nodes is usually associated with the site of an underlying infection, inflammation, or tumor. In most cases, the infectious organisms are *Streptococci* or *Staphylococci*. If the lymphatic vessels are also infected, in a condition referred to as lymphangitis, there will be red streaks extending from the wound in the direction of the lymph nodes, throbbing **pain**, and high **fever** and/or chills. The child will generally feel ill, with loss of appetite, **headache**, and muscle aches.

The extensive network of lymphatic vessels throughout the body and their relation to the lymph

nodes helps to explain why bacterial infection of the nodes can spread rapidly to or from other parts of the body. Lymphadenitis in children often occurs in the neck area because these lymph nodes are close to the ears and throat, which are frequent locations of bacterial infections in children.

Lymphadenitis is also referred to as lymph node infection, lymph gland infection, or localized lymphadenopathy.

Demographics

Lymphadenitis and lymphangitis are common complications of bacterial infections.

Causes and symptoms

Streptococcal and staphylococcal bacteria are the most common causes of lymphadenitis, although viruses, protozoa, rickettsiae, fungi, and the **tuberculosis** bacillus can also infect the lymph nodes. Diseases or disorders that involve lymph nodes in specific areas of the body include rabbit fever (tularemia), **cat-scratch disease**, lymphogranuloma venereum, chancroid, genital herpes, infected **acne**, dental abscesses, and bubonic plague. Lymphadenitis can also occur in conjunction with cellulitis, which is a deep, widespread tissue infection that develops from a cut or sore. In children, **tonsillitis** or bacterial sore throats are the most common causes of lymphadenitis in the neck area. Diseases that involve lymph nodes throughout the body include mononucleosis, **cytomegalovirus infection**, **toxoplasmosis**, and brucellosis.

The early symptoms of lymphadenitis are swelling of the nodes caused by a build-up of tissue fluid and an increased number of white blood cells resulting from the body's response to the infection. Further developments include fever with chills, loss of appetite, heavy perspiration, a rapid pulse, and general weakness.

Diagnosis

Physical examination

The diagnosis of lymphadenitis is usually based on a combination of the child's medical history, external symptoms, and laboratory cultures. The doctor will press (palpate) the affected lymph nodes to see if they are sore or tender, and search for an entry point for the infection, like a scratch or bite. Swollen nodes without soreness are sometimes caused by cat-scratch disease, which is an uncommon illness. In children, if the lymphadenitis is severe or persistent, the doctor may need to rule out

Swollen lymph node glands in a young girl's neck. *(Custom Medical Stock Photo Inc.)*

mumps, HIV, tumors in the neck region, and congenital cysts that resemble swollen lymph nodes.

Although lymphadenitis is usually diagnosed in lymph nodes in the neck, arms, or legs, it can also occur in lymph nodes in the chest or abdomen. If the child has acutely swollen lymph nodes in the groin, the doctor will need to rule out a **hernia** in the groin that has failed to reduce (incarcerated inguinal hernia). Hernias occur in 1 percent of the general population; 85 percent of children with hernias are male.

Laboratory tests

The most significant tests are a white blood cell count (WBC) and a blood culture to identify the organism. A high proportion of immature white blood cells indicates a bacterial infection. Blood cultures may be positive, most often for a species of staphylococcus or streptococcus. In some cases, the doctor may order a biopsy of the lymph node to look for unusual infection or lymphoma.

When to call the doctor

If a child develops symptoms of lymphadenitis, he or she should be taken to the doctor or emergency room.

KEY TERMS

Hernia—A rupture in the wall of a body cavity, through which an organ may protrude.

Lymph nodes—Small, bean-shaped collections of tissue located throughout the lymphatic system. They produce cells and proteins that fight infection and filter lymph. Nodes are sometimes called lymph glands.

Lymphangitis—Inflammation of the lymphatic vessels. It often occurs together with lymphadenitis (inflammation of the lymph nodes).

Septicemia—A systemic infection due to the presence of bacteria and their toxins in the bloodstream. Septicemia is sometimes called blood poisoning.

Streptococcus—Plural, *streptococci*. Any of several species of spherical bacteria that form pairs or chains. They cause a wide variety of infections including scarlet fever, tonsillitis, and pneumonia.

Treatment

Medications

The medications given for lymphadenitis vary according to the bacterium or virus that causes it. For bacterial infections, the child will be treated with **antibiotics**, usually a penicillin, clindamycin, a cephalosporin, or erythromycin.

Supportive care

Supportive care of lymphadenitis includes resting the affected area and applying hot moist compresses to reduce inflammation and pain.

Surgery

Cellulitis associated with lymphadenitis should not be treated surgically because of the risk of spreading the infection. Pus is drained only if there is an abscess and usually after the child has begun antibiotic treatment. In some cases, biopsy of an inflamed lymph node is necessary if no diagnosis has been made and no response to treatment has occurred.

Inflammation of lymph nodes due to other diseases requires treatment of the underlying causes.

Prognosis

The prognosis for recovery is good if the child is treated promptly with antibiotics. In most cases, the infection can be brought under control in three or four days. However, in some cases it may take weeks or months for swelling to disappear; the length of recovery depends on the underlying cause of the infection. Children with untreated lymphadenitis may develop abscesses, cellulitis, or blood poisoning (septicemia), which is sometimes fatal.

Prevention

Prevention of lymphadenitis depends on prompt treatment of bacterial and viral infections.

Parental concerns

Parents may be concerned that enlarged lymph nodes in their child are malignant. They should seek immediate medical attention for the child so concerns can be addressed in a timely manner.

Macrocephaly

Definition

Macrocephaly is a condition in which the head is larger than normal.

Description

Also called macrocephalia and megalocephaly, macrocephaly is diagnosed when the circumference of the head is more than two standard deviations above average for the child's age, sex, race, and period of gestation. The fontanelle (soft spot) of the newborn is wide, but facial features are usually normal. Macrocephaly is distinguished from **hydrocephalus** in that there is no increase in pressure within the head; however, hydrocephalus can result in macrocephaly in some children. The disorder can result from a defect in formation during the embryonic stage, as a result of certain degenerative diseases, as a part of various genetic syndromes, or as an inherited **family** trait. Mental deficiency, seizures, and **movement disorders** are common in macrocephalic children.

Demographics

Because of the many conditions that cause macrocephaly, a true assessment of its incidence is difficult. It is a relatively rare condition that does not appear to affect children of any particular race, gender, or nationality with more frequency.

Causes and symptoms

Macrocephaly may be caused by many conditions. The most common causes for an enlarged head are megalencephaly, or an enlarged brain, and hydrocephalus, or excessive cerebrospinal fluid (**CSF**) in the brain.

When macrocephaly is a result of megalencephaly, it is often impossible to determine the cause. However, megalencephaly is often associated with metabolic diseases such as Canavan's disease or Alexander's disease or with syndromes such as **gigantism**, achondroplasia (**dwarfism** or small stature), **osteogenesis imperfecta**, **neurofibromatosis**, and some chromosomal anomalies. In each of these disorders, there is an enlargement of brain tissues.

In hydrocephalus, excess CSF collects in the large sections of the brain called the ventricles. This may occur for many reasons, including **Chiari malformation**, abnormal cysts within the brain, and infections such as **meningitis**.

In some cases, a child may have benign macrocephaly. In these children, the only abnormality is an enlarged head. Usually there are other family members with large heads, and the condition is considered a family trait. These children do not have an underlying condition and usually do not have any additional complications.

The major symptom of macrocephaly is an enlarged head circumference. Other symptoms can include, delay in reaching developmental milestones, **mental retardation**, rapid head growth, and slowed growth of the rest of the body.

Diagnosis

Macrocephaly is usually diagnosed by the pediatrician during a physical examination. In some cases this may be the only diagnosis necessary. Some children will require additional diagnostic imaging procedures, such as **computed tomography** scan (CAT scan), x ray, and **magnetic resonance imaging** (MRI), to determine the cause of the macrocephaly and the appropriate treatment.

KEY TERMS

Achondroplasia—A congenital disturbance of growth plate development in long bones that results in a person having shortened limbs and a normal trunk.

Alexander's disease—A progressive, degenerative disorder of the central nervous system.

Canavan disease—A serious genetic disease more common in the Eastern European Jewish population that causes mental retardation and early death. Canavan disease is caused by the lack of an enzyme called aspartoacylase.

Chiari II anomaly—A structural abnormality of the lower portion of the brain (cerebellum and brainstem) associated with spina bifida. The lower structures of the brain are crowded and may be forced into the foramen magnum, the opening through which the brain and spinal cord are connected.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Fontanelle—One of several "soft spots" on the skull where the developing bones of the skull have yet to fuse.

Gigantism—Excessive growth, especially in height, resulting from overproduction of growth hormone during childhood or adolescence by a pituitary tumor. Untreated, the tumor eventually destroys the pituitary gland, resulting in death during early adulthood. If the tumor develops after growth has stopped, the result is acromegaly, not gigantism.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct detailed images of internal body structures and organs, including the brain.

Megalencephaly—A condition in which the brain is abnormally large.

Megalocephaly—An abnormally large head.

Neurofibromatosis—A progressive genetic condition often including multiple café-au-lait spots, multiple raised nodules on the skin (neurofibromas), developmental delays, slifhtly larger head size, and freckles in the armpits, groin, and iris. Also known as von Recklinghausen's disease.

Osteogensis imperfecta—An inherited disorder of the connective tissue which involves multiple symptoms, including weakened bones that break easily.

Standard deviation—A measure of the distribution of scores around the average (mean). In a normal distribution, two standard deviations above and below the mean includes about 95% of all samples.

Treatment

There is no specific treatment for macrocephaly. Medical care for children with macrocephaly focuses on management of specific symptoms such as developmental delays and mental retardation and treatment of the primary diagnosis responsible for the macrocephaly.

Prognosis

For children with benign familial macrocephaly, the prognosis is excellent. These children usually do not have any complications and have normal **intelligence**. For other children with macrocephaly, the prognosis is dependent upon the cause. In children with hydrocephalus, the prognosis can be excellent depending on what type of hydrocephalus they have. Unfortunately, many children with macrocephaly experience delayed development, slow growth, seizure disorders, and limited intelligence. All of these are related to the underlying condition that caused the macrocephaly.

Prevention

Macrocephaly is often present at birth or is a result of conditions that are present at birth. As of 2004 there was no known prevention.

Parental concerns

When mental deficiency and the attendant diseases or disorders are severe, the child may require a life-support system. When the mental deficiency is less severe, the child may be diagnosed with minimal brain dysfunction or as neurologically handicapped. Minimal brain dysfunction can include any or all of the following: memory and language problems, neuromotor functioning problems, and behavior and social problems. The degree of dysfunction is a key factor in parents' deciding whether the child can continue to live at home and what type of schooling is appropriate. Parents and teachers need to be cognizant of the nature of the child's dysfunction. What was once seen as laziness and lack of motivation on the child's part has begun in the early 2000s to be

recognized as a medical condition that can be corrected or modified through psychotherapy. Sometimes, though, a child may suffer several years of frustrating failure and abnormal development or behavior before the problem is recognized and he or she is properly diagnosed.

Magnetic resonance imaging

Definition

Magnetic resonance imaging (MRI) is a diagnostic imaging procedure that uses radio waves, a magnetic field, and a computer to generate images of the anatomy.

Purpose

MRI is used to visualize the body to assist doctors in their efforts to diagnose certain diseases or conditions and to evaluate injuries. For pediatric imaging, MRI is used for a variety of purposes, including the following:

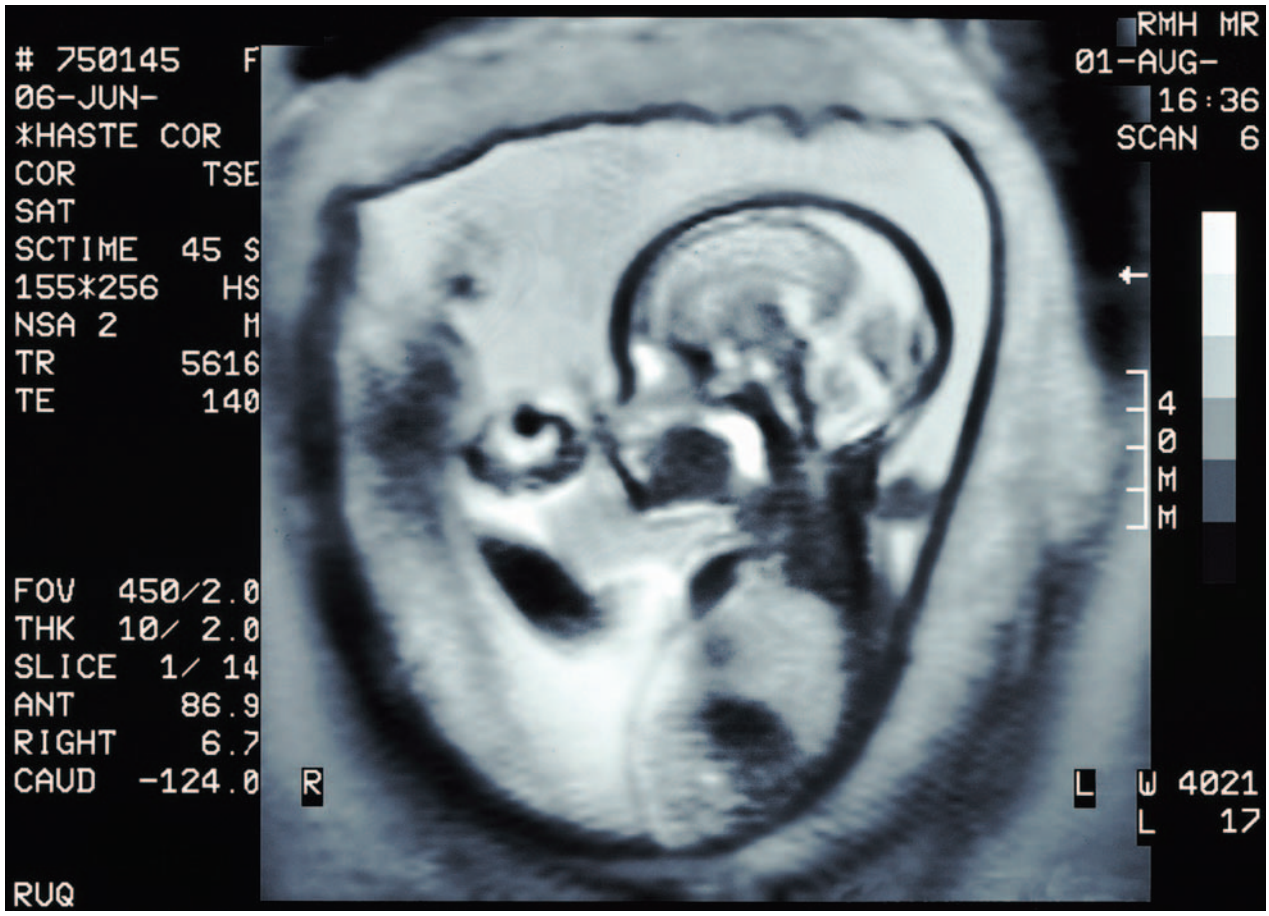
- diagnosing diseases of the central nervous system, including the brain and spine
- detecting musculoskeletal disorders and injuries
- identifying complications of infectious diseases, such as those associated with **Lyme disease** or acquired **immunodeficiency** syndrome (AIDS)
- imaging the cardiovascular system
- detecting congenital heart defects in neonates
- determining the stage of certain types of **cancer**
- evaluating bone marrow disease
- assessing blood vessels in the brain for **stroke** and other abnormalities
- assisting in the planning of surgery and cancer treatment
- evaluating the urinary tract

MRI provides images with excellent contrast that allow clinicians to clearly see details of soft tissue, bone, joints, and ligaments. MRI angiography is an imaging technique used to evaluate the blood vessels, for example, to detect aneurysms or cardiovascular problems. Because MRI does not use ionizing radiation to produce images, like x ray and CT, it is often the examination of choice for pediatric imaging and for imaging the male and female reproductive systems, pelvis and hips, and urinary tract and bladder.

MRI can also be used to evaluate brain function for assessing language, senses, neurologic disorders, and **pain**. This technique, called functional MRI, involves rapid imaging to display changes in the brain's blood flow in response to tasks or visual and auditory stimuli. Functional MRI is being researched to image neurologic disorders, such as attention deficit hyperactivity disorder (ADHD), delayed **cognitive development**, and epilepsy.

MRI spectroscopy is another emerging imaging technique for evaluating pediatric brain disorders. In MRI spectroscopy, chemicals in the brain are measured and brain tissue is imaged. This technique is being investigated to evaluate traumatic brain injury, speech delay, creatine deficiency syndromes, and **mood disorders** in young children.

Interventional and intraoperative MRI is another developing field that involves performing interventional procedures, primarily brain surgeries, using a specially designed MRI unit in an operating room.



Magnetic resonance imaging (MRI) of a fetus. *(© Lester Lefkowitz/Corbis.)*

Description

MRI is performed using a specialized scanner, a patient table, systems that generate radio waves and magnetic fields, and a computer workstation. The scanner, which is usually shaped like a large rectangle with a hole in the center, contains the systems that generate the magnetic field. A motorized and computer-controlled patient table moves into the scanner's center hole during the scan. A technologist operates the MRI scanner from an adjacent control room that contains a computer system and an intercom system for communicating with the patient during the scan.

In most MRI scanners, the patient opening is like a long tube, and some patients may become claustrophobic. To be more patient-friendly, different types of MRI scanners have been developed. Newer MRI scanners have shorter patient openings that allows the patient's head to remain outside the machine during body scans. Open MRI scanners are available with columns and open sides to alleviate claustrophobia.

Depending on the body area being scanned, special body coils may be used to enhance the images. These coils are foam and plastic braces or wraparound pads that are placed on the body part being imaged. For head imaging, the coil may be shaped like a head or neck rest.

Children undergoing an MRI scan are appropriately positioned on the patient table by the technologist. For some scans, an injected contrast material may be used and is administered using an intravenous catheter. Once the patient is positioned, the technologist goes to an adjacent control room to operate the scanner. The technologist uses an intercom system to instruct the child to hold their breath or remain still at certain times during the scan. Scans range from 30 minutes to 90 minutes, depending on the type of scan. When the MRI machine is scanning, the child hears loud clanging and whirring noises. To alleviate **fear** or stress related to hearing this noise and being in the small scanning tube, the child may be offered earplugs or specially designed head phones for listening to music. Centers that specialize in pediatric imaging often also have special video goggles so that the child can watch a cartoon or movie during the scan. For infants, neonatal noise guards—special padded ear shields—are available.

MRI scans are performed in a hospital radiology department for inpatients and emergency cases. For scans requested by a physician, the MRI examination can be performed in the hospital radiology department on an outpatient basis or in an imaging center. Hospitals that do not have their own MRI systems may schedule MRI scans by contracting with a company that brings an MRI scanner in a specially designed mobile trailer. Mobile MRI services are frequently used in rural areas. For some conditions, such as orthopedic disorders or injuries, an MRI may be performed in a physician's office using a small MRI unit called an extremity MRI scanner. These scanners are designed to image only the joints or the head. During this type of scan, only the body part to be scanned is placed in the smaller scanner while the patient lies on a couch or sits in a chair.

The images from an MRI examination are called slices, because they are acquired in very small (millimeter-size) sections of the body. The image slices are displayed on a computer monitor for viewing or printed as a film. A specialist called a radiologist interprets the images produced during the MRI examination. For emergency scans, images are interpreted immediately so that the child can be treated quickly. For non-urgent outpatient MRI scans, the radiologist interprets the images and sends a report to the referring physician within a few days.

Precautions

MRI is a safe procedure that does not involve radiation. However, the magnetic field generated during an MRI examination is so strong that metal objects or objects with metal in them, such as jewelry, **eyeglasses**, oxygen canisters, and even wheelchairs, will be pulled toward the machine. Therefore, MRI staff must take special precautions to ensure that no metallic objects enter the MRI suite. MRI technologists inspect patient clothing and accessories to make sure there are no metals on them during the scan.

Preparation

Prior to any MRI scan, patients are required to remove all metal objects and remove any clothing with metal on them (zippers, snaps). In most cases, parents have to complete a survey regarding their child's past surgical procedures and medical history to indicate whether the child has any metallic implants. Metallic implants include artificial joints, pacemakers, aneurysm clips, metal plates, pins or screws, and surgical staples. Children with metallic implants are likely to undergo a **computed tomography** (CT) examination instead of an MRI.

Unlike CT, no fasting or **laxatives** are required prior to an MRI scan. Only one type of MRI scan, called a magnetic resonance cholangiopancreatography (MRCP), which scans the bile ducts, requires that the child not eat or drink anything for two to three hours prior to the scan.

During the examination, the child must lie still. The MRI scanner does make loud noises throughout the examination, which can be frightening for some children. Before the examination, the procedure should be explained to the child, and it should be emphasized that the examination is painless. Most facilities have specially designed music systems so that patients can wear headsets and listen to music during the scan; some facilities even have special video goggles so children can watch a cartoon or movie during the scan.

Aftercare

No special aftercare is required following MRI scans, unless sedation or general anesthesia was used during the scan. Then children are required to remain in a supervised recovery area for an hour or more following the procedure to monitor for reactions to anesthesia. If injected contrast material is used, some minor first aid (small bandage, pain relief) for the injection site may be necessary.

KEY TERMS

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

Cholangiopancreatography—An examination of the bile ducts and pancreas.

Claustrophobia—Fear of small, enclosed spaces.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Intravenous—Into a vein; a needle is inserted into a vein in the back of the hand, inside the elbow, or some other location on the body. Fluids, nutrients, and drugs can be injected. Commonly called IV.

Radiography—Examination of any part of the body through the use of x rays. The process produces an image of shadows and contrasts on film.

Radiologist—A medical doctor specially trained in radiology, the branch of medicine concerned with radioactive substances and their use for the diagnosis and treatment of disease.

Risks

MRIs present no radiation exposure. Magnetic fields used in MRI have no side effects for the patient. The contrast material used in MRI contains a material called gadolinium, that is much less likely to cause severe anaphylactic (allergic) reactions than the iodinated material used for CT scans.

Because the MRI examination is long and the patient opening in the machine is small, some children and adolescents may feel claustrophobic. Light sedation or relaxants may be administered, or an MRI scanner with a more open design may be used. For younger infants and children that require sedation or anesthesia to complete the examination, reactions to the anesthesia are possible, including headaches and **vomiting**.

Parental concerns

Younger children may be frightened of the MRI scanner, and a parent or other **family** member may be required to be present in the scanning room. To help alleviate fear, taking the child into the MRI room to see the equipment prior to the procedure may be helpful. Anyone remaining in the scanning room during the MRI examination must remove any metal objects, including jewelry and eyeglasses.

Malnutrition

Definition

Malnutrition is a condition that develops when the body does not get the proper amount of protein, energy (calories), **vitamins**, and other nutrients it needs to maintain healthy tissues and organ function.

Description

Poor eating habits or lack of available food may lead to malnutrition. Malnutrition occurs in children who are either undernourished or overnourished. Children who are overnourished may become overweight or obese, which may lead to long-term health problems and social stress.

Undernutrition

Undernutrition is a consequence of consuming little energy and other essential nutrients, or using or excreting them more rapidly than they can be replaced. This state of malnutrition is often characterized by infections and disease. Malnutrition intensifies the effect of every disease. Severe malnutrition is most often found in developing countries. Rarely in the United States do children suffer from severe malnutrition that is not related to severe chronic illness. Deficiency in one nutrient occurs less often than deficiency in several nutrients. A child suffering from malnutrition is usually deficient in a variety of nutrients.

The leading cause of death in children in developing countries is **protein-energy malnutrition**. This type of malnutrition is the result of inadequate intake of protein and energy. Children who are already undernourished can suffer from protein-energy malnutrition when rapid growth, infection, or disease increases the need for protein and essential nutrients.

Overnutrition

In the United States, nutritional deficiencies have generally been replaced by dietary imbalances or excesses

associated with many of the leading causes of death and disability. Overnutrition results from eating too much, eating too many of the wrong foods, not exercising enough, or taking too many vitamins or other dietary replacements.

Risk of overnutrition is also increased by being more than 20 percent overweight, consuming a diet high in fat and salt, and taking high doses of:

- nicotinic acid (niacin) to lower elevated cholesterol levels
- vitamin B_6 to relieve premenstrual syndrome
- vitamin A to clear up skin problems
- iron or other trace **minerals** not prescribed by a doctor

Nutritional disorders can affect any system in the body and the senses of sight, taste, and smell. Malnutrition begins with changes in nutrient levels in blood and tissues. Alterations in enzyme levels, tissue abnormalities, and organ malfunction may be followed by illness and death.

Complications

Poorly nourished children often have weakened immune systems, thus increasing their chances of illness. Underweight, malnourished teenagers (such as those with an eating disorder) have an increased risk of osteoporosis and may not have menstrual periods. They may have heart and other organ problems with severe malnutrition. Malnutrition, if left untreated, can lead to physical or mental disability, or even death.

Children who are overweight have an increased risk for long-term conditions and diseases, including cardiovascular disease, **high cholesterol**, high blood pressure, type 2 diabetes, **asthma**, **sleep** apnea, and certain cancers. Health consequences range from a higher risk of premature death to chronic conditions that reduce a person's quality of life.

Demographics

Malnutrition is a major cause of illness and death throughout the world. Throughout the developing world, malnutrition affects almost 800 million people, or 20 percent of the population. Approximately half of the 10.4 million children who die each year are malnourished. It often causes disease and disability in the children who survive. Diarrheal diseases are also a major world health problem, and may be a cause of malnutrition. Nearly all of these deaths occur in impoverished parts of Africa and Asia, where they often result from contamination of the water supply by animal and human feces.

Worldwide, the most common form of malnutrition is iron deficiency, affecting up to 80 percent of the population, as many as four or five billion people.

In contrast, children in many parts of the world are becoming increasingly overweight. What was thought of as a problem for industrialized nations only until recently, is now affecting children in developing countries. Approximately 25–30 percent of school-age children in the United States are overweight.

Causes and symptoms

Worldwide, poverty and lack of food are the primary reasons why malnutrition occurs. Families of low-income households do not always have enough healthy food to eat. When there is a household food shortage, children are the most vulnerable to malnutrition because of their high energy needs.

There is an increased risk of malnutrition associated with chronic diseases, especially disease of the intestinal tract, kidneys, and liver. Children with chronic diseases like **cancer**, **cystic fibrosis**, **AIDS**, **celiac disease**, and intestinal disorders may lose weight rapidly and become susceptible to malnutrition because they cannot absorb valuable vitamins, iron, and other necessary nutrients. Children who are lactose intolerant have difficulty digesting milk and milk products, and may be at risk for malnutrition, particularly a calcium deficiency.

Symptoms of malnutrition vary, depending on what nutrients are deficient in the body. Unintentionally losing weight may be a sign of malnutrition. Children who are malnourished may be skinny or bloated and may be short for their age (stunted). Their skin is pale, thick, dry, and easily bruised. **Rashes** and changes in pigmentation are common.

Hair is thin, tightly curled, and easily pulled out. Joints ache and bones are soft and tender. The gums bleed. The tongue may be swollen, or shriveled and cracked. Visual disturbances include night blindness and increased sensitivity to light and glare.

Other symptoms of malnutrition include:

- fatigue
- dizziness
- anemia
- **diarrhea**
- disorientation
- goiter (enlarged thyroid gland)
- loss of reflexes and lack of coordination
- muscle twitches
- decreased immune response
- scaling and cracking of the lips and mouth

Children who are overnourished are visibly overweight or obese, and consume more food than their bodies need (or expend too little energy through physical activity).

When to call the doctor

Parents who worry about malnutrition can discuss their concerns with a doctor, registered dietitian, or other health care provider. Though not an exhaustive list, treatment should be sought for a child if:

- there is a change in bodily functions (impairment)
- the child is not growing
- the child faints
- the child rapidly loses hair
- a girl at **puberty** stops menstruating or is underweight and fails to start menstruating

Diagnosis

Overall appearance, behavior, body-fat distribution, and organ function can alert a **family** physician, internist, or **nutrition** specialist to the presence of malnutrition. Parents may be asked to record what a child eats during a specific period. **X rays** or a CT scan can determine bone density and reveal gastrointestinal disturbances, as well as heart and lung damage.

Blood and urine tests are used to measure levels of vitamins, minerals, and waste products. Nutritional status can also be determined by:

- comparing a child's weight to standardized charts
- calculating body mass index (BMI) according to a formula that divides height into weight
- measuring skin-fold thickness or the circumference of the upper arm

Treatment

Normalizing nutritional status starts with a nutritional **assessment**. This process enables a registered dietitian or nutritionist to confirm the presence of malnutrition, assess the effects of the disorder, and formulate a diet that will restore adequate nutrition. For children suffering malnutrition due to an illness or underlying disorder, the condition should be treated concurrently.

Nutritional concerns

Children who cannot or will not eat, or who are unable to absorb nutrients taken by mouth, may be fed intravenously (parenteral nutrition) or through a tube inserted into the gastrointestinal tract (enteral nutrition).

Child suffering from the severe effects of malnutrition. *(Photograph by Bruce Brander. National Audubon Society Collection/Photo Researchers, Inc.)*

Tube feeding is often used to provide nutrients to children who have **burns**, inflammatory bowel disease, or other long-term conditions that cause chronic malnutrition or malabsorption (e.g. cystic fibrosis or AIDS), and interfere with the ability to take in enough calories. This procedure involves inserting a thin tube through the nose and carefully guiding it along the throat until it reaches the stomach or small intestine. If long-term tube feeding is necessary, the tube may be placed directly into the stomach or small intestine through an incision in the abdomen.

Tube feeding cannot always deliver adequate nutrients to children who:

- are severely malnourished
- require surgery
- are undergoing **chemotherapy** or radiation treatments
- have been seriously burned
- have persistent diarrhea or vomiting
- have a gastrointestinal tract that is not functional

Intravenous feeding can also supply some or all of the nutrients these children need.

Doctors or registered dietitians can help parents can monitor overweight or obese children. These professionals may suggest a weight loss program if the child is more than 40 percent overweight. Keeping weight gain under control can be accomplished by changing eating habits, lowering fat intake, and increasing physical activity.

Prognosis

Some children with protein-energy malnutrition recover completely. Others have many health problems throughout life, including mental disabilities and the inability to absorb nutrients through the intestinal tract. Prognosis is dependent on age and the length and severity of the malnutrition, with young children having the highest rate of long-term complications and death. Death usually results from heart failure, electrolyte imbalance, or low body temperature. Children with semiconsciousness, persistent diarrhea, **jaundice**, or low blood sodium levels have a poorer prognosis.

A good prognosis exists for overweight children who make lifestyle changes and adhere to a diet and **exercise** program.

Prevention

Every child admitted to the hospital for poor weight gain or malnutrition should be screened for the presence of illnesses and conditions that could lead to protein-energy malnutrition. Children with higher-than-average risk for malnutrition should be more closely assessed, and evaluated often.

Nutritional concerns

Proper nutrition is required to ensure optimal health. Consumption of a wide variety of foods, with adequate vitamin and mineral intake, is the basis of a healthy diet. Researchers state that no single nutrient is the key to good health, but that optimum nutrition is derived from eating a diverse diet, including a variety of fruits and vegetables. Because foods such as fruits and vegetables provide many more nutrients than vitamin supplements, food is the best source for acquiring needed vitamins and minerals.

Breastfeeding a baby for at least six months is considered the best way to prevent early-childhood malnutrition. The United States Department of Agriculture and Health and Human Services recommends that all Americans over the age of two:

- consume plenty of fruits, grains, and vegetables
- eat a variety of foods that are low in fats and cholesterol, and contain only moderate amounts of salt, sugars, and sodium
- engage in moderate physical activity for at least 30 minutes, at least several times a week
- achieve or maintain their ideal weight
- use alcohol sparingly or avoid it altogether

Iron deficiency can be prevented by consuming red meat, egg yolks, and fortified breads, flour, and cereals.

KEY TERMS

Anemia— A condition in which there is an abnormally low number of red blood cells in the bloodstream. It may be due to loss of blood, an increase in red blood cell destruction, or a decrease in red blood cell production. Major symptoms are paleness, shortness of breath, unusually fast or strong heart beats, and tiredness.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Minerals—Inorganic chemical elements that are found in plants and animals and are essential for life. There are two types of minerals: major minerals, which the body requires in large amounts, and trace elements, which the body needs only in minute amounts.

Nutrient—Substances in food that supply the body with the elements needed for metabolism. Examples of nutrients are vitamins, minerals, carbohydrates, fats, and proteins.

Vitamins—Small compounds required for metabolism that must be supplied by diet, microorganisms in the gut (vitamin K) or sunlight (UV light converts pre-vitamin D to vitamin D).

Parental concerns

Infants, young children, and teenagers need additional nutrients to provide for growth requirements. This is also true for women who are pregnant or breastfeeding; a mother's nutritional status affects her baby. Nutrient loss can be accelerated by diarrhea, excessive sweating, heavy bleeding (hemorrhage), or kidney failure. Nutrient intake can be restricted by age-related illnesses and conditions, excessive dieting, severe injury,

serious illness, a lengthy **hospitalization**, or substance abuse.

Children usually eat as much or as little as they need in order to feel satisfied. Children should be allowed to select what they want to eat among healthy food choices; they should be allowed to stop eating when they feel full. An underweight, overweight, or normal weight child should be allowed to decide how much to eat or whether to eat at all, within reason.

Parents must proactively prevent childhood **obesity** by recognizing weight imbalances when they begin. They can help an overweight child to lose weight (if medically necessary) by being supportive, rather than scolding. Parents should offer their children nutritious food choices and encourage physical activity. With proper intervention, an overweight child is not destined to become an overweight adult, but weight loss goals should be realistic.

Malocclusion

Definition

Malocclusion is the misalignment of the upper and lower teeth when biting or chewing.

Description

The word malocclusion literally means "bad bite." The condition may also be referred to as an irregular bite, crossbite, or overbite. Malocclusion may be seen as crooked, crowded, or protruding teeth. It may affect a child's appearance, speech, and/or ability to eat.

Demographics

Most children have some degree of malocclusion. Malocclusion usually does not require treatment except for cosmetic reasons. It is more likely to occur if the parents have malocclusion, the child sucks his or her thumb or a pacifier, or if a tooth is lost prematurely.

Causes and symptoms

Malocclusions are most often inherited, but may be acquired. Inherited conditions include too many or too few teeth, too much or too little space between teeth, irregular mouth and jaw size and shape, and atypical formations of the jaws and face, such as a **cleft palate**. Malocclusions may be acquired from habits like finger or **thumb sucking**, tongue thrusting, premature loss of teeth from an accident or dental disease, and possibly from medical conditions such as enlarged tonsils and adenoids that lead to mouth breathing.

Malocclusions may cause no symptoms, or they may produce **pain** from the increased stress on oral structures. Teeth may show abnormal signs of wear on the chewing surfaces or decay in areas of tight overlap. Chewing may be difficult.

When to call the doctor

A dentist or orthodontist should be consulted if a child's teeth seem to be particularly misaligned or if a child complains of dental or jaw pain.

Diagnosis

Malocclusion is most often found during a routine dental examination. A dentist will check a patient's occlusion by watching how the teeth make contact when the child bites down normally. The dentist may ask the

This patient's teeth are misarranged because of excessive thumb sucking. *(Photograph by K.L. Boyd. Custom Medical Stock Photo, Inc.)*

KEY TERMS

Braces—An orthodontic appliance consisting of brackets cemented to the surface of each tooth and wires of stainless steel or nickel titanium alloy. Braces are used to treat malocclusion by changing the position of the teeth.

Impression—In dentistry, an imprint of the upper or lower teeth made in a pliable material that sets. When this material has hardened, it may be filled with plaster, plastic, or artificial stone to make an exact model of the teeth.

Occlusion—The way upper and lower teeth fit together during biting and chewing. Also refers to the blockage of some area or channel of the body.

Retainer—An orthodontic appliance that is worn to stabilize teeth in a new position.

Space maintainer—An orthodontic appliance that is worn to prevent adjacent teeth from moving into the space left by an unerupted or prematurely lost tooth.

child to bite down with a piece of coated paper between the upper and lower teeth. This paper will leave colored marks at the points of contact. When malocclusion is suspected, photographs and **x rays** of the face and mouth may be taken for further study. To confirm the presence and extent of malocclusion, the dentist makes plaster or plastic models of the patient's teeth from impressions. These models duplicate the fit of the teeth and are very useful in planning treatment.

Treatment

Malocclusion may be remedied by orthodontic treatment. **Orthodontics** is a specialty of dentistry that manages the growth and correction of dental and facial structures. Braces are the most commonly used orthodontic appliances in the treatment of malocclusion. At any given time, approximately four million people in the United States are wearing braces, most of whom are children and teenagers.

Braces apply constant gentle force to slowly change the position of the teeth, straightening and properly aligning them with the opposing teeth. Braces consist of brackets cemented to the surface of each tooth and wires of stainless steel or nickel titanium alloy. When the wires are threaded through the brackets, they exert pressure against the teeth, causing them to gradually move.

Braces are not removable for daily tooth brushing. To prevent **tooth decay**, the child must be especially diligent about keeping the mouth clean and removing food particles that become easily trapped. Crunchy foods should be avoided to minimize the risk of breaking the appliance. Hard fruits, vegetables, and breads must be cut into bite-sized pieces before eating. Foods that are sticky, including chewing gum, should be avoided because they may pull off the brackets or weaken the cement. Carbonated beverages may also weaken the cement, as well as contribute to tooth decay. Teeth should be brushed immediately after eating. Special floss threaders are available to make flossing easier.

If overcrowding is creating malocclusion, one or more teeth may be extracted (surgically removed), giving the others room to move. If a tooth has not yet erupted or is prematurely lost, the orthodontist may insert an appliance, called a space maintainer, to keep the other teeth from moving out of their natural position. In severe cases of malocclusion, surgery may be necessary and the patient is referred to another specialist, an oral or maxillofacial surgeon.

Once the teeth have been moved into their new position, the braces are removed, and a retainer is worn until the teeth stabilize in that position. Retainers do not move teeth, they only hold them in place. Often a retainer is initially worn all the time; its use is gradually tapered until it is only worn at night, and eventually not at all.

Orthodontic treatment is the only effective treatment for malocclusion not requiring surgery. However,

depending on the cause and severity of the condition, an orthodontist may be able to suggest other appliances as alternatives to braces. If the malocclusion is thought to be caused by the child sucking on fingers or a pacifier and the child is stopped early enough, the malocclusion may resolve spontaneously without treatment.

Alternative treatment

There are some techniques of craniosacral therapy that can alter structure. This therapy may allow correction of some cases of malocclusion. If surgery is required, pre- and post-surgical care with homeopathic remedies, as well as vitamin and mineral supplements, can enhance recovery. Night guards are sometimes recommended to ease the strain on the jaw and to limit teeth grinding.

Prognosis

Depending on the cause and severity of the malocclusion and the appliance used in treatment, a patient may expect correction of the condition to take two or more years. Patients typically wear braces 18–24 months, and a retainer for another year. Treatment is faster and more successful in children and teens whose teeth and bones are still developing. The time needed for treatment is also affected by how well the patient follows orthodontic instructions.

Prevention

In general, malocclusion is not preventable. It may be minimized by controlling habits such as thumb sucking. An initial consultation with an orthodontist before a child is seven years of age may lead to appropriate management of the growth and development of the child's dental and facial structures, circumventing many of the factors contributing to malocclusion.

Parental concerns

Most of the time, malocclusion is treated for cosmetic reasons. Children, however, may not want treatment because they will have to wear braces. It is usually possible to schedule the beginning of treatment for a time that is convenient for the child and the parent. Talking with children or teenagers and obtaining their input about treatment may be beneficial in increasing compliance. Full compliance with the orthodontist's instructions helps to ensure that the treatment is successful.

Marfan syndrome

Definition

Marfan syndrome is an inherited disorder of the connective tissue that causes abnormalities of a child's eyes, cardiovascular system, and musculoskeletal system. It is named for the French pediatrician, Antoine Marfan (1858-1942), who first described it in 1896.

Description

Marfan syndrome affects three major organ systems of the body: the heart and circulatory system, the bones and muscles, and the eyes. The genetic mutation responsible for Marfan was discovered in 1991. It affects the body's production of fibrillin, which is a protein that is an important part of connective tissue. Fibrillin is the primary component of the microfibrils that allow tissues to stretch repeatedly without weakening. Because the child's fibrillin is abnormal, his or her connective tissues are looser than usual, which weakens or damages the support structures of the entire body.

The most common external signs associated with Marfan syndrome include excessively long arms and legs, with the child's arm span being greater than his or her height. The fingers and toes may be long and slender, with loose joints that can be bent beyond their normal

limits. This unusual flexibility is called hypermobility. The child's face may also be long and narrow, and he or she may have a noticeable curvature of the spine. It is important to note, however, that children with Marfan vary widely in the external signs of their disorder and in their severity; even two children from the same **family** may look quite different. Most of the external features of Marfan syndrome become more pronounced as the child gets older, so that diagnosis of the disorder is often easier in adults than in children. In many cases, the child may have few or very minor outward signs of the disorder, and the diagnosis may be missed until the child develops vision problems or cardiac symptoms.

Marfan syndrome by itself does not affect a child's **intelligence** or ability to learn. There is, however, some clinical evidence that children with Marfan have a slightly higher rate of hyperactivity and attention-deficit disorder (ADD) than the general population. In addition, a child with undiagnosed nearsightedness related to Marfan may have difficulty seeing the blackboard or reading printed materials, and thus do poorly in school.

Marfan syndrome affects males and females equally, and appears to be distributed equally among all races and ethnic groups. The rate of mutation of the fibrillin gene, however, appears to be related to the age of the child's father; older fathers are more likely to have new mutations appear in chromosome 15.

Marfan syndrome is sometimes called arachnodactyly, which means "spider-like fingers" in Greek, since one of the characteristic signs of the disease is disproportionately long fingers and toes.

Demographics

It is estimated that one person in every 3000-5000 has Marfan syndrome, or about 50,000 people in the United States. Marfan syndrome is one of the more common inheritable disorders.

Causes and symptoms

Marfan syndrome is caused by a single gene for fibrillin on chromosome 15, which is inherited in most cases from an affected parent. Between 15 and 25 percent of cases result from spontaneous mutations. Mutations of the fibrillin gene (FBNI) are unique to each family affected by Marfan, which makes rapid genetic diagnosis impossible, given present technology. The syndrome is an autosomal dominant disorder, which means that someone who has it has a 50 percent chance of passing it on to any offspring.

Another important genetic characteristic of Marfan syndrome is variable expression. This term means that the mutated fibrillin gene can produce a variety of symptoms of very different degrees of severity, even in members of the same family.

Cardiac and circulatory abnormalities

The most important complications of Marfan are those affecting the heart and major blood vessels; some are potentially life-threatening. About 90 percent of children with Marfan will develop cardiac complications, including:

- Aortic enlargement. This is the most serious potential complication of Marfan syndrome. Because of the abnormalities of the child's fibrillin, the walls of the aorta (the large blood vessel that carries blood away from the heart) are weaker than normal and tend to stretch and bulge out of shape. This stretching increases the likelihood of an aortic dissection, which is a tear or separation between the layers of tissue that make up the aorta. An aortic dissection usually causes severe **pain** in the abdomen, back, or chest, depending on the section of the aorta that is affected. Rupture of the aorta is a medical emergency requiring immediate surgery and medication.
- Aortic regurgitation. A weakened and enlarged aorta may allow some blood to leak back into the heart during each heartbeat; this condition is called aortic regurgitation. Aortic regurgitation occasionally causes shortness of breath during normal activity. In serious cases, it causes the left ventricle of the heart to enlarge and may eventually lead to heart failure.
- Mitral valve prolapse. Between 75 and 85% of children with Marfan have loose or "floppy" mitral valves, which are the valves that separate the chambers of the heart. When these valves do not cover the opening between the chambers completely, the condition is called mitral valve prolapse. Complications of mitral valve prolapse include **heart murmurs** and arrhythmias. In rare cases, mitral valve prolapse can cause sudden death.
- Infective endocarditis. Infective endocarditis is an infection of the endothelium, the tissue that lines the heart. In children with Marfan, it is the abnormal mitral valve that is most likely to become infected.
- Other complications. Some children with Marfan develop cystic disease of the lungs or recurrent spontaneous pneumothorax, which is a condition in which air accumulates in the space around the lungs. Many will also eventually develop emphysema.

Musculoskeletal abnormalities

Marfan syndrome causes an increase in the length of the child's bones, with decreased support from the ligaments that hold the bones together. As a result, the child

may develop various deformities of the skeleton or disorders related to the relative looseness of the ligaments.

Disorders of the spine

Children with Marfan syndrome also can experience spinal disorders, including:

- **Scoliosis**. Scoliosis, or curvature of the spine, is a disorder in which the vertebrae that make up the spine twist out of line from side to side into an S-shape or a spiral. It is caused by a combination of the rapid growth of children with Marfan, and the looseness of the ligaments that help the spine to keep its shape.
- Kyphosis. Kyphosis is an abnormal outward curvature of the spine at the back, sometimes called hunch back when it occurs in the upper back. Children with Marfan may develop kyphosis either in the upper (thoracic) spine or the lower (lumbar) spine.
- Spondylolisthesis. Spondylolisthesis is the medical term for a forward slippage of one vertebra on the one below it. It produces an ache or stiffness in the lower back.
- Dural ectasia. The dura is the tough, fibrous outermost membrane covering the brain and the spinal cord. The weak dura in a child with Marfan swells or bulges under the pressure of the spinal fluid. This swelling is called ectasia. In most cases, dural ectasia occurs in the lower spine, producing low back ache, a burning feeling, or **numbness** or weakness in the legs.

Disorders of the chest and lower body

Disorders of the chest and lower body of children with Marfan include:

- Pectus excavatum. Pectus excavatum is a malformation of the chest in which the child's breastbone, or sternum, is sunken inward. It can cause difficulties in breathing, especially if the heart, spine, and lung have been affected by Marfan. It also usually causes concerns about appearance.
- Pectus carinatum. In other children with Marfan, the sternum is pushed outward and narrowed. Although pectus carinatum does not cause breathing difficulties, it can cause embarassment about appearance. A few children with Marfan may have a pectus excavatum on one side of their chest and a pectus carinatum on the other.
- Foot disorders. Children with Marfan are more likely to develop pes planus (flat feet) or so-called "claw" or "hammer" toes than people in the general population. They are also more likely to suffer from chronic pain in their feet.
- Protrusio acetabulae. The acetabulum is the socket of the hip joint. In a child with Marfan, the acetabulum becomes deeper than normal during growth, for reasons that are not yet understood. Although protrusio acetabulae does not cause problems during childhood and **adolescence**, it can lead to a painful form of arthritis in adult life.

Disorders of the eyes and face

Although the visual problems that are related to Marfan syndrome are rarely life-threatening, they are important in that they may be the child's first indication of the disorder. Eye disorders related to the syndrome include the following:

- Myopia (nearsightedness). Most children with Marfan develop nearsightedness, usually in childhood.
- Ectopia lentis. Ectopia lentis is the medical term for dislocation of the lens of the eye. Between 65 and 75 percent of children with Marfan have dislocated lenses. This condition is an important indication for diagnosis of the syndrome because there are relatively few other disorders that produce it.
- Glaucoma. This condition is much more prevalent in children with Marfan syndrome than in the general population.
- Cataracts. Children with Marfan are more likely to develop cataracts, and to develop them much earlier in life, sometimes as early as 40 years of age.
- Retinal detachment. Children with Marfan are more vulnerable to this disorder because of the weakness of their connective tissues. Untreated retinal detachment can cause blindness. The danger of retinal detachment is an important reason for children to avoid contact **sports** or other activities that could cause a blow on the head or being knocked to the ground.
- Other facial problems. Children with Marfan sometimes develop dental problems related to crowding of the teeth caused by a high-arched palate and a narrow jaw.

Other disorders

Other disorders associated with Marfan syndrome include:

- Striae. Striae are stretch marks in the skin caused by rapid weight gain or growth; they frequently occur in pregnant women, for example. Children with Marfan often develop striae over the shoulders, hips, and lower back at an early age because of rapid bone growth. Although the child may be self-conscious about the striae, they are not a danger to health.
- Obstructive **sleep** apnea. Obstructive sleep apnea refers to partial obstruction of the airway during sleep, causing irregular breathing and sometimes snoring. In children with Marfan, obstructive sleep apnea is

caused by the unusual flexibility of the tissues lining the child's airway. This disturbed breathing pattern increases the risk of aortic dissection.

When to call the doctor

Prospective parents with a family history of Marfan syndrome should check with their doctor concerning genetic counseling. Also a doctor should be called if a child has symptoms suggestive of Marfan syndrome.

Diagnosis

Presently, there is no objective diagnostic test for Marfan syndrome, in part because the disorder does not produce any measurable biochemical changes in the child's blood or body fluids, or cellular changes that can be detected from a tissue sample. Although researchers in molecular biology are currently investigating the FBNI gene through a process called mutational analysis, it is presently not useful as a diagnostic test because there is evidence that there can be mutations in the fibrillin gene that do not produce Marfan. Similarly, there is no reliable prenatal test, although some physicians have used ultrasound to try to determine the length of fetal limbs in at-risk pregnancies.

The diagnosis is made by taking a family history and a thorough examination of the child's eyes, heart, and bone structure. The examination should include an echocardiogram taken by a cardiologist, a slit-lamp eye examination by an ophthalmologist, and a work-up of the child's spinal column by an orthopedic specialist. In terms of the cardiac examination, a standard electrocardiogram (EKG) is not sufficient for diagnosis; only the echocardiogram can detect possible enlargement of the aorta. The importance of the slit-lamp examination is that it allows the doctor to detect a dislocated lens, which is a significant indication of the syndrome.

The symptoms of Marfan syndrome in some children resemble the symptoms of homocystinuria, which is an inherited disorder marked by extremely high levels of homocystine in the child's blood and urine. This possibility can be excluded by a urine test.

In other cases, the diagnosis remains uncertain because of the mildness of the child's symptoms, the absence of a family history of the syndrome, and other variables. These borderline conditions are sometimes referred to as marfanoid syndromes.

Treatment

The treatment and management of Marfan is tailored to the specific symptoms of each child. Some children find that the syndrome has little impact on their overall lifestyle; others have found their lives centered on the disorder.

Cardiovascular system

After a child has been diagnosed with Marfan, he or she should be monitored with an echocardiogram every six months until it is clear that the aorta is not growing larger. After that, he or she should have an echocardiogram once a year. If the echocardiogram does not allow the physician to visualize all portions of the aorta, CT (**computed tomography**) or MRI (**magnetic resonance imaging**) may be used. In cases involving a possible aortic dissection, the child may be given a TEE (transesophageal echocardiogram).

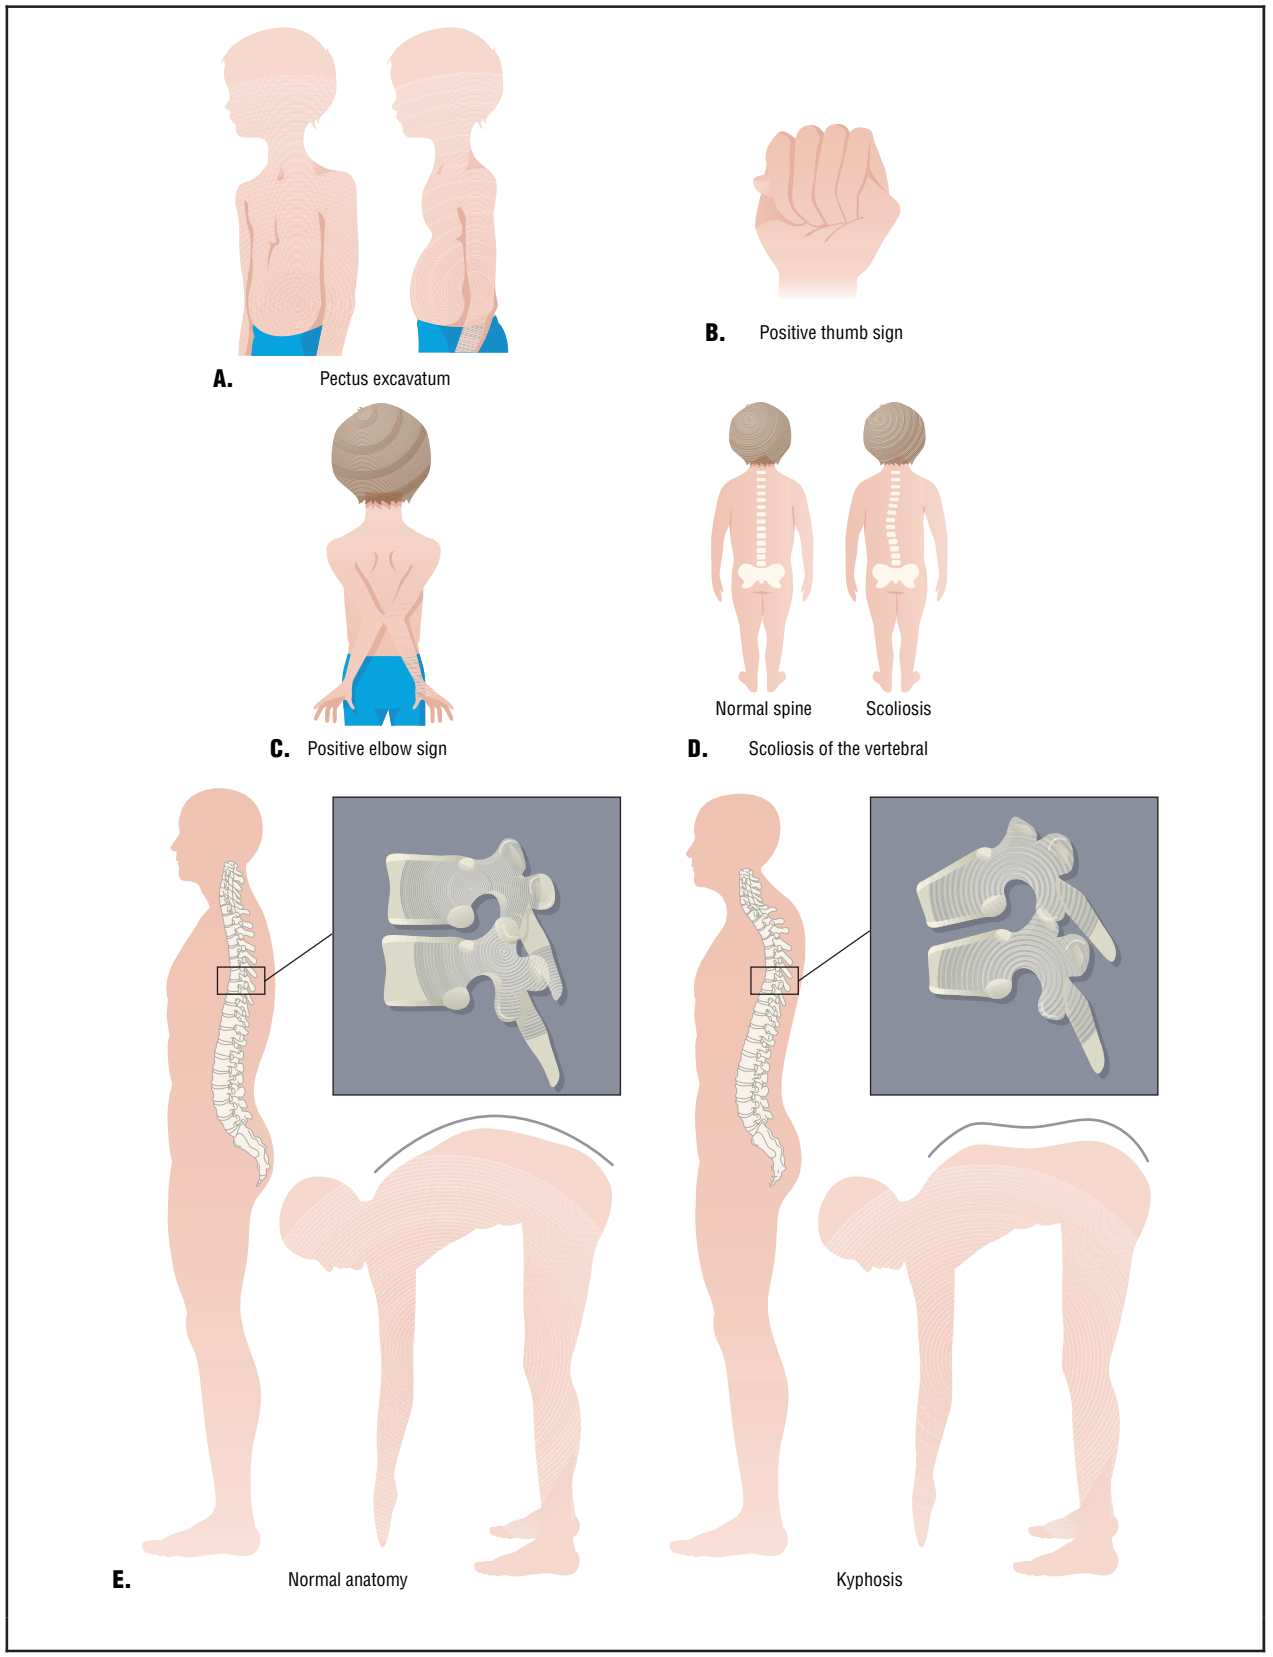
Medications. A child with Marfan may be given drugs called beta-blockers to slow down the rate of aortic enlargement and decrease the risk of dissection by lowering the blood pressure and decreasing the forcefulness of the heartbeat. The most commonly used beta-blockers in chidren with Marfan are propranolol (Inderal) and atenolol (Tenormin). Children who are allergic to beta-blockers may be given a calcium blocker such as verapamil.

Because children with Marfan are at increased risk for infective endocarditis, they must take a prophylactic dose of an antibiotic before having dental work or minor surgery, as these procedures may allow bacteria to enter the bloodstream. Penicillin and amoxicillin are the **antibiotics** most often used.

Surgical treatment. Surgery may be necessary if the width of the child's aorta increases rapidly or reaches a critical size (about 2 inches [5 cm]). The most common surgical treatment involves replacing the child's aortic valve and several inches of the aorta itself with a composite graft, which is a prosthetic heart valve sewn into one end of a Dacron tube. This surgery has been performed widely since about 1985; most children who have had a composite graft have not needed additional surgery. Children who have had a valve replaced must take an anticoagulant medication, usually warfarin (Coumadin), in order to minimize the possibility of a clot forming on the prosthetic valve.

Musculoskeletal system

Children diagnosed with Marfan should be checked for scoliosis by their pediatricians at each annual physical examination. The doctor simply asks the child to bend forward while the back is examined for changes in the curvature. In addition, the child's spine should be x rayed in order to measure the extent of scoliosis or kyphosis. The curve is measured in degrees by the angle between the vertebrae as seen on the x ray. Curves of 20 degrees or less are not likely to become worse. Curves between 20 and 40



Five clinical signs of Marfan syndrome: (left to right) pectus excavatum, positive thumb sign, positive elbow sign, normal spine compared with scoliosis, normal anatomy compared with kyphosis. *(Illustration by Argosy, Inc.)*

degrees are likely to increase in children or adolescents. Curves of 40 degrees or more are highly likely to worsen, even in an adult, because the spine is so badly imbalanced that the force of gravity will increase the curvature.

Scoliosis between 20 and 40 degrees in children is usually treated with a back brace. The child must wear this appliance about 23 hours a day until growth is complete. If the spinal curvature increases to 40 or 50 degrees, the child may require surgery in order to prevent lung problems, back pain, and further deformity. Surgical treatment of scoliosis involves straightening the spine with metal rods and fusing the vertebrae in the straightened position.

Spondylolisthesis is treated with a brace in mild cases. If the slippage is more than 30 degrees, the slipped vertebra may require surgical realignment.

Dural ectasia can be distinguished from other causes of back pain on an MRI. Mild cases are usually not treated. Medication or spinal shunting to remove some of the spinal fluid are used to treat severe cases.

Pectus excavatum and pectus carinatum can be treated by surgery. In pectus excavatum, the deformed breastbone and ribs are raised and straightened by a metal bar. After four to six months, the bar is removed in an outpatient procedure.

Protrusio acetabulae may require artificial hip joint surgery in adult life, if the arthritic pains are severe.

Pain in the feet or limbs is usually treated with a mild analgesic such as **acetaminophen**. Children with Marfan should consider wearing shoes with low heels, special cushions, or orthotic inserts. Foot surgery is rarely necessary.

Visual and dental concerns

Children with Marfan should have a thorough eye examination, including a slit-lamp examination, to test for dislocation of the lens as well as nearsightedness. Dislocation can be treated by a combination of special glasses and daily use of one percent atropine sulfate ophthalmic drops, or by surgery.

Because children with Marfan are at increased risk of glaucoma, they should have the fluid pressure inside the eye measured every year as part of an eye examination. Glaucoma can be treated with medications or with surgery.

Cataracts are treated with increasing success by implant surgery. It is important, however, to seek treatment at medical centers with eye surgeons familiar with the possible complications of cataract surgery in children with Marfan syndrome.

All children with Marfan should be taught to recognize the signs of retinal detachment (sudden blurring of vision in one eye becoming progressively worse without pain or redness) and ask their parents to seek professional help immediately.

Children with Marfan should be evaluated by their dentist at each checkup for crowding of the teeth and possible misalignment and referred to an orthodontist if necessary.

Athletic activities and occupational choice

Children with Marfan should avoid sports or occupations that require heavy weight lifting, rough physical contact, or rapid changes in atmospheric pressure (e.g., scuba diving). Weight lifting increases blood pressure, which in turn may enlarge the aorta. Rough physical contact may cause retinal detachment. Sudden changes in air pressure may produce pneumothorax. Regular noncompetitive physical **exercise**, however, is beneficial for children with Marfan. Good choices include brisk walking, shooting baskets, and slow-paced tennis.

Social and lifestyle issues

Smoking is particularly harmful for children and adolescents with Marfan because it increases their risk of emphysema.

KEY TERMS

Arachnodactyly—A condition characterized by abnormally long and slender fingers and toes.

Ectopia lentis—Dislocation of the lens of the eye. It is one of the most important single indicators in diagnosing Marfan syndrome.

Fibrillin—A protein that is an important part of the structure of the body's connective tissue. In Marfan's syndrome, the gene responsible for fibrillin has mutated, causing the body to produce a defective protein.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Kyphosis—An extreme, abnormal outward curvature of the spine, with a hump at the upper back.

Pectus carinatum—An abnormality of the chest in which the sternum (breastbone) is pushed outward. It is sometimes called "pigeon breast."

Pectus excavatum—An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called "funnel chest."

Scoliosis—An abnormal, side-to-side curvature of the spine.

Children and adolescents with Marfan may benefit from supportive counseling regarding appearance, particularly if their symptoms are severe enough to cause them to withdraw from social activities.

Prognosis

The prognosis for children with Marfan has improved markedly in recent years. By 1995, the life expectancy of people with the syndrome increased to 72 years, up from 48 years in 1972. This dramatic improvement is attributed to new surgical techniques, improved diagnosis, and new techniques of medical treatment.

The most important single factor in improving the child's prognosis is early diagnosis. The earlier that a child can benefit from the new techniques and lifestyle modifications, the more likely he or she is to have a longer life expectancy.

Prevention

Marfan syndrome that occurs because of spontaneous new mutations (15% to 25% of the cases) cannot be prevented. However, for prospective parents with a family history of Marfan syndrome, genetic counseling is recommended. Also, older fathers are more likely to have new mutations appear in chromosome 15.

Parental concerns

Families may wish to seek counseling regarding the effects of the syndrome on relationships within the family. Many people respond with guilt, **fear**, or blame when a genetic disorder is diagnosed in the family, or they may overprotect the affected member. Support groups are often good sources of information about Marfan; they can offer helpful suggestions about living with it as well as emotional support.

Massage therapy

Definition

Massage therapy is the scientific manipulation of the soft tissues of the body, consisting primarily of manual (hands-on) techniques such as applying fixed or movable pressure, holding, and moving muscles and body tissues.

Purpose

Generally, massage is delivered to improve the flow of blood and lymph (fluid in lymph glands, part of immune system), to reduce muscular tension or flaccidity, to affect the nervous system through stimulation or sedation, and to enhance tissue healing. Therapeutic massage may be recommended for children and adults to deliver benefits such as the following:

- reducing muscle tension and stiffness
- relieving muscle spasms
- increasing joint and limb flexibility and range of motion
- increasing ease and efficiency of movement
- relieving points of tension and overall stress; inducing relaxation
- promoting deeper and easier breathing

- improving blood circulation and movement of lymph
- relieving tension-related headaches and eyestrain
- promoting faster healing of soft tissue injuries, such as pulled muscles and sprained ligaments
- reducing **pain** and swelling related to injuries
- reducing the formation of scar tissue following soft tissue injuries
- enhancing health and nourishment of skin
- improving posture by changing tension patterns that affect posture
- reducing emotional or physical stress and reducing **anxiety**
- promoting feelings of well-being
- increasing awareness of the mind-body connection and improving mental awareness and alertness generally

Massage therapy may also be recommended for its documented clinical benefits such as improving pulmonary function in young **asthma** patients, reducing psychoemotional distress in individuals who suffer from chronic inflammatory bowel disease, helping with weight gain, improving motor development in premature infants, and enhancing immune system functioning.

Description

Massage therapy is one of the oldest healthcare practices known. References to massage are found in ancient Chinese medical texts written more than 4,000 years ago. Massage has been advocated in Western healthcare practices since the time of Hippocrates, the "father of medicine."

Massage therapy is the scientific manipulation of the soft tissues of the body for the purpose of normalizing those tissues and consists of a group of manual techniques that include applying fixed or movable pressure, holding, and/or causing movement to parts of the body. While massage therapy is applied primarily with the hands, sometimes the forearms or elbows are used. These techniques affect the muscular, skeletal, circulatory, lymphatic, nervous, and other systems of the body. The basic philosophy of massage therapy embraces the concept of *vis Medicatrix naturae*, which means "aiding the ability of the body to heal itself."

Touch is the fundamental medium of massage therapy. While massage can be described in terms of the type of techniques performed, touch is not used solely in a mechanistic way in massage therapy. Because massage usually involves applying touch with some degree of pressure and movement, the massage therapist must use touch with sensitivity in order to determine the optimal amount of pressure to use for each person. For example, using too much pressure may cause the body to tense up, while using too little may not have enough effect. Touch used with sensitivity also allows the massage therapist to receive useful information via his or her hands about the individual's body, such as locating areas of muscle tension and other soft tissue problems. Because touch is also a form of communication, sensitive touch can convey a sense of caring to the person receiving massage, enhancing the individual's sense of self and well being.

In practice, many massage therapists use more than one technique or method in their work and sometimes combine several. Effective massage therapists ascertain each person's needs and then use the techniques that will best meet those needs.

Swedish massage is the most commonly used form of massage. It uses a system of long gliding strokes, kneading, and friction techniques on the more superficial layers of muscles, generally in the direction of blood flow toward the heart, and sometimes combined with active and passive movements of the joints. It is used to promote general relaxation, improve circulation and range of motion, and relieve muscle tension.

Deep tissue massage is used to release chronic patterns of muscular tension using slow strokes, direct pressure, or friction directed across the grain of the muscles. It is applied with greater pressure and to deeper layers of muscle than Swedish, which is why it is called deep tissue and is effective for chronic muscular tension.

Sports massage uses techniques that are similar to Swedish and deep tissue but are specially adapted to deal with the effects of athletic performance on the body and the needs of athletes regarding training, performing, and recovery from injury.

Neuromuscular massage is a form of deep massage that is applied to individual muscles. It is used primarily to release trigger points (intense knots of muscle tension that refer pain to other parts of the body) and also to increase blood flow. It is often used to reduce pain. Trigger point massage and myotherapy are similar forms.

Acupressure applies finger or thumb pressure to specific points located on the energy pathways or "meridians" in order to release blocked energy along these meridians that may be causing physical discomfort. The rebalance of energy flow releases tension and restores function of organs and muscles in the body. Shiatsu is a Japanese form of acupressure that applies these principles.

Massage therapy sessions can be at home or in a professional office. Most sessions are one hour. Frequency of massage sessions can vary widely as needed based on

A young boy receives a massage. *(© Owen Franken/Corbis.)*

the condition being treated. The cost of massage therapy varies according to geographic location, experience of the massage therapist, and length of the massage. In the United States, as of 2004, the average range is from $35 to $60 for a one-hour session.

The first appointment generally begins with information gathering, such as the reason for getting massage therapy, physical condition and medical history, and other areas. The client is asked to remove clothing to one's level of comfort. Undressing takes place in private, and a sheet or towel is provided for draping. The massage therapist will undrape only the part of the body being massaged. The individual's modesty is respected at all times. The massage therapist may use an oil or cream, which is quickly absorbed into the skin.

Insurance coverage for massage therapy varies widely. There tends to be greater coverage in states that license massage therapy. In most cases, a physician's prescription for massage therapy is needed. Once massage therapy is prescribed, authorization from the insurer may be needed if coverage is not clearly spelled out in one's policy or plan.

Massage therapy may be recommended for children to help relieve conditions such as **allergies**, anxiety and stress, arthritis, asthma and **bronchitis**, joint or limb injuries, post-surgical muscle rehabilitation, chronic and temporary pain, circulatory problems, depression, digestive disorders, tension headaches, **sleep** problems or insomnia, myofascial pain, **sports injuries**, and eating problems associated with temporomandibular joint dysfunction.

Precautions

Massage is comparatively safe; however, it should not be used if the child has one of the following conditions.

- advanced heart disease
- hypertension (high blood pressure)
- phlebitis
- thrombosis
- embolism
- kidney failure

If the child has **cancer**, massage is not advisable if the cancer is the kind that can spread to other organs (metastatic cancer) or if it involves tissue damage due to

chemotherapy or other treatment. Massage may also not be advisable if the child has any of the following conditions.

- a cold
- an infectious disease
- a contagious skin conditions
- an acute inflammation
- an infected injuries
- an unhealed fractures
- dislocations
- is postoperative with a condition in which pain and muscular splinting are increased
- has frostbite
- has large hernias
- has torn ligaments
- has any condition prone to hemorrhage
- has a psychosis
- has any other psychological state that may impair communication or perception

Massage should not be used locally on affected areas (i.e., avoid using massage on the specific areas of the body that are affected by the condition) for the following conditions: eczema, goiter (thyroid dysfunction), and open skin lesions. Massage may be used on the areas of the body that are not affected by these conditions. The decision to use massage must be based on whether it may cause harm. A physician's recommendation is appropriate before a child with any health condition receives massage therapy.

Preparation

Going for a massage requires little in the way of preparation. Generally, one should be clean and should not eat just before a massage. Massage therapists generally work by appointment and usually provide information about how to prepare for an appointment. To receive the most benefit from a massage, parents should give the therapist accurate health information about the child and report discomfort of any kind (whether it is from the massage itself or due to the room temperature or any other distractions). The child can be encouraged to be as receptive to the process as possible.

Aftercare

There are no special recommendations for after a massage. A period of quiet activity or rest following the massage helps maintain full benefits from the procedure.

KEY TERMS

Lymph—Clear, slightly yellow fluid carried by a network of thin tubes to every part of the body. Cells that fight infection are carried in the lymph.

Manipulation—Moving muscles or connective tissue to enhance function, ease tension, and reduce pain in those tissues as well as other beneficial effects.

Mind-body connection—Rather than relying on an understanding of the term "psychosomatic," mind-body medicine acknowledges the influence of thinking and the cognitive process on the behavior of chemicals in the body, involving the mind in both creating the conditions for disease and helping to heal the effects of disease.

Psychoses—Mental illness that interferes with an individual's ability to manage life's challenges and everyday activities. The impairment of cognitive ability that distorts reality.

Risks

Massage therapy does not have notable side effects. Rather than feeling too relaxed or too mentally unfocused after a massage, a child may be both more relaxed and more alert.

Parental concerns

Parents who may not have experienced therapeutic massage themselves or who have doubts about its effectiveness may be interested in the results of research studies, particularly those conducted on groups of children. Well designed studies have documented the benefits of massage therapy for the treatment of acute and chronic pain, acute and chronic inflammation, chronic lymphedema, **nausea**, muscle spasm, various soft tissue dysfunctions, anxiety, depression, insomnia, and psychoemotional stress, which may aggravate mental illness.

Premature infants treated with daily massage therapy gain more weight and have shorter hospital stays than infants who are not massaged. A study of 40 low-birth-weight babies found that the 20 massaged babies had a 47 percent greater weight gain per day and stayed in the hospital an average of six fewer days than 20 infants who did not receive massage, resulting in a cost savings of approximately $3,000 per infant. Cocaine-exposed, preterm infants given massage three times daily for a 10-day period showed significant improvement. Results indicated that massaged infants had fewer postnatal complications and exhibited fewer stress behaviors

during the 10-day period, had a 28 percent greater daily weight gain, and demonstrated more mature motor behaviors.

A study comparing 52 hospitalized depressed and adjustment disorder children and adolescents with a control group that viewed relaxation videotapes, found massage therapy subjects were less depressed and anxious and had lower saliva cortisol levels (an indicator of less depression).

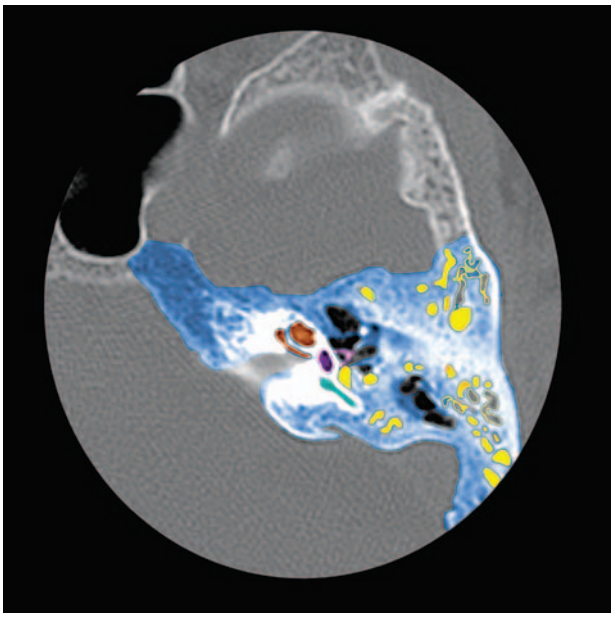
Mastoiditis

Definition

Mastoiditis is a bacterial infection of the air cells in the mastoid bone of the skull. Mastoiditis most commonly affects children. Before the use of **antibiotics**, mastoiditis was one of the leading causes of death in children. As of the early 2000s, it is a relatively uncommon and much less dangerous disorder.

Description

Mastoiditis is usually a consequence of a middle ear infection called acute **otitis media** (AOM). The infection may spread from the ear to the mastoid bone of the skull, which is the bony bump off the base of the skull, located just behind the ears slightly above the level of the earlobe. The mastoid bone is composed of air cells that are in communication with the middle ear. If the air cells fill with infected materials, the mastoid honeycomb-like structure may deteriorate. Mastoiditis has been classified into two types, acute and subacute. Acute or classic mastoiditis refers to acute disease following AOM and involves the development of an abscess behind the ear. Subacute mastoiditis refers to a more chronic disease, often following partial treatment of AOM with antibiotics.



Computed tomography scan (CT scan) showing inflammation and fluid within the air spaces (represented in yellow) of the mastoid. *(© Neil Borden/Photo Researchers, Inc.)*

Demographics

In the United States and first world countries, the incidence of mastoiditis is 0.004 percent. Developing countries have a higher incidence of mastoiditis, presumably resulting from untreated otitis media. The highest incidence occurs in infants aged six to 13 months. As of 2004 reports indicated that acute mastoiditis is on the increase.

Causes and symptoms

The bacteria that cause mastoiditis are those most commonly associated with AOM. They include the following:

KEY TERMS

Abscess—A localized collection of pus in the skin or other body tissue caused by infection.

Audiogram—A chart or graph of the results of a hearing test conducted with audiographic equipment. The chart reflects the softest (lowest volume) sounds that can be heard at various frequencies or pitches.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Gram-negative—Refers tof bacteria that have a cell wall composed of a thin layer of peptidoglycan surrounded by an outer membrane made of polysaccharides and proteins. They take on the red color of the counterstain used in the Gram stain procedure.

Mastoid bone—The prominent bone behind the ear that projects from the temporal bone of the skull.

Mastoiditis—An inflammation of the bone behind the ear (the mastoid bone) caused by an infection spreading from the middle ear to the cavity in the mastoid bone.

Myringotomy—A surgical procedure in which an incision is made in the ear drum to allow fluid or pus to escape from the middle ear.

Otitis—Inflammation of the ear, which may be marked by pain, fever, abnormalities of hearing, hearing loss, noise in the ears, and dizzy spells.

Otoscope—A hand-held instrument with a tiny light and a funnel-shaped attachment called an ear speculum, which is used to examine the ear canal and eardrum.

- *Streptococcus pneumoniae*
- *Haemophilus influenzae*
- *Moraxella catarrhalis*
- *Staphylococcus aureus*
- *Pseuodomonas aeruginosa*
- *Klebsiella*
- *Escherichia coli*
- *Proteus*
- *Prevotella*
- *Fusobacterium*
- *Porphyromonas*
- *Bacteroides*

Gram-negative organisms are found more frequently in chronic mastoiditis, and in young infants, which may be due to prolonged antibiotic therapy.

The main symptoms of mastoiditis are increasing earache, **fever**, and the development of redness and swelling behind the ear. The eardrum is inflamed with swelling of the ear canal wall. Mastoiditis typically develops over the few days following an ear infection. This interval is sometimes more prolonged particularly if the initial infection was treated with antibiotics but not completely eliminated (subacute mastoiditis).

When to call the doctor

Children will usually complain of severe **pain** in the affected ear, which may become swollen. Parents should contact their healthcare provider if a child's symptoms indicate mastoiditis. Appointments with the healthcare provider should also be made if a known ear infection does not respond to treatment or is followed by new symptoms.

Diagnosis

In addition to a complete medical history and physical examination, the physician inspects using an otoscope the outer ears and eardrums of the child. Diagnosis is established by clinical tests showing bacterial growth in cultures of ear drainage. Pus taken from the ear or sucked out of the abscess with a needle is sent to a laboratory so that the infecting bacteria can be identified. Imaging studies are used to confirm diagnosis. X rays are considered unreliable but can show clouding of the mastoid air cells. A head CT scan or CT of the ear may show a fluid-filled middle ear and an abnormality in the mastoid bone. Audiograms can also be performed to assess hearing loss.

Treatment

Antibiotics are typically the first course of action in treating mastoiditis. If these do not work, a tube can be inserted to drain off pus or fluid. An incision can be made with the same end purpose. Surgery may also be a recourse, to remove the affected portion of the mastoid bone, to remove a cyst should one be present, and do any further repair required.

Prognosis

Mastoiditis is curable with treatment but may be hard to treat and may recur. Acute mastoiditis usually recovers completely after treatment with no long term damage to hearing and no increased risk of further ear trouble later in life if complications have not occurred.

Prevention

Rapid and complete treatment of ear infections significantly lowers the risk of developing mastoiditis.

Parental concerns

Ear pain is a common complaint from children, but parents should suspect serious ear infection if the ear area is red and swollen. Mastoiditis often causes the ear to be sticking out at an angle. Parents should be aware that ear infections are very common in children, especially those younger than two years of age.

Masturbation

Definition

Masturbation is the erotic stimulation of one's own genitals for pleasure.

Description

Masturbation is the self-stimulation of the sex organs, most often to the point of orgasm. Sixty to ninety percent of adolescent boys and 40 percent of girls masturbate. Although people's attitudes about masturbation differ widely, there is no evidence that masturbation is in any way physically, psychologically, or emotionally harmful. For many young people, masturbation is an opportunity for private sexual exploration before deciding to engage is sexual activity with another person. It is also considered the safest form of sex in the prevention of **sexually transmitted diseases**, including human **immunodeficiency** virus (HIV).

Masturbation allows a healthy way to express and explore one's sexuality and to release sexual tension without the associated risks of sexual intercourse, according to many healthcare providers. They also agree that masturbation is a natural, normal, and healthy way of self-exploration and sexual expression.

It is increasingly recognized among mental health professionals that masturbation can relieve depression and lead to a higher sense of self worth. Masturbation can also be particularly useful in relationships in which one partner wants more sexual activity than the other, in which case masturbation provides a balancing effect.

Many conservative religious groups teach that masturbation is a sinful practice. The Catechism of the Catholic Church, paragraph 2352, lists masturbation as

one of the "Offenses against Chastity" and calls it "an intrinsically and gravely disordered action" because "use of the sexual faculty, for whatever reason, outside of marriage is essentially contrary to its purpose." It goes on to caution that extenuating factors could exist, such as immaturity, habitual, or psychological problems.

The discussion of masturbation has been controversial for hundreds of years and still is to some extent in the early 2000s, more so in the United States than Europe and other Western nations. Children caught by their parents masturbating are often punished and told it is a sin. In fact, there is no mention of the word "masturbation" or "self-pleasure" in the Bible. Children are also often told it is wrong or unhealthy, myths that are not supported by medical research.

In the early 2000s, masturbation has become more accepted for both males and females yet there is still a stigma about discussing it openly. College courses on human sexuality include materials and discussion of masturbation, and many parenting manuals deal with ways to affirm a child's self-pleasing habits rather than degrading or punishing the child. Many sex therapists believe that to have better sexual experiences with a partner, an individual needs to learn to masturbate first since it is the best way to learn what one likes and does not like in his or her sex acts.

Most people think of masturbation as a very personal and private act involving using only the hands to manipulate the genitals. Ways of masturbating common to both males and females include pressing or rubbing the genital area against an object, inserting a finger or other object into the anus, and stimulating the penis or clitoris with electric vibrators, which can also be inserted into the anus or vagina. Some males and females enjoy touching, rubbing, or pinching their nipples while masturbating, and both sexes also sometimes use lubricants, such as hand lotion, to improve the sensation.

Masturbation in males

The most common form of masturbation, especially in circumcised males, is to wrap one or both hands or several fingers and thumb around the erect penis and stroke it up and down until ejaculation. This action results in no direct stimulation of the head of the penis and ejaculation is achieved almost entirely from stimulation of the penis shaft and its contact against the underside of the head of the penis only. In uncircumcised males, it is most common to grip the skin of the penis and move it up and down, resulting in repeated sliding of the foreskin back and forth over the head of the penis until orgasm is reached.

Another common method is to rub the erect penis against a smooth surface, such as a mattress or pillow until ejaculation is reached. Less common masturbation techniques include use of an artificial vagina or other "sex toy."

In 2003, an Australian research team led by Graham Giles of the **Cancer** Council published a medical study that concluded frequent masturbation by males may help prevent the development of prostate cancer and that it would be more helpful than ejaculation through sexual intercourse because intercourse can transmit diseases which can increase the risk of cancer instead.

Masturbation in females

Females most commonly masturbate by stroking or rubbing the vulva, especially the clitoris, with hands and fingers until orgasm is reached. Females also may use running water to stimulate the vulva or insert fingers or a hard object into the vagina. Many women are only able to achieve orgasm through masturbation. Some women can experience sexual stimulation simply by crossing their legs tightly.

One enduring myth is that female masturbation can lead to decreased sensitivity of the clitoris resulting in a decrease in the frequency and intensity of female orgasm. However, the evidence points the other way and suggests that women who have engaged in masturbation have a better understanding of their own genital anatomy and can guide their sexual partners in appreciating the specific sexual acts that contribute to female orgasm.

Infancy and toddlerhood

Some and probably all children are capable of what appear to be sexual responses even in earliest years. Most infants probably explore and fondle their own genitals, but not in a goal directed way. Masturbation by infants is also referred to as gratification disorder or infantile masturbation. It is sometimes mistakenly identified by physicians for epilepsy. A study published in the March 2004 issue of *Archives of Disease in Childhood* reported the median age at first symptoms was ten and one-half months, with an age range of three months to five years and five months. The median frequency was seven times a week and the median length was two and one-half minutes. Masturbation in infants is difficult to recognize because it often does not involve manual stimulation of the genitals at all, the study reported.

Preschool

Occasional masturbation is a normal behavior in preschool-age children and most commonly occurs

"when a child is sleepy, bored, watching television, or under stress," according to a 2002 advisory in the annual journal *Clinical Reference Systems*. The advisory states that up to one third of preschool-age children discover masturbation while exploring their bodies. They often continue to masturbate simply because it feels good. Some children masturbate frequently because they are unhappy or under stress or are reacting to punishment or pressure to stop masturbation completely. Once a child discovers masturbation, he or she seldom stops doing it completely, according to the advisory. It is not abnormal or excessive unless it is deliberately done in public places after age five or six, when most children learn discretion and masturbate only in private.

"It is impossible to eliminate masturbation in a child. Accept the fact you're your child has learned about it and enjoys it," the advisory states. "The only thing you can control is where he or she does it. A reasonable goal is to permit it in the bedroom and bathroom only. . . . If you completely ignore the masturbation, no matter where it's done, your child will think he or she can do it freely in any setting."

School age

As a child grows, masturbation to orgasm becomes more and more likely. Researchers and experts disagree on how many children masturbate before **adolescence**. Most children seem to have the biological capacity to derive pleasure from self-stimulation. Masturbation becomes almost universal at **puberty** in response to normal surges in sex hormones and sexual drive. Most studies suggest that approximately 94 percent of teenage males and about 70 percent of teenage girls admit they masturbate. The actual number of youngsters who masturbate is believed to be higher, since the use of the word "admit" in surveys can imply wrong-doing.

Most males learn to masturbate during adolescence; fewer females do. Some sex therapists believe that girls who do not masturbate miss an important step in their sexual development, since masturbation provides an opportunity to learn how one's body responds to erotic stimulation. Because boys usually masturbate and girls often do not, boys are more likely to learn a sexuality that is genitally focused. Boys learn their sexuality in a context with other boys who bestow a sense of esteem on them. Boys often masturbate with another boy or group of boys. This in itself does not imply **homosexuality** or **bisexuality**. Girls who masturbate almost always discover it alone. Girls generally talk among themselves about masturbation but do not perform with other girls or in front of others. There is no peer support for sexual exploration or reward for teaching orgasm. Boys emerge from adolescence both sexually advantaged and disadvantaged. They are practiced at having orgasms and comfortable with the physical aspects of sex. They are less adept at handling emotional relationships with girls.

Common problems

There is no credible scientific or medical evidence that manual masturbation is damaging to either one's physical or mental health. The exception to this includes some cases of Peyronie's disease in which aggressive manipulation, such as inversion during adolescence, and bending or twisting of the penis, results in a localized benign tumor, distorting the erectile appearance.

Contrary to popular myth, masturbation does not make the palms hairy or cause blindness or genital shrinkage. It has also been alleged that masturbation can reduce sensitivity in the male penis. This statement is also false. The only side-effects recorded are that repeated masturbation may result in tiredness or soreness, which tend to make repeated masturbation self-limiting in any case and that the volume of ejaculate is temporarily reduced in men after multiple ejaculations until normal semen volume is regained in a day or so. Also, people from a socially conservative or religious background may experience feelings of guilt during or after masturbation.

Parental concerns

Studies show that kids who feel they can talk with their parents about masturbation and other sexual issues—because their moms and dads speak openly and listen carefully to them—are less likely to engage in high-risk behavior as teens than kids who do not feel they can talk with their parents about the subject. Parents should explore their own feelings about sex and masturbation. Parents who are uncomfortable with the subject should read books or articles on masturbation and discuss their feelings with a trusted friend, relative, physician, or clergy member. The more parents examine the subject, the more confident they will feel discussing it. If a child has not started asking questions about masturbation, parents should look for a good opportunity to mention it.

While children need to know the biological facts about masturbation, they also need to understand that sexual relationships involve caring, concern, and responsibility. If parents discuss with their children the emotional aspect of a sexual relationships, the children will be better informed to make decisions later on and to resist **peer pressure**.

KEY TERMS

Circumcision—A surgical procedure, usually with religious or cultural significance, where the prepuce or skin covering the tip of the penis on a boy, or the clitoris on a girl, is cut away.

Clitoris—The most sensitive area of the external genitals. Stimulation of the clitoris causes most women to reach orgasm.

Ejaculation—The process by which semen (made up in part of prostatic fluid) is ejected by the erect penis.

Genital—Refers to the sexual or reproductive organs that are visible outside the body.

Infantile masturbation—The masturbation by infants, also called gratification disorder.

Orgasm—Another word for sexual climax. In the male, orgasm is usually accompanied by ejaculation but may be experienced as distinct from ejaculation.

Peyronie's disease—A disease of unknown origin which causes a hardening of the corpora cavernosa, the erectile tissue of the penis. The penis may become misshapen and/or curved as a result and erections are painful.

Vulva—The external genital organs of a woman, including the outer and inner lips, clitoris, and opening of the vagina.

When to call the doctor

In the vast majority of cases masturbation is considered to be a normal activity but the following scenarios may suggest that a problem exists:

- If a child masturbates frequently and appears to be relating to adults in a sexually precocious manner.
- If masturbation becomes a compulsive activity and the person is driven to do it at certain times each day and it almost becomes a ritualistic activity, at the exclusion of almost all else.
- If masturbation takes place in a public place.

Maxillofacial trauma

Definition

Maxillofacial trauma refers to any injury to the face or jaw caused by physical force, the presence of **foreign objects**, animal or human **bites**, or **burns**.

Description

Maxillofacial trauma includes injuries to any of the bony or fleshy structures of the face. Any part of the face may be affected. Teeth may be knocked out or loosened.

The eyes and their muscles, nerves, and blood vessels may be injured as well as the eye socket (orbit), which can be fractured by a forceful blow. The lower jaw (mandible) may be dislocated by force. Although anchored by strong muscles for chewing, the jaw is unstable in comparison with other bones and is easily dislocated from the temporomandibular joints that attach it to the skull. A fractured nose or jaw may affect the ability to breathe or eat. Any maxillofacial injury may also prevent the passage of air or be severe enough to cause a **concussion** or more serious brain damage.

Athletes are particularly at risk of maxillofacial injuries; one researcher estimates that 10.4 percent of all **fractures** of the facial bones are related to **sports**. Boxers suffer repeated blows to the face and occasional knockouts (traumatic brain injury). Football, basketball, hockey, and soccer players, and many other athletes are at risk for milder forms of brain injury called concussions. Burns to the face are also categorized as maxillofacial trauma.

Demographics

About 3 million injuries to the face and jaw occur in the United States each year. Falls account for 78 percent of facial injuries in preschoolers and 47 percent of such injuries in children between the ages of six and 15. In older adolescents and adults, violent crime or other personal assaults account for almost 50 percent of facial injuries, with automobile accidents accounting for 29 percent and sports-related accidents for another 11 percent. One researcher estimates that about 2 percent of all children or adolescents who participate in sports eventually suffer a facial injury severe enough to require medical attention. Patients between the ages of 17 and 30 are more likely to suffer facial injuries from gunshot **wounds**, while older adults are more likely to be injured by attacks with blunt objects. About 10 percent of facial injuries in young children are caused by parental abuse.

Children who grow up on farms are at significant risk for injury by animals. Of one group of 96 children who required inpatient treatment for head or facial injuries, 39 had been kicked or bitten by horses or other farm animals. Another 37 children had been injured by farm machinery, most commonly a tractor.

Causes and symptoms

Causes

Automobile accidents are a major cause of maxillofacial trauma, as well as participation in sports, fights, and other violent acts. Athletes may sustain facial injuries from colliding with other players (as in football or rugby), from direct contact with equipment (baseball bats, hockey sticks, goal posts, parallel bars, etc.), or from contact with other objects related to the sport (baseballs, hockey pucks, lacrosse balls, skis, etc.) People most at risk are athletes, anyone who drives a vehicle or rides in one, and those who live on farms, do dangerous work, or engage in aggressive types of behavior.

Animals are a common cause of maxillofacial trauma. Horses and other large farm animals can cause severe injury to the face and jaw from kicks or bites. In addition, some large pet dogs can bite hard enough to fracture a small child's facial bones.

Domestic violence and abuse is also a common cause of facial injuries in children and adolescents.

Symptoms

The major symptoms of most facial injuries are **pain**, swelling, bleeding, and bruising, although a fractured jaw also prevents the person from working his jaw properly. Symptoms of a fractured nose include black eyes and possible blockage of the airway due to swelling and bleeding.

Symptoms of eye injury or orbital fracture can include blurred or double vision, decreased mobility of the eye, and **numbness** in the area of the eye. In severe injuries there can be temporary or permanent loss of vision.

Burn symptoms include pain, redness, and possibly blisters, **fever**, and **headache**. Extensive burns can cause the victim to go into shock. In that situation, the person will have low blood pressure and a rapid pulse.

Symptoms of traumatic brain injury include problems with thinking, memory, and judgment as well as mood swings and difficulty with coordination and balance. These symptoms may linger for weeks or months and in severe cases can be permanent. Double vision for months after the injury is not uncommon.

When to call the doctor

Parents should call 911 or take their child to an emergency room at once in the event of a facial injury. The following describe emergency situations that require immediate medical care:

- The child or adolescent is bleeding profusely.
- The patient is having difficulty breathing normally.
- The child or adolescent has lost consciousness or is comatose.
- The patient is nauseated and **vomiting**.

- There are penetrating injuries of the skin, ear, or eye.
- The injury involves a gun, blunt instrument, or animal or human bites.
- The child is seeing double, has other visual disturbances, or staggers when trying to walk.
- Blood or watery fluid is leaking from the child's nose or ears.

Diagnosis

Maxillofacial trauma is often diagnosed and treated by specialists in emergency medicine. About 50 percent of patients with facial injuries have suffered trauma to other organ systems or other parts of the body, however, and may need care from specialists in ophthalmology, plastic surgery, otolaryngology, trauma surgery, oral surgery, and psychiatry as well as from doctors with specialized training in emergency medicine. Injuries to the face and jaw area require special attention because they involve the senses of sight, hearing, taste, and smell as well as such vital functions as breathing. From a psychological perspective, maxillofacial trauma can be additionally upsetting if the patient's appearance is permanently affected.

The doctor will begin by taking a history, either from the patient if he is able to talk or from the parents or other witnesses. In the case of a known accident, sports injury, or assault, the doctor begin with the ABCs, which means that he or she will check the child or adolescent's *airway*, *breathing*, and *circulation*. The doctor will usually have the patient sit upright or lie on one side and will remove blood clots, broken teeth, vomitus, or other foreign bodies from the nose or throat. He or she will then carry out a systematic examination of the patient's face and head. The most common pattern of examination moves from the inside of the nose and mouth to the outside of the face, and from the bottom of the face to the top.

The doctor looks for signs of bruising and tissue swelling as well as bleeding and gently palpates, or touches, the various facial bones for movement and stability. If the doctor suspects that the nose is fractured, he or she will listen for crepitus (a crackling sound) when the nose is gently moved and will look for evidence of a dislocated septum or a septal hematoma, which appears as a bluish bulging mass within the nasal septum. The child's teeth will be examined for looseness, and the muscles and nerves of the face will be evaluated. If there is a discharge from the nose, the doctor will look at it to see whether it contains cerebrospinal fluid, which would indicate damage to the bones of the skull as well as the nasal bones. Lastly, the doctor examines the patient's eyes to make sure that the pupils are responding normally to light and that the patient is not seeing double or having other visual problems that might indicate nerve damage or damage to the eye itself.

In cases involving animal kicks, bites, or other tearing or crushing injuries to the skin and external tissues of the face and jaw, the doctor carefully cleanses the broken skin with soap and water or benzalkonium chloride and checks for fractured facial bones.

Emergency room doctors are required by law to report to local law enforcement authorities cases of suspected **family** abuse.

Treatment

Treatment of maxillofacial trauma varies according to the type and extent of the injury.

Jaw

Dislocation of the jaw can be treated by a primary care physician by exerting pressure in the proper manner. If muscle spasm prevents the jaw from moving back into alignment, a sedative is administered intravenously (IV) to relax the muscles. Afterward, the child must avoid opening the jaw wide to minimize the risk of another dislocation.

A jaw fracture may be minor enough to heal with simple limitation of movement and time. More serious fractures require complicated multistep treatment. The jaw must be surgically immobilized by a qualified oral or maxillofacial surgeon or an otolaryngologist. The jaw is properly aligned and secured with metal pins and wires. Proper alignment is necessary to ensure that the bite is correct. If the bite is off, the patient may develop a painful disorder called temporomandibular joint syndrome.

During the weeks of healing the patient is limited to a liquid diet sipped through a straw and must be careful not to choke or vomit since he cannot open his mouth to expel the vomitus. The surgeon will prescribe pain relievers and perhaps muscle relaxants. The recovery time varies according to the patient's overall health but takes at least several weeks.

Nose

Another common maxillofacial fracture is a broken nose. The bones that form the bridge of the nose may be fractured, but cartilage may also be damaged, particularly the nasal septum that separates the two nostrils. If the child's nose is hit from the side, the bones and cartilage are displaced to the side, but if hit from the front,

they are splayed out. Severe swelling can inhibit diagnosis and treatment. Mild trauma to the nose can sometimes heal without the person being aware of the fracture unless there is an obvious deformity. The nose will be tender for at least three weeks.

Either before the swelling begins or after it subsides, some ten days after the injury, the doctor can assess the extent of the damage. Physical examination of the inside using a speculum and the outside, in addition to a detailed history of how the injury occurred, determines appropriate treatment. The doctor should be informed of any previous nasal fractures, nasal surgery, or such chronic diseases as diabetes or bleeding disorders. Sometimes an x-ray is useful for diagnosis, but it is not always required.

A primary care physician may treat a nasal fracture himself, but if there is extensive damage or the air passage is blocked, he will refer the patient to an otolaryngologist or a plastic surgeon for treatment. Initially the nose may be packed to control bleeding and hold the shape. It is reset under anesthesia. A protective shield or bandage may be placed over it while the fracture heals.

Eyes

In the case of orbital fractures, there is great danger of permanent damage to vision. Double vision and decreased mobility of the eye are common complications of facial trauma. Surgical reconstruction may be required if the fracture changes the position of the eye or there is other facial deformity. Proper treatment of these injuries requires a maxillofacial surgeon.

When the eyes have been exposed to chemicals, they must be washed out for 15 minutes with clear water. **Contact lenses** may be removed only after rinsing the eyes. The eyes should then be kept covered until the person can be evaluated by a primary care physician or ophthalmologist.

When a foreign object is lodged in the eye, the person should not rub the eye or put pressure on it which would further injure the eyeball. The eye should be covered to protect it until medical attention can be obtained.

Mouth and teeth

Several kinds of traumatic injuries can occur to the mouth. A person can suffer a laceration (cut) to the lips or tongue or loosening of teeth or have teeth knocked out. Such injuries often accompany a jaw fracture or other facial injury. Wounds to the soft tissues of the mouth bleed freely, but the plentiful blood supply that leads to this heavy bleeding also helps healing. It is important to clean mouth wounds thoroughly with salt water or a hydrogen peroxide rinse to prevent infection. Large cuts may require sutures and should be done by a maxillofacial surgeon for a good cosmetic result, particularly when the laceration is on the edge of the lip line (vermilion). The doctor will prescribe an antibiotic because there is normally a large amount of bacteria present in the mouth.

Any injury to the teeth should be evaluated by a dentist for treatment and prevention of infection. Implantation of a tooth is sometimes possible if it has been handled carefully and protected. The tooth should be held by the crown, not the root, and kept in milk, saline, or contact lens fluid. The child's dentist can refer him to a specialist in this field.

Facial burns

For first-degree burns, the child's parent can put a cold-water compress on the area or run cold water on it and cover it with a clean bandage for protection. Second- and third-degree burn victims must be taken to the hospital for treatment.

In the hospital, the child will be given replacement fluids through an IV. This treatment is vital since a patient in shock will die unless those lost fluids are replaced quickly. **Antibiotics** are given to combat infection since the burns make the body vulnerable to infection.

Head injuries

Treatment for a **head injury** requires examination by a primary care physician unless the child's symptoms point to a more serious injury. In that case, the victim must seek emergency care. A concussion is treated with rest and avoidance of contact sports. Very often athletes who have suffered a concussion are allowed to **play** again too soon, perhaps in the mistaken impression that the injury is not so bad if the player did not lose consciousness. Anyone who has had one concussion is at increased risk of another one.

Danger signs that a head injury is more serious include worsening headaches, vomiting, weakness, numbness, unsteadiness, change in the appearance of the eyes, seizures, slurred speech, confusion, agitation, or a change in mental status. These signs require immediate transport to the hospital. A neurologist will evaluate the situation, usually with a CT scan. A stay in a rehabilitation facility may be necessary.

In the case of animal bites on the face or head, the child may be given passive or active immunization against **rabies** if there is a chance that the animal is rabid. This precaution is particularly important, as the

incubation period of the rabies virus is much shorter for bites on the head and neck than for bites elsewhere on the body.

Alternative treatment

Fractures, burns, and deep lacerations require treatment by a doctor but alternative treatments can help the body withstand injury and assist the healing process. Calcium, **minerals**, **vitamins**, all part of a balanced and nutrient-rich diet, as well as regular **exercise**, build strong bones that can withstand force well. After an injury, craniosacral therapy may help healing and ease the headaches that follow a concussion or other head trauma. A physical therapist can offer ultrasound treatment, which raises skin temperature to ease pain, or biofeedback, a technique in which the patient learns how to tense and relax muscles to relieve pain. Hydrotherapy may ease the emotional stress of recovering from trauma. Traditional Chinese medicine seeks to reconnect the chi (energy flow) along the body's meridians and thus aid healing. Homeopathic physicians may prescribe such remedies as *Arnica* or *Symphytum* to enhance healing.

Prognosis

When appropriate treatment is obtained quickly after a facial injury, the prognosis can be excellent. If the child or adolescent has a weakened immune system or a debilitating chronic disease, healing is more problematic. Healing also depends upon the extent of the injury. An automobile accident or a gunshot wound, for example, can cause severe facial trauma that may require multiple surgical procedures and a considerable amount of time to heal. Burns and lacerations cause scarring that might be improved by plastic surgery.

Prevention

Safety equipment is vital for preventing maxillofacial trauma from automobile accidents and sports. Here is a partial list of equipment people should always use:

- seatbelts
- automobile air bags
- approved child safety seats
- helmets for riding motorcycles or bicycles, skateboarding, snowboarding, and other sports
- safety glasses for yard work and sports
- such other approved safety equipment for sports as mouthguards, masks, and goggles

KEY TERMS

Corneal abrasion—A scratch on the surface of the cornea.

Crepitus—A crackling sound.

Hematoma—A localized collection of blood, often clotted, in body tissue or an organ, usually due to a break or tear in the wall of blood vessel.

Mandible—The lower jaw, a U-shaped bone attached to the skull at the temporomandibular joints.

Maxilla—The bone of the upper jaw which serves as a foundation of the face and supports the orbits.

Nasal septum—The partition that separates the nostrils.

Orbit—The eye socket which contains the eyeball, muscles, nerves, and blood vessels that serve the eye.

Otolaryngologist—A doctor who is trained to treat injuries, defects, diseases, or conditions of the ear, nose, and throat. Also sometimes known as an otorhinolaryngologist.

Shock—A medical emergency in which the organs and tissues of the body are not receiving an adequate flow of blood. This deprives the organs and tissues of oxygen and allows the build-up of waste products. Shock can be caused by certain diseases, serious injury, or blood loss.

Temporomandibular joint disorder—Inflammation, irritation, and pain of the jaw caused by improper opening and closing of the temporomandibular joint. Other symptoms include clicking of the jaw and a limited range of motion. Also called temporomandibular joint syndrome.

Temporomandibular joint (TMJ)—One of a pair of joints that attaches the mandible of the jaw to the temporal bone of the skull. It is a combination of a hinge and a gliding joint.

Vermilion border—The line between the lip and the skin.

Parental concerns

Parental concerns regarding maxillofacial trauma depend on the cause and severity of the injury. Minor **bruises** and uncomplicated fractures caused by accidents generally heal without problems and are quickly absorbed into the family's routine. Complex fractures or

other injuries requiring a second operation may require explanation or discussion with the child. Facial injuries, particularly repeated injuries related to the neighborhood or farm setting, lifestyle choices, or family violence, however, suggest the importance of professional counseling and changes in the family's structure, geographical location, or level of functioning. Children or adolescents who are severely disfigured by facial injuries may require extra reassurance from family members as well as professional counseling in order to cope with their changed appearance.

Measles

Definition

Measles is an infection caused by a virus, which causes an illness displaying a characteristic skin rash known as an exanthem. Measles is also sometimes called rubeola, five-day measles, or hard measles.

Description

Measles is a very contagious disease primarily characterized by **cough**, runny nose, red eyes (**conjunctivitis**), and a characteristic rash on the skin and inside of the cheeks. The most common complications are ear infection and **diarrhea**, although more serious complications can include **pneumonia**, **meningitis**, or **encephalitis**. Measles is fatal (due to complications) in about two out of every 1,000 cases.

Demographics

Measles infections appear all over the world. Prior the effective immunization program used in the early

2000s, large-scale measles outbreaks occurred on a two to three-year cycle, usually in the winter and spring. Smaller outbreaks occurred during the off years. Babies up to about eight months of age are usually protected from contracting measles, due to immune cells they receive from their mothers in the uterus. Once someone has had measles infection, he or she can never get it again.

Causes and symptoms

Measles is caused by a type of virus called a paramyxovirus. It is an extremely contagious infection, spread through the tiny droplets that may spray into the air when an individual carrying the virus sneezes or coughs. About 85 percent of those people exposed to the virus will become infected with it. About 95 percent of those people infected with the virus will develop the illness called measles. Once someone is infected with the virus, it takes about seven to 18 days before he or she actually becomes ill. The most contagious time period is the three to five days before symptoms begin through about four days after the characteristic measles rash has begun to appear.

The first signs of measles infection are **fever**; extremely runny nose; red, runny eyes; and a cough. A few days later, a rash appears in the mouth, particularly on the mucous membrane that lines the cheeks. This rash consists of tiny white dots (like grains of salt or sand) on a reddish bump. These are called Koplik's spots and are unique to measles infection. The throat becomes red, swollen, and sore.

A couple of days after the appearance of the Koplik's spots, the measles rash begins. It appears in a characteristic progression, from the head, face, and neck, to the trunk, then abdomen, and next out along the arms and legs. The rash starts out as flat, red patches but eventually develops some bumps. The rash may be somewhat itchy. When the rash begins to appear, the fever usually climbs higher, sometimes reaching as high as 105°F (40.5°C). There may be **nausea**, **vomiting**, diarrhea, and multiple swollen lymph nodes. The cough is usually more problematic at this point, and the patient feels awful. The rash usually lasts about five days. As it fades, it turns a brownish color and eventually the affected skin becomes dry and flaky.

Many patients (about 5–15%) develop other complications. Bacterial infections, such as ear infections, sinus infections, and pneumonia are common, especially in children. Other viral infections may also strike the patient, including **croup**, **bronchitis**, laryngitis, or viral pneumonia. Inflammation of the liver, appendix, intestine, or lymph nodes within the abdomen may cause other complications. Rarely, inflammations of the heart or kidneys, a drop in **platelet count** (causing episodes of difficult-to-control bleeding), or reactivation of an old **tuberculosis** infection can occur.

An extremely serious complication of measles infection is swelling of the brain. Called encephalitis, this condition can occur up to several weeks after the basic measles symptoms have resolved. About one out of every thousand patients develops this complication, and about 10 to 15 percent of these patients die. Symptoms include fever, **headache**, sleepiness, seizures, and coma. Long-term problems following recovery from measles encephalitis may include seizures and **mental retardation**.

A very rare complication of measles can occur up to ten years following the initial infection. Called subacute sclerosing panencephalitis, this is a slowly progressing, smoldering swelling and destruction of the entire brain. It is most common among people who had measles infection prior to the age of two years. Symptoms include changes in personality, decreased **intelligence** with accompanying school problems, decreased coordination, involuntary jerks and movements of the body. The disease progresses so that the individual becomes increasingly dependent, ultimately becoming bedridden and unaware of his or her surroundings. Blindness may develop, and the temperature may spike (rise rapidly) and fall unpredictably as the brain structures responsible for temperature regulation are affected. Death is inevitable.

Measles during pregnancy is a serious disease, leading to increased risk of a miscarriage or stillbirth. In addition, the mother's illness may progress to pneumonia.

Diagnosis

Measles infection is almost always diagnosed based on its characteristic symptoms, including Koplik's spots, and a rash which spreads from central body structures out towards the arms and legs. If there is any doubt as to the diagnosis, then a specimen of body fluids (mucus, urine) can be collected and combined with fluorescent-tagged measles virus antibodies. Antibodies are produced by the body's immune cells that can recognize and bind to markers (antigens) on the outside of specific organisms, in this case the measles virus. Once the fluorescent antibodies have attached themselves to the measles antigens in the specimen, the specimen can be viewed under a special microscope to verify the presence of measles virus.

Measles rash on a child's face. *(© CNRI/Photo Researchers, Inc.)*

Treatment

As of 2004 there are no treatments available to stop measles infection. Treatment is primarily aimed at helping the patient to be as comfortable as possible and watching carefully so that **antibiotics** can be started promptly if a bacterial infection develops. Fever and discomfort can be treated with **acetaminophen**. Children with measles should never be given aspirin, as aspirin is correlated with the fatal disease **Reye's syndrome**. A cool-mist vaporizer may help decrease the cough. Patients should be given a lot of liquids to drink, in order to avoid **dehydration** from the fever.

Some studies have shown that children with measles encephalitis benefit from relatively large doses of vitamin A.

Prognosis

The prognosis for an otherwise healthy, well-nourished child who contracts measles is usually quite good. In developing countries, however, death rates may reach 15 to 25 percent. Adolescents and adults usually have a more difficult course. Women who contract the disease while pregnant may give birth to a baby with **hearing impairment**. Although only one in 1,000 patients with measles will develop encephalitis, 10 to 15 percent of those who do will die, and about another 25 percent will be left with permanent brain damage.

KEY TERMS

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's immune response.

Encephalitis—Inflammation of the brain, usually caused by a virus. The inflammation may interfere with normal brain function and may cause seizures, sleepiness, confusion, personality changes, weakness in one or more parts of the body, and even coma.

Exanthem—A skin eruption regarded as a characteristic sign of such diseases as measles, German measles, and scarlet fever.

Koplik's spots—Tiny spots occurring inside the mouth, especially on the inside of the cheek. These spots consist of minuscule white dots (like grains of salt or sand) set onto a reddened bump and are characteristic of measles.

Prevention

Measles is a highly preventable infection. A very effective vaccine exists, made of live measles viruses that have been treated so that they cannot cause actual infection. The important markers on the viruses are intact, however, which causes an individual's immune system to react. Immune cells called antibodies are produced, which in the event of a future infection with measles virus quickly recognize the organism and kill it off. Measles vaccines are usually given to children at about 15 months of age; prior to that age, the baby's immune system is not mature enough to initiate a reaction strong enough to insure long-term protection from the virus. A repeat injection should be given at about ten or 11 years of age. Outbreaks on college campuses have occurred among students who were not immunized or who were incorrectly immunized.

Measles vaccine should not be given to pregnant women, however, in spite of the seriousness of gestational measles. The reason for not giving this particular vaccine during pregnancy is the risk of transmitting measles to the unborn child.

Parental concerns

New cases of measles began being reported in some countries—including Great Britain—in 2001 because of parents' fears about vaccine safety. The combined vaccine for measles, **mumps**, and **rubella** (MMR) was claimed to cause **autism** or bowel disorders in some children. However, the World Health Organization (WHO) position is there is no scientific merit to these claims. The United Nations expressed concern that unwarranted **fear** of the vaccine would begin spreading the disease in developing countries and ultimately in developed countries as well. Parents in Britain began demanding the measles vaccine as a separate dose, and scientists were exploring that option as an alternative to the combined **MMR vaccine**. Unfortunately, several children died during an outbreak of measles in Dublin because they had not received the vaccine. Child mortality due to measles is considered largely preventable, and making the MMR vaccine widely available in developing countries is part of WHO strategy to reduce child mortality by two-thirds by the year 2015.

Meningitis

Definition

Meningitis is a serious inflammation of the meninges, the membranes (lining) that surround the brain and spinal cord. It can be of bacterial, viral, or fungal origin.

Description

Meningitis is usually the result of a viral or bacterial infection. Viral meningitis, also called aseptic meningitis, is generally less severe and often disappears without specific treatment, while bacterial meningitis can be quite serious and may result in brain damage, hearing loss, or learning disabilities in children. The infection may even cause death.

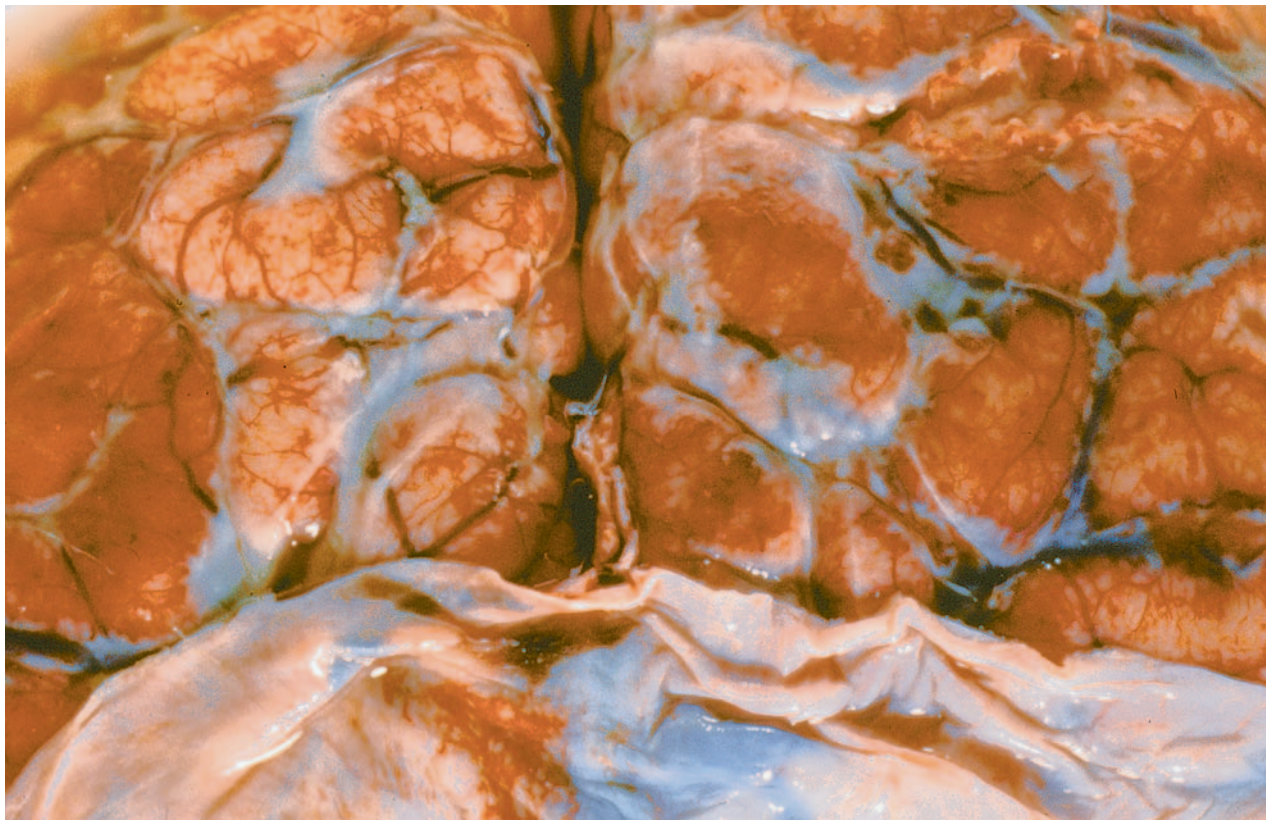
Bacterial meningitis is either monococcal or pneumococcal, depending on the type of bacteria responsible for the infection. Meningitis caused by *Haemophilus influenzae* and related strains (A, B C, Y, and W135) is also called meningococcal meningitis. Similarly, meningitis due to *Streptococcus pneumoniae* is also called pneumococcal meningitis.

Transmission

Most types of meningitis are contagious. A person may be exposed to meningitis bacteria when someone with meningitis coughs or sneezes. The bacteria can also spread through kissing or sharing eating utensils or a toothbrush.

Demographics

According to the National Institute of Neurological Disorders and Stroke (NINDS), some 6,000 cases of pneumococcal meningitis are reported in the United States each year. Meningococcal meningitis is common in minors ages two to 18. Each year about 2,600 people get this highly contagious disease. High-risk groups include infants under the age of one year, people with suppressed immune systems, travelers to foreign countries where the disease is endemic, and college students and Army recruits who reside in dormitories and other close quarters. Between 10 and 15 percent of cases are fatal, with another 10 to 15 percent involving brain damage and other serious side effects.



Brain tissue infected with acute meningitis. *(© Custom Medical Stock Photo, Inc.)*

Causes and symptoms

The bacteria which cause bacterial meningitis live in the back of the nose and throat region and are carried by 10 to 25 percent of the population. They cause meningitis when they get into the bloodstream and travel to the meninges.

At least 50 kinds of bacteria can cause bacterial meningitis. According to the Centers for Disease Control (CDC), before the 1990s, *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis, but subsequent vaccines given to all children as part of their routine immunizations have reduced the occurrence of the disease due to *H. influenzae*. As of 2004, *Streptococcus pneumoniae* and *Neisseria meningitidis* were the leading causes of bacterial meningitis.

In newborns, the most common agents of meningitis are those that are contracted from the newborn's mother, including Group B streptococci (becoming an increasingly common infecting organism in the newborn period), *Escherichia coli*, and *Listeria monocytogenes*. The highest incidence of meningitis occurs in babies less than a month old, with an increased risk of meningitis continuing through about two years of age.

Older children are more frequently infected by the bacteria *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococci pneumoniae*.

Most cases of viral meningitis are caused by enteroviruses (viruses that typically cause stomach flu). However, many other types of viruses, such as the **herpes simplex** virus, the **mumps** and **measles** viruses (against which most children are protected due to mass immunization programs), the virus that causes **chickenpox**, the **rabies** virus, and a number of viruses that are acquired through the **bites** of infected mosquitoes.

Meningitis symptoms include high **fever**, **headache**, and stiff neck in children over the age of two years. These symptoms can develop over several hours, or they may take one to two days. Other symptoms may include **nausea**, **vomiting**, discomfort looking into bright lights, confusion, and sleepiness. In some cases, a rash may be present. In newborns and small infants, these symptoms may be absent or difficult to detect, and the infant may only appear slow or inactive, or be irritable, have vomiting, or be feeding poorly. As the disease progresses, patients of any age may also have seizures.

When to call the doctor

Parents should call a doctor if a child has a temperature above 101°F (38.5°C). If any meningitis symptoms occur, the child should see a doctor immediately, as early diagnosis and treatment are very important for a successful outcome.

Diagnosis

Viral meningitis often remains undiagnosed because its symptoms are similar to those of the common flu. As for bacterial meningitis, the diagnosis is established by growing bacteria from a sample of spinal fluid. The spinal fluid is obtained by performing a lumbar puncture (also called a spinal tap), in which a needle is inserted into an area in the lower back where fluid in the spinal canal is readily accessible.

Treatment

Bacterial meningitis treatment usually involves intravenous administered **antibiotics**, for a minimum of four days. The type of meningitis contracted will determine the specific antibiotic used. It is imperative that treatment start as early as possible, in order to avoid brain damage and death.

Viral meningitis cases usually resolve without complications, but typically, antibiotics are ineffective in treating it, so none are prescribed. The child will be told to get as much rest as he or she can. If the child has **pain** related to the disease such as headaches or other body pains, medication can be used to treat it.

Prognosis

The long-term outlook for children who develop bacterial meningitis varies significantly. The outcome depends on the child's age, the bacteria causing the infection, complications, and the treatment the child receives. The complications of bacterial meningitis can be severe and include neurological problems such as hearing loss, visual impairment, seizures, and learning disabilities. The heart, kidneys, and adrenal glands may also be affected. Although some children develop long-lasting problems, most children who receive prompt diagnosis and treatment recover fully.

The majority of cases of viral meningitis resolve with no complications.

KEY TERMS

Analgesics—A class of pain-relieving medicines, including aspirin and Tylenol.

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's immune response.

Bacterial meningitis—Meningitis caused by bacteria. Depending on the type of bacteria responsible for the infection, bacterial meningitis is either classified as monococcal or pneumococcal.

Immunization—A process or procedure that protects the body against an infectious disease by stimulating the production of antibodies. A vaccination is a type of immunization.

Meninges—The three-layer membranous covering of the brain and spinal cord, composed of the dura mater, arachnoid, and pia mater. It provides protection for the brain and spinal cord, as well as housing many blood vessels and participating in the appropriate flow of cerebrospinal fluid.

Viral meningitis—Meningitis caused by a virus. Also called aseptic meningitis.

Prevention

Many children as of 2004 routinely receive vaccines against meningitis, starting at about two months of age. Immunizations are recommended by the American Academy of Pediatrics and many other organizations. If a child has not been vaccinated, parents should talk to their doctor about the Hib and pneumococcal (Prevnar 7) vaccines.

Vaccines are available for both meningococcal and pneumococcal meningitis. Specifically, there are vaccines against Hib and against some strains of *N. meningitidis* and many types of *Streptococcus pneumoniae*. The vaccines against Hib are very safe and highly effective. There is a vaccine that protects against four strains of *N. meningitidis*, but it is not routinely used in the United States. There are also vaccines to prevent meningitis due

to *S. pneumoniae*, which can also prevent other forms of infection due to *S. pneumoniae*.

Parents should teach children to wash their hands often, especially before they eat and after using the bathroom, or after petting animals. They should be taught how to wash their hands vigorously, covering both the front and back of each hand with soap and rinsing thoroughly under running water.

Parental concerns

Some forms of bacterial meningitis are contagious. The bacteria are spread through coughing, kissing, and sneezing. Fortunately, the bacteria that cause meningitis are not as contagious as the **common cold** or the flu, and they are not spread by casual contact or by simply breathing the air where a person with meningitis has been. However, people in the same household or daycare center, or anyone with direct contact with a patient's oral secretions is considered at increased risk of acquiring the infection.

Awareness of the symptoms and signs of meningitis, especially the rash which may accompany meningococcal meningitis is very important.

Meningococcal meningitis vaccine

Definition

The meningococcal **meningitis** vaccine is given by injection (shots) to provide immunization against meningococcal disease and meningitis caused by the bacterium *Neisseria meningitides*.

Description

Meningococcal disease, or **meningococcemia**, is a leading cause of meningitis in children, and then disease can also lead to infections of the blood. People who acquire the disease can become very ill, especially the young children. Meningococcal disease is treated with **antibiotics**, and the vaccine is not routinely recommended for most people in the United States. Particularly, it is not for children under age two, except under special circumstances.

Meningococcal meningitis is different from the meningitis in infants for which **vaccination** is routinely given. Before the 1990s, *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis. However, vaccines given to all children as part of their routine immunization have reduced the frequency of the invasive diseases caused by *H. influenzae* and *Streptococcus pneumonia,* leaving neisseria meningitis as one of the leading causes of bacterial meningitis.

The meningococcal vaccine contains inactivated bacteria and cannot cause the disease. It is effective against four of the five subtypes of meningococcal meningitis. It is a one-time injection (except for the very young), and the effects last for four to five years. Adverse reactions are uncommon with this vaccine. Localized redness at the injection site lasting one or two days may occur. Less likely is an allergic reaction to the vaccine.

General use

Meningococcal vaccine is recommended for children and young adults as follows:

- children two years old and older in a population where an outbreak has occurred
- college students who live in close quarters (dormitories), who consume alcohol, smoke, or are regularly around smokers
- those with certain chronic conditions, including those with spleen damage or immune disease
- anyone traveling to or living in a part of the world where meningococcal disease is common, such as West Africa
- household or institutional members who have contact with anyone with meningococcal disease (The same individuals should also receive prophylaxis antibiotic therapy.)
- medical and laboratory personnel at risk of exposure to meningococcal disease

Precautions

Children who are mildly ill at the time the shot is due can still get meningococcal vaccine. Children with moderately severe illnesses should wait until they recover. Children two years old and over receive one dose, while children three months to two years old need two doses, three months apart. Immunizations should be deferred during any acute illness. Pregnant women should not receive the vaccine because it may affect the fetus.

KEY TERMS

Acute—Refers to a disease or symptom that has a sudden onset and lasts a relatively short period of time.

Antibiotics—Drugs that are designed to kill or inhibit the growth of the bacteria that cause infections.

Antibody—A special protein made by the body's immune system as a defense against foreign material (bacteria, viruses, etc.) that enters the body. It is uniquely designed to attack and neutralize the specific antigen that triggered the immune response.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's immune response.

Efficacy—The effectiveness of a drug in treating a disease or condition.

Immunity—Ability to resist the effects of agents, such as bacteria and viruses, that cause disease.

Side effects

Children who get the meningitis vaccine may have mild side effects, such as tenderness, redness, or a painful lump on the skin at the injection site; symptoms usually last one to two days. A small percentage of the patients who receive the vaccine develop a slight **fever**. The meningitis vaccine, like any other injection, may in rare cases lead to a serious allergic reaction. Symptoms of allergic reaction include swelling in the mouth or throat, trouble breathing, weakness, hoarseness or wheezing, a fast heart beat, **hives**, **dizziness**, paleness, and a high fever. If a serious allergic reaction occurs the symptoms will start within a few minutes to a few hours after the shot. The child should be seen immediately by a doctor. The doctor will need to know the date of the vaccination and when exactly the symptoms started. A health-care provider should file a report using the vaccine adverse events reporting system (VAERS) form.

Interactions

If the vaccine is given to children receiving immunosuppressive therapy, as in **chemotherapy** for **cancer** or HIV/AIDs, the immune response may not take place. Moreover, the meningitis vaccine should not be given to

individuals known to be sensitive to thimerosal (mercury derivative) or other ingredients of the vaccine.

Parental concerns

Meningitis passes from person to person, mainly by coughing and sneezing. The risk of contracting the disease increases if the child spends time in close contact with the local population at schools, crowded markets, or public buildings. In addition, young adults living in close quarters on college campuses are at risk for contracting the disease. Vaccines are available at student health services on campuses.

Meningococcemia

Definition

Meningococcemia is the presence of meningococcus in the bloodstream. Meningococcus, a bacteria formally called *Neisseria meningitidis*, can be one of the most dramatic and rapidly fatal of all infectious diseases.

Causes and symptoms

Meningococcemia, a relatively uncommon infection, occurs most commonly in children and young adults. In susceptible people, it may cause a very severe illness that can produce death within hours. The bacteria, which can spread from person to person, usually first causes a colonization in the upper airway, but without symptoms. From there, it can penetrate into the bloodstream to the central nervous system and cause **meningitis** or develop into a full-blown bloodstream infection (meningococcemia). Fortunately in most colonized people, this does not happen, and the result of this colonization is long-lasting immunity against the particular strain.

A close-up image of a person's hand with meningococcemia, caused by *Neisseria meningitidis*. The organism can cause multiple illnesses and can damage small blood vessels. *(Custom Medical Stock Photo Inc.)*

After colonization is established, symptoms can develop within one day to one to two weeks. After a short period of time (one hour up to one to two days) when the patient complains of **fever** and muscle aches, more severe symptoms can develop. Unfortunately during this early stage, a doctor cannot tell this illness from any other illness, such as a viral infection like **influenza**. Unless the case is occurring in a person known to have been exposed to or in the midst of an epidemic of meningococcal disease, there may be no specific symptoms or signs found that help the doctor diagnose the problem. Rarely, a low-grade bloodstream infection called chronic meningococcemia can occur.

After this initial period, the patient will often complain of continued fever, shaking chills, overwhelming weakness, and even a feeling of impending doom. The organism is multiplying in the bloodstream, unchecked by the immune system. The severity of the illness and its dire complications are caused by the damage the organism does to the small blood vessel walls. This damage is called a vasculitis, an inflammation of a blood vessel. Damage to the small vessels causes them to become leaky. The first signs of the infection's severity are small bleeding spots seen on the skin (petechiae). A doctor

should always suspect meningococcemia when he or she finds an acutely ill patient with fever, chills, and petechiae.

Quickly (within hours), the blood vessel damage increases, and large bleeding areas on the skin (purpura) are seen. The same changes are taking place in the affected person's internal organs. The blood pressure is often low, and there may be signs of bleeding from other organs (like coughing up blood, nose bleeds, blood in the urine). The organism not only damages the blood vessels by causing them to leak, but also causes clotting inside the vessels. If this clotting occurs in the larger arteries, it results in major tissue damage. Essentially, large areas of skin, muscle, and internal organs die from lack of blood and oxygen. Even if the disease is quickly diagnosed and treated, the patient has a high risk of dying.

Diagnosis

The diagnosis of meningococcemia can be made by the growth of the organism from blood cultures. Treatment should begin when the diagnosis is suspected and should not be delayed by the doctor's waiting for positive cultures. Obtaining fluid from a petechial spot and staining it in the laboratory can assist in quickly seeing the organism.

Treatment

Immediate treatment of a suspected case of meningococcemia begins with **antibiotics** that work against the organism. Possible choices include penicillin G, ceftriaxone (Rocephin), cefotaxime (Claforan), or trimethoprim/sulfamethoxazole (Bactrim, Septra). If the patient is diagnosed in a doctor's office, antibiotics should be given immediately if possible, even before transfer to the hospital and even if cultures cannot be obtained before treatment. It is most likely that the speed of initial treatment will affect the ultimate outcome.

Prognosis

As many as 15 to 20 percent of patients with meningococcemia will die as a result of the acute infection. A significant percentage of the survivors have tissue damage that requires surgical treatment. This treatment may consist of skin grafts, or even partial or full amputations of an arm or leg. Certain people with immune system defects (particularly those with defects in the complement system) may have recurrent episodes of meningococcemia. These patients, however, seem to have a less serious outcome.

KEY TERMS

Blood culture—A procedure where blood is collected from a vein and is placed in a small bottle that contains a special liquid; the liquid will make any organisms that are present in the blood sample grow. These organisms can then be grown and identified in the laboratory so that the proper antibiotic can be given to the patient.

Colonization—The presence of bacteria on a body surface (like on the skin, mouth, intestines or airway) without causing disease in the person.

Complement—One of several proteins in the blood that acts with other proteins to assist in killing bacteria.

Meningitis—An infection or inflammation of the membranes that cover the brain and spinal cord. It is usually caused by bacteria or a virus.

Prevention

Although a vaccine is available for meningococcus, it is still difficult as of 2004 to produce a vaccine for the type B organism, the most common one in the United States. Because of this and the short time that the vaccine seems to offer protection, the product has not been routinely used in the United States. It can be used for travelers going to areas where meningococcal disease is more common or is epidemic. In the early 2000s, the vaccine has been suggested for use in incoming college freshmen, particularly those living in dormitories. These students appear to have a somewhat higher risk of meningococcal infections.

It is, however, recommended that all people take certain antibiotics if they have had contact (like at home or in a daycare) with a person who has meningococcal infection. The most common antibiotics given are rifampin (Rifadin) or ciprofloxacin (Cipro). These medicines are usually taken by mouth twice a day for two days. This treatment will decrease the risk of infection in these people who have been exposed. However, the overall risk to people who have been exposed, even without antibiotic use, is probably no more than 1 to 2 percent.

Menstruation

Definition

Menstruation is the vaginal bleeding that occurs in adolescent girls and women as a result of hormonal changes. It normally happens in a predictable pattern, once a month.

Description

Menstruation is part of the menstrual cycle, which helps a woman's body prepare for the possibility of pregnancy each month. The parts of the body involved in the menstrual cycle include the uterus and cervix, the ovaries, fallopian tubes, the brain and pituitary gland, and the vagina. Certain body chemicals known as hormones rise and fall during the month, causing the menstrual cycle to occur.

In the first half of the menstrual cycle, estrogen levels rise, causing the lining of the uterus to grow and thicken. This lining is called the endometrium. The two small, grape-shaped organs inside the abdomen on either side of the uterus, known as the ovaries, are filled with hundreds of thousands of eggs and are the organs that allow pregnancy to occur. When a girl reaches **puberty**, the ovaries respond to a rise in follicle-stimulating hormone and cause one of the eggs to mature. About half way through the menstrual cycle, a surge of luteinizing hormone takes place, and the egg is released. This mature egg is called an ovum, and its release is called ovulation. When the egg is released it travels through one of the two fallopian tubes and down towards the uterus. If the ovum is fertilized by a sperm at this time, pregnancy occurs. However, if a sperm does not fertilize the egg, the body no longer needs the uterine lining to support the fertilized egg. Estrogen and progesterone levels then drop, triggering the uterine lining to gently fall away from the wall of the uterus, and to be shed through the vagina. The discharge of this lining is the menstrual flow. The entire process is called menstruation.

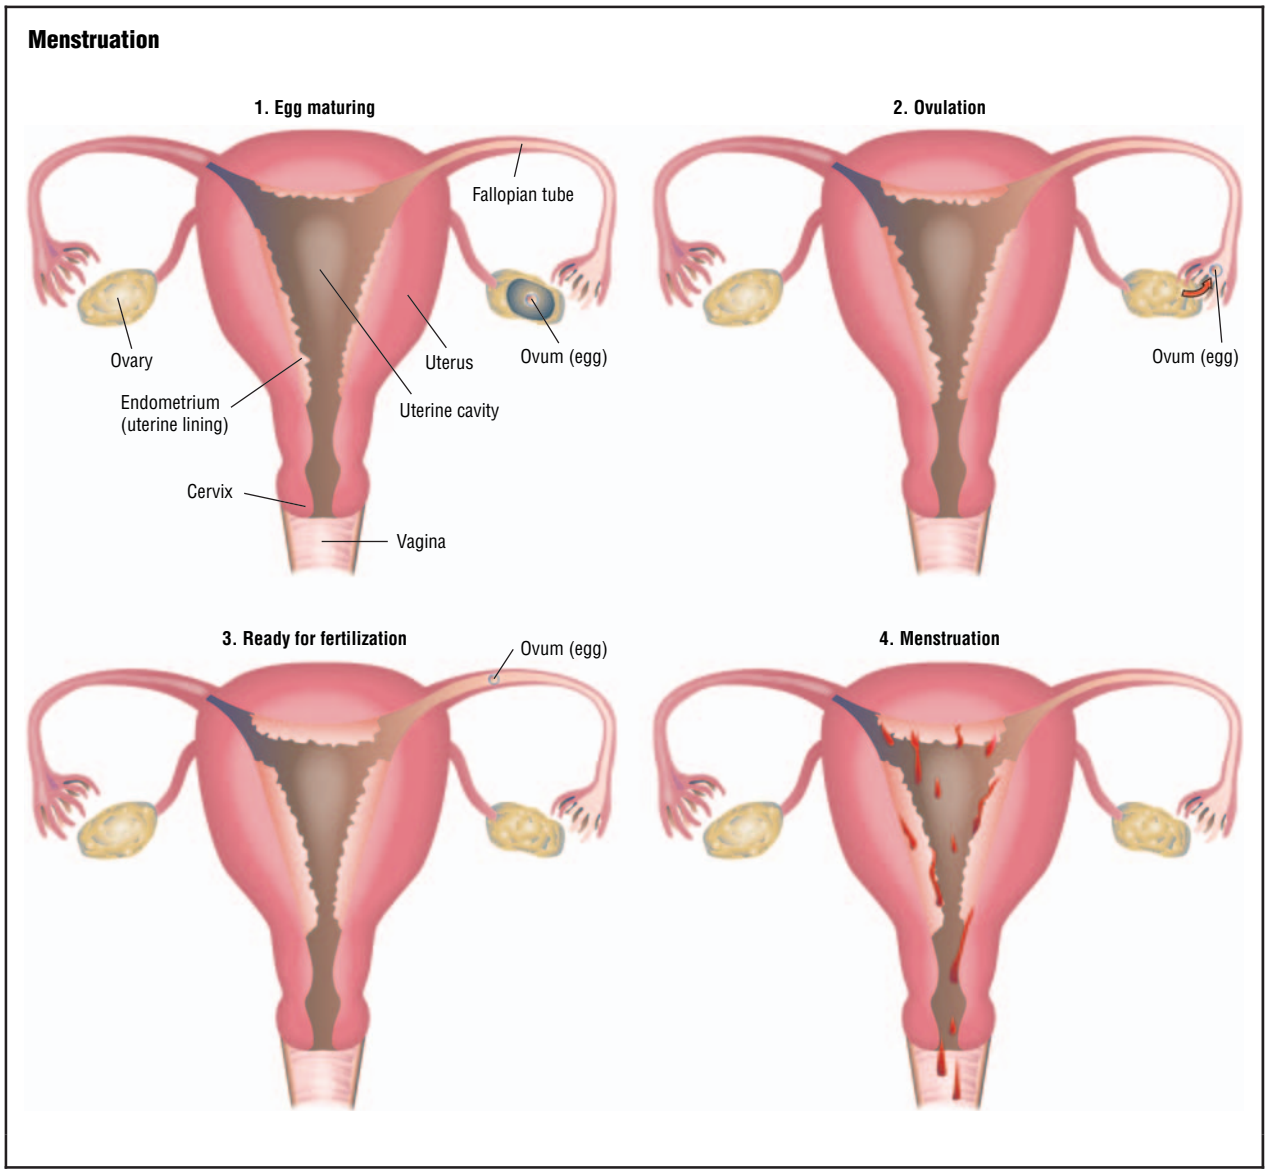
A "normal" menstrual period usually occurs every 28 days, from the first day of a period to the first day of the next. However, this can vary from 22 to 36 days. Each period usually lasts from three to seven days, with the average being five. It may take several years from the start of menstruation for periods to settle into a pattern. Irregular periods are common in early **adolescence**. Even after adolescence, many factors can throw off the timing of menstruation. These include weight changes, starting a new job or school, and relationship problems.

Menstrual hygiene products

Once a girl begins menstruating, she needs to choose from the various menstrual hygiene products which are available. Menstrual hygiene products can be divided into two basic categories: sanitary pads and tampons. Absorbency and a comfortable fit are the main features girls need to look for when purchasing menstrual products. Because a girl's menstrual flow may vary from day to day during the cycle, she may want to use different types of products during her period.

Sanitary pads are worn inside the underwear where they collect the menstrual flow. They come in different sizes, thicknesses, and styles. Some pads have flaps or "wings" that wrap around and attach to the underside of underwear. Others have deodorant and contain perfume. Some girls find that the perfume irritates their skin.

Tampons are the another option for absorbing menstrual flow. Tampons come in various absorbency categories and should be chosen based on the amount of flow experienced. The absorbency of a tampon can be determined by how often it needs to be changed. Girls should use the tampon with the least absorbency necessary to absorb the flow. Tampons should be changed every four to six hours. Tampons also come with a variety of applicators, including plastic and cardboard. Tampons are comfortable to wear and may be a good choice for active girls. They should be inserted carefully to avoid any irritation. A rare, but serious, condition called **toxic shock syndrome** (TSS) can be connected to tampon use. The higher the absorbency of tampons used, the higher the risk for TSS. To decrease the risk of TSS, girls should choose the lowest absorbency necessary.



In this illustration, the menstrual cycle is divided into four stages. First, an egg matures inside the ovary (1), which then releases the egg (2), allowing it to travel through the fallopian tube, where it rests awaiting fertilization (3). If the egg is not fertilized, it is flushed out with the menstrual flow (4). *(Illustration by GGS Information Services.)*

Problems with menstruation

DYSMENORRHEA **Dysmenorrhea** is the medical term for menstrual cramps, the dull or throbbing **pain** in the lower abdomen that many women experience just before and during their menstrual periods. It can be primary or secondary. Primary dysmenorrhea involves no abnormality. Secondary dysmenorrhea involves an underlying physical cause, such as uterine fibroids, pelvic inflammatory disease, or endometriosis. Signs and symptoms of dysmenorrhea, whether it is primary or secondary, may include the following:

- dull, throbbing pain in the lower abdomen
- radiating pain to the lower back and thighs
- nausea, loose stools, sweating, and **dizziness** (though these are much less common)

If menstrual cramps become severe enough to keep a girl from going about her day-to-day routine, she should see a doctor. The doctor will perform a medical history and physical examination, including a pelvic exam, where he or she will look for any abnormalities, signs of infection, and possible causes of secondary dysmenorrheal. In addition, the doctor may request a variety

of diagnostic tests, such as imaging tests, laparoscopy, and hysteroscopy.

Complications can arise from secondary dysmenorrhea. If pelvic inflammatory disease is present, the fallopian tubes may become scarred and possibly cause later infertility or other reproductive problems. Endometriosis can also lead to fertility problems as well.

Many experts believe that prostaglandins, hormone-like substances involved in pain and inflammation and which trigger uterine muscle contractions, are responsible for causing menstrual cramping. Whether the dysmenorrhea is primary or secondary, there are effective ways to treat menstrual pain. **Nonsteroidal anti-inflammatory drugs** (NSAIDS), such as ibuprofen or naproxen, may block the production of prostaglandins and can be very effective in the treatment of menstrual cramps. In the case of severe cramping, doctors may recommend a low-dose oral contraceptive to prevent ovulation, which may reduce the release of prostaglandins and the severity of the cramps.

DYSFUNCTIONAL UTERINE BLEEDING Dysfunctional uterine bleeding (DUB) is prolonged or heavy bleeding that often occurs in a menstrual cycle where ovulation did not occur. Heavy bleeding is defined as more than 15 soaked pads or tampons per period, and prolonged bleeding is that which lasts for more than 8 to 10 days. Although DUB is quite common in the first few years after menstruation starts, it can be frightening and should always be reported to a physician. DUB that is accompanied by dizziness and a low blood pressure should be considered a medical emergency. DUB is usually caused by hormonal imbalances. Other causes of bleeding are sexually transmitted disease, an ectopic pregnancy, ovarian cysts, and uterine fibroids or polyps. Young women within the first menstrual period are not usually treated unless symptoms are exceptionally severe or if anemia develops.

Demographics

Girls may start their menstrual period as early as nine years of age and as late as 16 years old. The average age a girl begins menstruating is 12. Girls who are very active in **sports** or who are quite thin may not develop until a later age. Losing weight while experiencing a growth spurt may also delay menstruation.

In the early 2000s, some people have voiced concern about girls starting their periods at younger and younger ages. However, a study reported in 2003 found that overall, girls in the United States are not beginning menstruation earlier than in the past. Less than 10 percent of girls start their periods before 11 years of age, and 90 percent of all U.S. girls are menstruating by age 14. This age is not significantly different than that reported for girls in 1973. African-American girls on average begin menstruating before Caucasian- and Hispanic-American girls.

Causes and symptoms

The menstrual cycle takes place each month in response to the hormonal changes which occur when pregnancy does not take place. A number of symptoms can occur just before and during a girl's period which may cause discomfort. These include:

- having pelvic area cramps
- feeling bloated or puffy
- breast tenderness or swelling
- headaches and backaches
- acne breakouts
- mild nausea

These symptoms usually stop or lessen a day or two after the period begins.

Diagnosis

There are several reasons why a girl should see her healthcare provider regarding her menstrual cycle. These include:

- if menstruation has not started by the age of 16
- if a menstrual period lasts for more than seven days
- if periods suddenly stop
- if she is experiencing excessive bleeding
- if she feels suddenly ill while using tampons
- if she bleeds more than a few drops between periods
- if she experiences excessive pain during her period

Treatment

No specific medical treatment is necessary for an uncomplicated menstrual cycle, as it is a normal, healthy process in girls and women.

Alternative treatment

Some girls may find relief from menstrual discomfort through meditation, **yoga**, or massage. These stress-relieving activities are unlikely to cause any harm.

KEY TERMS

Dysmenorrhea—Painful menstruation.

Menarche—The first menstrual cycle in a girl's life.

Parental concerns

Though menstruation is no longer the taboo subject it once was, many parents still find that discussing the issue with their daughters can be uncomfortable. This is especially common in families in which the mother is not present. Still, it is important to discuss menstruation with girls when they are preteens, so that they do not experience the potential embarrassment or trauma if they start their first period without knowledge about what is happening to their bodies. Taking the time to prepare may help to make this discussion less awkward.

Mental retardation

Definition

Mental retardation is a developmental disability that first appears in children under the age of 18. It is defined as an intellectual functioning level (as measured by standard tests for **intelligence** quotient) that is well below average and significant limitations in daily living skills (adaptive functioning).

Description

According to statistics made available by the Centers for Disease Control and Prevention in the 1990s, mental retardation occurs in 2.5 to 3 percent of the general population. About 6 to 7.5 million mentally retarded individuals live in the United States alone. Mental retardation begins in childhood or **adolescence** before the age of 18. In most cases, it persists throughout adulthood. A diagnosis of mental retardation is made if an individual has an intellectual functioning level well below average and significant limitations in two or more adaptive skill areas. Intellectual functioning level is defined by standardized tests that measure the ability to reason in terms of mental age (intelligence quotient or IQ). Mental retardation is defined as IQ score below 70 to 75. Adaptive skills are the skills needed for daily life. Such skills include the ability to produce and understand language (communication); home-living skills; use of community resources; health, **safety**, leisure, self-care, and social skills; self-direction; functional academic skills (reading, writing, and arithmetic); and work skills.

In general, mentally retarded children reach developmental milestones such as walking and talking much later than the general population. Symptoms of mental retardation may appear at birth or later in childhood. Time of onset depends on the suspected cause of the disability. Some cases of mild mental retardation are not diagnosed before the child enters **preschool**. These children typically have difficulties with social, communication, and functional academic skills. Children who have a neurological disorder or illness such as **encephalitis** or **meningitis** may suddenly show signs of cognitive impairment and adaptive difficulties.

Mental retardation varies in severity. There are four different degrees of mental retardation: mild, moderate, severe, and profound. These categories are based on the functioning level of the individual.

Mild mental retardation

Approximately 85 percent of the mentally retarded population is in the mildly retarded category. Their IQ score ranges from 50 to 75, and they can often acquire academic skills up to the sixth grade level. They can become fairly self-sufficient and in some cases live independently, with community and social support.

Moderate mental retardation

About 10 percent of the mentally retarded population is considered moderately retarded. Moderately retarded individuals have IQ scores ranging from 35 to 55. They can carry out work and self-care tasks with moderate supervision. They typically acquire **communication skills** in childhood and are able to live and function successfully within the community in a supervised environment such as a group home.

Severe mental retardation

About 3 to 4 percent of the mentally retarded population is severely retarded. Severely retarded individuals have IQ scores of 20 to 40. They may master very basic self-care skills and some communication skills. Many severely retarded individuals are able to live in a group home.

Profound mental retardation

Only 1 to 2 percent of the mentally retarded population is classified as profoundly retarded. Profoundly retarded individuals have IQ scores under 20 to 25. They may be able to develop basic self-care and communication skills with appropriate support and training. Their retardation is often caused by an accompanying neurological disorder. The profoundly retarded need a high level of structure and supervision.

The American Association on Mental Retardation (AAMR) has developed another widely accepted diagnostic classification system for mental retardation. The AAMR classification system focuses on the capabilities of the retarded individual rather than on the limitations. The categories describe the level of support required. They are: intermittent support, limited support, extensive support, and pervasive support. Intermittent support, for example, is support needed only occasionally, perhaps during times of stress or crisis. It is the type of support typically required for most mildly retarded individuals. At the other end of the spectrum, pervasive support, or life-long, daily support for most adaptive areas, would be required for profoundly retarded individuals.

Demographics

For children, the mental retardation rate is 11.4 per 1,000 and varies approximately nine fold, ranging from 3.2 in New Jersey to 31.4 in Alabama. For adults, the rate is 6.6 and varies approximately six fold, ranging from 2.5 in Alaska to 15.7 in West Virginia. In 42 states, the rate for children is higher than that for adults; in seven states, the rate for adults is higher, and in two states, both rates are similar. The correlation between state-specific rates for children and for adults is 0.66. Overall, 69 percent of the state-specific variation in prevalence rates for adults is accounted for by median household income, the percentage of total births to teenaged mothers, and the percentage of the population with less than a ninth-grade education. Low educational attainment was the most important correlate of mental retardation rates among adults.

Causes and symptoms

Low IQ scores and limitations in adaptive skills are the hallmarks of mental retardation. Aggression, self-injury, and **mood disorders** are sometimes associated with the disability. The severity of the symptoms and the age at which they first appear depend on the cause. Children who are mentally retarded reach developmental milestones significantly later than expected, if at all. If retardation is caused by chromosomal or other genetic disorders, it is often apparent from infancy. If retardation is caused by childhood illnesses or injuries, learning and adaptive skills that were once easy may suddenly become difficult or impossible to master. In about 35 percent of cases, the cause of mental retardation cannot be found. Biological and environmental factors that can cause mental retardation include genetics, prenatal illnesses and issues, childhood illnesses and injuries, and environmental factors.

Genetics

About 5 percent of mental retardation is caused by hereditary factors. Mental retardation may be caused by an inherited abnormality of the genes, such as **fragile X syndrome**. Fragile X, a defect in the chromosome that determines sex, is the most common inherited cause of mental retardation. Single gene defects such as **phenylketonuria** (PKU) and other inborn errors of metabolism may also cause mental retardation if they are not found and treated early. An accident or mutation in genetic

development may also cause retardation. Examples of such accidents are development of an extra chromosome 18 (trisomy 18) and **Down syndrome**. Down syndrome is caused by an abnormality in the development of chromosome 21. It is the most common genetic cause of mental retardation.

Prenatal illnesses and issues

Fetal alcohol syndrome affects one in 600 children in the United States. It is caused by excessive alcohol intake in the first twelve weeks (trimester) of pregnancy. Some studies have shown that even moderate alcohol use during pregnancy may cause learning disabilities in children. Drug abuse and cigarette **smoking** during pregnancy have also been linked to mental retardation.

Maternal infections and illnesses such as glandular disorders, **rubella**, **toxoplasmosis**, and **cytomegalovirus infection** may cause mental retardation. When the mother has high blood pressure (**hypertension**) or blood poisoning (toxemia), the flow of oxygen to the fetus may be reduced, causing brain damage and mental retardation.

Birth defects that cause physical deformities of the head, brain, and central nervous system frequently cause mental retardation. Neural tube defect, for example, is a birth defect in which the neural tube that forms the spinal cord does not close completely. This defect may cause children to develop an accumulation of cerebrospinal fluid on the brain (**hydrocephalus**). By putting pressure on the brain hydrocephalus can cause learning impairment.

Childhood illnesses and injuries

Hyperthyroidism, **whooping cough**, **chickenpox**, **measles**, and Hib disease (a bacterial infection) may cause mental retardation if they are not treated adequately. An infection of the membrane covering the brain (meningitis) or an inflammation of the brain itself (encephalitis) cause swelling that in turn may cause brain damage and mental retardation. Traumatic brain injury caused by a blow or a violent shake to the head may also cause brain damage and mental retardation in children.

Environmental factors

Ignored or neglected infants who are not provided the mental and physical stimulation required for normal development may suffer irreversible learning impairments. Children who live in poverty and suffer from **malnutrition**, unhealthy living conditions, and improper or inadequate medical care are at a higher risk. Exposure to lead can also cause mental retardation. Many children develop **lead poisoning** by eating the flaking lead-based paint often found in older buildings.

When to call the doctor

If mental retardation is suspected, a comprehensive physical examination and medical history should be done immediately to discover any organic cause of symptoms. Conditions such as hyperthyroidism and PKU are treatable. If these conditions are discovered early, the progression of retardation can be stopped and, in some cases, partially reversed. If a neurological cause such as brain injury is suspected, the child may be referred to a neurologist or neuropsychologist for testing.

The symptoms of mental retardation are usually evident by a child's first or second year. In the case of Down syndrome, which involves distinctive physical characteristics, a diagnosis can usually be made shortly after birth. Mentally retarded children lag behind their peers in developmental milestones such as smiling, sitting up, walking, and talking. They often demonstrate lower than normal levels of interest in their environment and responsiveness to others, and they are slower than other children in reacting to visual or auditory stimulation. By the time a child reaches the age of two or three, retardation can be determined using physical and **psychological tests**. Testing is important at this age if a child shows signs of possible retardation because alternate causes, such as impaired hearing, may be found and treated.

Diagnosis

A complete medical, **family**, social, and educational history is compiled from existing medical and school records (if applicable) and from interviews with parents. Children are given intelligence tests to measure their learning abilities and intellectual functioning. Such tests include the Stanford-Binet Intelligence Scale, the Wechsler Intelligence Scales, the Wechsler Preschool and Primary Scale of Intelligence, and the Kaufmann Assessment Battery for Children. For infants, the **Bayley Scales of Infant Development** may be used to assess motor, language, and problem-solving skills. Interviews with parents or other caregivers are used to assess the child's daily living, muscle control, communication, and social skills. The Woodcock-Johnson Scales of Independent Behavior and the Vineland Adaptive Behavior Scale (VABS) are frequently used to test these skills.

Treatment

Federal legislation entitles mentally retarded children to free testing and appropriate, individualized education and skills training within the school system from ages three to 21. For children under the age of three, many states have established early intervention programs that assess, recommend, and begin treatment programs. Many day schools are available to help train retarded children in basic skills such as bathing and feeding themselves. **Extracurricular activities** and social programs are also important in helping retarded children and adolescents gain **self-esteem**.

Training in independent living and job skills is often begun in early adulthood. The level of training depends on the degree of retardation. Mildly retarded individuals can often acquire the skills needed to live independently and hold an outside job. Moderate to profoundly retarded individuals usually require supervised community living. **Family therapy** can help relatives of the mentally retarded develop coping skills. It can also help parents deal with feelings of guilt or anger. A supportive, warm home environment is essential to help the mentally retarded reach their full potential. However, as of 2004, there is no cure for mental retardation.

A promising but controversial treatment for mental retardation involves stem cell research. In the early 2000s scientists are exploring the potential of adult stem cells in treating mental retardation. They have transplanted bone marrow cells into living embryos in the uteri of animals to approach congenital diseases, birth defects, and mental retardation. Stem cells are primitive cells that are capable of forming diverse types of tissue. Because of this remarkable quality, human stem cells hold huge promise for the development of therapies to regenerate damaged organs and heal people who are suffering from terrible diseases. Embryonic stem cells are derived from human embryos. Their use is controversial because such stem cells cannot be used in research without destroying the living embryo. Other sources of stem cells are available, however, and can be harvested from umbilical cord blood as well as from fat, bone marrow, and other adult tissue without harm to the donor. An enormous amount of research involving adult stem cells is going on as of 2004 in laboratories in the United States.

Prognosis

Individuals with mild to moderate mental retardation are frequently able to achieve some self-sufficiency and to lead happy and fulfilling lives. To reach these goals, they need appropriate and consistent educational, community, social, family, and vocational supports. The outlook is less promising for those with severe to profound retardation. Studies have shown that these individuals have a shortened life expectancy. The diseases that are usually associated with severe retardation may cause the shorter life span. People with Down syndrome develop in later life the brain changes that characterize Alzheimer's disease and may develop the clinical symptoms of this disease as well.

Prevention

Immunization against diseases such as measles and Hib prevents many of the illnesses that can cause mental retardation. In addition, all children should undergo routine developmental screening as part of their pediatric care. Screening is particularly critical for those children who may be neglected or undernourished or may live in disease-producing conditions. Newborn screening and immediate treatment for PKU and hyperthyroidism can usually catch these disorders early enough to prevent retardation. Good prenatal care can also help prevent retardation. Pregnant women should be educated about the risks of drinking and the need to maintain good **nutrition** during pregnancy. Tests such as **amniocentesis** and ultrasonography can determine whether a fetus is developing normally in the womb.

Parental concerns

All states are required by law to offer early intervention programs for mentally retarded children from the time they are born. The sooner the diagnosis of mental retardation is made, the more the child can be helped. With mentally retarded infants, the treatment emphasis is on sensorimotor development, which can be stimulated by exercises and special types of **play**. It is required that **special education** programs be available for retarded children starting at three years of age. These programs concentrate on essential self-care, such as feeding, dressing, and **toilet training**. There is also specialized help available for language and communication difficulties and physical disabilities. As children grow older, training in daily living skills, as well as academic subjects, is offered.

Counseling and therapy are another important type of treatment for the mentally retarded. Retarded children are prone to behavioral problems caused by short attention span, low tolerance for frustration, and poor impulse control. Behavior therapy with a mental health professional can help combat negative behavior patterns and replace them with more functional ones. A counselor or therapist can also help retarded children cope with the

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby for analysis. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Developmental delay—The failure of a child to meet certain developmental milestones, such as sitting, walking, and talking, at the average age. Developmental delay may indicate a problem in development of the central nervous system.

Down syndrome—A chromosomal disorder caused by an extra copy or a rearrangement of chromosome 21. Children with Down syndrome have varying degrees of mental retardation and may have heart defects.

Hib disease—An infection caused by *Haemophilus influenza* type b (Hib). This disease mainly affects children under the age of five. In that age group, it is the leading cause of bacterial meningitis, pneumonia, joint and bone infections, and throat inflammations.

Inborn error of metabolism—One of a group of rare conditions characterized by an inherited defect in an enzyme or other protein. Inborn errors of metabolism can cause brain damage and mental retardation if left untreated. Phenylketonuria, Tay-Sachs disease, and galactosemia are inborn errors of metabolism.

Phenylketonuria (PKU)—A rare, inherited, metabolic disorder in which the enzyme necessary to break down and use phenylalanine, an amino acid necessary for normal growth and development, is lacking. As a result, phenylalanine builds up in the body causing mental retardation and other neurological problems.

Trisomy—An abnormal condition where three copies of one chromosome are present in the cells of an individual's body instead of two, the normal number.

Ultrasonography—A medical test in which sound waves are directed against internal structures in the body. As sound waves bounce off the internal structure, they create an image on a video screen. Ultrasonography is often used to diagnose fetal abnormalities, gallstones, heart defects, and tumors. Also called ultrasound imaging.

low self-esteem that often results from the realization that they are different from other children, including siblings. Counseling can also be valuable for the family of a retarded child to help parents cope with painful feelings about the child's condition and with the extra time and patience needed for the care and education of a special-needs child. Siblings may need to talk about the pressures they face, such as accepting the extra time and attention their parents must devote to a retarded brother or sister. Sometimes parents have trouble **bonding** with an infant who is retarded and need professional help and reassurance to establish a close and loving relationship.

Current social and healthcare policies encourage keeping mentally retarded persons in their own homes or in informal group home settings rather than institutions. The variety of social and mental health services available to the mentally retarded, including pre-vocational and vocational training, are geared toward making this possible.

Methamphetamine *see* **Stimulant drugs**

Methylphenidate

Definition

The generic name for the drug Ritalin, the most commonly prescribed medication for treating children with attention-deficit hyperactivity disorder (ADHD).

Description

Methylphenidate is one of a group of drugs called central nervous system (CNS) stimulants. It is used to treat attention-deficit hyperactivity disorder, **narcolepsy** (uncontrollable desire for **sleep** or sudden attacks of deep sleep), and other conditions as determined by a physician or other healthcare provider.

Psychostimulants such as methylphenidate (Ritalin) are commonly prescribed to treat attention-deficit/hyperactivity disorder (AD/HD). *(Photo Researchers, Inc.)*

Methylphenidate contributes to the treatment of ADHD by increasing attention and decreasing restlessness in children and adults who are overactive, cannot concentrate for very long, or are easily distracted, and are impulsive. Methylphenidate is intended to be used as part of a total treatment program that also includes social, educational, and psychological treatment.

A central nervous system stimulant, methylphenidate is also used to control narcolepsy, a condition characterized by an overpowering desire to sleep. Methylphenidate comes in short- and long-acting tablets. The latter should be swallowed whole, never broken into smaller pieces or chewed.

General use

Initially methylphenidate is prescribed in two daily doses of 2.5 mg each, taken at breakfast and lunch time. The dosage is gradually increased until the daily amount reaches 10.0 mg. The dosages should be strictly followed, and since anorexia is an important side effect, the dosages should always be accompanied by a meal or snack. The primary side effect of methylphenidate is growth suppression. Others include irritability, restlessness, agitation, **nausea**, and headaches. Occasionally it causes sleeplessness, in which case the last dosage of the day should be a short-action tablet. Physicians often recommend regular drug-free periods to combat these side effects. In many cases, a child only takes methylphenidate during the school year.

Precautions

Methylphenidate can be addictive and dosage should be tapered off gradually. Signs of physical depen-

KEY TERMS

Attention deficit hyperactivity disorder (ADHD)—A condition in which a person (usually a child) has an unusually high activity level and a short attention span. People with the disorder may act impulsively and may have learning and behavioral problems.

Narcolepsy—A life-long sleep disorder marked by four symptoms: sudden brief sleep attacks, cataplexy (a sudden loss of muscle tone usually lasting up to 30 minutes), temporary paralysis, and hallucinations. The hallucinations are associated with falling asleep or the transition from sleeping to waking.

dency include the need to increase the dosage in order to achieve results, mental depression, unusual behavior, and unusual tiredness or weakness. Some medical professionals believe that methylphenidate is prescribed too often. They call for better diagnostic procedures conducted by trained personnel rather than relying primarily on subjective observations by parents and teachers.

The dosage of methylphenidate is different for different people. It is important to follow the prescribing physician's orders or the instructions that appear on the label of the container. Do not change dosages unless a physician approves such an alteration.

Side effects

Any serious reaction to the drug, such as shortness of breath, irregular heartbeat, or allergic reaction, should be reported to one's doctor. Less severe, more common side effects include blurred vision, insomnia, drowsiness, gastrointestinal distress (nausea or **vomiting**), **dizziness**, headaches, and possible **addiction**.

Interactions

Persons taking methylphenidate should be aware of the possible adverse interactions with the following drugs: amphetamines, appetite suppressants, **caffeine**, chlophedianol, cocaine, **asthma** medication, cold, sinus and hay fever medications, nabilone, pemoline, monoamine oxidase inhibitors, and pimozide. Methylphenidate is also affected by epilepsy, Tourette's syndrome, glaucoma, high blood pressure, psychosis, severe **anxiety**, and **tics**.

Parental concerns

The use of methyphenidate has been subject to controversy over the last several years. Parents concerned about whether the drug is being properly prescribed for their children should seek out the opinion of the most suitable physician for the type of problems their child is having. If a parent is uncomfortable with a physician's response, they should not hesitate to get a second opinion.

Mineral deficiency

Definition

Mineral deficiency is a reduced level of any of the **minerals** essential to human health. An abnormally low mineral concentration is usually defined as a level that may impair a function dependent on that mineral.

Description

Minerals are essential nutrients for every living cell in the human body. Defined in the study of human **nutrition** as all the inorganic elements or molecules required for life, minerals assist in body functions such as producing energy, growing, and healing. Minerals are required for fluid balance, blood and bone development, maintaining a healthy nervous system, and regulating muscles, including heart muscles. Minerals, like **vitamins**, function as coenzymes. They participate in all enzyme reactions in the body and help in the assimilation and use of vitamins and other nutrients.

Minerals occur either as bulk minerals (macrominerals) or trace minerals (microminerals). The body needs more bulk minerals than it does trace minerals, although both are essential for health. Minerals are consumed in food from plants and plant-eating animals. These sources of minerals develop in a sequence that takes millions of years, beginning with rock formation, the breakdown of rocks into mineral salts, and the assimilation of these salts into soil that nourishes edible plants.

Recommended daily allowances exist for a number of minerals, such as calcium. However, minimum daily requirements for some minerals such as boron, chromium, and molybdenum, do not exist. The essential bulk minerals include:

- Calcium—essential for strong bones and teeth, healthy gums, and bone growth and mineral density in children. Calcium helps regulate the heart rate and nerve impulses, lower cholesterol, prevent atherosclerosis, develop muscles, and prevent muscle cramping. Calcium is an important component of blood clotting. Calcium and phosphorus are closely related minerals that should be balanced. About 99 percent of calcium and 85 percent of phosphate occur in the skeleton as crystals of calcium phosphate. Both nutrients occur in a variety of foods such as milk, eggs, and green, leafy vegetables. Calcium deficiency due to lack of dietary calcium occurs only rarely and is often due to **vitamin D deficiency**, because vitamin D is required for efficient absorption of dietary calcium. Significant depletion of calcium stores can lead to osteoporosis.
- Magnesium—assists in the utilization of calcium and potassium, and functions in enzyme reactions to produce energy. Magnesium protects the lining of arteries and helps form bones. It helps prevent cardiovascular disease, osteoporosis, and some cancers. By acting with vitamin B_6, magnesium can help prevent or dissolve calcium oxylate kidney stones, the most common kind of stones. Dietary magnesium deficiency is uncommon, but may occur in chronic alcoholics, persons taking diuretic drugs, and as a result of severe, prolonged **diarrhea**.
- Sodium—sodium deficiency (hyponatremia) is a serious deficiency, arising most often after excessive losses of body fluid (**dehydration**) during prolonged and severe diarrhea or **vomiting**. Sodium and potassium are electrolytes that must be balanced in the body. Since most people get more than enough salt in the diet, potassium may be needed to balance it. Together, these minerals control fluid balance through a mechanism called "the sodium/potassium pump." Prolonged imbalances in sodium and potassium can contribute to heart disease.
- Potassium—important for a healthy nervous system and a steady heart rate, helps to prevent **stroke**, and, with sodium, is critical in maintaining fluid balance. Potassium, an electrolyte, must be balanced with sodium. Potassium deficiency is usually associated

with sodium deficiency and both are associated with dehydration stemming from excessive losses of body fluid.

- Phosphorus—helps form bones and teeth, supports cell growth, and regulates heart muscle contraction and kidney function. Phosphorus converts food to energy and supports the utilization of vitamins. Deficiency is rare because phosphate is plentiful in plant and animal foods and is efficiently absorbed from the diet. Phosphorus is closely related to calcium and the two minerals should be in balance with each other and with magnesium. Deficiency in one will affect all and will ultimately have an unwanted effect on body function. Calcium and phosphorus are stored in the bones as crystals of calcium phosphate. Milk, eggs, and green, leafy vegetables are rich in calcium and phosphate.

Trace minerals essential for human health include:

- Boron—required for healthy bones, brain function, alertness, and the metabolism of bulk minerals such as calcium, phosphorus, and magnesium. Deficiencies are rare except in aging, when supplementation may help absorb calcium. A deficiency in boron is associated with vitamin D deficiency. Boron supplements can improve calcium levels as well as vitamin D levels, and can help prevent osteoporosis in postmenopausal women by promoting calcium absorption.
- Chromium—required for maintaining energy levels. Chromium helps metabolize glucose and stabilize glucose levels. It helps the body manufacture and use cholesterol and protein.
- Copper—helps form healthy bones, joints, and nerves as well as hemoglobin and red blood cells. Copper contributes to healing, energy production, taste, and hair and skin color. It is essential in forming collagen for healthy bones and connective tissue, and helps prevent osteoporosis. Except in osteoporosis, copper deficiency is rare, although dramatic changes in copper metabolism occur in two serious genetic diseases, Wilson disease and Menkes' disease.
- Germanium—helps improve the delivery of oxygen to tissues and remove toxins and poisons from the body. Germanium gives garlic its natural antibiotic properties.
- Iodine—helps promote healthy physical and mental development in children. Iodine is required for thyroid gland function and metabolizing fats. Iodine deficiency is a public health problem in parts of the world that have iodine-deficient soils. Iodine is needed to make thyroid hormone, which has a variety of roles in human embryo development. A deficiency during pregnancy can cause serious birth defects. Deficiency in adults can result in an enlarged thyroid gland (goiter) in the neck.
- Iron—critical in the production of hemoglobin, the oxygen-carrying protein in red blood cells, and myoglobin found in muscle tissue. Iron is essential for important enzyme reactions, growth, and maintaining a healthy immune system. In the blood, iron is found in larger amounts than any other mineral. Iron deficiency causes anemia (low hemoglobin and reduced numbers of red blood cells), which results in tiredness and shortness of breath because of poor oxygen delivery.
- Manganese—essential for metabolizing fat and protein, regulating blood glucose, and supporting immune system and nervous system function. Manganese is necessary for normal bone growth and cartilage development. It is involved in reproductive functions and helps produce mother's milk. Along with B vitamins, manganese produces feelings of well-being. Deficiency can lead to convulsions, vision and hearing problems, muscle contractions, tooth-grinding and other problems in children; and atherosclerosis, heart disease, and **hypertension** in older adults.
- Molybdenum—found in bones, kidneys, and liver. Only extremely small amounts are needed to metabolize nitrogen and promote proper cell function. Molybdenum is present in beans, peas, legumes, whole grains, and green leafy vegetables. A diet low in these foods can lead to mouth and gum problems and cancer.
- Selenium—an important antioxidant that works with vitamin E to protect the immune system, heart, and liver, and may help prevent tumor formation. Selenium deficiency occurs in regions of the world where soils are selenium-poor and low-selenium foods are produced. Premature infants are naturally low in selenium with no known serious effects.
- Silicon—helps form bones and connective tissue, nails, skin, and hair. Silicon is important in preventing cardiovascular disease.
- Sulfur—disinfects the blood and helps to rid the body of harmful bacteria and toxic substances.
- Vanadium—vital to cell metabolism, and helps reduce cholesterol and form healthy bones and teeth. Vanadium functions in reproduction. Deficiencies may be associated with heart and kidney disease and reproductive disorders. Vanadium deficiency may be associated with infant mortality.
- Zinc—important in the growth of reproductive organs and regulation of oil glands. Zinc is required for protein synthesis, immune system function, protection of the liver, collagen formation, and wound healing. A component of insulin and major body enzymes, zinc

helps vitamin absorption, particularly vitamins A and E. Deficiency is rare.

Trace and bulk minerals are stored in muscles and bones and delivered to tissue cells through blood circulation. They work together synergistically and must be chemically balanced in the body; if one is deficient or out of balance, it can affect all the others, often resulting in illness. If zinc, for example, is present at high levels, calcium levels will be reduced because the two minerals compete for absorption. Similarly, too much calcium will deplete magnesium, and so on. Deficiency in one nutrient occurs less often than deficiency in several nutrients. A child suffering from **malnutrition** will likely be deficient in a variety of nutrients. Deficiencies in one nutrient do occur, however, such as in populations living in iodine-poor regions, and in iron deficient persons who lose excess iron by abnormal bleeding. All uncorrected mineral deficiencies can affect body functions, produce symptoms, and result in illness.

Demographics

Statistics are not available for most individual mineral deficiencies, most likely because such deficiencies are rare in the United States. Surveys of lower-income families in the United States reveal that about 6 percent of infants are anemic, indicating a possible deficiency of iron in the diet (all **anemias** are not iron-deficiency related).

Diarrheal diseases and related sodium and potassium deficiencies are responsible for about two million infant deaths each year worldwide. Few of these deaths occur in the United States.

Causes and symptoms

Calcium and phosphorus deficiencies

Calcium and phosphorus are plentiful in foods, and dietary deficiencies are rare. Vitamin D deficiency impairs the absorption of dietary calcium and can provoke calcium deficiency (hypocalcemia) even when adequate calcium is consumed. Vitamin D deficiency can be found among young infants and the elderly who may be shielded from sunshine for prolonged periods. As women age, reductions in the hormone estrogen can affect the rate of calcium loss. Significant depletion of calcium stores can lead to osteoporosis. Deficiency of calcium or imbalances with phosphorus and magnesium can produce muscle cramping and digestive problems. Symptoms of calcium deficiency include joint **pain**, brittle nails, eczema, **high cholesterol**, insomnia, high blood pressure, nervousness, and **tooth decay**. Calcium deficiency can also contribute to cognitive problems (confusion, inattention, learning, and memory), convulsions, depression, and hyperactivity. Phosphorus deficiency can produce **anxiety**.

Sodium and potassium deficiencies

Deficiency or imbalance in sodium and potassium does not usually result from a lack of these minerals in the diet, but from imbalances in body fluids. This can be caused by excessive losses of body fluid (dehydration) from severe diarrhea or vomiting; laxative abuse; or during treatment of heart disease or high blood pressure (hypertension) with diuretic drugs, which are used to reduce fluid overload. Sodium and potassium imbalances can cause cardiac arrhythmias and shock (a reduced flow of blood and oxygen to tissues throughout the body). Although diarrheal fluids deplete a number of electrolytes (sodium, potassium, chloride, calcium, phosphorus, and magnesium), the main concern in avoiding shock is replacing sodium and water. Potassium deficiency alone can also affect nerve function.

Magnesium deficiency

Dietary magnesium deficiency is rare because the mineral is found in nearly all foods, but it can occur through poor diet or in malnutrition, or result from excessive losses due to severe diarrhea or vomiting. Symptoms of magnesium deficiency include faulty transmission of nerve and muscle impulses, irritability, nervousness, and **tantrums**. Confusion, poor digestion, rapid or irregular heartbeat (arrhythmia), and seizures can also result. Magnesium deficiency is associated with cardiac arrest, **asthma**, chronic fatigue syndrome, chronic pain, depression, insomnia, **irritable bowel syndrome**, and lung conditions.

Boron deficiency

Boron deficiency is rare, although reduced levels do occur with aging and with reduced levels of vitamin D. Because boron is involved in the absorption of calcium, the only symptom may be reduced levels of calcium or the inability to absorb supplemental calcium.

Chromium deficiency

Many Americans are deficient in dietary chromium, which can be associated with poor regulation of insulin and related imbalances in glucose (either diabetes or **hypoglycemia**). Symptoms include fatigue, anxiety, poor protein metabolism, and glucose intolerance (as in diabetes). In adults, chromium deficiency can be a sign of coronary artery disease.

Copper deficiency

Copper is obtained through a balanced diet and deficiency is rare. Signs of copper deficiency may include anemia, diarrhea, weakness, poor respiratory function, baldness, skin sores, and increased lipid (fat) levels in the blood. Severe alterations in copper metabolism are seen in two rare genetic diseases: Wilson disease and Menkes' disease, which occur in about one in 100,000 births. Both diseases involve mutations in copper transport proteins, special channels that allow copper ions to pass through cell membranes. Menkes' disease, called the "kinky hair disease," results in tangled, grayish, steely, or kinky hair and chubby, rosy cheeks. Untreated Menkes' disease is associated with **mental retardation** and death before three years of age. Wilson disease involves decreases in copper in blood cells, the liver and brain; and increases in copper (copper toxicosis) in the cells of the intestines and kidneys. It results in degenerative changes in the brain, liver disease, and hemolytic anemia. Children older than five years who have any form of liver disease are often evaluated for serum and cellular copper levels to determine if Wilson disease is present.

Germanium deficiency

Germanium deficiency is rare; in fact, there is no established deficiency level.

Iodine deficiency

Iodine deficiency occurs when soil is iodine-poor and foods grown in the soil are correspondingly low in iodine. An iodine intake of 0.10–0.15 mg/day is considered to be nutritionally adequate. Iodine deficiency occurs when intake is below 0.05 mg/day. Goiter, an enlargement of the thyroid gland in the neck, results from iodine deficiency. Although goiter continues to be a problem in other parts of the world, it no longer occurs in the United States because of the fortification of foods with iodine. Iodine deficiency during pregnancy can result in cretinism in newborns, involving mental retardation and a large tongue.

Iron deficiency

Iron deficiency occurs most often because of poor iron intake and poor absorption. In children, iron deficiency is due to periods of dietary deficiency and heavy demands for iron during rapid growth. Human milk and cow's milk both contain low levels of iron; however, the iron in human milk is in a highly absorbable form. Infants are at risk for acquiring iron deficiency because their rapid rate of growth needs a corresponding increased supply of dietary iron, for use in making blood and muscles. Cow's milk formula is fortified with iron. Human milk is a better source of iron than cow's milk, since about half of the iron in human breast milk is absorbed by the infant's digestive tract. In contrast, only 10 percent of the iron in cow's milk is absorbed by the infant. Toddlers who drink excessive whole cow's milk are at risk for iron deficiency. Iron deficiency can also be caused by excess phosphorus in the diet, chronic intestinal bleeding, poor digestion and absorption, prolonged illness, ulcers, and the use of antacids. In women and teenage girls, blood loss through **menstruation** can result in iron deficiency. Symptoms of iron deficiency include anemia and resulting fatigue and weakness, especially during physical exertion. Fragile bones, brittle hair and nails, hair loss, spoon-shaped fingernails or ridges from the base of the nails to the ends, difficulty swallowing, nervousness, paleness, and lagging mental responses are also possible iron deficiency symptoms.

Manganese deficiency

Deficiency of manganese is very rare. Experimental studies of individuals fed a manganese deficient diet have revealed that the deficiency produces a scaly, red rash on the skin of the upper torso.

Selenium deficiency

Selenium deficiency may occur in premature infants who naturally tend to have about one-third the selenium levels of full-term infants. It is not known if these lower levels result in adverse consequences. Selenium deficiency occurs in regions of the world containing low-selenium soils, including parts of China, New Zealand, and Finland. In Keshan Province, China, a condition (Keshan disease) occurs that results in deterioration of regions of the heart and the development of fibers in these areas. Keshan disease, which may be fatal, is thought to result from a combination of selenium deficiency and a virus.

Zinc deficiency

Zinc deficiency can be caused by diarrhea, liver and kidney disease, **alcoholism**, diabetes, malabsorption, and overconsumption of fiber. Symptoms of zinc deficiency include **acne**, recurrent colds and flu, loss of senses of taste and smell, poor night vision, slow growth, lack of sexual maturation, lack of pubic hair, and small stature. Studies have shown that signs of zinc deficiency are detectable after two to five weeks of consuming a zinc-free diet. Signs include a rash on the face, groin, hands and feet, and diarrhea. Administering zinc will correct these symptoms.

When to call the doctor

Mineral deficiencies present with a wide variety of symptoms. Parents should observe children closely and report any unusual symptoms to the pediatrician, such as tiredness, weakness, depression or anxiety, irritability, nervousness, skin irritations, dehydration from vomiting or diarrhea, and slow growth or development of skills. Other than providing regular vitamin supplements and a balanced diet to prevent deficiencies, parents should not attempt to diagnose and treat deficiencies on their own.

Diagnosis

Individual minerals can be measured in blood serum, red blood cells, tissue cells, or urine, to estimate available levels and determine normal or abnormal status. Since each mineral performs strikingly different functions, tests to confirm deficiency are markedly different from each other. Testing can range from simple to extensive. Physicians will consider the possible consequences of each type of deficiency and evaluate the function of organ systems affected by the particular mineral.

In addition to determining serum calcium, phosphorus, and vitamin D levels, the diagnosis of calcium and phosphorus deficiency may involve taking **x rays** of the skeleton.

Diagnosing iron deficiency will require measuring iron levels and investigating anemia by performing blood tests such as a complete blood count (CBC) to determine the number of red blood cells, hemoglobin level, red cell volume, and cell maturity (morphology). A stair-stepping test may be used to evaluate stamina, but a blood test is required to diagnose iron deficiency.

Diagnosing low levels or imbalances of the electrolytes sodium, potassium, calcium, magnesium, or phosphate involves measuring the serum levels of each. Measurement determines the circulating blood level at the time blood was drawn. Laboratory values of sodium and potassium, which are present within cells and in the fluid between cells, can change rapidly depending on the individual's overall condition. They may be measured repeatedly to determine a trend and to monitor correction of the deficiency or imbalance after diagnosis.

Normal serum magnesium levels are 1.2–2.0 mE/l, while levels in deficiency (hypomagnesemia) are below 0.8 mE/l. Because calcium and magnesium must remain balanced, magnesium levels below 0.5 mE/l can provoke a decline in serum calcium levels. Hypomagnesemia can also result in low serum potassium. Symptoms of hypomagnesemia, such as twitching and convulsions, may actually result from the hypocalcemia. Other symptoms, such as cardiac arrhythmias, actually occur because of low potassium. All three minerals will be measured.

Iodine deficiency is diagnosed by measuring the concentration of iodine in urine. A urinary level greater than 0.05 mg iodine per gram of creatinine (another metabolite excreted in urine) indicates adequate iodine status. Levels under 0.025 mg iodine/gram creatinine indicate serious risk. The doctor may also examine the neck with the eyes and hands to see if a goiter is present.

Urinary zinc levels will differ between normal dietary intake (16 mg per day) and low-zinc diets (0.3 mg per day); normal urinary zinc is about 0.45 mg per day while low-zinc urinary levels are about 0.150 mg per day. Plasma zinc levels tend to be maintained during a dietary deficiency in zinc. Plasma and urinary zinc levels can be influenced by a variety of factors, and for this reason cannot provide a clear picture of zinc status.

Selenium can be measured in plasma or red blood cells and compared to normal values. The activity of an enzyme (glutathione peroxidase) in platelets (small blood cells essential in blood clotting) may be evaluated to assess selenium status.

Treatment

Most mineral deficiencies can be successfully treated through diet or supplementation, except when caused by disease, which requires treatment of the disease.

Treating fluid imbalances and related deficiencies in sodium, potassium, calcium, and phosphate usually requires intravenous (IV) infusion of the deficient mineral in fluid over a period of time. Sudden changes in sodium and potassium levels can be just as dangerous as low levels; caution is used to restore balance gradually. Children may be given oral pediatric preparations to gradually restore fluids and minerals.

Iron deficiency requires oral supplementation or injectable iron. Vitamin C helps to assimilate iron.

Iodine deficiency is easily treated and prevented by consuming foods fortified with iodine, such as table salt. Goiter is reversible with treatment but cretinism is not.

A magnesium-rich diet will correct magnesium deficiency. If deficiency is due to prolonged depletion, treatment may include injections of magnesium sulfate; if severe enough to provoke convulsions, intravenous infusions may be given.

Selenium deficiency can be treated by supplementation. Children can be given supplements containing 1.0 mg sodium selenite.

Zinc and copper deficiencies are rare and can be treated with supplementation.

Prognosis

The prognosis for mineral deficiencies depends on the extent of deficiency at diagnosis, the degree of effects or symptoms, and the overall health of the individual. Correction through diet or supplements usually produces good results. Symptoms may sometimes be relieved promptly with supplementation. Some deficiencies produce permanent effects of varying severity.

In iodine deficiency, the prognosis for treating goiter is excellent. Sodium and potassium deficiencies or imbalances can be corrected if diagnosed and treated promptly, but can be life-threatening if untreated. Anemia and other effects of iron deficiency are not usually life-threatening and can be corrected with supplementation. "Silent" or undiagnosed calcium loss may result in osteoporosis, which may produce disability or complications by the time it is diagnosed.

Alternative treatment

Sea vegetables (sea weeds such as dulse, kelp, wakambe, and hijiki) are an excellent source of minerals obtained from the ocean. They can be used to make soup stock, added to stews and casseroles, or served with vegetables. Herbs are a valuable source of minerals as well. For example, calcium is found in alfalfa, burdock root, chamomile, dandelion, flaxseed, paprika, raspberry leaves, rose hips, and other herbs. Iron is found in the same herbs as calcium, and in the Chinese herb *dong quai* (angelica), as well as other herbs.

KEY TERMS

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Nutrient—Substances in food that supply the body with the elements needed for metabolism. Examples of nutrients are vitamins, minerals, carbohydrates, fats, and proteins.

Osteoporosis—Literally meaning "porous bones," this condition occurs when bones lose an excessive amount of their protein and mineral content, particularly calcium. Over time, bone mass and strength are reduced leading to increased risk of fractures.

Recommended Dietary Allowance (RDA)—The Recommended Dietary Allowances (RDAs) are quantities of nutrients in the diet that are required to maintain good health in people. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences, and may be revised every few years. A separate RDA value exists for each nutrient. The RDA values refer to the amount of nutrient expected to maintain good health in people. The actual amounts of each nutrient required to maintain good health in specific individuals differ from person to person.

Prevention

Ensuring an adequate intake of essential nutrients through a balanced diet and supplements is the best way to prevent mineral deficiencies. The Required Dietary Allowances (RDA) guidelines can help ensure that minerals are being obtained. Safe amounts of certain minerals are often included in multivitamins. Because excess mineral levels can also cause health problems, taking excessive amounts of any mineral supplement is not advised unless a deficiency is diagnosed. When mineral deficiency is the result of disease, medical attention, other than preventive measures, is required.

Nutritional concerns

A balanced diet includes fresh vegetables and fruits, legumes, whole grains (cereal, bread, rice, pasta, and other grains), eggs, dairy products, fish, fowl, and lean meat as preferred. A diet high in refined foods, prepared foods, sugars, and fats will not provide sufficient quantities of essential minerals. Water delivers nutrients throughout the body; it is essential to drink enough clean water daily to maintain fluid balance and distribute nutrients.

Essential mineral nutrients are found in a variety of sources, as in these examples:

- Boron is abundant in apples, pears, grapes, leafy greens, carrots, whole grains, and nuts.
- Primary calcium sources are dairy foods, eggs, fish, and green leafy vegetables. Other calcium-rich foods are figs, broccoli, cabbage, oats, almonds and filberts, yogurt, and blackstrap molasses. Spinach and Swiss chard bind calcium in the digestive tract and are not a ready source.

- Chromium is found in brown rice and other whole grains, cheeses, meats, dried beans, corn, eggs, mushrooms, and potatoes.
- Copper is found in nuts, mushrooms, broccoli, garlic, lentils, salmon, and green vegetables. It is also found in plumbing and cooking pots, which may leach into food and water.
- Germanium occurs primarily in garlic, shiitake mushrooms, and onions.
- Iron can be provided by eating green leafy vegetables, raisins, meat, eggs, liver, fish and fowl, nuts, and whole grains. It can also be obtained by cooking in iron skillets.
- Magnesium is found in most foods, primarily animal and fish sources.
- Potassium food sources include dairy foods, fish, fresh and dried fruits, beans and peas, meats, fish and fowl, and whole grains.
- Zinc sources include brewer's yeast, eggs, fish, meats, beans, mushrooms, nuts and seeds, and whole grains.

Parental concerns

Good nutrition is a concern of all parents. In the United States, it is relatively easy to provide a balanced diet with essential nutrients if a wide variety of whole foods are prepared for **family** meals and snacks, while avoiding refined and prepared foods high in fats and sugars. RDA guidelines and public health resources can help assure parents that they can prevent dietary deficiencies in their young children and teens.

Mineral toxicity

Definition

The term mineral toxicity refers to a condition in which the concentration in the body of any one of the **minerals** necessary for life is abnormally high, and which has an adverse effect on health.

Description

The mineral nutrients are defined as all the inorganic elements or inorganic molecules that are required for life. As far as human **nutrition** is concerned, the inorganic nutrients include water, sodium, potassium, chloride, calcium, phosphate, sulfate, magnesium, iron, fluorine, copper, zinc, chromium, manganese, iodine, selenium, and molybdenum. The last nine elements in this list are sometimes called trace minerals or micronutrients because humans need only small amounts of them in the diet. In high doses all nine trace minerals can be toxic in humans.

In general, mineral toxicity results when a person accidentally consumes too much of any mineral, as with drinking ocean water (sodium toxicity), or is overexposed to industrial pollutants, household chemicals, or certain drugs. Iron toxicity in children, for example, frequently results from accidental swallowing of dietary supplement tablets.

Mineral toxicity may also refer to toxic conditions resulting from certain diseases or injuries. For example, a disorder known as hemochromatosis leads to iron toxicity, while Wilson's disease results in copper toxicity. Severe trauma can lead to hyperkalemia or potassium toxicity.

Demographics

Iron **poisoning** is the most common form of mineral toxicity in children in the United States and is one of the leading causes of fatal poisoning in children younger than six years of age. About 20,000 children are reported as accidentally swallowing iron tablets each year in the United States, although not all of these cases end in death. In one Indian study of 21 children treated for iron poisoning, four of the patients died.

With regard to diseases leading to mineral toxicity, about one person in ten in the United States has the genetic mutation that can lead to hemochromatosis; however, not everyone with this mutation necessarily develops the disease. It is thought that there are about 1 million persons in the United States with hemachromatosis

as of the early 2000s. About one person in 30,000 has the genetic defect that causes Wilson's disease, while about 1.1 percent of the general population are carriers of the mutant gene. The incidence of Menkes disease, which primarily affects boys, is variously estimated at one in 50,000 to one in 250,000 persons. Wilson's disease and Menkes disease occur at the same rate in all races and ethnic groups.

Causes and symptoms

The causes and symptoms of mineral toxicity depend on the specific mineral in question:

- Sodium: An increase in sodium concentration in the bloodstream can be toxic. The normal concentration of sodium in human blood plasma is 136–145 mM, while levels over 152 mM can result in seizures and death. Increased plasma sodium, which is called hypernatremia, causes the cells in various body tissues, including those of the brain, to shrink. Shrinkage of the brain cells results in confusion, coma, paralysis of the lung muscles, and death. Death has occurred when table salt (sodium chloride) was accidentally used to feed infants instead of sugar. Death due to sodium toxicity has also resulted when baking soda (sodium bicarbonate) was used to treat excessive **diarrhea** or **vomiting**. Although a variety of processed foods contain high levels of sodium chloride, the levels in these items are not enough to result in sodium toxicity.
- Potassium: The normal level of potassium in the bloodstream is in the range of 3.5–5.0 mM, while levels of 6.3–8.0 mM (severe hyperkalemia) result in cardiac arrhythmias or even death due to cardiac arrest. Potassium is potentially quite toxic; however, potassium poisoning is usually prevented because of the vomiting reflex. The consumption of food results in mild increases in the concentration of potassium in the bloodstream, but these levels of potassium do not become toxic because of the uptake of potassium by various cells of the body as well as by the action of the kidneys transferring the potassium ions from the blood to the urine. The body's regulatory mechanisms can easily be overwhelmed, however, when potassium chloride is injected intravenously, as high doses of injected potassium can easily result in death.
- Iodine: Iodine toxicity can result from an intake of 2.0 mg of iodide per day. Toxic levels of iodine inhibit the secretion of thyroid hormone, resulting in lower levels of thyroid hormone in the bloodstream. As a result, the thyroid gland becomes enlarged. This condition is known as goiter or **hyperthyroidism**. Goiter is usually caused by iodine deficiency. In addition to goiter, iodine toxicity produces a brassy taste in the mouth, excessive production of saliva, and ulcers on the skin. This skin condition has been called kelp **acne** because of its association with eating kelp, an ocean plant that contains high levels of iodine. Iodine toxicity occurs fairly frequently in Japan, where people consume large amounts of seaweed.
- Iron: Iron toxicity is not unusual in small children due to the wide distribution of dietary supplements containing iron. A lethal dose of iron is in the range of 200—250 mg iron/kg body weight, meaning that a child who accidentally eats 20 or more iron tablets may die as a result of iron poisoning. Children are unfortunately likely to take large amounts of these pills because they look like candy. Within six hours of ingestion, iron toxicity can result in vomiting, diarrhea, abdominal **pain**, seizures, and possibly coma. In the second period of iron poisoning, the patient's symptoms appear to improve; however, this phase is followed by a terminal phase in which shock, low blood sugar levels, liver damage, convulsions, and death occur 12 to 48 hours after the fatal dose.
- Nitrite: Nitrite poisoning should be considered along with iron toxicity, since nitrite produces its toxic effect by reacting with the iron atom in hemoglobin. Hemoglobin is an iron-containing protein that resides within the red blood cells. This protein is responsible for transporting nearly all of the oxygen acquired from the lungs to various tissues and organs of the body. Hemoglobin accounts for the red color of red blood cells. A very small fraction of hemoglobin spontaneously oxidizes per day, producing a protein of a slightly different structure called methemoglobin. Normally, the amount of methemoglobin constitutes less than 1 percent of the total hemoglobin. Methemoglobin can accumulate in the blood as a result of nitrite poisoning. Infants are especially susceptible to poisoning by nitrite.
- Nitrate: Nitrate is naturally present in green leafy vegetables and in the water supply. It is rapidly converted to nitrite by the bacteria that live in the mouth as well as in the intestines and then absorbed into the bloodstream. The amount of nitrate that is supplied by leafy vegetables and drinking water is generally about 100 to 170 mg/day. The amount of nitrite supplied by a typical diet is much lower, about 0.1 mg nitrite per day. Poisoning by nitrite (or nitrate after its conversion to nitrite) results in the inability of hemoglobin to carry oxygen throughout the body. This condition can be seen by the blue color of the skin. Adverse symptoms occur when over 30 percent of the hemoglobin has been converted to methemoglobin. These symptoms include cardiac arrhythmias, **headache**, **nausea and vomiting**, and in severe cases, seizures.

- Calcium and phosphate: Calcium and phosphate are closely related nutrients. Calcium toxicity is rare, but overconsumption of calcium supplements may lead to deposits of calcium phosphate in the soft tissues of the body. Phosphate toxicity can result from the overuse of **laxatives** or enemas that contain phosphate. Severe phosphate toxicity can result in hypocalcemia and in various symptoms resulting from low plasma calcium levels. Moderate phosphate toxicity occurring over a period of months may result in the deposit of calcium phosphate crystals in various tissues of the body.
- Zinc: Zinc toxicity is rare but is more likely to occur in adults than in children. It is usually related to occupational hazards and has been reported to occur in metal workers exposed to fumes containing zinc. A few instances of zinc toxicity have been reported in people who consumed acidic food or beverages that had been stored in galvanized zinc containers. Taking excessive supplemental zinc can result in **nausea**, vomiting, and diarrhea. The chronic intake of excessive zinc supplements can result in copper deficiency, as zinc inhibits the absorption of copper.
- Copper: Copper toxicity in humans is usually the result of disease. Severe alterations in copper metabolism occur in two genetic diseases, Wilson's disease and Menkes disease. These diseases are rare. They involve mutations in the proteins that transport copper, that is, in special channels that allow the passage of copper ions through cell membranes. Wilson's disease, which is caused by a mutation of the ATP7B gene on chromosome 13, first produces symptoms in teenagers and young adults. Copper accumulates in the liver, kidney, and brain, resulting in damage to the liver and nervous system. In Menkes disease, which is usually first noticed in infancy, impaired transport of copper from the digestive tract results in low levels of copper in the blood, while copper accumulates in the kidney, pancreas, and skeletal muscle. Children with Menkes disease have characteristic kinky hair, seizures, developmental failures, and progressive degeneration of the brain.
- Selenium: Selenium toxicity occurs in a few regions of the world, most notably some parts of China where soils contain high levels of the mineral. A daily intake of 0.75 to 5.0 mg selenium may occur in these regions due to the presence of selenium in foods and water. Early signs of selenium toxicity include nausea, weakness, and diarrhea. Continued intake of selenium results in changes in the fingernails, hair loss, and damage to the nervous system. The person's breath may acquire a characteristic garlic odor as a result of the increased production of dimethylselenide in the body and its release via the lungs.
- Manganese: Manganese toxicity is most likely to affect adults rather than children. It occurs most commonly in workers in manganese mines who must breathe air containing high levels of manganese dust (in a concentration of 5–250 mg/cubic meter). Manganese toxicity in miners has been documented in Chile, India, Japan, Mexico, and elsewhere. Symptoms of manganese poisoning typically occur within several months or years of exposure. These symptoms include a mental disorder resembling **schizophrenia** as well as hyperirritability, violent acts, hallucinations, and difficulty in walking.

When to call the doctor

The most common form of mineral toxicity for children and adolescents in the United States is accidental poisoning from iron supplements. Parents should take a child who is known to have swallowed iron tablets to the doctor or a hospital emergency room for treatment as soon as possible, as an iron overdose is potentially fatal.

Children born into families with a history of Wilson's disease should have a blood test for the disease at some point in their second year of life, before symptoms of the disease develop.

Diagnosis

An initial diagnosis of mineral toxicity requires taking a careful history. The doctor asks the parents of a small child questions intended to identify any unusual aspects of the family's diet or intake of drugs and chemicals. An older teenager in the workforce may be asked about possible occupational exposure. The mineral content of the body may be measured by testing samples of body fluids, most commonly blood plasma, red blood cells from whole blood, and urine. Diagnosis of mineral toxicities also involves measuring the concentration of various metals in the plasma or urine. Concentrations that are above the normal range can confirm the initial suspected diagnosis.

Menkes disease may be diagnosed by the unusual appearance of the hair, skin, and facial features in male infants with the disorder as well as by their developmental problems.

In addition to a deficiency in blood plasma of a protein known as ceruloplasmin, Wilson's disease is characterized by gold or greenish-gold discolorations of the cornea of the eye known as Kayser-Fleischer rings. These rings may be detected by an ophthalmologist during a slit-lamp examination. The doctor may also suspect

Wilson's disease in a child above the age of five with unexplained episodes of hepatitis or such symptoms of copper toxicity in the brain as drooling, loss of coordination, tremor, sudden drop in academic performance, or frank psychotic episodes. The clinical symptoms of Wilson's disease do not appear in young children; however, measurements of serum ceruloplasmin can be taken in children over 12 months of age if a **family** history of Wilson's disease is a risk factor.

Treatment

Iron toxicity is treated by efforts to remove the remaining iron from the stomach by administering a solution of 5 percent sodium bicarbonate. Where plasma iron levels have risen above 0.35 mg/dL, the patient is treated with deferoxamine. Treatment of manganese toxicity involves removal of the patient from the high manganese environment as well as giving him or her lifelong doses of the drug L-dopa. The treatment is only partially successful. Treatment of nitrite or nitrate toxicity involves inhalation of 100 percent oxygen for several hours. If oxygen treatment is not effective, then a solution of 1.0 percent methylene blue may be injected in a dose of 1.0 mg methylene blue/kg body weight.

With regard to disorders of copper metabolism, Wilson's disease can be successfully controlled by lifelong treatment with d-penicillamine, trientine, and zinc acetate. Treatment also involves avoiding foods that are high in copper, such as liver, nuts, chocolate, and mollusks. After an initial period of treatment with penicillamine, Wilson's disease may be treated with zinc (150 mg oral Zn/day). The zinc inhibits the absorption of dietary copper. Patients with this disease must, however, comply with treatment for the rest of their lives, as untreated Wilson's disease is invariably fatal. Patients who develop liver failure as a result of the disease may be candidates for a liver transplant.

Children with Menkes disease are sometimes helped temporarily by intravenous injections of copper supplements. There is, however, no cure for the disease as of the early 2000s, and most children with the disorder live only a few years.

Nutritional concerns

Families consuming a well-balanced diet without overuse of dietary supplements are unlikely to have problems with mineral toxicity. Children or adolescents diagnosed with Wilson's disease must observe the dietary limitations described earlier.

Prognosis

The prognosis for mineral toxicity due to sodium, potassium, calcium, and phosphate is usually excellent. Toxicity due to the deposit of calcium phosphate crystals is not usually reversible. The prognosis for treating iodine toxicity is excellent. For any mineral overdose that causes coma or seizures, the prognosis for recovery is often poor, and death results in a small fraction of patients. For any mineral toxicity that causes nerve damage, the prognosis is often fair to poor. Wilson's disease is fatal, usually before age 30, unless the patient complies with continual lifelong treatment to prevent brain or liver disease. Children diagnosed with Menkes disease rarely live past their third birthday.

Prevention

When mineral toxicity results from the excessive consumption of mineral supplements, toxicity can be prevented by minimizing the use of dietary supplements and keeping iron tablets in particular out of the reach of children. Zinc toxicity may be prevented by not storing food or beverages in zinc containers. In the case of iodine, toxicity can be prevented by avoiding overconsumption of seaweed or kelp. In the case of selenium toxicity resulting from high-selenium soils, toxicity can be prevented by relying on food and water acquired from a low-selenium region.

Such genetic diseases as Wilson's disease and Menkes disease cannot be prevented as of the early 2000s.

Parental concerns

Parental concerns about mineral toxicity in most children should be directed toward preventing accidental consumption of iron and other mineral supplements in young children and in monitoring the adoption of fad diets in teenagers.

In the case of children with hemachromatosis or Wilson's disease, parents will need to make sure that the affected child complies with all aspects of necessary treatment. In the case of a child with Menkes disease, parents should seek genetic counseling, as the grim prognosis of this illness places a heavy emotional as well as economic burden on a family.

See also Heavy metal poisoning; Poisoning.

KEY TERMS

Arrhythmia—Any deviation from a normal heart beat.

Goiter—Chronic enlargement of the thyroid gland.

Hemochromatosis—An inherited blood disorder that causes the body to retain excessive amounts of iron. This iron overload can lead to serious health consequences, including painful joints, diabetes, and liver damage, if the iron concentration is not lowered.

Hyperkalemia—An abnormally high level of potassium in the blood.

Hypernatremia—An abnormally high level of sodium in the blood.

Hypocalcemia—A condition characterized by an abnormally low level of calcium in the blood.

Menkes disease—A genetic disease caused by a mutation on the X chromosome and resulting in impaired transport of copper from the digestive tract. It was first identified in 1962.

Methemoglobin—A compound formed from hemoglobin by oxidation of its iron component. Methemoglobin cannot carry oxygen.

Micronutrient—An organic compound such as vitamins or minerals essential in small amounts and necessary to the growth and health of humans and animals.

Trace element—An element that is required in only minute quantities for the maintenance of good health. Trace elements are also called micronutrients.

Wilson's disease—A rare inherited disease in which excessive amounts of copper accumulate in the liver or brain. It is fatal unless the patient complies with lifelong treatment with penicillamine and zinc oxidase. Wilson's disease is also known as inherited copper toxicosis.

Minerals

Definition

Minerals are inorganic nutrients. That is, they are materials found in foods that are essential for growth and health and do not contain the element carbon. The minerals that are relevant to human **nutrition** are water, sodium, potassium, chloride, calcium, phosphate, sulfate, magnesium, iron, copper, zinc, manganese, iodine, selenium, and molybdenum. Cobalt is a required mineral

for human health, but it is supplied by vitamin B_{12}. There is some evidence that chromium, boron, and other inorganic elements play some part in human nutrition, but their role has not been proven.

Description

Minerals should be provided by a normal, healthy diet. In special cases, additional mineral supplements may be called for. Preterm (low birth weight) infants have special needs for calcium, phosphorus, and sodium, as well as extra needs for vitamin D. Iron supplements may also be recommended.

The amount of each mineral that is needed to support growth during infancy and childhood, to maintain body weight and health, and to facilitate pregnancy and **lactation**, are listed in a table called the Recommended Dietary Allowances (RDA). This table was compiled by the Food and Nutrition Board, a committee that serves the United States government. The values listed in the RDA indicate the daily amounts that are expected to maintain health throughout most of the general population. The actual levels of each inorganic nutrient required by any given individual is likely to be less than that stated by the RDA. The RDAs are all based on studies that provided the exact, minimal requirement of each mineral needed to maintain health. However, the RDA values are actually greater than the minimal requirement, as determined by studies on small groups of healthy human subjects, in order to accommodate the variability expected among the general population.

Because of differences in individual diets and individual needs, the decision regarding any child's need for supplements should be made by the parents after discussion with the pediatrician and, where appropriate, a nutritionist. Children on a well-balanced diet do not require supplements, while those who are picky eaters or who routinely eat a poor diet may benefit from supplementation.

Girls should get their calcium from foods, particularly dairy products, rather than supplements. Dairy products were associated with higher bone mineral density in the spine, while calcium supplements had no such benefit.

General use

The following discussion describes the role of the major minerals in human nutrition.

Iron is essential for the formation of hemoglobin, the chemical in the blood that carries oxygen to the cells. Low levels of iron cause anemia. In severe cases, the children become flabby, and they fail to grow normally. Milder cases of iron deficiency may not produce any physical symptoms, but children may learn at a slower pace than children with a proper amount of iron in their diet. The combination of rice, beans, and meat consumed with fresh citrus fruit provides an excellent source of absorbable iron. Iron supplements are suggested for children who cannot or will not follow a proper diet through the first two years of life.

Calcium is required for proper development of bones and teeth. It is also needed for proper muscle activity and blood clotting. Lack of calcium can cause rickets, a condition in which the bones are soft and develop in abnormal shapes. Calcium must be accompanied by vitamin D in order to have the proper effects. Foods rich in calcium include almonds, swiss cheese, collards, sardines and salmon with bones, spinach, ice cream, kale, beet greens, cheddar cheese, molasses, oysters, milk, and broccoli.

Zinc deficiency has been associated with reduced growth and **mental retardation**. The best foods for zinc are lamb, beef, leafy grains, root vegetables such as potatoes and carrots, shellfish, and organ meats such as liver or kidneys. While a high fiber diet is important for health, too much fiber can reduce the absorption of zinc and lead to a zinc deficiency.

Iodine is needed in the diet for proper thyroid function. The best source of iodine is fish, but table salt normally has iodine added to it, and even modest amounts of salt will meet the daily iodine requirements.

Fluoride is needed for strong teeth. In many areas, drinking water contains fluoride that meets all normal needs, but for children who do not drink water or drink filtered or bottled water, fluoride supplements may be useful. Fluoride supplements may be useful for infants and then may be discontinued as the child gets older and starts drinking water.

Magnesium is found in so many parts of the body that it is almost impossible to describe the effects of low magnesium levels. The most common problems are twitching, and, because of the need for magnesium in the parathyroid gland, soft bones even when calcium and vitamin D are adequate. Because magnesium is found in most foods, deficiency is usually associated with absorption problems and requires medical attention.

Copper is required for blood and nerve fiber development. It is found in liver, nuts, and seafood.

Phosporus is needed for energy production, metabolism, and healthy bone development. The best sources

are milk, cheese, meats, whole grains, eggs, peas, and beans.

Potassium is needed for muscle contractions and nerve function. Good sources of potassium are orange juice, milk, cheese, whole grains, and vegetables.

Selenium is needed for proper thyroid function. It has also been associated with prevention of some types of **cancer** in adults. Selenium supplements are not normally required except in children with **phenylketonuria** receiving a low-protein diet, although it may sometimes be associated with thyroid problems. In these cases, medical care is required.

Precautions

Although the greatest nutritional concern is with inadequate levels of minerals, it is possible to take too much, particularly when people already eating a normally healthy diet take supplements. The daily intake of minerals should be reviewed to prevent adverse effects.

Excess calcium may lead to **constipation** and kidney problems. Too much zinc may lead to **diarrhea**, **vomiting**, and kidney and heart problems. Excess iron may cause problems of the stomach and digestive tract, liver problems, an increased risk of diabetes, and male sexual problems.

Side effects

When minerals are taken properly, they have no side effects.

Interactions

Minerals can interact with drugs and in excess with each other. Iron and calcium are known to bind to drugs of the tetracycline family and inactivate the antibiotic. The compound of calcium and tetracycline may also be absorbed into a child's teeth, causing discoloration.

Too much calcium in the diet may inhibit absorption of iron, magnesium, phosphorus, and zinc. Excess iron may reduce the absorption of zinc.

Parental concerns

Following a proper balanced diet is the best prevention of both **mineral deficiency** and mineral overdose. Since many children and adolescents cannot or will not eat a balanced diet, the possible need for supplements should be discussed with an appropriate professional.

Many children fail to follow a proper diet. This may be because of excess intake of fast foods and snack foods of low nutritional value. It is important for parents to teach children the benefits of proper nutrition and the importance of maintaining a healthful diet.

At the same time, adolescents, particularly those who engage in **sports**, may feel that they will do better with increased levels of nutrients. Because of the risk of toxic reactions to minerals and some **vitamins**, children should be discouraged from taking vitamin supplements unless there is clear evidence of increased need.

KEY TERMS

Inorganic—Pertaining to chemical compounds that are not hydrocarbons or their derivatives.

Parathyroid gland—A pair of glands adjacent to the thyroid gland that primarily regulate blood calcium levels.

Phenylketonuria (PKU)—A rare, inherited, metabolic disorder in which the enzyme necessary to break down and use phenylalanine, an amino acid necessary for normal growth and development, is lacking. As a result, phenylalanine builds up in the body causing mental retardation and other neurological problems.

Rickets—A condition caused by the dietary deficiency of vitamin D, calcium, and usually phosphorus, seen primarily in infancy and childhood, and characterized by abnormal bone formation.

Minnesota Multiphasic Personality Inventory

Definition

The Minnesota Multiphasic Personality Inventory (MMPI-2; MMPI-A) is a written psychological **assessment**, or test, used to diagnose mental disorders.

Purpose

The MMPI is used to screen for personality and psychosocial disorders in adults (i.e., over age 18) and adolescents age 14 to 18. It is also frequently administered as part of a neuropsychological test battery to evaluate cognitive functioning.

Description

The original MMPI was developed at the University of Minnesota and introduced in 1942. The current standardized version for adults 18 and over, the MMPI-2, was released in 1989, with a subsequent revision of certain test elements in early 2001. The MMPI-A, a version of the inventory developed specifically for adolescents age 14 to 18, was published in 1992.

The adolescent inventory is shorter than the standard adult version, was developed at a sixth-grade reading level, and is geared towards adolescent issues and personality "norms." The MMPI-A has 478 true/false items, or questions, (compared to 567 items on the MMPI-2) and takes 45 minutes to an hour to complete (compared to 60 to 90 minutes for the MMPI-2). There is also a short form of the test that is comprised of the first 350 items from the long-form MMPI-A.

The questions asked on the MMPI-A are designed to evaluate the thoughts, emotions, attitudes, and behavioral traits that comprise personality. The results of the test reflect an adolescent's personality strengths and weaknesses, and may identify certain disturbances of personality (psychopathologies) or mental deficits caused by neurological problems.

There are eight validity scales and ten basic clinical or personality scales scored in the MMPI-A, and a number of supplementary scales and subscales that may be used with the test. The validity scales are used to determine whether the test results are actually valid (i.e., if the test taker was truthful, answered cooperatively and not randomly) and to assess the test taker's response style (i.e., cooperative, defensive). Each clinical scale uses a set or subset of MMPI-A questions to evaluate a specific personality trait. Some were designed to assess potential problems that are associated with **adolescence**, such as eating disorders, social problems, **family** conflicts, and alcohol or chemical dependency.

Precautions

The MMPI should be administered, scored, and interpreted by a qualified clinical professional trained in its use, preferably a psychologist or psychiatrist. The MMPI is only one element of psychological assessment, and should never be used as the sole basis for a diagnosis. A detailed history of the test subject and a review of psychological, medical, educational, or other relevant records are required to lay the groundwork for interpreting the results of any psychological measurement.

Cultural and language differences in the test subject may affect test performance and may result in inaccurate MMPI results. The test administrator should be informed before psychological testing begins if the test taker is not fluent in English and/or has a unique cultural background.

Preparation

The administrator should provide the test subject with information on the nature of the test and its intended use, and complete standardized instructions for taking the MMPI (including any time limits, and information on the confidentiality of the results).

The MMPI should be scored and interpreted by a trained professional. When interpreting test results for test subjects, the test administrator will review what the test evaluates, its precision in evaluation and any margins of error involved in scoring, and what the individual scores mean in the context of overall norms for the test and the background of the test subject.

Risks

There are no risks involved in taking the MMPI. However, parents should try to make sure the test is properly administered, and the results evaluated appropriately, to avoid an unnecessary negative label on their child.

Parental concerns

Test anxiety can have an impact on a child's performance, so parents should attempt to take the stress off their child by making sure they understand that the MMPI is not an achievement test and the child's honest answers are all that is required. Parents can also ensure

Minority health

Definition

Minority health addresses the special medical and health needs associated with specific ethnic and other minority groups.

Description

The United States, along with many other countries, experiences cultural diversity. This fact poses health issues that are specific to ethnic and other minority groups. Additionally, the propensity for certain diseases or illnesses is of concern in certain minority groups. These specific health issues include **infant mortality** rates, **cancer**, cardiovascular disease, diabetes, **HIV infection**, and immunizations. The primary minority groups in the United States are Hispanics, African Americans, Native Americans and Native Alaskans, Native Hawaiians and other Pacific Islanders, and gays and lesbians.

One of the major health problems in the United States is overweight and **obesity**, which lead to increased risks for a wide variety of conditions, including cardiovascular disease, diabetes, **hypertension**, and cancer. A 2003 study by the Agency for Healthcare Research and Quality shows that African-American and Hispanic children face much higher odds of being overweight than non-Hispanic white or Asian-American and Pacific Islander children. African-American children ages six to 11 are more than twice as likely as non-Hispanic white children to be overweight, and Hispanic children are roughly twice as likely. The odds change dramatically when children become teenagers. For example, as children, Asian Americans and Pacific Islanders have the lowest prevalence of being overweight, but once they reach **adolescence**, the reverse is true. As teens, they have the highest prevalence of being overweight—more than four times that of non-Hispanic white teenagers. African American children have the highest rate of being overweight, but once they reach their teen years, they are no more likely than white children to be overweight. Hispanic teens are one-and-a-half times more likely than white or African American teens to be overweight.

Researchers and policymakers have attributed the poorer health of minority Americans in part to their reduced access to medical care and the lower quality of primary care they receive. Indeed, when asked about the primary care they receive, minority patients—particularly Asian Americans—give the primary care they receive lower marks than white patients do, according to a 2001 report by the Agency for Healthcare Research and Quality. After adjustment for socioeconomic and other factors, Asian Americans gave their primary care significantly lower scores (out of 100 total) than whites for communication (69 versus 79) and comprehensive knowledge of patients (48 versus 56), as well as all other areas of primary care except continuity of care and integration of care. African American and Hispanics reported significantly less financial access to care than whites (60 and 56, respectively, versus 65), and African Americans reported significantly less continuity of care than whites (74 versus 78), but their assessments of other aspects of primary care did not differ significantly from whites. This study agrees with others which show that Asian Americans tend to be the least satisfied with quality of care. However, this study was limited by the small number of Asian and Hispanic patients surveyed, as well as the lack of patient's country of origin and physician's ethnicity, factors that may affect patient evaluations of primary care.

Infant mortality rates

Infant mortality rates (IMRs) in the United States and in all countries worldwide are an accurate indicator of health status. They provide information concerning programs about pregnancy education and counseling, technological advances, and procedures and aftercare. IMRs vary among racial groups. Infant mortality among African Americans in 2000 occurred at a rate of 14.1 deaths per 1,000 live births. This is more than twice the national average of 6.9 deaths per 1,000 live births. The leading causes of infant death include congenital abnormalities, pre-term/low birth weight, **sudden infant death syndrome** (SIDS), problems related to complications of pregnancy, and **respiratory distress syndrome**. SIDS deaths among Native American and Alaska Natives is 2.3 times the rate for non-Hispanic white mothers.

Cancer

Cancer is a serious national, worldwide, and minority health concern. It is the second cause of death in the United States, claiming over 500,000 lives each year. Approximately 50 percent of persons who develop cancer die of the disease. There is great disparity among the cancer rates in minority groups. Across genders, cancer death rates for African Americans are 35 percent higher when compared to statistics for Caucasians. The death rates for prostate cancer (two times more) and lung cancer (27 times more) are disproportionately higher when compared to Caucasians. There are also gender differences among ethnic groups and specific cancers. Lung cancers in African American and Hawaiian men are evaluated compared with Caucasian males. Vietnamese females who live in the United States have five times more new cases of cervical cancer when compared to Caucasian women. Hispanic females also have a greater incidence of cervical cancer than Caucasian females. Additionally, Alaskan native men and women have a greater propensity for cancers in the rectum and colon than do Caucasians.

Cardiovascular disease

Cardiovascular disease is the leading cause of disability and death, about equal to the rate of death from all other diseases combined. Cardiovascular disease can affect the patient's lifestyle and function in addition to having an impact on **family** members. The financial costs are very high. Among ethnic and racial groups cardiovascular disease is the leading cause of death. **Stroke** is the leading cause of cardiovascular-related death, which occurs in higher numbers for Asian-American males when compared to Caucasian men. Mexican-American men and women and African-American males have a higher incidence of hypertension. African American women have higher rates of being overweight, which is a major risk factor of cardiovascular disease. African Americans are 13 percent less likely to undergo coronary angioplasty and one-third less likely to undergo bypass surgery than are Caucasians.

Diabetes

Diabetes, a serious health problem among Americans and ethnic groups, is the seventh leading cause of death in the United States. The prevalence of diabetes in African Americans is about 70 percent higher than Caucasians. The burden of diabetes is much greater for minority populations than the white population. For example, 10.8 percent of non-Hispanic blacks, 10.6 percent of Hispanics, and 9 percent of Native Americans and Native Alaskans have diabetes, compared with 6.2 percent of whites. Certain minorities also have much higher rates of diabetes-related complications and death, in some instances by as much as 50 percent more than the total population. Diabetes-related mortality rates for African Americans, Hispanic Americans, and Native Americans and Native Alaskans are higher than those for white people. Asians and Pacific Islanders have the lowest diabetes-related mortality of any racial/ethnic group in the United States.

HIV and AIDS

HIV infection/AIDS is the most common cause of death for all persons age 25 to 44 years old. Ethnic groups account for 25 percent of the U.S. population and 54 percent of all **AIDS** cases. In addition to sexual transmission there is an increase in HIV among ethnic groups related to intravenous drug usage. African Americans with HIV infection are less likely to be on antiretroviral therapy, less likely to receive prophylaxis for Pneumocystis **pneumonia**, and less likely to be receiving protease inhibitors than other persons with HIV. An HIV infection data coordinating center, under development in 2004, will allow researchers to compare contemporary data on HIV care to determine whether disparities in care among groups are being addressed and to identify any new patterns in treatment that arise. Among children, the disparities are dramatic, with African-American and Hispanic children representing more than 80 percent of pediatric AIDS cases in 2000. Approximately 78 percent of HIV-infected women are minorities and most become infected through heterosexual transmission.

In 2002, African Americans accounted for 50 percent of all new AIDS cases, while Hispanics accounted for 20 percent, according to the Centers for Disease

Control and Prevention (CDC). Although the virus is still most likely to be passed on by gay and bisexual males, as of 2004 more than 25 percent of AIDS cases are women, most of whom are African American or Hispanic. According to the National Center for Health Statistics, black females age 15 and older are 15.5 times more likely to die of AIDS than whites—a figure even more dramatic than the one presented in the vice presidential debates, according to an article in the October 16, 2004 *Los Angeles Times*.

Immunizations

Data show that in 2000 children living below the poverty level have lower immunization coverage rates. Although significant progress has been made in improving childhood immunization rates, some disparities in overall immunization coverage rates among racial and ethnic groups continue. This disparity is of great concern in large urban areas with underserved populations because of the potential for outbreaks of vaccine-preventable diseases.

Demographics

The overall health of the U.S. population improved during the last decades of the twentieth century, but all Americans have not shared equally in these improvements. Among nonelderly adults, for example, 17 percent of Hispanic and 16 percent of black Americans report they are in minimally fair or poor health, compared with 10 percent of white Americans.

Causes and symptoms

Most IMRs are correlated with prenatal care. Women who receive adequate prenatal care tend to have better pregnancy outcomes when compared to those who receive little or no care. Women who receive inadequate prenatal care tend to have increased chances of delivering a very low birth weight (VLBW) infant, which is linked to risk of early death.

Cancer is related to several preventable lifestyle choices. Diet and tobacco and sun exposure can be shaped by lifestyle modifications. Additionally many cancers can occur due to lack of interest in and/or lack of availability for screening and educational programs.

Cardiovascular diseases are higher among persons with high blood cholesterol and high blood pressure. Certain lifestyle choices that may increase the chance for heart disease include lack of **exercise**, overweight, and cigarette use. Cardiovascular disease is responsible for over 50 percent of the deaths in persons with diabetes.

HIV occurs at a higher frequency among gay males (the number of African-American males who have AIDS through sex with men has as of 2004 increased). Additionally unprotected sexual intercourse and sharing used needles for IV drug injection are strongly correlated with infection.

Vaccinations are an effective method of preventing certain disease such as **polio**, **tetanus**, pertussis, **diphtheria**, **influenza**, **hepatitis b**, and pneumococcal infections. Approximately 90 percent of influenza-related mortality is associated with persons aged 65 and older. This is mostly due to neglect of vaccinations. About 45,000 adults each year die of diseases related to hepatitis B, pneumococcal and influenza infections.

When to call the doctor

Parents of minority children should contact their family physician or other healthcare provider when they have any concern about their child's health.

Diagnosis

The diagnosis of VLBW occurs when newborns are weighed. Infants who weigh 52.5 ounces (1,500 grams) are at high risk for death. For cancer, the diagnosis can be made through screening procedures such as mammography (for breast cancer), PAP smear (for cervical cancer). Lifestyle modifications such as avoidance of sun, cessation of cigarette **smoking**, maintaining a balanced diet, and adequate **nutrition**, all positively affect one's health. Other specific screening tests (PSA, prostate surface antigen) are helpful for diagnosing prostate cancer. Cardiovascular diseases can be detected by medical check-up. Blood pressure and cholesterol levels can be measured. Obesity can be diagnosed by assessing a person's weight compared to the person's height. Diabetes and its complications can be detected by blood tests, in-depth eye examinations, and studies that assess the flow of blood through blood vessels in the legs. HIV can be detected through a careful history and physical examination and analysis of blood using a special test called a western blot. Infections caused by lack of immunizations can either be detected by conducting physical examination and culturing the specific microorganism in the laboratory.

Treatment

Treatment should be directed toward the primary causes(s) that minorities have increased chances of developing disease(s). Cancer may require treatment using surgery, radiotherapy, or **chemotherapy**. Cardiovascular diseases may require surgical procedures for

establishing a diagnosis and initiating treatment. Depending on the extent of disease, cardiovascular management can become complicated requiring medications and daily lifestyle modifications. Treatment usually includes medications, dietary modifications, and—if complications arise—specific interventions tailored to alleviating the problem. HIV can be treated with specific medications and more often than not with symptomatic treatment as complications arise. Diseases caused by lack of immunizations are treated based on the primary disease. The best method of treatment is through prevention and generating public awareness through widespread education on the topic.

Alternative treatment

Alternative therapies do exist, but as of 2004 more research is needed to substantiate available data. Most physicians say the diseases that relate to minority health are best treated with nationally accepted standards of care.

Prognosis

Generally the prognosis is related to the diagnosis, patients' state of health, age, and the presence of another disease or complication in addition to the presenting problem. The course for IMRs is related to educational programs and prenatal care, which includes medical and psychological treatments. The prognosis for chronic diseases such as cardiovascular problems, high blood pressure, cancer, and diabetes is variable. As of 2004, these diseases are not cured, and control is achieved by standardized treatment options. Eventually complications, despite treatment, can occur. For HIV the clinical course as of 2004 is death, even though this process may take years. Educational programs with an emphasis on disease prevention can potentially improve outcomes concerning pediatric and geriatric diseases.

Prevention

Prevention is accomplished best through educational programs specific to target populations. IMRs can be prevented by increasing awareness, interest, and accessibility for prenatal care that offers a comprehensive approach for the needs of each patient. Regular physicals and special screening tests can potentially prevent certain cancers in high-risk groups. Educational programs concerning lifestyle modifications, diet, exercise, and testing may prevent the development of cardiovascular disease and diabetes. Educational programs for illicit IV drug abusers and persons who engage in unprotected sexual intercourse may decrease the incidence of HIV infection.

Parental concerns

All children should have regular well-child check ups according to the schedule recommended by their physician or pediatrician. The American Academy of Pediatrics (AAP) advises that children be seen for well-baby check ups at two weeks, two months, four months, six months, nine months, 12 months, 15 months, and 18 months of age. Well-child visits are recommended at ages two, three, four, five, six, eight, ten, and annually thereafter through age 21. Parents can take some precautions to ensure the health of their children. **Childproofing** the home, following a recommended immunization schedule, educating kids on **safety**, learning **cardiopulmonary resuscitation** (CPR), and taking kids for regular well-child check-ups all help to protect against physical harm. In addition, encouraging open communication with children can help them grow both emotionally and socially. Providing a loving and supportive home environment can help to nurture an emotionally healthy child who is independent, self-confident, socially skilled, insightful, and empathetic towards others.

Mitochondrial disorders

Definition

Mitochondrial disorders, also called mitochondrial cytopathies, are a diverse group of diseases caused by damage to small structures found in human cells that are essential in converting food to energy. The result is decreased energy production and associated symptoms.

Description

Cells are the building blocks of the human body, microscopic structures that are bound by a membrane and contain numerous components called organelles that are responsible for functions such as cell reproduction, transportation of materials, and protein synthesis. Cellular respiration, a process by which food molecules are converted into high-energy molecules used as a source of energy, takes place in structures called mitochondria. The energy produced by mitochondria is essential for cell functions.

Before the mid-twentieth century, little was known about mitochondrial disorders. The first diagnosis of a mitochondrial disorder occurred in 1959, and the genetic material of microchondria, called mtDNA, was discovered in 1963. In the 1970s and 1980s, as more was learned about the mitochondria and more mitochondrial disorders were discovered, the term "mitochondrial myopathies" (myopathy meaning a disease of muscle tissue) was coined to describe the group of diseases. Further research in the 1990s led to classification of mitochondrial disorders. As it became evident that tissues other than muscle could be affected by mitochondrial defects, the term "mitochondrial cytopathies" (cytopathy meaning cell disorder) was adopted.

Disorders in which skeletal muscle is the primary target of the mitochondrial dysfunction are called mitochondrial **myopathies**. Mitochondrial encephalomyopathies are disorders in which muscle and brain tissue is involved.

Common mitochondrial disorders

As of 2004 there were more than 40 distinct mitochondrial cytopathies. Some of the more common disorders include:

- Kearns-Sayre syndrome (KSS). Onset of KSS usually occurs before the age of 20. Symptoms include progressively constrained eye movements, droopy eye lids, muscle weakness, short stature, hearing loss, loss of coordination, heart problems, cognitive delays, and diabetes.

- Myoclonus epilepsy with ragged-red fibers (MERRF). MERFF is a mitochondrial encephalomyopathy in which a mitochondrial defect as well as a tissue abnormality called "ragged-red fibers" (an accumulation of diseased mitochondria) is found microscopically. The resulting symptoms include seizures, loss of coordination, short stature, build-up of lactic acid in the blood, difficulty speaking, dementia, and muscle weakness.
- Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS). MELAS is a progressive mitochondrial disease that involves multiple organ systems including the central nervous system, cardiac muscle, skeletal muscle, and gastrointestinal system. Symptoms include muscle weakness, stroke-like events, eye muscle paralysis, and cognitive impairment.
- Leber hereditary optic neuropathy (LHON). LHON causes progressive loss of vision resulting in various degrees of blindness and primarily affects men over the age of 20. Heart abnormalities may also occur.
- Leigh syndrome. This degenerative brain disorder is usually diagnosed at a young age (e.g. before age two). Deterioration is often rapid with symptoms such as seizures, dementia, feeding and speech difficulties, respiratory dysfunction, heart problems, and muscle weakness. Prognosis is poor with death typically occurring within a few years of diagnosis.
- Myoneurogenic gastrointestinal encephalopathy (MNGIE). Key features include symptoms that mimic gastrointestinal obstruction and nervous system abnormalities. Other symptoms may include eye muscle paralysis, muscle weakness, loss of coordination, and brain abnormalities.
- Pearson syndrome. With symptoms usually first appearing in childhood, the characteristics of this rare syndrome include pancreatic dysfunction and anemia (low red blood cells). Difficulty gaining weight, **diarrhea**, and enlarged liver are other signs of Pearson syndrome.
- Neuropathy, ataxia, and retinitis pigmentosa (NARP). The symptoms implied by this disorder's name include nervous system abnormalities, loss of coordination, and progressive loss of vision. Developmental delays, dementia, and muscle weakness may also result. Onset usually occurs in childhood.

Demographics

Approximately 1,000 to 4,000 children are born with mitochondrial disease in the United States each year. Typically, by the age of ten, approximately one in 4,000 American children is diagnosed with mitochondrial disease.

Causes and symptoms

Although mitochondrial disorders may be caused by distinctly different damage to the mitochondrial genetic material, and thus affect any of the hundreds of chemical reactions required to convert food and oxygen into energy, they all share a common feature: the ability of mitochondria to generate energy is damaged. Byproducts of the numerous reactions can begin to accumulate in the cells and interfere with other chemical reactions and over time damage the mitochondria further.

Inheritance of mitochondrial disorders

In many cases, a mitochondrial disorder is passed genetically from parent to child (inheritance). It can often be helpful for the type of inheritance to be determined, as parents can then make an educated decision about the risks of passing the condition on to another child or the risks of another **family** member developing the disease. Genetic defects may be passed through nuclear DNA (nDNA), the genetic material found in each cell that determines the majority of hereditary characteristics, or through mtDNA. Some types of mitochondrial disorder inheritance include:

- Autosomal recessive inheritance. Each individual has two sets of genes, one inherited from each parent. In some genetic diseases, a person needs to have two copies of a defective gene in order to show symptoms of the disease; if only one of the two genes is defective, the person is considered a carrier. In autosomal recessive inheritance, the affected individual has inherited a defective gene from each parent.
- Maternal inheritance. mtDNA is only passed from mother to child because the mitochondria of a sperm is located in the sperm's tail, which is not involved in conception. Some mitochondrial disorders are, therefore, only passed from mother to child.
- X-linked recessive inheritance. The sex of a child is determined through the inheritance of strands of DNA called chromosomes. A female child inherits two X chromosomes, while a male child inherits an X chromosome from one parent and a Y chromosome from the other. If a defective gene encoding for a disease is found on the X chromosome, then a male child cannot have a healthy copy of the gene (since he only has one X chromosome); therefore, he will develop the disorder. Female children are at less risk because they have to have two copies of the defective gene (one on each X chromosome) in order to develop the disease.

- Autosomal dominant inheritance. As opposed to autosomal recessive inheritance, only one defective copy of a gene needs to be inherited in order for an individual to develop the disease. Each successive child, therefore, has a 50 percent chance of developing the disorder.

In some cases, no other family members are affected by the disease and there appears to be no genetic link. These cases are called random or sporadic occurrences and may be caused by a number of environmental factors including certain drugs (e.g. medications used to treat human **immunodeficiency** virus [HIV] have been linked to mitochondrial damage), **anorexia nervosa** (a disease characterized by self-starvation), exposure to certain toxins, prolonged periods of insufficient oxygen, or older parental age (mtDNA mutations may accumulate over time).

Symptoms

Because more than 90 percent of the energy needed by the human body to function is generated by mitochondria, the effects of mitochondrial disorders can be far-reaching. Research has shown that cells of the brain, nerves, skeletal muscles, liver, heart, kidneys, ears, eyes, and pancreas seem to be particularly affected because of their high energy requirements. Some of the more common symptoms of mitochondrial diseases by organ system include the following:

- brain: confusion, memory loss, headaches, seizures, developmental delays, and stroke-like episodes
- nerves: **pain** caused by nerve abnormalities (neuropathic pain), gastrointestinal problems linked to nerve abnormalities, abnormal sweating, and fainting
- skeletal muscles: muscle weakness, muscle cramping, muscle pain, loss of coordination, **exercise** intolerance, and poor growth
- liver: liver failure not due to excessive alcohol use and low blood sugar (hypoglycemia)
- heart: heart muscle weakness and disturbed electrical signals in the heart (called heart block)
- kidneys: abnormalities that cause difficulty with absorbing nutrients and electrolytes back into the body (called Fanconi syndrome)
- ears: hearing loss
- eyes: eye muscle paralysis, progressive loss of vision
- pancreas: diabetes (a group of conditions characterized by excessive urine excretion and persistent thirst) and pancreatic failure

Other symptoms include **failure to thrive** in infants, poor growth, short stature, fatigue, respiratory disorders, swallowing difficulties, and increased risk of infection.

When to call the doctor

The array of symptoms that are displayed by children suffering from mitochondrial disorders are common to many other diseases, and the age of onset can range from early infancy to adulthood. Often, the hallmark sign of a mitochondrial disorder that distinguishes it from other diseases with similar symptoms is additional features (such as the above symptoms) that do not normally appear with the non-mitochondrial disease. Parents should notify their healthcare provider if their child develops symptoms atypical for their previously diagnosed condition or if those symptoms get worse or recur with infection.

Diagnosis

Because of the complex nature of mitochondrial disorders, physicians take a multi-faceted approach to diagnosing such diseases. The process usually starts with a comprehensive physical exam and evaluation of the patient's medical and family history. Often a neurological exam is performed to determine if there are any brain abnormalities. To diagnose a mitochondrial disorder and rule out other diseases, more extensive tests may need to be performed. Some examples are as follows:

- Initial evaluation. The first line of testing usually involves the least invasive methods, such as sending a sample of blood for evaluation. In some cases a diagnosis can be made based on blood tests; in others, blood tests may indicate that further testing is necessary.
- Secondary evaluation. These tests may be more intensive, more invasive, and/or carry more risks. Examples include lumbar puncture (spinal tap), urine collection, **magnetic resonance imaging** (MRI), additional blood tests, or electrocardiogram (ECG).
- Tertiary evaluation. Complex and/or invasive procedures such as skin or muscle biopsy (taking a small sample of tissue for microscopic evaluation) are considered tertiary tests. In some cases such tests are necessary to make a definitive diagnosis.

In some cases, a physician may not be able to diagnose the patient with a specific mitochondrial disorder even after extensive evaluation. Parents should, therefore, be advised that despite the complexity of testing for mitochondrial disorders, diagnosis is not always possible.

Treatment

As of 2004, there are no cures for mitochondrial disorders. Treatment plans focus on delaying progression of the disease or reducing a patient's symptoms. The method of treatment depends on many factors, including the patient's disease, age, affected organs, and health status. Not all patients benefit from treatment; those with less severe disease generally respond better. Treatment may consist of **vitamins**, supplements, physical or occupational therapy, or traditional medications. Examples of these include:

- vitamins, such as B vitamins (thiamine, riboflavin, niacin, folate, biotin, and pantothenic acid), vitamin E, and vitamin C
- coenzyme Q10 (CoQ10), which is involved in cellular respiration in normal mitochondria
- levocarnitine (Carnitor), taken orally or intravenously, to replace a cofactor necessary in cellular respiration
- antioxidant therapy, a treatment under investigation that may help to keep mitochondrial damage under control
- physical or occupational therapy for myopathies

Alternative treatment

For some patients, avoiding physiological stressors such as extreme cold, extreme heat, poor **nutrition**, fasting, and lack of **sleep** may improve their condition. Alcohol, cigarette smoke, and monosodium glutamate (MSG, added to many Asian foods) may also exacerbate a mitochondrial disorder.

Nutritional concerns

In some cases, a properly devised diet is necessary to avoid worsening symptoms. Parents of a child affected with a mitochondrial disorder may be referred to a dietician to help formulate a diet specific to his or her disease. The plan is individualized to the child and may include suggestions such as avoiding long periods of time without eating, eating small but frequent meals, increasing or decreasing the amount of fat consumed, and avoiding or supplementing with certain vitamins or **minerals**.

Prognosis

The prognosis of mitochondrial disease depends on many factors, including the specific disorder, the mode of inheritance, the age of onset, and what organs are affected. Two children suffering from the same mitochondrial disorder may have two distinctly different courses. In some cases, patients may be able to control their symptoms to a great degree with various treatments, or progression of the disease is slow. In other cases, the disease progresses rapidly and inevitably leads to death.

Prevention

Prevention of inherited mitochondrial disorders is not possible unless parents decide against having more children. In the case of mitochondrial cytopathies that are caused by environmental factors such as certain drugs or toxins, avoidance of these substances may minimize the risk of developing mitochondrial disease.

Parental concerns

Because of the potential of passing on inherited mitochondrial disorders to other children, parents may be interested in genetic counseling. Genetic counselors are health professionals who are trained to help families determine the risk or probability of developing or passing on a genetic disorder. Genetic testing, however, cannot determine with certainty if or when a child will develop a mitochondrial disease or what the severity will be.

MMR vaccine

Definition

MMR vaccine is a combined vaccine to protect children against **measles**, **mumps**, and **rubella**, which are dangerous and potentially deadly diseases. Alternative names are rubella **vaccination**, mumps vaccination, vaccine-MMR.

Description

The MMR, which does not contain mercury, consists of live viruses that have been weakened (attenuated) so that the vaccine is still capable of inducing a productive immune response but does not cause the disease that the original or "wild-type" viruses can. The MMR vaccine is a mix of three vaccines: attenuvax (measles), mumpsvax (mumps), and meruvax II (rubella).

The three-in-one MMR vaccine protects against measles, mumps, and rubella. Although single antigen (individual) vaccines are available for each part of the MMR, they are only used in specific situations, in which one of the three diseases occurs and public health officials decide to immunize infants six to 15 months of age for that particular disease. (Single antigen vaccines pose less risk to children younger than the recommended age of 15 months for the MMR.)

Measles (rubeola)

Before vaccination, epidemics of measles peaked in the spring every two to four years. Measles is an endemic disease in many undeveloped countries and in countries where measles immunization levels are low. Because the risk of contracting measles in other countries is greater than in the United States, infants and children should be as well protected as possible before traveling.

Measles is caused by a virus that grows in the nose, mouth, throat, and the eyes, and in their secretions. It is highly communicable and may not be recognized early because the symptoms often resemble cold symptoms. The incubation period is 10 to 11 days. Measles begins with slight temperature rise and a runny nose and eyes. About the second or third day, blush-white pinpoint spots with a red rim, known as Koplick's spots, appear in the mouth. Small dark red pimples appear on the head and spread gradually over the body. These pimples grow larger and in groups, giving a blotchy appearance, which is an important difference between measles and **scarlet fever**. In scarlet fever, the skin appears red all over.

The respiratory symptoms grow worse. The child sneezes often, the eyes are sore, and nasal secretion becomes purulent. Light hurts the eyes (photophobia). The child's throat is sore. The rash is greatest about the fourth day, and it may last up to ten days. During the second week, the skin begins to flake off, and it continues to do so for five to ten days.

Treatment is limited to combating the symptoms of measles because **antiviral drugs** as of 2004 are ineffective. The disease has serious possible complications. For example, encephalomyelitis (inflammation of the brain and spinal cord) occurs in one to two cases out of 1000 patients; the disease is fatal at that same rate. Immune globulin injections help prevent or reduce measles infection if given within six days of exposure. Complications can be brought on by measles. **Encephalitis** occurs in one out of 6000 cases; 20 percent of these infections are fatal. Thrombocytopenic purpura (skin hemorrhages because of decreased **platelet count**) occur in one out of 3000 cases.

Mumps (epidemic parotitis)

Mumps, another viral disease, affects the salivary glands, especially the parotid gland. Children under the age of two years old seldom have mumps; adults rarely have this disease. A closer contact is necessary to transmit mumps than other contagious diseases. The incubation period lasts from two to three weeks, averaging about 18 days.

In most cases, the first sign of mumps is a swelling in the parotid glands; occasionally, mumps may begin with a slight fever, **headache**, and malaise before the swelling appears. Sometimes only one of the parotid glands is affected, but both may be inflamed at the same time or one after the other. The glands become swollen and tender and are painful. It hurts for the child to suck while nursing or in older children to open his mouth and eat, but otherwise he may not feel sick at all. After two or three days, the swelling begins to go down, and usually disappears by the tenth day. As a rule, keeping children isolated or out of school for two weeks is long enough to prevent communicating the infection to others. Treatment is entirely palliative; as of 2004, there was no effective antiviral treatment.

Mumps can cause certain complications. The nervous system is affected in 65 percent of patients; 10 percent display symptoms of this, and 2 percent of these cases are fatal. Testicular complications occur in 14 to 35 percent of post-pubertal boys, and complications regarding the ovaries in 7 percent of post-pubertal females. These complications are rare in prepubescent children, however. Deafness in one or both ears occurs in one out of 15,000 cases. More than half of the deaths from mumps occur in those over 19 years of age. Mumps infection during the first trimester of pregnancy increases the risk of spontaneous abortion.

Rubella (German measles)

Rubella is also caused by a virus, but the disease is mild and last only a short time. The symptoms are like measles but are not nearly as severe, and spots never appear on the mucous membranes of the mouth. Sometimes the rash that appears on the face is the first noticeable sign of a rubella infection. The rash spreads quickly and disappears just as rapidly; sometimes it is gone from the face and the neck by the time it reaches the arms and the legs. The rash usually lasts two to four days.

Isolation from other children is brief or not carried out at all; since the infectious stage is so brief, there is little danger of passing on the infection after the rash appears. The greatest risk of German measles is fetal malformations which occur when a mother is infected in the early months of pregnancy.

Children and adults may can have rubella more than once; 3 to 10 percent of those who have had rubella and 14 to 18 percent of those immunized become infected on exposure to the virus. Some reinfections are subclinical (i.e., have no visible symptoms). In fact, some 25 to 50 percent of rubella infections are asymptomatic.

General use

Recommended MMR vaccination schedule

Because the risk of serious disease from infection with either mumps or rubella in infants is low, mumps and rubella vaccines should not be given to infants younger than 12 months old. When the measles vaccine is needed a single-antigen measles vaccine is given. However, parents of an infant less than 12 months of age should be immune to mumps and rubella so they will not expose the infant or become infected if the infant becomes ill.

The first dose of the vaccine is given to children 12 to 15 months old. The second dose of the MMR vaccine should be given at four to six years of age. All children are to be fully immunized before starting school in the United States. Children who have not the second dose as recommended should complete the immunization by 11 or 12 years of age.

MMR traveling recommendations

Before infants and children of 12 months of age or older leave the United States, they should receive two doses of MMR vaccine separated by at least 28 days, with the first dose given on their birthday. Infants under 12 months of age should receive a dose of monovalent (single antigen) measles vaccine before departure. If monovalent vaccine is not available, no specific contraindication exists to giving MMR to infants six to eleven months of age. The risk for serious disease from either mumps or rubella infection among infants is low.

Infants who receive the monovalent measles vaccine or MMR before their first birthday are vulnerable to all three diseases and should be revaccinated with two doses of MMR. The first should be given when the infant is 12 to 15 months of age (12 months if the infant remains in an area where disease risk is high) and the second at least 28 days later.

Parents or adults who travel or live abroad with infants less than 12 months old should have evidence of immunity to rubella and mumps, as well as measles, to

avoid becoming infected if the infants are exposed to the diseases.

An infant less than six months of age is usually protected against measles, mumps, and rubella by maternal antibodies. As a rule, the infant does not need added protection unless the mother is diagnosed with measles.

Maternal immunity to MMR

Most fetuses receive some natural immunity to measles from their mothers in utero. This passive immunity fades over time and is less effective in children of immunized mothers than in children of mothers who had the measles.

The duration of protection is dependent to a great extent on the maternal antibody titer and the antibodies received by the infant during pregnancy. Women who have had the disease have higher measles antibody titers than women who have not had measles but have been vaccinated. Women who have not had measles nor vaccination have no measles antibodies.

Precautions

There are few reasons not to be vaccinated. Some of these are as follows:

- being allergic to gelatin or neomycin or having had an allergic reaction to a previous MMR vaccination
- being moderately or severely ill
- being pregnant
- in males, mumps can cause inflammation of the testes; in female, the ovaries, external genitals, or breasts may be affected

Side effects

Most of the time inactivated vaccines are given intramuscularly (IM), and live virus vaccines are given subcutaneously (SC). Vaccines that are used intramuscularly may cause local reactions (such as irritation, skin discoloration, inflammation, and granuloma formation) if injected into subcutaneous tissue. The vaccine may also be less effective if it is not given by the proper route.

Interactions

There is varying incidence of vaccine reactions. Some of these are as follows:

- fever (one out of six)
- mild rash (one out of 20)
- swollen glands (rare)
- seizure (one out of 3,000)
- **pain** and joint stiffness (one out of 20)
- low platelet count (one out of 30,000)
- serious allergic reaction (less than one out of 1,000,000)

Parental concerns

Parents often express concern about combining three vaccines in one injection. As of 2004 there is no published evidence showing a benefit to separating the

KEY TERMS

Acellular—Without whole cells. An acellular vaccine contains on parts of the cells which can produce immunity in a person receiving the vaccine.

Active immunity—Produced by the body when the immune system is triggered to produce antibodies, either by immunization or a disease.

Adverse effect—A negative side effect of a vaccine.

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

Encephalitis—Inflammation of the brain, usually caused by a virus. The inflammation may interfere with normal brain function and may cause seizures, sleepiness, confusion, personality changes, weakness in one or more parts of the body, and even coma.

Incubation period—The time period between exposure to an infectious agent, such as a virus or bacteria, and the appearance of symptoms of illness. Also called the latent period.

Inflammation—Pain, redness, swelling, and heat that develop in response to tissue irritation or injury. It usually is caused by the immune system's response to the body's contact with a foreign substance, such as an allergen or pathogen.

Passive immunity—The body reception of proteins that act as antibodies instead of making the antibodies itself. Immunoglobulins may produce this immunity. All babies have antibodies from their mothers, which give them short-term protection.

combination MMR vaccine into three individual shots. The CDC continues to recommend two doses of the combined MMR vaccine for all children.

Because signs of **autism** may appear around the time children receive the MMR vaccine, some parents worry that the vaccine causes autism. Research has not found a relationship between MMR vaccine and autism.

It is sometimes difficult for parents to adhere to the recommended vaccine schedule, including the spacing between doses. If the intervals between doses is longer than usual, there is no need to restart the series of any vaccine.

MMR vaccinations are appropriate for children with chronic diseases such as diabetes and cardiovascular condition as advised by the pediatrician.

Symptoms of low-grade fever, irritability, and soreness at the injection site following the MMR immunization can be relieved with an analgesic such as acetaminophen as recommended by the pediatrician. Cool compresses to the injection site are also comforting.

Moles

Definition

A mole (nevus) is a pigmented (colored) spot on the outer layer of the skin (epidermis).

Description

Moles can be round, oval, flat, or raised. They can occur singly or in clusters on any part of the body. Most moles are brown, but colors can range from pinkish flesh tones to yellow, dark blue, or black.

A mole usually lasts about 50 years before beginning to fade. Some moles disappear completely, and some never lighten at all. Some moles develop stalks that raise them above the skin's surface; these moles eventually drop off.

Types of moles

Moles that are present at birth are called congenital nevi.

Other types of moles include:

- junctional moles, which are usually brown and may be flat or slightly raised
- compound moles, which are slightly raised, range in color from tan to dark brown, and involve pigment-producing cells (melanocytes) in both the upper and lower layers of the skin (epidermis and dermis)
- dermal moles, which range from flesh-color to brown, are elevated, most common on the upper body, and may contain hairs
- sebaceous moles, which are produced by over-active oil glands and are yellow and rough-textured
- blue moles, which are slightly raised, colored by pigment deep within the skin, and most common on the head, neck, and arms of women

Most moles are benign (not cancerous), but atypical moles (dysplastic nevi) may develop into malignant melanoma, a potentially fatal form of skin **cancer**. Atypical moles are usually hereditary. Most are bigger than a pencil eraser, and the shape and pigmentation are irregular.

Congenital nevi are more apt to become cancerous than moles that develop after birth, especially if they are more than eight inches in diameter. Lentigo maligna (melanotic freckle of Hutchinson), most common on the face and after the age of 50, first appears as a flat spot containing two or more shades of tan. It gradually becomes larger and darker. One in three of these moles develop into a form of skin cancer known as lentigo maligna melanoma.

Demographics

Nearly everyone has at least a few moles. They generally appear by the time a person is 20 and at first resemble freckles. A mole's color and shape do not usually change; however, changes in hormone levels that occur during **puberty** and pregnancy can make moles larger and darker. New moles may also appear during

this period. About 1 to 3 percent of all babies have one or more moles when they are born. Only about one in 1 million moles is cancerous.

Causes and symptoms

The cause of moles is unknown, although atypical moles seem to run in families and result from exposure to sunlight. During the early 2000s, researchers identified two genes known as CDKN2A and CDK4 that govern susceptibility to melanoma in humans. Other susceptibility genes are being sought. Most experts, however, think that these susceptibility genes are not sufficient by themselves to account for moles becoming cancerous but are influenced by a combination of other inherited traits and environmental factors.

When to call the doctor

Only a small percentage of moles require medical attention. A mole that has the following symptoms should be evaluated by a dermatologist (a physician specializing in skin diseases):

- bleeds
- itches
- looks unusual or changes in any way

Diagnosis

A doctor who suspects skin cancer will remove all or part of the mole for microscopic examination. This procedure, which is usually performed in a doctor's office, is simple, relatively painless, and does not take more than a few minutes. It does leave a scar.

The doctor may also use a dermatoscope to examine the mole before removal. The dermatoscope, which can be used to distinguish between benign moles and melanomas, is an instrument that resembles an ophthalmoscope used to look at the eye. An oil is first applied to the mole to make the outer layers of skin transparent.

A combination of high-frequency ultrasound and color Doppler studies has also been shown to have a high degree of accuracy in distinguishing between melanomas and benign moles.

Treatment

If laboratory analysis confirms that a mole is cancerous, the dermatologist will remove the rest of the mole. Patients should realize that slicing off a section of a malignant mole will not cause the cancer to spread.

Removing a mole for cosmetic reasons involves numbing the area and using scissors or a scalpel to remove the elevated portion. The patient is left with a flat mole the same color as the original growth. Cutting out parts of the mole above and beneath the surface of the skin can leave a scar more noticeable than the mole.

Scissors or a razor can be used to temporarily remove hair from a mole. Permanent hair removal, however, requires electrolysis or surgical removal of the mole.

Prognosis

Moles are rarely cancerous and, once removed, unlikely to recur. A dermatologist should be consulted if a mole reappears after being removed.

Prevention

Wearing a sunscreen and limiting sun exposure may prevent some moles. Anyone who has moles should examine them every month and see a dermatologist if changes in size, shape, color, or texture occur or if new moles appear.

A team of researchers at Duke University reported in 2003 that topical application of a combination of 15 percent vitamin C and 1 percent vitamin E over a four-day period offered significant protection against **sunburn**. The researchers suggest that this combination may protect skin against aging caused by sunlight as well.

Anyone with a **family** history of melanoma should see a dermatologist for an annual skin examination. Everyone should know the ABCDEs of melanoma:

- A: asymmetry, which occurs when the two halves of the mole are not identical
- B: borders that are irregular or indistinct
- C: color that varies in a single mole
- D: diameter, which should be no larger than a pencil eraser (about 6 mm)
- E: elevated above the surrounding tissue

A mole with any of these characteristics should be evaluated by a dermatologist.

Advances in photographic technique had as of 2004 made it easier to track the development of moles with the help of whole-body photographs. A growing number of hospitals are offering these photographs as part of outpatient mole-monitoring services.

Close up of a mole. *(Custom Medical Stock Photo Inc.)*

Parental concerns

Very few moles are cancerous. Moles on the face or other frequently exposed areas of skin may be troubling for children. If a child is particularly troubled by a mole, a dermatologist can be consulted about its possible removal, although this often leaves a scar.

Mood disorders

Definition

Mood disorders are mental disorders characterized by periods of depression, sometimes alternating with periods of elevated mood.

Description

While many people go through sad or elated moods from time to time, people with mood disorders suffer from severe or prolonged mood states that disrupt their daily functioning. Among the general mood disorders are major depressive disorder, **bipolar disorder**, and dysthymia. In classifying and diagnosing mood disorders, doctors determine if the mood disorder is unipolar or bipolar. When only one extreme in mood (the depressed state) is experienced, this condition is called unipolar. Major depression refers to a single severe period of depression, marked by negative or hopeless thoughts and physical symptoms like fatigue. In major depressive disorder, some patients have isolated episodes of depression. In between these episodes, the patient does not feel depressed or have other symptoms associated with depression. Other patients have more frequent episodes.

Bipolar depression or bipolar disorder (sometimes called manic depression) refers to a condition in which people experience two extremes in mood. They alternate between depression (the low mood) and mania or hypomania (the high mood). These patients go from depression to a frenzied, abnormal elevation in mood. Mania and hypomania are similar, but mania is usually more severe and debilitating to the patient. Dysthymia is a recurrent or lengthy depression that may last a lifetime. It is similar to major depressive disorder, but dysthymia is chronic, long-lasting, persistent, and mild. Patients may have symptoms that are not as severe as major depression, but the symptoms last for many years. It seems that a mild form of the depression is always present. In some cases, people may also experience a major depressive episode on top of their dysthymia, a condition sometimes referred to as double depression.

Psychologists have identified the teenage years as one of the most difficult phases of human life. Although they are often seen as a time for enjoying friendship and engaging in activities that adults would not usually do, the teenage period can be difficult. Many changes in the human mind take place during **puberty**. Apart from the onset of sexual maturity, teenagers must also make key decisions about their future, develop their identities, change schools and meet a new sets of friends, find out about their family's past, and cope with a wide range of other issues. Many young people have difficulty coping with these stresses.

Four out of five teenagers who commit **suicide** are male, but the average female teenager is prone to attempt suicide four more times during her teen years than the average male. White teenage males are more likely to commit suicide than any other ethnic group, but teenage suicide among blacks was as of 2004 increasing. Teenagers who have unsuccessfully tried to commit suicide in the past are more likely to attempt suicide in the future. The odds increase after each failed attempt. There are two groups of teens that are at the highest risk for committing suicide: Native Americans and teens who are gay, lesbian, bisexual, and transgendered.

Gay and bisexual male teens, which represent about 10 percent of the male teen population, are six to seven times more at risk for attempting suicide than their heterosexual peers. Several surveys show gay and lesbian youth account for 30 percent of all suicides among teens, according to the U.S. Department of Health and Human Services. Yet most studies of teen suicide have not been concerned with identifying sexual orientation.

Demographics

As many as 14 percent of children will experience at least one episode of major depression by age 15. Girls are significantly more likely to experience depression than boys after the age of 16. Out of 100,000 adolescents, two to three thousand will have mood disorders out of which 8 to 10 will commit suicide. In the early 2000s, suicide, attempted suicide, and thoughts of committing suicide are growing problems among adolescents in the United States and much of the world. It is the third leading cause of death among 15 to 19 year olds in the United States and the sixth leading cause of death among 10 to 14 year olds. About 2 percent of adolescent girls and 1 percent of adolescent boys attempt suicide each year in the United States. Another 5 to 10 percent of children and teens each year come up with a plan to commit suicide.

Causes and symptoms

Mood disorders tend to run in families. These disorders are associated with imbalances in certain chemicals that carry signals between brain cells (neurotransmitters). These chemicals include serotonin, norepinephrine, and dopamine. Women are more vulnerable to unipolar depression than are men. In adults, major life stressors (like **divorce**, serious financial problems, death of a **family** member, etc.) will often provoke the symptoms of depression in susceptible people. Children's versions of these stressors contribute to their vulnerability to depression.

Major depression is more serious than just feeling sad or "blue." The symptoms of major depression may include the following:

- loss of appetite
- change in the **sleep** pattern, like not sleeping (insomnia) or sleeping too much

Light therapy is a treatment for mood disorders. *(Photograph by Najlah Feanny. © Stock Boston, Inc.)*

- feelings of worthlessness, hopelessness, or inappropriate guilt
- fatigue
- difficulty in concentrating or making decisions
- overwhelming and intense feelings of sadness or grief
- disturbed thinking
- certain physical symptoms such as stomachaches or headaches

Bipolar disorder includes mania or hypomania. Mania is an abnormal elevation in mood. These individuals may be excessively cheerful, have grandiose ideas, and may sleep less. They may talk nonstop for hours, have unending enthusiasm, and demonstrate poor judgment. Sometimes the elevation in mood is marked by irritability and hostility rather than cheerfulness. While the person may at first seem normal with an increase in energy, others who know the person well see a marked difference in behavior. The patient may seem to be in a frenzy and will often make poor, bizarre, or dangerous choices in his or her personal and professional lives. Hypomania is not as severe as mania and does not cause the level of impairment in work and social activities that mania can.

When to call the doctor

There are many methods for helping teenagers deal with mood disorders, both medical and psychological. Most teenagers who have mood disorders believe their problems are too hard or embarrassing to talk about, so it is important for a helper to show they can be trusted and talked to. Seeing a psychologist is widely recommended as well. Psychologists can improve a teenager's vision of life by listening to them and making them feel it will work out for the best.

If a child or teen is so depressed that he or she is talking about suicide, doctors recommend that parents or other helpers do not ask the adolescent what reason they have to think of such a thing to do; rather, one should listen and wait for the child to gain trust enough so that he or she finally can feel comfortable in talking about the problem. Helpers should, however, show understanding of the teenager's situation. Doctors also recommend that helpers do not mention any ''reasons to live'' to the teen-

ager, as that might send the teenager back into depressing thoughts, e.g. "What reason do I have to live?" Many doctors recommend that teenagers be taken to a hospital immediately after they express the desire to commit suicide.

Diagnosis

Doctors diagnose mood disorders based on the patient's description of the symptoms as well as the patient's family history. The length of time the patient has had symptoms is also important. Generally patients are diagnosed with dysthymia if they feel depressed more days than not for at least two years. The depression is mild but long lasting. In major depressive disorder, the patient is depressed almost all day nearly every day of the week for at least two weeks. The depression is severe. Sometimes laboratory tests are performed to rule out other causes for the symptoms (like thyroid disease). The diagnosis may be confirmed when a patient responds well to medication.

Treatment

The most effective treatment for mood disorders is a combination of medication and psychotherapy. The four different classes of drugs used in mood disorders are as follows:

- heterocyclic **antidepressants** (HCAs), such as amitriptyline (Elavil)
- selective serotonin reuptake inhibitors (SSRI inhibitors), such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft)
- monoamine oxidase inhibitors (MAOI inhibitors), such as phenelzine sulfate (Nardil) and tranylcypromine sulfate (Parnate)
- mood stabilizers, such as lithium carbonate (Eskalith) and valproate, often used in people with bipolar mood disorders

A number of psychotherapy approaches are useful as well. Interpersonal psychotherapy helps the patient recognize the interaction between the mood disorder and interpersonal relationships. Cognitive-behavioral therapy explores how the patient's view of the world may be affecting his or her mood and outlook.

When depression fails to respond to treatment or when there is a high risk of suicide, electroconvulsive therapy (ECT) is sometimes used. ECT is believed to affect neurotransmitters like the medications do. Patients are anesthetized and given muscle relaxants to minimize discomfort. Then low-level electric current is passed through the brain to cause a brief convulsion. The most common side effect of ECT is mild, short-term memory loss.

Alternative treatment

There are many alternative therapies that may help in the treatment of mood disorders, including acupuncture, botanical medicine, homeopathy, aromatherapy, constitutional hydrotherapy, and light therapy. The therapy used is an individual choice. Short-term clinical studies have shown that the herb St. John's wort (*Hypericum perforatum*) can effectively treat some types of depression. Though it appears very safe, the herb may have some side effects and its long-term effectiveness has not been proven. It has not been tested in patients with bipolar disorder. St. John's wort and antidepressant drugs should not be taken simultaneously, so patients should tell their doctor if they are taking St. John's wort.

Prognosis

Most cases of mood disorders can be successfully managed if properly diagnosed and treated.

Prevention

People can take steps to improve mild depression and keep it from becoming worse. They can learn stress management (like relaxation training or breathing exercises), **exercise** regularly, and avoid drugs or alcohol.

Parental concerns

Parents who are concerned that their child may have a mood disorder should seek help, such as from a psychiatrist, psychologist, or counselor. Make an appointment with a therapist or counselor who can talk to the child about his or her problems and ways to cope. There are a number of ways parents can help children and teens deal with loneliness, depression, and suicidal feelings. First, parents should let the child do the talking, and they should listen very carefully. They should let the child know they take his or her feelings and thoughts seriously. They should try to find out what is the root of the problem. They may also ask direct questions of the child, such as "Are you thinking of committing suicide?" or "Are you thinking of ending your life?" Third, they should stay with the child. They should not leave the child alone if they say they want to commit suicide. By staying with the child, the parent may be saving the child's life.

KEY TERMS

Cognitive therapy—Psychological treatment aimed at changing a person's way of thinking in order to change his or her behavior and emotional state.

Electroconvulsive therapy (ECT)—A psychological treatment in which a series of controlled electrical impulses are delivered to the brain in order to induce a seizure within the brain. This type of therapy is used to treat major depression and severe mental illness that does not respond to medications.

Neurotransmitter—A chemical messenger that transmits an impulse from one nerve cell to the next.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Moral development

Definition

Moral development is the process throught which children develop proper attitudes and behaviors toward other people in society, based on social and cultural norms, rules, and laws.

Description

Moral development is a concern for every parent. Teaching a child to distinguish right from wrong and to behave accordingly is a goal of parenting.

Moral development is a complex issue that—since the beginning of human civilization—has been a topic of discussion among some of the world's most distinguished psychologists, theologians, and culture theorists. It was not studied scientifically until the late 1950s.

Piaget's theory of moral reasoning

Jean Piaget, a Swiss psychologist, explored how children developed moral reasoning. He rejected the idea that children learn and internalize the rules and morals of

society by being given the rules and forced to adhere to them. Through his research on how children formed their judgments about moral behavior, he recognized that children learn morality best by having to deal with others in groups. He reasoned that there was a process by which children conform to society's norms of what is right and wrong, and that the process was active rather than passive.

Piaget found two main differences in how children thought about moral behavior. Very young children's thinking is based on how actions affected them or what the results of an action were. For example, young children will say that when trying to reach a forbidden cookie jar, breaking 10 cups is worse than breaking one. They also recognize the sanctity of rules. For example, they understand that they cannot make up new rules to a game; they have to play by what the rule book says or what is commonly known to be the rules. Piaget called this "moral realism with objective responsibility." It explains why young children are concerned with outcomes rather than intentions.

Older children look at motives behind actions rather than consequences of actions. They are also able to examine rules, determining whether they are fair or not, and apply these rules and their modifications to situations requiring negotiation, assuring that everyone affected by the rules is treated fairly. Piaget felt that the best moral learning came from these cooperative decision-making and problem-solving events. He also believed that children developed moral reasoning quickly and at an early age.

Kohlberg's theory of moral development

Lawrence Kohlberg, an American psychologist, extended Piaget's work in cognitive reasoning into **adolescence** and adulthood. He felt that moral development was a slow process and evolved over time. Still, his six stages of moral development, drafted in 1958, mirrors Piaget's early model. Kohlberg believed that individuals made progress by mastering each stage, one at a time. A person could not skip stages. He also felt that the only way to encourage growth through these stages was by discussion of moral dilemmas and by participation in consensus democracy within small groups. Consensus democracy was rule by agreement of the group, not majority rule. This would stimulate and broaden the thinking of children and adults, allowing them to progress from one stage to another.

PRECONVENTIONAL LEVEL The child at the first and most basic level, the preconventional level, is concerned with avoiding punishment and getting needs met. This level has two stages and applies to children up to 10 years of age.

Stage one is the Punishment-Obedience stage. Children obey rules because they are told to do so by an authority figure (parent or teacher), and they **fear** punishment if they do not follow rules. Children at this stage are not able to see someone else's side.

Stage two is the Individual, Instrumentation, and Exchange stage. Here, the behavior is governed by moral reciprocity. The child will follow rules if there is a known benefit to him or her. Children at this stage also mete out justice in an eye-for-an-eye manner or according to Golden Rule logic. In other words, if one child hits another, the injured child will hit back. This is considered equitable justice. Children in this stage are very concerned with what is fair.

Children will also make deals with each other and even adults. They will agree to behave in a certain way for a payoff. "I'll do this, if you will do that." Sometimes, the payoff is in the knowledge that behaving correctly is in the child's own best interest. They receive approval from authority figures or admiration from peers, avoid blame, or behave in accordance with their concept of self. They are just beginning to understand that others have their own needs and drives.

CONVENTIONAL LEVEL This level broadens the scope of human wants and needs. Children in this level are concerned about being accepted by others and living up to their expectations. This stage begins around age 10 but lasts well into adulthood, and is the stage most adults remain at throughout their lives.

Stage three, Interpersonal Conformity, is often called the "good boy/good girl" stage. Here, children do the right thing because it is good for the **family**, peer group, team, school, or church. They understand the concepts of trust, loyalty, and gratitude. They abide by the Golden Rule as it applies to people around them every day. Morality is acting in accordance to what the social group says is right and moral.

Stage four is the Law and Order, or Social System and Conscience stage. Children and adults at this stage abide by the rules of the society in which they live. These laws and rules become the backbone for all right and wrong actions. Children and adults feel compelled to do their duty and show respect for authority. This is still moral behavior based on authority, but reflects a shift from the social group to society at large.

POST-CONVENTIONAL LEVEL Some teenagers and adults move beyond conventional morality and enter morality based on reason, examining the relative values and opinions of the groups with which they interact. Few adults reach this stage.

Correct behavior is governed by the sixth stage, the Social Contract and Individual Rights stage. Individuals in this stage understand that codes of conduct are relative to their social group. This varies from culture to culture and subgroup to subgroup. With that in mind, the individual enters into a contract with fellow human beings to treat them fairly and kindly and to respect authority when it is equally moral and deserved. They also agree to obey laws and social rules of conduct that promote respect for individuals and value the few universal moral values that they recognize. Moral behavior and moral decisions are based on the greatest good for the greatest number.

Stage six is the Principled Conscience or the Universal/Ethical Principles stage. Here, individuals examine the validity of society's laws and govern themselves by what they consider to be universal moral principles, usually involving equal rights and respect. They obey laws and social rules that fall in line with these universal principles, but not others they deem as aberrant. Adults here are motivated by individual conscience that transcends cultural, religious, or social convention rules. Kohlberg recognized this last stage but found so few people who lived by this concept of moral behavior that he could not study it in detail.

Carol Gilligan and the morality of care

Kohlberg's and Piaget's theories have come under fire. Kohlberg's six stages of moral development, for example, have been criticized for elevating Western, urban, intellectual (upper class) understandings of morality, while discrediting rural, tribal, working class, or Eastern moral understandings. Feminists have pointed out potential sexist elements in moral development theories devised by male researchers using male subjects only (such as Kohlberg's early work). Because women's experiences in the world differ from men's in every culture, it would stand to reason that women's moral development might differ from men's, perhaps in significant ways.

Carol Gilligan deemed Kohlberg's research biased because he only used male subjects to reach his findings. Because of this, his model is based on a concept of morality based on equity and justice, which places most men in stage five or six. Gilligan found that women, who value social interaction more than men, base their moral decisions on a culture of caring for other human beings. This would place them at stage three, making women appear to be inferior morally to men. Men determine immorality based on treating others unfairly, and women base it on turning away someone in need.

Gilligan's work, however, doesn't solve the gender question, because newer research has found that both males and females often base their moral judgments and behaviors on both justice and care. Nevertheless, the morality of care theory opened up explorations of moral reasoning in many groups and cultures.

Bronfenbrenner

Urie Bronfenbrenner studied children and schools in different cultures since many ethnic, religious, and social groups often have their own rules for moral behavior. His research found five moral orientations, regardless of culture, social group, or developmental stage. Movement from the first stage to any of the others was dependent on participation in the family and other social institutions within each culture. Movement to the last stage involved exposure to a different moral system that might be in conflict with one's own. This moral pluralism forces individuals to examine their own moral reasoning and beliefs. This often occurs when people work in other countries or cultures and come face to face with different sets of moral conventions.

Bronfenbrenner also noted that individuals could slide back into a previous moral orientation when they experienced the breakdown of their familiar social order as in war, regime changes, genocide, famine, or large scale natural disasters that destroy social infrastructures. People narrow their attention to their own pressing needs and ignore the welfare of the larger society.

Self-oriented morality coincided with Kohlberg's pre-conventional morality. Behavior is based on self-interest and motivated by who can help children get what they want or who is hindering that process. This stage was found in all children and some adults in all cultures.

Authority-oriented morality again is similar to Kohlberg's Law and Order stage. This applies not only to parents' rules but to teachers, religious leaders, and government officials. This moral orientation was culturally defined. It was very evident in Middle Eastern cultures where religious authority is the law.

Peer-authority morality is moral conformity based on the conventions and rules of a social group. This is evident among teenagers in Western cultures and even among some adults.

Collective-oriented morality is an extension of the peer-authority stage. Here a larger group's rule supercedes individual rights and interests. Duty is the law. This moral orientation was found in Asian cultures.

Objectively-oriented morality is akin to Kohlberg's universal principles stage. Here, however, these rules

transcend individual moral perspectives and become entities in themselves. Like Kohlberg's last stage, this moral orientation was found in relatively few people in any culture.

Other theories

There are several other approaches to the study of moral development, which are categorized in a variety of ways. Briefly, the social learning theory approach claims that humans develop morality by learning the rules of acceptable behavior from their external environment, an essentially behaviorist approach. Psychoanalytic theory proposes instead that morality develops through humans' conflict between their instinctual drives and the demands of society. **Cognitive development** theories view morality as an outgrowth of cognition, or reasoning, whereas personality theories are holistic in their approach, taking into account all the factors that contribute to human development.

The differences between these approaches rest on two questions: How moral are infants at birth? and How is moral maturity defined? The contrasting philosophies at the heart of the answers to these questions determine the essential perspective of each moral development theory. Those who believe infants are born with no moral sense tend toward social learning or behaviorist theories, because all morality must therefore be learned from the external environment. Others who believe humans are innately aggressive and completely self-oriented are more likely to accept psychoanalytic theories where morality is the learned management of socially destructive internal drives. Those who believe it is the reasoning abilities that separate humans from the rest of creation will find cognitive development theories the most attractive. And those who view humans as holistic beings born with a full range of potentialities will most likely be drawn to personality theories.

What constitutes mature morality is a subject of great controversy. Each society develops its own set of norms and standards for acceptable behavior, leading many to say that morality is entirely culturally conditioned. There is debate over whether or not this means that there are no universal truths, and no cross-cultural standards for human behavior. This debate fuels the critiques of many moral development theories.

Definitions of what is or is not moral are in a state of upheaval within individual societies. Controversies rage over the morality of warfare (especially nuclear), ecological conservation, genetic research and manipulation, alternative fertility and childbearing methods, abortion, sexuality, pornography, drug use, euthanasia, racism, sexism, and human rights issues, among others. Determining the limits of moral behavior becomes increasingly difficult as human capabilities, choices, and responsibilities proliferate with advances in technology and scientific knowledge. For example, prenatal testing techniques that determine birth defects in the womb force parents to make new moral choices about whether to give birth to a child.

The rise in crime, drug and alcohol abuse, gang violence, teen parenthood, and **suicide** in Western society has also caused a rise in concern over morality and moral development. Parents and teachers want to know how to raise moral children, and they turn to moral development theorists to find answers. Freudian personality theories became more widely known to the Western public in the 1960s and were understood to imply that repression of a child's natural drives would lead to neuroses. Many parents and teachers were therefore afraid to **discipline** their children, and permissiveness became the rule. Cognitive development theories did little to change things, as they focus on reasoning and disregard behavior. Behaviorist theories, with their complete denial of free will in moral decision-making, are unattractive to many and require precise, dedicated, behavior modification techniques.

Schools are returning to character education programs, popular in the 1920s and 1930s, where certain virtues such as honesty, fairness, and loyalty, are taught to students along with the regular academic subjects. Unfortunately, there is little or no agreement as to which virtues are important and what exactly each virtue entails.

Another approach to moral education that became popular in the 1960s and 1970s is known as values clarification or values modification. The purpose of these programs is to guide students to establish or discern their own system of values on which to base their moral decisions. Students are also taught that others may have different values systems, and that they must be tolerant of those differences. The advantages of this approach are that it promotes self-investigation and awareness and the development of internal moral motivations, which are more reliable than external motivations, and prevents fanaticism, authoritarianism, and moral coercion. The disadvantage is that it encourages moral relativism, the belief that "anything goes." Values clarification is generally seen as a valuable component of moral education, but incomplete on its own.

Lawrence Kohlberg devised a moral education program in the 1960s based on his cognitive development theory. Called the Just Community program, it utilizes age-appropriate or stage-appropriate discussions of moral dilemmas, democratic consensus rule-making, and

the creation of a community context where students and teachers could act on their moral decisions. Just Community programs have been established in schools, prisons, and other institutions with a fair amount of success. Exposure to moral questions and the opportunity to practice moral behavior in a supportive community appear to foster deeper moral reasoning and more constructive behavior.

Overall, democratic family and school systems are much more likely to promote the development of internal self-controls and moral growth than are authoritarian or permissive systems. Permissive systems fail to instill any controls, while authoritarian systems instill only fear of punishment, which is not an effective deterrent unless there is a real chance of being caught or punishment becomes a reward because it brings attention to the offender. True moral behavior involves a number of internal processes that are best developed through warm, caring parenting with clear and consistent expectations, emphasis on the reinforcement of positive behaviors rather than the punishment of negative ones, modeling of moral behavior by adults, and creation of opportunities for the child to practice moral reasoning and actions.

According to personal (social) goal theory, moral behavior is motivated by the desire to satisfy a variety of personal and social goals, some of which are self-oriented (selfish), and some of which are other-oriented (altruistic). The four major internal motivations for moral behavior as presented by personal (social) goal theorists are: 1) empathy; 2) the belief that people are valuable in and of themselves and therefore should be helped; 3) the desire to fulfill moral rules; and 4) self-interest.

In social domain theory, moral reasoning is said to develop within particular social domains: 1) moral (e.g., welfare, justice, rights); 2) social-conventional (social rules for the orderly function of society); and 3) personal (pure self-interest, exempt from social or moral rules).

Most people have more than one moral voice and shift among them depending on the situation. In one context, a person may respond out of empathy and place care for an individual over concern for social rules. In a different context, that same person might instead insist on following social rules for the good of society, even though someone may suffer because of it. People also show a lack of consistent morality by sometimes choosing to act in a way that they know is not moral, while continuing to consider themselves moral people. This discrepancy between moral judgment (perceiving an act as morally right or wrong) and moral choice (deciding whether to act in the morally right way) can be explained in a number of ways, any one of which may be true in a given situation:

- weakness of will (the person is overwhelmed by desire)
- weakness of conscience (guilt feelings are not strong enough to overcome temptation)
- limited/flexible morality (some latitude allowed in moral behavior while still maintaining a "moral" identity)

The Moral Balance model proposes that most humans operate out of a limited or flexible morality. Rather than expecting moral perfection from ourselves or others, people set certain limits beyond which they cannot go. Within those limits, however, there is some flexibility in moral decision-making. Actions such as taking coins left in the change-box of a public telephone may be deemed acceptable (though not perfectly moral), while **stealing** money from an open, unattended cash register is not. Many factors are involved in the determination of moral acceptability from situation to situation, and the limits on moral behavior are often slippery. If given proper encouragement and the opportunity to practice a coherent inner sense of morality, however, most people will develop a balanced morality to guide their day-to-day interactions with their world.

Common problems

Religious development often goes hand in hand with moral development. Children's concepts of divinity, right and wrong, and who is ultimately responsible for the world's woes are shaped by the family and by the religious social group to which each child belongs. Their concepts also mirror cognitive and moral developmental stages.

In general, in the earliest stage (up to age two years), the child knows that religious objects and books are to be respected. The concept of a divine being is vague, but the child enjoys the regularity of the religious rituals such as prayer.

In the next stage (from two to 10 years), children begin to orient religion concepts to themselves as in the catechism litany, "Who made you? God made me." The concept of a divine being is usually described in anthropomorphic ways for children around six years old. In other words, children perceive God to look like a human being only bigger or living in the sky. At this stage, God is physically powerful and often is portrayed as a superhero. God may also be the wish-granter and can fix anything. Children embrace religious holidays and rituals during this stage.

KEY TERMS

Altruistic—Thinking of others.

Anthropomorphic—Taking on human characteristics or looking like humans.

Cognition—The act or process of knowing or perceiving.

Flat affect—Showing no emotion.

Moral choice—Deciding whether to act in the morally right way.

Moral judgment—Perceiving an act as morally right or wrong.

In the Intermediate Stage during pre-adolescence, children are considered to be in the pre-religious stage. The anthropomorphized divinity is pictured as being very old and wise. God is also thought of as doing supernatural things: having a halo, floating over the world, or performing miracles. Children in this stage understand the panoply of religious or divine beings within the religious belief system. For example, Christian children will distinguish between God and Jesus and the disciples or saints.

The last stage in adolescence focuses on personalizing religious rituals and drawing closer to a divine being. Teenagers begin to think of God in abstract terms and look at the mystical side of the religious experience. They may also rebel against organized religion as they begin to question the world and the rules around them.

Some adults who are considered highly religious consider God to be an anthropomorphized divine being or may reject the supernatural or mystical religious experience. This does not mean that these adults have somehow been arrested in their religious development. This just means that the variation among these stages is great and is determined by the particular religious community in which the individual is involved.

Parental concerns

When to call the doctor

Every child misbehaves and will sometimes act selfishly and hurtfully. It is when these acts increase, impulses cannot be controlled, or authority defiance becomes troublesome, that parents may need to seek professional help. Lack of impulse control and authority defiance can be symptoms of medical conditions and psychological disorders. Self-centered behavior, coupled with lack of acceptance of wrongdoing that continues into older childhood and adolescence, may be a problem that requires family or individual counseling.

Risky behaviors such as speeding, drinking, **smoking**, doing drugs, or engaging in sexual behavior may be related to **peer pressure** and wanting to conform to the group or may be a way to defy authority. These behaviors, though deemed morally wrong by most societies, may also be symptoms of deeper psychological troubles.

Of extreme concern is the rare child who acts with no remorse, and appears to have to conscience. This is usually signaled by early violent outbursts, destructive behavior, or by acts of cruelty to pets or other children. After each incident, the child has a flat affect (no emotion) or fails to admit that there was anything wrong with the his or her actions. These children need intervention immediately. Behaviors such as these may be indicators of sociopathic disorders.

Motion sickness

Definition

Motion sickness is uncomfortable **dizziness**, **nausea**, and **vomiting** that people experience when their sense of balance and equilibrium is disturbed because their brain cannot make sense of conflicting information about their body's location in space and motion in their environment.

Description

Motion sickness is connected to the role of the sensory organs. The sensory organs control a body's sense of balance by telling the brain what direction the body is pointing, the direction it is moving, and if it is standing still or turning. These messages are relayed by the inner ear (or labyrinth); the eyes; the skin pressure receptors (such as in those in the feet), the muscle and joint sensory receptors, which track what body parts are moving to the central nervous system (the brain and spinal cord). The brain then is responsible for processing all incoming information and making sense out of it. Riding in a car, being on a ship, or taking an amusement park ride can cause conflicting stimulation of the different sense organs. The result is motion sickness.

For example, when reading a book in the back seat of a moving car, the inner ears and skin receptors sense the motion, but the eyes register only the stationary pages of the book. This conflicting information may cause the usual motion sickness symptoms of dizziness, nausea, and vomiting. While motion sickness can be bothersome, it is not a serious illness, and it can be prevented.

Demographics

Although nearly 80 percent of the general population experiences motion sickness at one time in their lives, children between the ages of four and ten are most vulnerable. Children often out grow motion sickness. Toddlers under age two are rarely motion sick. Adults who frequently get migraine headaches are more likely than others to have recurrent episodes of motion sickness.

Researchers at the Naval Medical Center in San Diego, California, reported in 2003 that 70 percent of research subjects with severe motion sickness had abnormalities of the vestibular system. Research also suggests that some people inherit a predisposition to motion sickness. This predisposition is more marked in some ethnic groups than in others. One study published in 2002 found that persons of Chinese or Japanese ancestry are significantly more vulnerable to motion sickness than persons of British ancestry.

Causes and symptoms

While all of the body's sensory organs contribute to motion sickness, excess stimulation to the vestibular system within the inner ear (the body's balance center) has been shown to be one of the primary reasons for this condition. Balance problems (vertigo) are often caused by a conflict between what is seen and how the inner ear perceives it, leading to confusion in the brain. This confusion may result in higher heart rates, rapid breathing, nausea and sweating, along with dizziness and vomiting.

Additional factors that may contribute to the occurrence or severity of motion sickness include the following:

- poor ventilation
- anxiety or **fear** (Both have been found to lower a person's threshold for experiencing motion sickness symptoms.)
- food (A heavy meal of spicy and greasy foods before traveling is thought to increase motion sickness symptoms.)
- alcohol consumption
- genetic factors
- pregnancy (Susceptibility in women to vomiting during pregnancy appears to be related to motion sickness, although the precise connections are not well understood as of 2004.)

Often viewed as a minor annoyance, some travelers are temporarily immobilized by motion sickness, and a few continue to feel its effects for hours and even days after a trip.

When to call the doctor

Most cases of motion sickness are mild and self-limiting. Parents should call the doctor before giving young children over-the-counter medications for motion sickness. Some remedies are recommended only for older children.

Diagnosis

Most cases of motion sickness are self-diagnosed. If symptoms such as dizziness become chronic, a doctor may be able to help alleviate the discomfort by looking further into a patient's general health. Questions regarding medications, head injuries, recent infections, and other questions about the ear and neurological system will be asked. An examination of the ears, nose, and throat, as well as tests of nerve and balance function, may also be performed.

Severe cases of motion sickness or those that become progressively worse may require additional, specific tests. Diagnosis in these situations deserves the attention and care of a doctor with specialized skills in diseases of the ear, nose, throat, equilibrium, and neurological system.

Treatment

Medications to help ease the symptoms of motion sickness are available without a prescription (over-the-counter or OTC). Normally these are taken 30 to 60 minutes before traveling to prevent motion sickness symptoms, as well as during extended trips.

Over-the-counter drugs

The following OTC drugs contain ingredients that are considered by the United States Food and Drug Administration (FDA) to be safe and effective for the treatment of motion sickness:

- Marezine (and others) includes the active ingredient cyclizine and is not for use in children under six years of age.
- Benadryl (and others) includes the active ingredient diphenhydramine and is not for use in children under age two without a doctor's permission.
- Dramamine (and others) includes the active ingredient dimenhydrinate and is not for use in children under two years of age.
- Bonine (and others) includes the active ingredient meclizine and is not for use in children under age 12.

The FDA recommends that people with emphysema, chronic **bronchitis**, glaucoma, or difficulty urinating due to an enlarged prostate do not use OTC drugs for motion sickness unless directed by their doctor. Children should not be given OTC motion sickness medication without first checking with a healthcare professional.

Prescription drugs

Longer trips may require a prescription medication called scopolamine available in the form of a skin patch or gel that is rubbed on the skin. Another prescription drug that is sometimes given for motion sickness is ondansetron (Zofran), which was originally developed to treat nausea associated with **cancer chemotherapy**. It appears to be safe for use in children under the age of six. In March 2003, the FDA approved a new anti-emetic (anti-nausea) drug. Known as aprepitant, it is sold under the brand name Emend.

Alternative treatment

Ginger (*Zingiber officinale*) in its various forms is often used to calm the stomach, and the oils it contains (gingerols and shogaols) appear to relax the intestinal tract in addition to mildly depressing the central nervous system. Some of the most effective forms of ginger are the powdered, encapsulated form; ginger tea prepared from sliced ginger root; and candied pieces. All forms of ginger should be taken on an empty stomach.

Placing manual pressure on the Neiguan or Pericardium-6 acupuncture point (located about three finger-widths above the wrist on the inner arm), either by acupuncture, acupressure, or a mild, electrical pulse, has shown to be effective against the symptoms of motion sickness. Elastic wristbands sold at most drugstores are

also used as a source of relief due to the pressure they place in this area. Pressing the small intestine 17 (just below the earlobes in the indentations behind the jawbone) may also help in the functioning of the ear's balancing mechanism.

There are several homeopathic remedies that work specifically for motion sickness. They include *Cocculus*, *Petroleum*, and *Tabacum*.

Prognosis

Motion sickness is not a serious disorder and almost always resolves once the conflicting motion messages have stopped.

Prevention

Because motion sickness is easier to prevent than treat once it has begun, the best treatment is prevention. The following steps may help deter the unpleasant symptoms of motion sickness before they occur:

- Avoid reading while traveling.
- Ride in a location that allows the eyes to see the same motion that the body and inner ears feel. Safe positions include the front seat of the car (for older children) while looking at distant scenery; the deck of a ship where the horizon can be seen; and sitting by the window of an airplane. The least motion on an airplane is in a seat over the wings.
- Maintain a fairly straight-ahead view.
- Eat a light meal before traveling, or if already nauseated, avoid food altogether.
- Avoid watching or talking to another traveler who is having motion sickness.
- Take motion sickness medicine at least 30 to 60 minutes before travel begins or as recommended by a physician.

Even those who frequently endure motion sickness can learn to travel by anticipating the conditions of their next trip. Research also suggests that increased exposure to the stimulation that causes motion sickness may help decrease symptoms on future trips.

Parental concerns

Parental concerns center primarily on making the child comfortable and anticipating the logistics of traveling with a child who is motion sick. Rarely do children vomit to the point of becoming dehydrated. Prevention and practical steps such as taking something for the child to vomit into and carrying a change of clothes can ease parents' worries about motion sickness.

KEY TERMS

Acupressure—Often described as acupuncture without needles, acupressure is a traditional Chinese medical technique based on theory of *qi* (life energy) flowing in energy meridians or channels in the body. Applying pressure with the thumb and fingers to acupressure points can relieve specific conditions and promote overall balance and health. Also known as dian xue.

Acupuncture—Based on the same traditional Chinese medical foundation as acupressure, acupuncture uses sterile needles inserted at specific points to treat certain conditions or relieve pain.

Anti-emetic—A preparation or medication that relieves nausea and vomiting. Cola syrup, ginger, and motion sickness medications are examples of antiemetics.

Vertigo—A feeling of dizziness together with a sensation of movement and a feeling of rotating in space.

Vestibular system—The brain and parts of the inner ear that work together to detect movement and position.

Movement disorders

Definition

Movement disorders are a group of diseases and syndromes affecting the ability to produce and control bodily movements.

Description

It seems simple and effortless, but normal movement requires an astonishingly complex system of control. Disruption of any portion of this system can cause a person to produce movements that are too weak, too forceful, too uncoordinated, or too poorly controlled for the task at hand. Unwanted movements may occur at rest. Intentional movement may become impossible. Such conditions are called movement disorders.

Abnormal movements are symptoms of underlying disorders. In some cases, the abnormal movements are the only symptoms. Childhood disorders or conditions that may cause abnormal movements include:

- **cerebral palsy**
- choreoasthetosis
- encephalopathies
- essential tremor
- inherited ataxias (**Friedreich's ataxia**, Machado-Joseph disease, and spinocerebellar ataxias)
- multiple sclerosis
- parkinsonism and juvenile Parkinson's disease
- **poisoning** by carbon monoxide, cyanide, methanol, or manganese
- psychogenic disorders
- restless legs syndrome
- **spasticity**
- **stroke**
- **Tourette syndrome** and other tic disorders
- Wilson disease

Demographics

The incidence rates and demographics vary for different types of movement disorders. Restless legs syndrome (RLS) affects approximately 12 million people in the United States. The disorder can affect males and females and can begin at any age, although it may become worse as a person gets older. The most common ataxia is Friedreich's ataxia; in the United States, it affects one in 50,000 people, both male and female.

Causes and symptoms

Causes

Movement is produced and coordinated by several interacting brain centers, including the motor cortex, the cerebellum, and a group of structures in the inner portions of the brain called the basal ganglia. Sensory information provides critical input on the current position and velocity of body parts, and spinal nerve cells (neurons) help prevent opposing muscle groups from contracting at the same time.

To understand how movement disorders occur, it is helpful to consider a normal voluntary movement, such as reaching to touch a nearby object with the right index finger. To accomplish the desired movement, the arm must be lifted and extended. The hand must be held out to align with the forearm, and the forefinger must be extended while the other fingers remain flexed.

THE MOTOR CORTEX Voluntary motor commands begin in the motor cortex, located on the outer wrinkled surface of the brain. Movement of the right arm is begun by the left motor cortex, which generates a large volley of signals to the involved muscles. These electrical signals pass along upper motor neurons through the midbrain to the spinal cord. Within the spinal cord, they

connect to lower motor neurons, which convey the signals out of the spinal cord to the surface of the muscles involved. Electrical stimulation of the muscles causes contraction, and the force of contraction pulling on the skeleton causes movement of the arm, hand, and fingers.

Damage to or death of any of the neurons along this path causes weakness or paralysis of the affected muscles.

ANTAGONISTIC MUSCLE PAIRS The previous description of movement is too simple, however. One important refinement to it comes from considering the role of opposing, or antagonistic, muscle pairs. Contraction of the biceps muscle, located on the top of the upper arm, pulls on the forearm to flex the elbow and bend the arm. Contraction of the triceps, located on the opposite side, extends the elbow and straightens the arm. Within the spine, these muscles are normally wired so that willed (voluntary) contraction of one is automatically accompanied by blocking of the other. In other words, the command to contract the biceps provokes another command within the spine to prevent contraction of the triceps. In this way, these antagonist muscles are kept from resisting one another. Spinal cord or brain injury can damage this control system and cause involuntary simultaneous contraction and spasticity, an increase in resistance to movement during motion.

THE CEREBELLUM Once the movement of the arm is initiated, sensory information is needed to guide the finger to its precise destination. In addition to sight, the most important source of information comes from the ''position sense'' provided by the many sensory neurons located within the limbs (proprioception). Proprioception is what allows a person to touch a finger to his or her nose, even with eyes closed. The balance organs in the ears provide important information about posture. Both postural and proprioceptive information are processed by a structure at the rear of the brain called the cerebellum. The cerebellum sends out electrical signals to modify movements as they progress, ''sculpting'' the barrage of voluntary commands into a tightly controlled, constantly evolving pattern. Cerebellar disorders cause inability to control the force, fine positioning, and speed of movements (ataxia). Disorders of the cerebellum may also impair the ability to judge distance so that a person under- or over-reaches the target (dysmetria). Tremor during voluntary movements can also result from cerebellar damage.

THE BASAL GANGLIA Both the cerebellum and the motor cortex send information to a set of structures deep within the brain that help control involuntary components of movement (basal ganglia). The basal ganglia send output messages to the motor cortex, helping to initiate movements, regulate repetitive or patterned movements, and control muscle tone.

Circuits within the basal ganglia are complex. Within this structure, some groups of cells begin the action of other basal ganglia components and some groups of cells block the action. These complicated feedback circuits are not entirely understood. Disruptions of these circuits are known to cause several distinct movement disorders. A portion of the basal ganglia called the substantia nigra sends electrical signals that block output from another structure called the subthalamic nucleus. The subthalamic nucleus sends signals to the globus pallidus, which in turn blocks the thalamic nuclei. Finally, the thalamic nuclei send signals to the motor cortex. The substantia nigra, then, begins movement and the globus pallidus blocks it. This complicated circuit can be disrupted at several points.

Disruptions in other portions of the basal ganglia are thought to cause **tics**, tremors, dystonia, and a variety of other movement disorders, although the exact mechanisms are not well understood.

Some movement disorders, including Huntington's disease and inherited ataxias, are caused by inherited genetic defects. Some diseases that cause sustained muscle contraction limited to a particular muscle group (focal dystonia) are inherited, but others are caused by trauma. The cause of most cases of Parkinson's disease is unknown, although genes have been found for some familial forms.

Symptoms

Abnormal movements are broadly classified as either hyperkinetic (too much movement) and hypokinetic (too little movement). Hyperkinetic movements include:

- Dystonia—sustained muscle contractions, often causing twisting or repetitive movements and abnormal postures. Dystonia may be limited to one area (focal) or may affect the whole body (general). Focal dystonias may affect the neck (cervical dystonia or torticollis); the face (one-sided or hemifacial spasm, contraction of the eyelid or blepharospasm, contraction of the mouth and jaw or oromandibular dystonia, simultaneous spasm of the chin and eyelid or Meige syndrome); the vocal cords (laryngeal dystonia); or the arms and legs (writer's cramp or occupational cramps). Dystonia may be painful as well as incapacitating.
- Tremor—uncontrollable (involuntary) shaking of a body part. Tremor may occur only when muscles are relaxed or only during an action or while holding an active posture.

- Tics—involuntary, rapid, non-rhythmic movement or sound. Tics can be controlled briefly.
- Myoclonus—a sudden, brief, jerky, shock-like involuntary muscle contraction. Myoclonic jerks may occur singly or repetitively. Unlike tics, myoclonus cannot be controlled even briefly.
- Spasticity—an abnormal increase in muscle tone. It may be associated with involuntary **muscle spasms**, sustained muscle contractions, and exaggerated deep tendon reflexes that make movement difficult or uncontrollable.
- Chorea—rapid, non-rhythmic, uncontrolled jerky movements, most often in the arms and legs. Chorea also may affect the hands, feet, trunk, neck, and face. Choreoathetosis is a syndrome of continuous random movements that usually occur at rest and may appear to be fidgety, dancing, or writhing.
- Ballism—like chorea, but the movements are much larger, more explosive and involve more of the arm or leg. This condition, also called ballismus, can occur on both sides of the body or on one side only (hemiballismus).
- Akathisia—restlessness and a desire to move to relieve uncomfortable sensations. Sensations may include a feeling of crawling, **itching**, stretching, or creeping, usually in the legs.
- Athetosis—slow, writhing, continuous, uncontrollable movement of the arms and legs.

Hypokinetic movements include:

- Bradykinesia—extreme slowness and stiffness of movement.
- Freezing—inability to begin a movement or involuntary stopping of a movement before it is completed.
- Rigidity—an increase in muscle tension when an arm or leg is moved by an outside force.
- Postural instability—loss of the ability to maintain upright posture caused by slow or absent righting reflexes.

Diagnosis

Diagnosis of movement disorders requires a careful medical history and a thorough physical and neurological examination.

The medical history helps the physician evaluate the presence of other conditions or disorders that might contribute to or cause the disorder. Records of previous diagnoses, surgeries, and treatments are reviewed. The child's **family** medical history is evaluated to determine if there is a history of muscular or neurological disorders. Genetic testing is available for some forms of movement disorders.

The physical and neurological exams may include an evaluation of the child's motor reflexes, including muscle tone, mobility, strength, balance, and endurance; heart and lung function; cranial nerve function; and an examination of the child's abdomen, spine, throat, and ears. The child's height, weight, and blood pressure also are checked and recorded. Routine blood and urine analyses are performed.

Brain imaging studies are usually performed. Imaging techniques include **computed tomography** scan (CT scan), positron emission tomography (PET), or **magnetic resonance imaging** (MRI) scans. A lumbar puncture (spinal tap) may be necessary. Video recording of the abnormal movement is often used to analyze movement patterns and track progress of the disorder and its treatment.

Other tests may include **x rays** of the spine and hips or diagnostic blocks with local anesthetics to provide information on the effectiveness of potential treatments.

To aid diagnosis, a multi-disciplinary team may be consulted so the proper treatment can be planned. Occupational and physical therapy evaluations may be helpful to determine upper and lower extremity movement patterns and passive range of motion.

In some cases, nerve conduction studies with electromyography of the affected muscles may be performed to evaluate the child's muscular activity and provide a comprehensive **assessment** of nerve and muscle function.

In both tests, the examiner uses a computer, monitor, amplifier, loudspeaker, stimulator, and high-tech filters to see and hear how the muscles and nerves are responding during the test. In the nerve conduction study, small electrodes are placed on the skin over the muscles to be examined. A stimulator delivers a very small electrical current (that does not cause damage to the body) through the electrodes, causing the nerves to fire. In the electromyogram, a very thin, sterilized needle is inserted into various muscles. The needle is attached by wires to a recording machine. The patient is asked to relax and contract the muscles being examined. The electrical signals produced by the nerves and muscles during these tests are measured and recorded by a computer and displayed as electrical waves on the monitor. The test results are interpreted by a specially trained physician.

An EEG (**electroencephalogram**) may be performed to detect seizures, analyze general brain

functioning, and measure brain activity associated with movement or sensation. This test measures the electrical signals from the brain. Surface electrodes attached to the scalp measure voltages in the brain. The electrical activity can be measured while the child is resting or, in some cases, when the child is moving. An evoked potentials study may be part of the EEG test. Evoked potentials record the response of the brain to a sensory, visual, or auditory stimulus.

Treatment

Treatment of a movement disorder begins with a proper diagnostic evaluation. Treatment options include physical and occupational therapies, medications, surgery, or a combination of these treatments.

The goals of treatment are to increase the child's comfort, decrease **pain**, ease mobility, help with activities of daily living such as hygiene, ease rehabilitation procedures, and prevent or decrease the risk of developing a joint contracture. The type of treatment recommended will depend upon the severity of the disorder; the child's overall health; the potential benefits, limitations, and side effects of the treatment; and the impact of the treatment on the child's quality of life.

Clinicians should work with the child and parents or caregivers to develop an individual treatment plan. Specific treatment goals will vary from one person to the next. Treatment should be provided by a movement disorders specialist or specially trained pediatric neurologist and a multi-disciplinary team of specialists that may include a physiatrist, physical therapist, occupational therapist, gait and movement specialists, social worker, and surgical specialists as applicable, such as a pediatric orthopedic surgeon or pediatric neurosurgeon.

In some cases, treatment is not recommended or desired, because it would actually interfere with the patient's current mobility and it would not improve function. For example, some people with multiple sclerosis who experience significant leg weakness find that spasticity makes their legs more rigid, helping them to stand, transfer to a chair or bed, or walk.

Physical and occupational therapies

Physical therapy includes stretching exercises, muscle group strengthening exercises, and range of motion exercises to prevent muscles from shortening (contracture), preserve flexibility and range of motion, and reduce the severity of symptoms. Exercises should be practiced daily, as recommended by the physical therapist. Prolonged stretching can lengthen muscles, and strengthening exercises can restore the proper strength to affected muscles. Aquatic therapy also may be recommended, since there is less stress on the body when in the water.

A physical therapist can instruct the patient on proper posture guidelines. Proper posture is critical, especially while sitting and sleeping, to maintain proper alignment of the hips and back. Balancing rest and **exercise** is also important.

Occupational therapy may include splints, casts, or braces on the affected arm or leg to enable proper limb positioning, and maintain flexibility and range of motion. The therapy may include training for proper limb positioning while seated in a wheelchair or lying in bed.

Physical and occupational therapists can provide guidelines on how to adapt the child's environment to ensure **safety** and comfort.

Medications

Medications can help compensate for some imbalances of the basal ganglionic circuit. Drugs to treat movement disorders include oral medications, injected medications, and continuous delivery medications. These medications work by preventing nerves from signaling the muscles to contract, thereby preventing muscle contractions.

If treatment with a single medicine fails to effectively treat the disorder, a different medicine may be tried or an additional medicine may be prescribed. The most important medication guidelines are to ensure that the child takes the medication exactly as prescribed, and to never discontinue any medication without first talking to the child's doctor, even if the medication does not seem to be working or is causing unwanted side effects.

ORAL MEDICATIONS Baclofen (Lioresal) is a muscle relaxant that works on nerves in the spinal cord to reduce spasticity. The benefits of baclofen include decreased stretch reflexes, improved passive range of motion, and reduced muscle spasms, pain, and tightness. Side effects include drowsiness and sedation, as well as weakness, decreased muscle tone, confusion, fatigue, **nausea**, and **dizziness**. Baclofen should not be taken with central nervous system depressants or alcohol.

Levodopa (L-dopa) is a medication that is converted to dopamine in the brain. Dopamine is a chemical that aids in the transmission of nerve signals. Sinemet is a combination medication containing levodopa and carbidopa. Carbidopa enables L-dopa to be converted to dopamine after the L-dopa enters the brain, thereby lowering

the oral dose and decreasing side effects. Side effects include nausea, **diarrhea**, and low blood pressure.

Anticholinergics, including trihexyphenidyl (Artane) and benztropine (Benztrop MES, Cogentin), block acetylcholine receptors in the brain. Acetylcholine receptors are integral proteins that respond to the neurotransmitter acetylcholine by opening a pathway in the membrane for ion diffusion across the cell membrane. Side effects include dry mouth, blurred vision, **constipation**, urinary retention, and rapid heart rate. These side effects are usually much less frequent in children than adults; therefore, much higher doses are usually prescribed in children.

Benzodiazepines, such as diazepam (Valium), clonazepam (Klonopin, Rivotril), and lorazepam (Ativan) act on the central nervous system to improve passive range of motion, reduce muscle overactivity and painful spasms, and provide overall relaxation. These medications are often taken at night because they cause drowsiness, but they also can relieve muscle spasms that interrupt **sleep**. Side effects include unsteadiness, loss of strength, low blood pressure, gastrointestinal symptoms, memory problems, confusion, and behavioral problems.

Dantrolene sodium (Dantrium) acts on the muscles to directly interfere with the chemistry of the muscle contraction. It is generally used when other medications are not effective. Benefits may include improved passive movement, decreased muscle tone, and reduced muscle spasms, tightness, and pain. Side effects include generalized weakness—including weakness of the respiratory muscles—as well as drowsiness, fatigue, diarrhea, and sensitivity to the sun. Liver problems may occur with this medication, and frequent lab tests are performed to evaluate liver function.

Tizanidine (Zanaflex) acts on the central nervous system. It does not usually cause reduced muscle strength. The most common side effect is sedation, and other side effects include low blood pressure, dry mouth, dizziness, and hallucinations. Liver problems may occur with this medication, and frequent lab tests are performed to evaluate liver function.

A variety of other medications may be used to treat movement disorders, including antiepileptic drugs that stimulate GABA receptors in the brain's basal ganglia; neuroleptics that block dopamine D2-like receptors; Clonidine (Catapres) and selective serotonin reuptake inhibitors (SSRIs, such as fluoxetine, commonly known as Prozac) for the treatment of tics; and channel modulators that affect the behavior of channels that transport small molecules such as potassium, sodium, or calcium across cell membranes.

INJECTED MEDICATIONS Botulinum-toxin type A (Botox, Dysport) or type B (Myobloc) is injected locally into the affected muscle group to relax the muscles in dystonia or spasticity. It works by preventing nerves from sending signals to the muscles that cause them to contract. Although the treatment takes one to two weeks to reach its full effectiveness, the beneficial effects last three to four months. Botulinum-toxin allows more normal limb positioning and improved mobility. In some patients, the injections also decrease pain. Injections may be used to make casting easier, ease the adjustment of a new brace, or delay surgery.

Botulinum-toxin is made by the bacteria that cause **botulism**. However, the amount of botulinum-toxin injected to treat spasticity is such a small amount that it would not cause botulism poisoning. This treatment is very safe, and the injections can be given in a doctor's office without the use of sedation or anesthesia. Injections can be repeated, but should be spaced from three to six months apart to avoid exceeding the recommended dose. Botulinum-toxin injections may be used in combination with other treatments.

Botulinum-toxin injections are typically expensive and may not be covered by insurance. A Reimbursement Hotline established by Allergan, the manufacturer of Botox, is a resource for reimbursement questions: (800) 530-6680 or online at <www.botox.com>. Elan, the manufacturer of Myobloc, also has resources available to answer questions about reimbursement. Interested persons may call (888) 461-2255 or go online at <www.elan.com>.

Alcohol and phenol are injected in combination, but are less common treatments. The medications are injected directly onto nerves that supply spastic muscles to destroy them. The injections cut off the signals to those muscles, allowing them to relax. This treatment may be used to treat spasticity in larger muscle groups closer to the trunk, such as the thigh muscles. Although this treatment is generally less expensive than botulinum-toxin injections, there are more serious side effects.

Short-term medications such as lidocaine, a local anesthetic, can be used to assess the potential benefit of botulinum-toxin or alcohol and phenol injections.

CONTINUOUS DELIVERY MEDICATIONS Baclofen usually is taken as an oral medication but also can be delivered directly into the spinal fluid when the oral medication does not effectively control symptoms. An intrathecal baclofen delivery system, surgically placed by a neurosurgeon, continuously releases prescribed amounts of baclofen in small doses directly into the spinal fluid via a small catheter and pump. This type of

delivery system causes fewer and less severe side effects than the oral baclofen.

Pump refills and medication adjustments are generally made once every two to three months after the initial dosage is established. The pump system lasts from three to five years, at which time it needs to be replaced.

Surgery

Surgery is only recommended when all other treatments have been tried and have not effectively controlled the child's symptoms.

Selective dorsal rhizotomy surgery, also called selective posterior rhizotomy, involves a surgical resection of part of the spinal nerve. By cutting the sensory nerve rootlets that cause the spasticity, muscle stiffness is decreased while other functions are maintained. Potential benefits of this surgical procedure include pain relief, reduced spasticity to improve walking or aid sitting in a wheelchair, increased ability to bend at the waist, and improved use of the hands. Sometimes rhizotomy results in improved breathing and better control of the arms, legs, and head.

Thalamotomy is a surgical procedure used to destroy part of the thalamus, which is thought to produce abnormal brain activity that causes tremor. Pallidotomy is a surgical procedure used to destroy part of the globus pallidus, which is thought to become overactive with certain disorders, such as Parkinson's disease. Although effective, these surgeries have significant risks, including paralysis, loss of vision, or loss of speech if the precise location of the brain is not targeted during surgery. With the advent of a less invasive approach called deep brain stimulation, these surgeries have become less common.

Deep brain stimulation (DBS) is a way to inactivate the parts of the brain thought to cause overactivity or tremor in certain muscles, without destroying a part of the brain. It is currently a treatment option for adult patients with Parkinson's disease, but research is underway to determine if the procedure can benefit children with movement disorders.

During the DBS procedure, an electrode placed in a precise area of the brain delivers small, electrical shocks to interrupt the abnormal brain activity that leads to symptoms. The electrode has four metal contacts that can be used in different combinations. A few patients may have stimulators implanted on both sides of the brain, but this increases the risk for complications. The electrode is connected by a wire to a pacemaker-like device implanted under the skin in the chest. This device generates the electrical shocks. The electrical stimulation can be adjusted as the patient's condition progresses over time, and the stimulator can be turned off in the event that other beneficial therapies, such as brain cell transplantation, are performed.

Orthopedic surgery may be performed to correct a contracture. During contracture release surgery, the tendon of a contractured muscle is cut, the joint repositioned to a more normal angle, and a cast is applied. Regrowth of the tendon to this new length occurs over several weeks following surgery. After the cast is removed, physical therapy can help strengthen the muscles and improve range of motion. This procedure is most commonly performed on the Achilles tendon but may also be performed on the knees, hips, shoulders, elbows, and wrists. Tendon transfer surgery is another technique to treat contractures. During this procedure, the tendon attached to a spastic muscle is cut and transferred to a different site, preventing the muscle from being pulled into an abnormal position. The disadvantages of these orthopedic procedures are that they are irreversible and they may need to be repeated.

Other orthopedic surgeries that may accompany contracture release surgery include osteotomy, in which a small wedge is removed from a bone to allow repositioning. A cast is applied while the bone heals in a more natural position. Osteotomy is more commonly performed on the bones in the hips or feet. Arthrodesis is a fusing of bones that normally move independently, to limit the ability of a spastic muscle to pull the joint into an abnormal position. Arthrodesis is more commonly performed on the bones in the ankle.

Other treatments

Transplantation of fetal cells into the basal ganglia has produced mixed results in Parkinson's disease and is being researched for application in other movement disorders.

Brief application (about 10 minutes) of cold packs to spastic muscles may help ease pain and improve function for a short period of time.

Electrical stimulation may be used to stimulate a weak muscle to counteract the action of a stronger, spastic muscle.

Alternative treatment

Alternative and complementary therapies include approaches that are considered to be outside the mainstream of traditional health care. Among the therapies that may be helpful are acupuncture, homeopathy, touch therapies, postural alignment therapies, and biofeedback.

The progress made will depend on the individual and his or her condition.

Biofeedback training may be used to teach the patient how to consciously reduce muscle tension. Biofeedback uses an electrical signal that indicates when a spastic muscle relaxes. The patient may be able to use biofeedback to learn how to consciously reduce muscle tension and possibly reduce symptoms.

Coenzyme Q10 supplements may be beneficial, as some people with movement disorders may have low levels of this substance. Coenzyme Q10 is a natural substance produced by the body that transports electrons during cellular respiration, or the process in which cells get their energy from oxygen.

Initial trials of cannabinoids, the active ingredient in marijuana, have shown promise in the treatment of muscle stiffness and limb straightening associated with multiple sclerosis. Further research is needed to determine the beneficial effects of marijuana-derived substances on neuromuscular symptoms associated with movement disorders. Researchers caution that smoking marijuana is dangerous, especially since there may be other harmful substances mixed in with the illegal drug.

Before learning or practicing any particular technique, it is important for the parent or caregiver and child to learn about the therapy, its safety and effectiveness, potential side effects, and the expertise and qualifications of the practitioner. Although some practices are beneficial, others may be harmful to certain patients. Alternative therapies should not be used as a substitute for medical therapies prescribed by a doctor. Parents should discuss these alternative treatments with the child's doctor to determine the techniques and remedies that may be beneficial for the child.

Nutritional concerns

Dietary guidelines are individualized, based on the child's age, diagnosis, overall health, severity of disability, and level of functioning. Specific nutritional problems, such as swallowing or feeding difficulties, may be a concern in some patients and should be managed by a team of specialists, including a speech therapist. Early identification, treatment, and correction of specific feeding problems will improve the health and nutritional status of the patient.

A well-balanced and carefully planned diet will help maintain general good health for people with movement disorders. Specialists recommend that people with multiple sclerosis and other movement disorders adhere to the same low-fat, high fiber diet that is recommended for the general population. A diet rich in fresh fruits and vegetables will ensure adequate intake of antioxidants, substances that help protect against free radical damage.

Children with movement disorders may have different energy needs, depending on their condition. One study indicated that ambulatory and non-ambulatory adolescents with cerebral palsy had decreased energy needs compared with a control group of normal adolescents. Therefore, a child's specific calorie needs should be evaluated by a registered dietitian who can work with the parents to develop an individualized meal plan. The child's weight should be obtained once a week or at least once a month to determine if caloric intake is adequate.

A child's self-feeding skills can impact his or her health outcome. One study indicated that 90 percent of children with good to fair motor and feeding skills reached adulthood. In contrast, a lack of self-feeding skills was associated with a six-fold increase in mortality (rate of death).

Maintaining a healthy weight is important to prevent the development of chronic diseases such as diabetes, high blood pressure (**hypertension**), and heart disease.

Tube feedings may be required in some patients with **failure to thrive**, aspiration **pneumonia**, difficulty swallowing, or an inability to ingest adequate calories orally to maintain nutritional status or promote growth.

Prognosis

The prognosis for a patient with a movement disorder depends on the specific disorder. There is no cure for movement disorders. However, they can be well-managed with the proper combination of physical and occupational therapies, medication, and surgery. The long-term outlook depends on the severity of the disorder.

Prevention

Prevention depends on the specific disorder.

Parental concerns

Parents should work closely with the child's therapists and doctors to create an effective treatment plan. It is important for parents to communicate their treatment goals with the health care team. Parents should take an active role in the child's exercise program and help the child practice the exercises, as prescribed, every day.

There are many tips to make the home and school environments safer for a child with a movement disorder. An occupational therapist can work with parents to assess the home environment and provide resources for

KEY TERMS

Active motion—Spontaneous; produced by active efforts. Active range of motion exercises are those that are performed by the patient without assistance.

Activities of daily living (ADL)—The activities performed during the course of a normal day, for example, eating, bathing, dressing, toileting, etc.

Acupuncture—Based on the same traditional Chinese medical foundation as acupressure, acupuncture uses sterile needles inserted at specific points to treat certain conditions or relieve pain.

Anoxia—Lack of oxygen.

Ataxia—A condition marked by impaired muscular coordination, most frequently resulting from disorders in the brain or spinal cord.

Autonomic nervous system—The part of the nervous system that controls so-called involuntary functions, such as heart rate, salivary gland secretion, respiratory function, and pupil dilation.

Biofeedback—A training technique that enables an individual to gain some element of control over involuntary or automatic body functions.

Botulinum toxin—A potent bacterial toxin or poison made by *Clostridium botulinum*; causes paralysis in high doses, but is used medically in small, localized doses to treat disorders associated with involuntary muscle contraction and spasms, in addition to strabismus. Commonly known as Botox.

Bradykinesia—Extremely slow movement.

Central nervous system—Part of the nervous system consisting of the brain, cranial nerves, and spinal cord. The brain is the center of higher processes, such as thought and emotion and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system, that is the nerves present in the rest of body.

Cerebral palsy—A nonprogressive movement disability caused by abnormal development of or damage to motor control centers of the brain.

Chorea—Involuntary movements in which the arms or legs may jerk or flail uncontrollably.

Choreoathetosis—Involuntary rapid, irregular, jerky movements or slow, writhing movements that flow into one another.

Clonic—Referring to clonus, a series of muscle contractions and partial relaxations that alternate in some nervous diseases in the form of convulsive spasms.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures; also called computed axial tomography.

Contraction—A tightening of the uterus during pregnancy. Contractions may or may not be painful and may or may not indicate labor.

Contracture—A tightening or shortening of muscles that prevents normal movement of the associated limb or other body part.

Encephalopathy—Any abnormality in the structure or function of brain tissues.

Essential tremor—An uncontrollable (involuntary) shaking of the hands, head, and face. Also called familial tremor because it is sometimes inherited, it can begin in the teens or in middle age. The exact cause is not known.

Fasciculations—Small involuntary muscle contractions visible under the skin.

Fetal tissue transplantation—A method of treating Parkinson's and other neurological diseases by grafting brain cells from human fetuses onto the basal ganglia. Human adults cannot grow new brain cells but developing fetuses can. Grafting fetal tissue stimulates the growth of new brain cells in affected adult brains.

General anesthesia—Deep sleep induced by a combination of medicines that allows surgery to be performed.

Hereditary ataxia—One of a group of hereditary degenerative diseases of the spinal cord or cerebellum. These diseases cause tremor, spasm, and wasting of muscle.

Homeopathy—A holistic system of treatment developed in the eighteenth century. It is based on the idea that substances that produce symptoms of sickness in healthy people will have a curative effect when given in very dilute quantities to sick people who exhibit those same symptoms. Homeopathic remedies are believed to stimulate the body's own healing processes.

Huntington's disease—A rare hereditary disease that causes progressive chorea (jerky muscle movements) and mental deterioration that ends in dementia. Huntington's symptoms usually appear in patients in their 40s. Also called Huntington's chorea.

KEY TERMS (contd.)

Hyperactive reflexes—Reflexes that persist too long and may be too strong. For example, a hyperactive grasp reflex may cause the hand to stay clenched in a tight fist.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Hypertonia—Having excessive muscular tone or strength.

Levodopa (L-dopa)—A substance used in the treatment of Parkinson's disease. Levodopa can cross the blood-brain barrier that protects the brain. Once in the brain, it is converted to dopamine and thus can replace the dopamine lost in Parkinson's disease.

Local anesthesia—Pain-relieving medication used to numb an area while the patient remains awake. Also see general anesthesia.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct detailed images of internal body structures and organs, including the brain.

Mask—An expressionless look, caused by reduced movements of the face.

Motor neuron—A nerve cell that specifically controls and stimulates voluntary muscles.

Multiple sclerosis—A progressive, autoimmune disease of the central nervous system characterized by damage to the myelin sheath that covers nerves. The disease, which causes progressive paralysis, is marked by periods of exacerbation and remission.

Muscle spasm—Localized muscle contraction that occurs when the brain signals the muscle to contract.

Myoclonus—Involuntary contractions of a muscle or an interrelated group of muscles. Also known as myoclonic seizures.

Neurologist—A doctor who specializes in disorders of the nervous system, including the brain, spinal cord, and nerves.

Neurosurgeon—Physician who performs surgery on the nervous system.

Nocturnal leg cramps—Cramps that may be related to exertion and awaken a person during sleep.

Occupational therapist—A healthcare provider who specializes in adapting the physical environment to meet a patient's needs. An occupational therapist also assists patients and caregivers with activities of daily living and provide instructions on wheelchair use or other adaptive equipment.

Orthopedist—A doctor specializing in treatment of the musculoskeletal system.

Parkinsonism—A set of symptoms originally associated with Parkinson disease that can occur as side effects of neuroleptic medications. The symptoms include trembling of the fingers or hands, a shuffling gait, and tight or rigid muscles.

Parkinson's disease—A slowly progressive disease that destroys nerve cells in the basal ganglia and thus causes loss of dopamine, a chemical that aids in transmission of nerve signals (neurotransmitter). Parkinson's is characterized by shaking in resting muscles, a stooping posture, slurred speech, muscular stiffness, and weakness.

Passive movement—Movement that occurs under the power of an outside source such as a clinician. There is no voluntary muscular contraction by the individual who is being passively moved.

Periodic limb movement disorder—A disorder characterized by involuntary flexion of leg muscles, causing twitching and leg extension or kicking during sleep.

Peripheral nerves—Nerves outside the brain and spinal cord that provide the link between the body and the central nervous system.

Physiatrist—A physician who specializes in physical medicine and rehabilitation.

Physical therapist—A healthcare provider who teaches patients how to perform therapeutic exercises to maintain maximum mobility and range of motion.

Positron emission tomography (PET)—A computerized diagnostic technique that uses radioactive substances to examine structures of the body. When used to assess the brain, it produces a three-dimensional image that shows anatomy and function, including such information as blood flow, oxygen consumption, glucose metabolism, and concentrations of various molecules in brain tissue.

Progressive supranuclear palsy—A rare disease that gradually destroys nerve cells in the parts of the brain that control eye movements, breathing, and muscle coordination. The loss of nerve cells causes palsy, or paralysis, that slowly gets worse as the disease progresses. The palsy affects ability to move the eyes, relax the muscles, and control balance. Also called Steele-Richardson-Olszewski syndrome.

KEY TERMS (contd.)

Psychogenic disorders—A variety of unusual, involuntary movements that occur in children with psychiatric disorders or in response to anxiety, stress, depression, anger, or grief. Psychogenic movements are thought to represent the physical expression of an intolerable mental conflict.

Range of motion (ROM)—The range of motion of a joint from full extension to full flexion (bending) measured in degrees like a circle.

Restless legs syndrome (RLS)—A disorder in which the patient experiences crawling, aching, or other disagreeable sensations in the calves that can be relieved by movement. RLS is a frequent cause of difficulty falling asleep at night.

Rigidity—A constant resistance to passive motion.

Scissoring—Involuntary crossing of the legs.

Spinal cord injury—Injury to the spinal cord, via blunt or penetrating trauma.

Stroke—Interruption of blood flow to a part of the brain with consequent brain damage. A stroke may be caused by a blood clot or by hemorrhage due to a burst blood vessel. Also known as a cerebrovascular accident.

Tourette syndrome—A neurological disorder characterized by multiple involuntary movements and uncontrollable vocalizations called tics that come and go over years, usually beginning in childhood and becoming chronic. Sometimes the tics include inappropriate or obscene language (coprolalia).

Wilson disease—A rare, inherited disorder that causes excess copper to accumulate in the body. Steadily increasing amounts of copper circulating in the blood are deposited primarily in the brain, liver, kidneys, and the cornea of the eyes. It can cause psychiatric symptoms resembling schizophrenia.

adaptive equipment that may be helpful. Some of these tips include:

- All throw rugs should be removed unless they are firmly attached to the floor.
- There must be proper lighting. Nightlights should be placed along key pathways of the home.
- The top and bottom of stairs should be highlighted with a contrasting color or texture to distinguish them.
- The floor should be free of clutter, to prevent tripping or falling.
- Handrails should be installed, especially along stairways and in the bathroom.
- All electrical cords and other cords should be kept out of the way.

Raising a child with a movement disorder can be challenging. Support groups are available to provide information and assistance.

Mucopolysaccharidoses

Definition

Mucopolysaccharidosis (MPS) is a general term for many different related inherited disorders that are caused by the accumulation of mucopolysaccharides in body tissues. This accumulation interferes with the individual's development.

Description

Mucopolysaccharides are long chains of sugar molecules that are essential for building the bones, cartilage, skin, tendons, and other tissues in the body. Another name for mucopolysaccharides is glycosaminoglycans (GAGs). Normally, the human body continuously breaks down and rebuilds cells that contain GAGs. There are many different types of GAGs, and different GAGs are unable to be broken down in each of the MPS conditions. Several enzymes are involved in breaking down each GAG, and a deficiency or absence of any of the essential enzymes can cause the GAG not to be broken down completely. This condition results in the accumulation of GAGs in the tissues and organs in the body. The accumulating GAGs are stored in cellular structures called lysosomes, and these disorders are known as lysosomal storage diseases. When too many GAGs accumulate, organs and tissues become damaged or do not function properly.

Before specific deficient enzymes were identified, MPS disorders were diagnosed by the signs and symptoms seen in an individual. The discovery of individual enzyme deficits resulted in a reclassification of some of the MPS disorders. Types of MPS disorders are MPS I, MPS II, MPS III, MPS IV, MPS VI, MPS VII, and MPS IX. However, these conditions are also referred to by their original names, which are Hurler, Hurler-Scheie, Scheie (all MPS I), Hunter (MPS II), Sanfilippo (all MPS III), Morquio (all MPS IV), Maroteaux-Lamy (MPS VI), Sly (MPS VII), and Hyaluronidase deficiency (MPS IX).

Demographics

MPS disorders are rare, and the frequency with which they occur varies depending on the type of the disorder. For all MPS types combined, the disorder occurs in only about one of every 25,000 people. Except for MPS II, individuals of both genders are affected equally. Because of its inheritance pattern, MPS II is found only in males. All MPS disorders are present at birth, although symptoms appear at different times, depending on the type of disorder. There appears to be no race or ethnic component in the distribution of MPS disorders.

Causes and symptoms

All MPS disorder except MPS II are inherited in an autosomal recessive manner. An individual with an autosomal recessive disorder inherits one non-working genes from each parent. The parents are called carriers of the disorder. If the parent has one good copy of the gene and one defective copy, the parent will not have MPS and may be unaware that he or she has a defective gene. MPS only occurs when both of an individual's genes that produce the same enzyme contain a mutation or defect, causing them not to function properly. As a result, either no enzyme is produced, or the amount produced is inadequate. When two people are carriers for an autosomal recessive disorder, they have a 25 percent chance with each pregnancy to have a child with the disorder. Some individuals who have MPS are able to have children. Children of MPS parents are all carriers of the disorder, because they inherit one bad copy of the gene from the affected parent. However, these children are not at risk to develop the disorder unless the other parent is a carrier or affected with the same autosomal recessive condition.

Unlike the other MPS conditions, MPS II is inherited in an X-linked recessive manner, which means that the gene causing the condition is located on the X chromosome, one of the two sex chromosomes. A male child inherits an X chromosome from his mother and a Y chromosome from his father. He will have the disorder if the X chromosome inherited from his mother carries the defective gene, since he has only one (nonfunctioning) copy of the gene. Females inherit one X chromosome from their mother and a second X chromosome from their father. Because they have two X chromosomes, they are carriers of the disorder if one of their X chromosomes has the gene that causes the condition, while the other X chromosome does not.

Although MPS are all inherited disorders, each type is caused by a deficiency of one particular enzyme involved in breaking down GAGs. The accumulation of the GAGs in the tissues and organs in the body causes the symptoms characteristic of the MPS disorders. Symptoms and their time of onset vary widely depending on which form of the disorder the individual inherits.

MPS I

MPS I is caused by a deficiency of the enzyme alpha-L-iduronidase. Three conditions, Hurler, Hurler-Scheie, and Scheie syndromes, are caused by a deficiency of this enzyme. Initially, these three conditions were believed to be separate, because each was associated with different physical symptoms and prognoses. However, once the underlying cause of these conditions was identified, it was realized that these three conditions are variants of the same disorder.

MPS I H (Hurler syndrome)

About one child in 100,000 is born with Hurler syndrome. This tends to be the most severe form of MPS I. Symptoms of Hurler syndrome are often evident within the first year or two after birth. Often these infants initially grow faster than expected, but then reach a point where they begin to lose the skills that they have learned. Their growth slows and typically stops by age three.

Facial features begin to coarsen. These children develop a short nose, flatter face, thicker skin, and a protruding tongue. Their heads become larger, and they develop more hair on their bodies, with the hair becoming coarser. Their bones are also affected, and they usually develop joint contractures (stiff joints), kyphosis (a specific type of curve to the spine), and broad hands with short fingers. Many of these children have breathing difficulties, and respiratory infections are common. Other common problems include heart valve dysfunction, thickening of the heart muscle (cardiomyopathy), enlarged spleen and liver, clouding of the cornea, hearing loss, and carpal tunnel syndrome. These children typically do not live past age 12.

MPS I H/S (Hurler-Scheie syndrome)

Hurler-Scheie syndrome an intermediate form of MPS I, meaning that the symptoms are not as severe as those in individuals who have MPS I H but not as mild as those in MPS I S. Approximately one baby in 115,000 is born with Hurler-Scheie syndrome. These individuals tend to be shorter than expected. They can have normal **intelligence**; however, some individuals with MPS I H/S experience learning difficulties. These individuals may develop some of the same physical features as those with Hurler syndrome, but usually they are not as severe. The prognosis for children with MPS I H/S is variable with some individuals dying during childhood, while others live to adulthood.

MPS I S (Scheie syndrome)

Scheie syndrome is the mild form of MPS I. About one baby in 500,000 is born with Scheie syndrome. Individuals with MPS I S usually have normal intelligence, although there have been some reports of individuals with MPS I S developing psychiatric problems. Common physical problems include corneal clouding, heart abnormalities, and orthopedic difficulties involving their hands and back. Individuals with MPS I S do not develop the facial features seen with MPS I H and usually these individuals have a normal life span.

MPS II (Hunter syndrome)

Hunter syndrome is caused by a deficiency of the enzyme iduronate-2-sulphatase. All individuals with Hunter syndrome are male, because the gene that causes the condition is located on their single X chromosome. Like many MPS conditions, Hunter syndrome is divided into two forms, mild and severe. About one in 110,000 males are born with Hunter syndrome, with the severe form being three times more common than the mild form.

The severe form of MPS II is associated with progressive **mental retardation** and physical disability, with most individuals dying before age 15. In the milder form, most of these individuals live to adulthood and have normal intelligence or only mild mental impairments. Males with the mild form of Hunter syndrome develop physical differences similar to the males with the severe form, but not as quickly. Males with mild Hunter syndrome can have a normal life span and some have had children. Most males with Hunter syndrome develop joint stiffness, chronic **diarrhea**, enlarged liver and spleen, heart valve problems, hearing loss, and

kyphosis. They also tend to be shorter than expected. These symptoms progress at different rates depending on whether the individual has the mild or severe form of MPS II.

MPS III (Sanfilippo syndrome)

MPS III, like the other MPS conditions, was initially diagnosed by the individual having certain physical signs and symptoms. It was later discovered that the physical symptoms associated with Sanfilippo syndrome could be caused by a deficiency in one of four enzymes. MPS III is in the early 2000s subdivided into four groups, labeled A through D, based on the specific enzyme that is deficient. All four of these enzymes are involved in breaking down the same GAG, heparan sulfate. Heparan sulfate is mainly found in the central nervous system and accumulates in the brain when it cannot be broken down because one of those four enzymes is deficient or missing.

MPS III is a variable condition, with symptoms beginning to appear between two and six years of age. Because of the accumulation of heparan sulfate in the central nervous system (CNS), the CNS is severely affected. In MPS III, signs that the CNS is degenerating usually become evident between six and ten years of age. Many children with MPS III develop seizures, sleeplessness, thicker skin, joint contractures, enlarged tongues, cardiomyopathy, behavior problems, and mental retardation. The life expectancy in MPS III is also variable. On average, individuals with MPS III live until they are teenagers, with some living longer and others not that long.

MPS IIIA (Sanfilippo syndrome type A) is caused by a deficiency of the enzyme heparan N-sulfatase. Type IIIA is the most severe of the four types of MPS III. Symptoms appear and death occurs at an earlier age than in other subtypes. A study in British Columbia estimated that one in every 325,000 babies is born with MPS IIIA. MPS IIIA is the most common of the four types in Northwestern Europe. The gene that causes MPS IIIA is located on the long arm of chromosome 17.

MPS IIIB(Sanfilippo syndrome type B) is due to a deficiency in N-acetyl-alpha-D-glucosaminidase (NAG). This type of MPS III is not as severe as type IIIA, and the characteristic signs and symptoms vary. Type IIIB is the most common of the type III disorders in southeastern Europe. The gene associated with MPS IIIB is also located on the long arm of chromosome 17.

MPS IIIC (Sanfilippo syndrome type C) is caused by a deficiency in the enzyme acetyl-CoA-alpha-glucosaminide acetyltransferase. This is a rare form of MPS III. The gene involved in MPS IIIC is believed to be located on chromosome 14.

MPS IIID (Sanfilippo syndrome type D) is caused by a deficiency in the enzyme N-acetylglucosamine-6-sulfatase. This form of MPS III is also rare. The gene involved in MPS IIID is located on the long arm of chromosome 12.

MPS IV A (Morquio syndrome type A)

MPS IV A is the severe form of the disorder and is caused by a deficiency in the enzyme galactosamine-6-sulphatase. The gene involved with MPS IV A is located on the long arm of chromosome 16. The major organs affected by MPS IV are the cornea and the cartilage, particularly the cartilage of the neck. Bowel and bladder function also can be impaired. Respiratory problems and **sleep** apnea are common. Individuals with MPS IV appear healthy at birth but show skeletal deformities and growth retardation by age three. Death often occurs early in individuals with the severe form of this disorder.

MPS IV B (Morquio syndrome type B) is the milder form of the disorder. The enzyme, beta-galactosidase, is deficient in MPS IV B. The gene that produces beta-galactosidase is located on the short arm of chromosome 3. Individuals with the MPS IV B can have normal lifespans (into their 70s).

MPS VI (Maroteaux-Lamy syndrome)

MPS VI, which is another rare form of MPS, is caused by a deficiency of the enzyme N-acetylglucosamine-4-sulphatase. This condition is also variable; individuals may have a mild or severe form of the disorder. Typically, the nervous system or intelligence of an individual with MPS VI is not affected. Individuals with a more severe form of MPS VI can have airway obstruction, develop **hydrocephalus** (accumulation of fluid in the brain), and exhibit bone changes. Individuals with a severe form of MPS VI are more likely to die while in their teens. With a milder form of the disorder, individuals tend to be shorter than expected for their age, develop corneal clouding, and live longer. The gene involved in MPS VI is believed to be located on the long arm of chromosome 5.

MPS VII (Sly syndrome)

MPS VII is an extremely rare form of MPS and is caused by a deficiency of the enzyme beta-glucuronidase. It is also highly variable, but symptoms are generally similar to those seen in individuals with Hurler syndrome. The gene that causes MPS VII is located on the long arm of chromosome 7.

MPS IX (Hyaluronidase deficiency)

MPS IX, a condition first described in 1996, is caused by a deficiency of the enzyme hyaluronidase. In the few individuals described with this condition, the symptoms are variable. Some individuals develop soft tissue masses (growths) under the skin. Also, these individuals are shorter than expected for their age. The gene involved in MPS IX is believed to be located on the short arm of chromosome 3.

When to call the doctor

Parents should inform the doctor immediately if MPS runs in their **family**, so that early testing can be done on their children. In addition, any time they have questions about their child's growth and development, they should talk to their pediatrician.

Diagnosis

While a diagnosis for each type of MPS can be made based on the physical signs described above, several of the conditions have similar features. Therefore, enzyme analysis is used to determine the specific MPS disorder. Enzyme analysis often cannot accurately determine if an individual is a carrier for an MPS disorder, because the enzyme levels in individuals who are not carriers overlaps the enzyme levels seen in those individuals who are carrier for MPS. With many of the MPS conditions, several mutations have been found in each gene involved that can cause symptoms of each condition. If the specific mutation is known in a family, DNA analysis may be possible.

Once a couple has had a child with MPS, prenatal testing is available to them to help determine if another fetus is affected with the same MPS as their previous other child. This can be accomplished using procedures such as an **amniocentesis** or chorionic villus sampling (CVS), after which parents can explore their options relating to the pregnancy.

Treatment

As of 2004 there was no cure for MPS, although several types of experimental therapies are being investigated in the early 2000s. Typically, treatment involves trying to relieve the symptoms and improve quality of life. For MPS I and VI, bone marrow transplantation has been attempted as a treatment option. For those types of MPS, bone marrow transplantation has sometimes helped slow down the progression or reverse some of symptoms of the disorder in some children. The benefits of bone marrow transplantation are more likely to be noticed when performed on children less than two years of age. However, bone marrow transplantation is not thought to be helpful in other MPS disorders. Availability of donors is limited, and as a result, very few bone marrow transplantations are done for MPS. There are risks as well as benefits with this procedure, and mortality resulting from the procedure is high.

Another experimental treatment for MPS I involves extended treatment with recombinant human alpha-L-iduronidase. Some individuals treated with this technique show an improvement in some symptoms. Additionally, there is ongoing research involving gene replacement therapy (the insertion of normal copies of a gene into the cells of patients whose gene copies are defective), although this was as of 2004 still highly experimental.

Prognosis

The course of this disorder varies with the specific type of MPS the individual has. MPS I H is often fatal in childhood, with individuals rarely living past age 12. Individuals with MPS I H/S may die in childhood or live to adulthood. Individuals with MPS I H have health problems but usually have a normal lifespan. Individuals with mild MPS II live relatively normal lives, while individuals with the severe form of the disorder usually die in their teens. The life expectancy in MPS III and MPS IV is also variable, depending on the severity of the disorder. Individuals with MPS VI often have shorter than average life spans. As of 2004 MPS IX had been diagnosed so recently that little information is available.

Prevention

No specific measures can prevent the gene mutations that cause MPS. For some of the MPS diseases, biochemical tests may be able to identify healthy individuals who are carriers of the defective gene, allowing them to make informed reproductive decisions. Prenatal testing can also diagnose MPS in the fetus, but this testing is normally done only when there is some reason to expect to find the disorder (e.g. family history of the disease).

Parental concerns

Many individuals with an MPS condition have problems with airway constriction. This constriction may be so serious as to create significant difficulties in administering general anesthesia. Therefore, it is recommended that surgical procedures be performed under local anesthesia whenever possible.

KEY TERMS

Cardiomyopathy—A disease of the heart muscle.

Enzyme—A protein that catalyzes a biochemical reaction without changing its own structure or function.

Joint contractures—Stiffness of the joints that prevents full extension.

Kyphosis—An extreme, abnormal outward curvature of the spine, with a hump at the upper back.

Lysosome—A membrane-enclosed compartment in cells, containing many hydrolytic enzymes, where large molecules and cellular components are broken down.

Mucopolysaccharide—A complex molecule made of smaller sugar molecules strung together to form a chain. It is found in mucous secretions and intercellular spaces.

Recessive gene—A type of gene that is not expressed as a trait unless inherited by both parents.

X-linked gene—A gene carried on the X chromosome, one of the two sex chromosomes.

Multicultural education/ curriculum

Definition

Multicultural education describes a system of instruction that attempts to foster cultural pluralism and acknowledges the differences between races and cultures. It addresses the educational needs of a society that contains more than one set of traditions, that is a mixture of many cultures.

Description

The goal of multicultural education is to help students understand and appreciate cultural differences and similarities and to recognize the accomplishments of diverse ethnic, racial, and socioeconomic groups. It is a practice that hopes to transform the ways in which students are instructed by giving equal attention to the contributions of all the groups in a society. Special focus may be placed on minority groups that have been underrepresented in the past. A multicultural curriculum strives to present more than one perspective of a cultural phenomenon or an historical event. The old American melting pot metaphor is challenged as no longer being valid. Adherents of multicultural educational theory believe that the idea that students should be Americanized, in reality, assumed they should conform to a white, Eurocentric cultural model. In its place, multiculturalists believe school curricula should embrace a whole host of voices that exist in multicultural U.S. society. Their belief is that this transformation in the methods of learning is a start in addressing inequities in U.S. society. They believe this is increasingly important because of the changing population mix in the United States. For example, demographers estimate that by the year 2020, 46 percent of all public school students will be children of color.

The roots of multicultural education lie in the civil rights movements of various groups, including African Americans and women. In addition, the rise in ethnic consciousness and a more critical analysis of textbooks and other materials played a role. Community leaders, activists, and parents began to demand curricula that were more supportive and consistent with the cultural and racial diversity in the United States. In the late 1960s and 1970s, the concepts of multicultural education begin to emerge, and by the 1980s, an entire body of scholarship addressing multiculturalism existed.

One of the pioneers of multicultural education was James Banks, who believed all aspects of education needed to be transformed in order to create a multicultural school environment. These aspects include teaching methods, instructional materials, teacher attitudes, as well as the way the performance of students is assessed. Banks described five areas of multicultural education in which teachers and researchers are involved:

- Content integration: Concepts, values, and materials from a variety of cultures are included in teaching.
- Knowledge construction: This belief asserts that all knowledge is created in the minds of human beings and can, therefore, be challenged. A critical part of multicultural education, the idea that knowledge is a human construct challenges teachers to alter their own perceptions of the world before they can teach multiculturally.
- Equity pedagogy: Teachers must modify their methods of instruction by allowing for students' cultural differences before they can encourage academic achievement.
- Prejudice reduction: Teachers must work to shift students' prejudices regarding race and ethnicity. Prejudice reduction may also encompass teaching the tolerance of various religions, sexual preferences, and disabilities.
- Empowering school culture: Schools must identify those aspects of education that hinder learning and then empower families and students from all backgrounds, so that the full development of students is achieved.

Types of multicultural education programs

As of the early 2000s, there is no universally agreed upon multicultural curriculum. Teachers tend, however, to take one of two approaches. Some use what has been called the multicultural festival approach, in which students are invited to celebrate ethnic diversity by being exposed to foods, holidays, and festivals of other cultures. Many critics say that this conveys the notion that diversity is only important during celebratory moments. Other teachers apply a transformative approach, weaving different perspectives on cultures throughout the curriculum. Multicultural education can also be roughly divided into three different categories:

- Content-focused: These are the most common types of multicultural educational programs. Their overall objective is to include subject matter in the curriculum about various cultural groups in order to cultivate students' knowledge about these groups. Content may include holiday celebrations, recognizing heroes from different racial and ethnic groups, and focusing on the achievements of women and minorities. It may also include single-group studies, for example, black, ethnic, or women's studies programs.
- Student-focused: Many programs go beyond changes in the curriculum and specifically address the academic needs of defined groups of students, usually minorities. In this type of approach, the curriculum may not be changed significantly. Instead, the focus may be on aiding students in making the transition into the mainstream of education. Student-focused programs can take many forms, including efforts to draw on culturally-based learning styles and bilingual programs.
- Socially focused: These programs seek to reduce bias and increase cultural and racial tolerance. Included here might be desegregation programs, programs designed to increase contact among different races and cultures. Also, having teachers who are themselves members of minorities would be encouraged.

In spite of the fact that there are a variety of approaches to multicultural education, supporters point to several shared ideals among those who practice this kind of education. Shared ideals include:

- Each student must have equal opportunities to achieve his or her full potential.
- Every student must be able to participate in an increasingly multicultural society.
- Teachers must be able to facilitate learning for every student, no matter how similar or different each student is from the teacher.
- Schools must actively work towards ending oppression of all types, by ending it within their own walls.
- Education must include the voices and experiences of all students.

Common problems

There are many people who are either opposed to multicultural education or believe it has numerous problems. Some feel that the idea of multicultural education tends to divide cultures instead of building tolerance

KEY TERMS

Eurocentric—Centered or focused on Europe or European peoples, especially in relation to historical or cultural influence.

Multicultural education—A social or educational theory that encourages interest in many cultures within a society rather than in only a mainstream culture.

between them. They believe that American students should be taught to think of themselves as part of a whole rather than as people from different places who just happen to live in the same country.

Others believe multicultural education interferes with a child expressing his or her own individuality, by placing too much emphasis on ethnic or racial backgrounds. Even supporters recognize that someone's culture may be influenced as much by their sex or socioeconomic status as their race or ethnicity. Culture is itself complex and varies from community to community, **family** to family, or from person to person. The dynamic and variable nature of culture makes teaching about multiple cultural influences a daunting if not impossible task.

Critics also point out that educating students about the formation of U.S. democracy inevitably focuses on its European origins. If students are not informed that the dominant participants in the formation of the United States were white males, these critics say, students will not receive an accurate picture of U.S. history. In addition, there is the belief that if citizens are not willing to subordinate some parts of their heritage to the present set of dominant cultural values, then these citizens may find it even harder to integrate the mainstream.

Parental concerns

Parents should feel free to speak up about any concerns they have with the curriculum in their child's classroom. Multicultural education came about in part because parents expressed a need for the unique cultures of their children to be acknowledged and honored in school.

Multiple endocrine neoplasia syndromes

Definition

The multiple endocrine neoplasia (MEN) syndromes are three related inherited disorders affecting the thyroid and other hormone producing (endocrine) glands of the body. Before the early 2000s, MEN was called familial endocrine adenomatosis.

Description

There are three types of MEN: MEN 1 (Wermer's syndrome), MEN 2A (Sipple syndrome), and MEN 2B (previously known as MEN 3). All MEN types are the result of inherited genetic mutations that predispose the individual to excessive growth of cells (hyperplasia) and tumor formation in multiple endocrine glands. For all types of MEN, the children of an affected individual have a 50 percent chance of inheriting the defective gene that causes the disorder.

Demographics

MEN 1 is uncommon and occurs in only about one of every 30,000 individuals. The disorder runs in families, and males are twice as likely to develop the disorder as females. Individuals with MEN 1 can show symptoms of excessive parathyroid secretion by age five, and almost all individuals with MEN 1 show parathyroid symptoms by age 40.

MEN 2 affects about one in every 40,000 individuals. MEN 2A is ten to 20 times more common than MEN 2B.

Causes and symptoms

MEN 1 is caused by a mutation at the PYGM gene on chromosome 11. PYGM is one of a group of genes known as tumor suppressor genes that help to control cell division. An individual who inherits one defective copy of a tumor suppressor gene from either parent has a strong likelihood of developing MEN 1, because there is a high probability of another mutation developing in the other copy of the PYGM gene at some point during the thousands of cell divisions that occur with growth and development. When a second mutation occurs, the cell that contains the mutation no longer has any normal copy of the tumor suppressor gene. When both copies are defective, tumor suppression fails and tumors develop.

As a result, individuals with MEN 1 have uncontrolled cell growth and develop tumors in several endocrine glands, including the parathyroid glands (80–95% of patients), the pancreas (about 50% of patients) and the pituitary (around 25% of patients). The most frequent symptom of MEN 1 is hyperparathyroidism, which is excessive growth of the parathyroid gland and excessive secretion of parathyroid hormone. This condition leads to increased amounts of calcium in the blood, kidney stones, weakened bones, and nervous system depression. Children with MEN 1 can show signs of hyperparathyroidism as young as age five.

Tumors of the pancreas, known as gastrinomas, are also common in MEN 1. Excessive secretion of gastrin (a hormone secreted into the stomach to aid in digestion) by these tumors can cause upper gastrointestinal ulcers. The anterior pituitary gland and the adrenal glands can also be affected. Unlike MEN 2, the thyroid gland is rarely involved in MEN 1 symptoms. Children with MEN1 rarely develop tumors of the pancreas until they reach adulthood.

There are two types of MEN 2. Both MEN 2A and MEN 2B are caused by mutations in another gene, known as RET. A mutation in only one copy of the RET gene is sufficient to cause disease. A number of different mutations can lead to MEN 2A, but only one specific genetic alteration causes MEN 2B.

Patients with both MEN 2A and MEN 2B experience two main symptoms, medullary thyroid **cancer** (MTC) and a tumor of the adrenal gland medulla known as pheochromocytoma. MTC is a slow-growing cancer, but one that can be cured in less than 50 percent of cases. Pheochromocytoma is usually a benign (noncancerous) tumor that causes excessive secretion of adrenal hormones. This, in turn, can cause life-threatening high blood pressure (**hypertension**) and irregular heart beat (cardiac arrhythmia).

The two forms of MEN 2 are distinguished by other symptoms. Individuals with MEN 2A have a predisposition to develop tumors of the parathyroid gland. Although similar to MEN 1, less than 20 percent of MEN 2A patients show parathyroid involvement.

Individuals with MEN 2B show a variety of additional conditions: a characteristic facial appearance with swollen lips; tumors of the mucous membranes of the eye, mouth, tongue, and nasal cavity; enlarged colon; and skeletal abnormalities. Symptoms develop early in life (often before five years of age) in cases of MEN 2B and the medullary thyroid cancer is much more aggressive and may develop in patients who are one year old.

When to call the doctor

Since MEN is inherited and runs in families, the doctor should be informed of this history when the child is born, so that genetic testing can be done immediately.

Diagnosis

In the past, classical diagnosis of MEN was based on clinical features and on testing for elevated hormone levels. For MEN 1, the relevant hormone was parathyroid hormone. For both types of MEN 2, the greatest concern is development of medullary thyroid cancer. MTC

can be detected by measuring levels of the thyroid hormone, calcitonin. Numerous other hormone levels can be measured to assess the involvement of the various other endocrine glands.

Diagnosis of MEN 2B can be made by physical examination alone. However, MEN 2A shows no distinct physical features and must be identified by measuring hormone levels or by finding endocrine tumors.

Since 1994, genetic screening using DNA technology has been available for both MEN 1 and MEN 2. This methodology allows diagnosis before the onset of symptoms. Before the development of genetic testing, there was no way to definitively identify which children had inherited the defective gene. As a result, all offspring of individuals with MEN had to be considered at risk. In the case of MEN 2A and MEN 2B, children would undergo frequent calcitonin testing. Molecular techniques as of the early 2000s allow a positive distinction to be made between children who are and are not carrying the defective genes that cause MEN.

Treatment

As of 2004 no comprehensive treatment is available for genetic conditions such as MEN. However, some of the consequences of MEN can be symptomatically treated. Pheochromocytoma in both types of MEN 2 can be cured by surgical removal of this slow growing tumor.

Treatment of MTC is by surgical removal of the thyroid. After thyroidectomy, the patient receives normal levels of thyroid hormone by mouth or by injection. Even when thyroid surgery is performed early, metastatic spread of the cancer may have already occurred. Since MTC is slow growing, metastasis may not be obvious. Metastasis is very serious in MTC because **chemotherapy** and radiation therapy are not effective in controlling its spread.

Prognosis

Diagnosed early through genetic testing, the prognosis for the MEN diseases is reasonably good, even for MEN 2B, the most dangerous of the three forms. Even in the absence of treatment, a few individuals with MEN 2A mutations never show any symptoms at all. Analysis of at-risk **family** members using molecular genetic techniques leads to earlier treatment and improved outcomes.

Prevention

As of 2004 there is no way to block the occurrence of genetic mutations that cause MEN. One of the most serious consequences of MEN is MTC. Children who are identified as carriers of the RET gene can be offered total thyroidectomy as a preventative (prophylactic) measure to prevent the development of MTC.

KEY TERMS

Adrenal glands—A pair of endocrine glands (glands that secrete hormones directly into the bloodstream) that are located on top of the kidneys. The outer tissue of the glands (cortex) produces several steroid hormones, while the inner tissue (medulla) produces the hormones epinephrine (adrenaline) and norepinephrine.

Endocrine—Refers to glands that secrete hormones circulated in the bloodstream or lymphatic system.

Medullary thyroid cancer—A slow-growing tumor associated with multiple endocrine neoplasia syndromes.

Neoplasm—An abnormal formation of new tissue. A neoplasm may be malignant or benign.

Pancreas—A five-inch-long gland that lies behind the stomach and next to the duodenum. The pancreas releases glucagon, insulin, and some of the enzymes which aid digestion.

Parathyroid gland—A pair of glands adjacent to the thyroid gland that primarily regulate blood calcium levels.

Parathyroid hormone—A chemical substance produced by the parathyroid glands. This hormone plays a major role in regulating calcium concentration in the body.

Pheochromocytoma—A tumor that originates from the adrenal gland's chromaffin cells, causing overproduction of catecholamines, powerful hormones that induce high blood pressure and other symptoms.

Pituitary gland—The most important of the endocrine glands (glands that release hormones directly into the bloodstream), the pituitary is located at the base of the brain. Sometimes referred to as the "master gland," it regulates and controls the activities of other endocrine glands and many body processes including growth and reproductive function. Also called the hypophysis.

Thyroid gland—An endocrine gland in the neck overlying the windpipe (trachea) that regulates the speed of metabolic processes by producing a hormone, thyroxin.

Parental concerns

MEN is an inherited disorder. Individuals who have MEN in their families may wish to get genetic counseling before attempting a pregnancy.

Multiple pregnancy

Definition

Multiple pregnancy, usually referred to as multiple gestation, is one in which more than one fetus develops simultaneously in the mother's womb.

Description

The frequency of multiple births in the United States has been steadily increasing with advances in reproductive technologies. It is estimated that pregnancies resulting from assisted technologies have a 25–30 percent incidence of **twins** and a 5 percent incidence of triplets. The frequency of naturally occurring twins is approximately one in 80 births; however the frequency of multiple births in the United States for 2002 was as follows:

- twins, one in 32
- triplets, one in 583
- quadruplets, one in 9,267
- quintuplets and up, one in 58,286

Twin birth is by far the most common multiple birth. There are two types of twin pregnancy: fraternal and identical. Fraternal twins develop from two separate ova released at the same time and fertilized by two separate sperm. Fraternal twins are referred to as dizygotic twins, meaning that two unions of two gametes or male/female sex cells occurred to produce two separate embryos. Characteristically, with fraternal twins, each has its own placenta and amniotic sac. They may be the same or different sex, occur twice as frequently as identical twins, and have a mortality rate of 11.5 percent. Identical twins represent the splitting of a single fertilized zygote (union of two gametes or male/female sex cells to produce a developing embryo) into two separate individuals. Identical twins will have the same DNA, genetic material (genotype), but it may be expressed differently (phenotype). There are three ways identical twins can exist in the uterus: dichorionic-diamniotic twins; monochorionic-diamniotic twins; monochorionic-monoamniotic twins. In the instance of dichorionic-diamniotic twins, division of the fertilized egg occurs within 72 hours past fertilization, before the inner cell mass has developed. About 30 percent of identical twins have this classification, and each twin has its own chorion, amnion, and placenta. The mortality rate for this type of twinning is 9 percent. With monochorionic-diamniotic twins, division occurs in the range of four to eight days after fertilization, and the inner cell mass divides in two. The placenta has one chorion and two amnions, so each twin has its own amniotic sac. Approximately 68 percent of identical twins are in this classification, and they have a mortality rate of 25 percent. Thirdly, monochorionic-monoamniotic twins are contained in the same amniotic sac. The division of the fertilized egg in this case occurs nine to 13 days past fertilization or near the time of implantation in the uterus. Since they share an amniotic sac, they have an increased risk of their umbilical cords becoming entangled or knotted. Only 2 percent of identical twins are in this classification, and they have a mortality rate of greater than 50 percent. If a complete separation does not take place during the division process, the result is Siamese (or conjoined) twins.

The human female typically releases only one egg every menstrual cycle. A hormone called progesterone, released by the first egg to be produced, prevents any other egg from maturing during that cycle. When this control fails, fertilization of more than one egg is possible. Fertility drugs inhibit these controls, allowing multiple gestation to occur. It seems as if, however, that more pregnancies start out naturally with twins than was originally believed. The development of improved technology, such as ultrasound, has made it possible to determine more accurately the early pregnancy loss rate of

twins to include both complete pregnancy loss and spontaneous resorption of one twin, frequently referred to as the vanishing twin phenomenon. Recent research suggests that 75 percent of twin pregnancies are lost before the end of the first trimester. Moreover, only about 50 percent of pregnancies diagnosed in the first trimester with twins result in the birth of two live infants.

An old adage related to multiple gestation is the human female was not meant to have more than twins because she only had two breasts for feeding. Of course, pregnancies with more than two babies have occurred throughout history. However, once the number of babies reaches three, overexpansion of a woman's uterus begins to cause difficulties. The implantation of several embryos and placentas in the endometrium of the uterus results in a competition for space and inevitably some implant in an area without good circulation. During a pregnancy, it is essential that the uterus be well perfused to sustain the fetus with nutrients and oxygen. A lack of oxygen can cause central nervous system damage in the fetuses that implanted in a less than desirable area. Since the human female was not made to carry an indefinite number of fetuses, multiple gestations can have many of the following complications:

- increased rate of spontaneous abortion
- two to three times greater risk of developing severe **hypertension** or preeclampsia (increased blood pressure)
- maternal anemia due to increased fetal demands
- premature rupture of membranes (bag of water)
- incompetent cervix (cervix opens due to pressure)
- intrauterine growth restriction of one or more fetuses
- preterm labor due to overstretched uterus
- abnormal fetal presentations
- need for **cesarean section**
- rare complications with twins, such as twin-to-twin-transfusion syndrome (one fetus receives more nutrients than the other due to more blood vessels perfusing one baby)
- conjoined twins
- postpartum hemorrhage

Causes and symptoms

Twinning seems to run in some families, is mainly confined to fraternal (dizygotic twins) and seems to be entirely a property of the mother, not the father. The primary cause is an increased chance of multiple ovulation, when a woman releases two or more eggs. Another major factor is maternal age; a woman who gives birth at 37 is four times more likely to have fraternal twins than at age 18. The 37-year-old is also more likely to be unable to conceive, since many women's ovaries are already starting to fail at that age. The third major factor is race; West Africans are ten times more likely to have fraternal twins than Chinese or Japanese, with Caucasians intermediate. This increased chance is also seen in African Americans. In addition, the more pregnancies a woman has had, the greater her chances of having twins. In fact, by the fourth or fifth pregnancy, the likelihood of having twins is four times higher than it was for the first pregnancy.

The use of assisted reproduction techniques, particularly ovarian stimulation, has caused a dramatic increase in the number of twin and higher multiple births. The normal process of single ovulation is interrupted because fertility drugs permit more than one egg at a time to mature and be released. The first drug to be used for this was clomiphene (Clomid). This was followed by the development of two natural hormones, follicle-stimulating hormone and chorionic gonadotrophin (Pergonal) to produce multiple eggs ovulation. The chance of multiple gestation with in vitro fertilization (IVF) is about the same as with the use of fertility drugs, because several embryos are inserted into the womb to increase the odds of conception. Similarly, other fertility techniques such as gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT) are also more likely to result in multiple gestations. The use of intrauterine insemination or artificial insemination (the injection of sperm into a woman's uterus with a syringe) is the only fertility treatment that does not increase the chances of conceiving multiples—of course, the woman is usually taking fertility drugs with this procedure also.

Diagnosis

If a multiple pregnancy occurred spontaneously, the obstetrician would suspect a problem with the dates because the uterus would grow faster than usual. The gestational age of a pregnancy is determined from the first day of the last menstrual period (LMP). In a multiple gestation, the uterine measurements would be larger than dates, which normally correspond. If multiple gestation is suspected, an ultrasound may be performed to determine the gestational age of the fetus or to check for more than one fetus. With the use of assisted reproductive technology, an ultrasound is usually performed with ten days to see if any of the embryos were successful with implantation, and a multiple gestation would be revealed at that time. Following the birth of multiples, the placenta is carefully examined to determine if they are fraternal or identical. One placenta indicates identical twins.

A multiple pregnancy almost always means increased monitoring and surveillance for complications. This often means more frequent visits to the healthcare provider, serial ultrasounds to make sure that the babies are growing satisfactorily, **amniocentesis** to check for lung development, and close monitoring for preterm labor.

Treatment

Ultrasound examinations play an important role in the care and treatment of multiple gestations. It assists with dating the pregnancy, determining the number of fetuses, detecting fetal anomalies, following the growth and development of each fetus, and serves to monitor the length of the cervix in anticipation of preterm labor. Premature birth is the constant threat of multiple gestation, and the primary threat of **prematurity** is related to lung development. Premature infants lack a substance, called surfactant, that permits their lungs to expand and breathe normally. If it becomes apparent that a multiple gestation is going to have a preterm delivery, the mother will be given an injection of a steroid, beta-methasone, to help the lungs mature. It is more beneficial if the steroid can be given twice in a 48 hour period; however, if there is not time for this, surfactant has been developed that can be administered into the lungs of a premature infant to facilitate breathing. An additional problem with the premature infant involves the lack of body fat. In a normal pregnancy the fetus spends the last four to six weeks growing and gaining weight, primarily body fat. This fat helps a newborn maintain his or her body temperature. Since premature infants do not have this fat, they use energy they cannot afford to stay warm.

Although research has shown that bed rest is not effective, a woman is often placed on bed rest during a multiple pregnancy to try to prevent pre-term labor and delivery. If preterm labor is impossible to control at home, the mother may be hospitalized and medication used to attempt to control contractions and dilatation of the cervix. Multiple gestations greater than twins in number are almost always delivered via cesarean section.

Alternative treatment

There are no specific treatments to alleviate medical difficulties caused by multiple pregnancies; however, there are supportive measures that may help both mother and children recover from the birthing process. There are treatments to encourage breast milk production and to combat postpartum difficulties. Various homeopathic remedies and massage can be helpful to both mother and children during the early adjustment period after birth.

KEY TERMS

Amnion—Thin, tough, innermost layer of the amniotic sac.

Amniotic membrane—The thin tissue that creates the walls of the amniotic sac.

Chorion—The outer membrane of the amniotic sac. Chorionic villi develop from its outer surface early in pregnancy. The villi establish a physical connection with the wall of the uterus and eventually develop into the placenta.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Gestation—The period from conception to birth, during which the developing fetus is carried in the uterus.

Ova—The plural of ovum, it is the female reproductive cell.

Ovulate—To release a mature egg for fertilization.

Placenta—The organ that provides oxygen and nutrition from the mother to the unborn baby during pregnancy. The placenta is attached to the wall of the uterus and leads to the unborn baby via the umbilical cord.

Sequela—Plural, sequalae. An abnormal condition resulting from a previous disease or disorder.

Zygote—The result of the sperm successfully fertilizing the ovum. The zygote is a single cell that contains the genetic material of both the mother and the father.

Prognosis

Many multiple pregnancies reach fruition without difficulties; however, many do not. Despite medical advances, if the babies are born too early, they may survive but will have sequelae that limit the quality of life. If the babies are born prematurely, immediate medical care increases the chance of survival without any complications.

Parental concerns

Mothers with multiple pregnancy should be especially careful to get adequate prenatal care, including any necessary **vitamins** or recommended tests. Because

of the extra stress on the mother's body, increased rate of complications, and threat of prematurity, the mother should be vigilant in making sure she gets enough rest, reduces stress, and maintains a healthy diet.

Mumps

Definition

Mumps is a relatively mild short-term viral infection of the salivary glands that usually occurs during childhood.

Description

Typically, mumps is characterized by a painful swelling of both cheek areas, although the person could have swelling on one side or no perceivable swelling at all. The salivary glands are also called the parotid glands; therefore, mumps is sometimes referred to as an inflammation of the parotid glands (epidemic parotitis). The word mumps comes from an old English dialect, meaning lumps or bumps within the cheeks.

Demographics

Mumps is a very contagious infection that spreads easily in such highly populated environments as daycare centers and schools. Although not as contagious as **measles** or **chickenpox**, mumps was once quite common. Prior to the release of a mumps vaccine in the United States in 1967, approximately 92 percent of all children had been exposed to mumps by the age of 15. In the pre-vaccine years, most children contracted mumps between the ages of four and seven. Mumps epidemics came in two to five year cycles. The greatest mumps epidemic was in 1941 when approximately 250 cases were reported for every 100,000 people. In 1968, the year after the live mumps vaccine was released, only 76 cases were reported for every 100,000 people. By 1985, fewer than 3,000 cases of mumps were reported throughout the entire United States, the equivalent of about one case per 100,000 people. The reason for the decline in mumps was the increased usage of the mumps vaccine. However, 1987 noted a five-fold increase in the incidence of the disease because of the reluctance of some states to adopt comprehensive school immunization laws. After that, state-enforced school entry requirements achieved student immunization rates of nearly 100 percent in kindergarten and first grade. In 1996, the Centers for Disease Control and Prevention (CDC) reported only 751 cases of mumps nationwide, that is, about one case for every 5 million people.

Causes and symptoms

The paramyxovirus that causes mumps is harbored in the saliva and is spread by sneezing, coughing, and other direct contact with another person's infected saliva. Once the person is exposed to the virus, symptoms generally occur in 14 to 24 days. Initial symptoms include chills, **headache**, loss of appetite, and a lack of energy. However, an infected person may not experience these initial symptoms. Swelling of the salivary glands in the face (parotitis) generally occurs within 12 to 24 hours of the above symptoms. Accompanying the swollen glands is **pain** on chewing or swallowing, especially with acidic

beverages, such as lemonade. A **fever** as high as 104°F (40°C) is also common. Swelling of the glands reaches a maximum on about the second day and usually disappears by the seventh day. Once individuals have contracted mumps, they become immune to the disease, despite how mild or severe their symptoms may have been.

While the majority of cases of mumps are uncomplicated and pass without incident, some complications can occur. Complications are, however, more noticeable in adults who get the infection. In 15 percent of cases, the covering of the brain and spinal cord becomes inflamed (**meningitis**). Symptoms of meningitis usually develop within four or five days after the first signs of mumps. These symptoms include a stiff neck, headache, **vomiting**, and a lack of energy. Mumps meningitis is usually resolved within seven days, and damage to the brain is exceedingly rare.

The mumps infection can spread into the brain causing inflammation of the brain (**encephalitis**). Symptoms of mumps encephalitis include the inability to feel pain, seizures, and high fever. Encephalitis can occur during the parotitis stage or one to two weeks later. Recovery from mumps encephalitis is usually complete, although complications, such as seizure disorders, have been noted. Only about one person in 100 with mumps encephalitis dies from the complication.

About one-fourth of all post-pubertal males who contract mumps can develop a swelling of the scrotum (orchitis) about seven days after the parotitis stage. Symptoms include marked swelling of one or both testicles, severe pain, fever, **nausea**, and headache. Pain and swelling usually subside after five to seven days, although the testicles can remain tender for weeks.

Girls occasionally suffer an inflammation of the ovaries (oophoritis) as a complication of mumps, but this condition is far less painful than orchitis in boys.

Diagnosis

When mumps reaches epidemic proportions, diagnosis is relatively easy on the basis of the physical symptoms. The doctor will take the child's temperature, gently palpate (touch) the skin over the parotid glands, and look inside the child's mouth. If the child has mumps, the openings to the ducts inside the mouth will be slightly inflamed and have a "pouty" appearance. With so many people vaccinated as of the early 2000s, a case of mumps must be properly diagnosed in the event the salivary glands are swollen for reasons other than viral infection. For example, in persons with poor **oral hygiene**, the salivary glands can be infected with bacteria. In these cases, **antibiotics** are necessary. Also in rare cases, the salivary glands can become blocked, develop tumors, or swell due to the use of certain drugs, such as iodine. A test can be performed to determine whether the person with swelling of the salivary glands actually has the mumps virus.

In late 2002, researchers in London reported the development of a bioassay for measuring mumps-specific IgG. This test would allow a doctor to check whether an individual patient is immune to mumps and allow researchers to measure the susceptibility of a local population to mumps in areas with low rates of **vaccination**.

Treatment

When mumps does occurs, the illness is usually allowed to run its course. The symptoms, however, are treatable. Because of difficulty swallowing, the most important challenge is to keep the patient fed and hydrated. The individual should be provided a soft diet, consisting of cooked cereals, mashed potatoes, broth-based soups, prepared baby foods, or foods put through a home food processor. Aspirin (only for individuals over the age of 20), **acetaminophen**, or ibuprofen can relieve some of the pain due to swelling, headache, and fever. Patients should void fruit juices and other acidic foods or beverages that can irritate the salivary glands. They should also avoid dairy products that can be hard to digest. In the event of complications, a physician should be contacted at once. For example, if orchitis occurs, a physician should be called. Also, supporting the scrotum in a cotton bed on an adhesive-tape bridge between the thighs can minimize tension. Ice packs are also helpful.

Prognosis

When mumps is uncomplicated, prognosis is excellent. However, in rare cases, a relapse occurs after about two weeks. Complications can also delay complete recovery.

Prevention

A vaccine exists to protect against mumps. The vaccine preparation (MMR) is usually given as part of a combination injection that helps protect against measles, mumps, and **rubella**. MMR is a live vaccine administered in one dose between the ages of 12 and 15 months, between four and six years of age, or 11 and 12 years of age. Persons who are unsure of their mumps history and/or mumps vaccination history should be vaccinated. Susceptible healthcare workers, especially those who work in hospitals, should be vaccinated. Because mumps is

A young child with mumps. *(Photo Researchers, Inc.)*

still prevalent throughout the world, susceptible persons over the age of one year who are traveling abroad would benefit from receiving the mumps vaccine.

The mumps vaccine is extremely effective, and virtually everyone should be vaccinated against this disease. There are, however, a few reasons why people should not be vaccinated against mumps:

- Pregnant women who contract mumps during pregnancy have an increased rate of miscarriage but not birth defects. As a result, pregnant women should not receive the mumps vaccine because of the possibility of damage to the fetus. Women who have had the vaccine should postpone pregnancy for three months after being vaccinated.
- Unvaccinated persons who have been exposed to mumps should not get the vaccine, as it may not provide protection. The persons should, however, be vaccinated if no symptoms result from the exposure to mumps.
- Persons with minor fever-producing illnesses, such as an upper respiratory infection, should not get the vaccine until the illness has subsided.
- Because mumps vaccine is produced using eggs, individuals who develop **hives**, swelling of the mouth or throat, **dizziness**, or breathing difficulties after eating eggs should not receive the mumps vaccine.
- Persons with immune deficiency diseases and/or those whose immunity has been suppressed with anti-cancer drugs, corticosteroids, or radiation should not receive the vaccine. **Family** members of immunocompromised people, however, should get vaccinated to reduce the risk of mumps.
- The CDC recommends that all children infected with human **immunodeficiency** disease (HIV) who are asymptomatic should receive an the **MMR vaccine** at 15 months of age.

KEY TERMS

Asymptomatic—Persons who carry a disease and are usually capable of transmitting the disease but who do not exhibit symptoms of the disease are said to be asymptomatic.

Autism—A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

Encephalitis—Inflammation of the brain, usually caused by a virus. The inflammation may interfere with normal brain function and may cause seizures, sleepiness, confusion, personality changes, weakness in one or more parts of the body, and even coma.

Epidemic parotitis—The medical name for mumps.

Immunoglobulin G (IgG)—Immunoglobulin type gamma, the most common type found in the blood and tissue fluids.

Meningitis—An infection or inflammation of the membranes that cover the brain and spinal cord. It is usually caused by bacteria or a virus.

Orchitis—Inflammation of one or both testes, accompanied by swelling, pain, fever, and a sensation of heaviness in the affected area.

Paramyxovirus—A genus of viruses that includes the causative agent of mumps.

Parotitis—Inflammation and swelling of one or both of the parotid salivary glands.

Parental concerns

The mumps vaccine has been controversial in the early 2000s because of concern that its use was linked to an increased rate of childhood **autism**. The negative publicity given to the vaccine in the mass media led some parents to refuse to immunize their children with the MMR vaccine. One result has been an increase in the number of mumps outbreaks in several European countries, including Italy and the United Kingdom.

In the fall of 2002, the *New England Journal of Medicine* published a major Danish study disproving the hypothesis of a connection between the MMR vaccine

and autism. A second study in Finland showed that the vaccine is also not associated with aseptic meningitis or encephalitis. Since these studies were published, U.S. primary care physicians have once again reminded parents of the importance of immunizing their children against mumps and other childhood diseases.

Munchausen syndrome

Definition

Munchausen syndrome is a psychiatric disorder that causes an individual to self-inflict injury or illness or to fabricate symptoms of physical or mental illness in order to receive medical care or **hospitalization**. In a variation of the disorder, Munchausen by proxy (MSBP), an individual, typically a mother, intentionally causes or fabricates illness in a child or other person under her care.

Description

Munchausen syndrome takes its name from Baron Karl Friederich von Munchausen, an eighteenth century German military man known for his tall tales. The disorder first appeared in psychiatric literature in the early 1950s when it was used to describe patients who sought hospitalization by inventing symptoms and complicated medical histories, and/or inducing illness and injury in themselves. Categorized as a factitious disorder (a disorder in which the physical or psychological symptoms are under voluntary control), Munchausen syndrome seems to be motivated by a need to assume the role of a patient. Unlike malingering, there does not seem to be any clear secondary gain (e.g., money) in Munchausen syndrome.

Individuals with Munchausen by proxy syndrome use their child (or another dependent person) to fulfill their need to step into the patient role. The disorder most commonly victimizes children from birth to eight years old. Parents or caregivers with MSBP may only exaggerate or fabricate their child's symptoms, or they may deliberately induce symptoms through various methods, including **poisoning**, suffocation, starvation, or introducing bacteria into open **wounds**. They often display an extraordinary depth of medical knowledge and may even be in the medical profession themselves.

Demographics

Both Munchausen syndrome and Munchausen syndrome by proxy are thought to be rare, but there are no solid statistics on the frequency of either diagnosis. Data on Munchausen syndrome in children and adolescents specifically are very limited. In 2000 one review found that among the 42 cases reported in the medical literature, 71 percent were female and the mean age was 14 years of age. Children age 14 and younger were more likely to admit to falsifying symptoms when confronted than those between the ages of 15 and 18.

Munchausen syndrome by proxy is also hard to quantify due to the number of undetected or undiagnosed cases. The incidence of the condition in the United States is not known, but a 1996 study of children in Ireland and the United Kingdom estimated that Munchausen syndrome by proxy occurred annually in 0.5 of every 100,000 children under age 16, and in 2.8 of every 100,000 children under the age of one.

Causes and symptoms

The exact cause of Munchausen syndrome is unknown. It has been theorized that Munchausen patients are motivated by a desire to be cared for, a need for attention, dependency, an ambivalence toward doctors, or a need to suffer. Factors that may predispose an individual to Munchausen include a serious illness in childhood or an existing personality disorder. Some research indicates that children and adolescents who develop Munchausen syndrome are more likely to have been previous victims of Munchausen syndrome by proxy.

The Munchausen and Munchausen by proxy patient can appear to have a wide array of physical or psychiatric symptoms, usually limited only by their (or their caregiver's) medical knowledge. Many Munchausen patients are very familiar with medical terminology and symptoms. Some common complaints include fevers, **rashes**, abscesses, bleeding, and **vomiting**. Common Munchausen by proxy symptoms include apnea (cessation of breathing), **fever**, vomiting, and **diarrhea**. In both Munchausen and MSBP syndromes, the suspected illness does not respond to a normal course of treatment, and

diagnostic tests turn up nothing out of the ordinary. Patients or parents may push for invasive procedures and display an extraordinary depth of knowledge of medical therapies.

Diagnosis

Because Munchausen sufferers often go from doctor to doctor, gaining admission into many hospitals along the way, diagnosis can be difficult. They are typically detected rather than diagnosed. During a course of treatment, they may be discovered by a hospital employee who encountered them during a previous hospitalization. Their caregivers may also notice that symptoms such as high fever occur only when the patient is left unattended. Occasionally, medication used to induce symptoms is found with the patient's belongings. When the patient is confronted, they often react with outrage and check out of the hospital to seek treatment at another facility with a new caregiver.

A diagnosis of Munchausen syndrome may be even more difficult in children and adolescents. A physician may be able to recognize a pattern of symptoms (e.g., those that occur only when the child is alone or that begin only when the parent is present with the child) or the child may admit to fabricating or self-inflicting symptoms upon questioning. Surveillance video may record the child or the child's caregiver inducing symptoms.

Treatment

There is no clearly effective treatment for Munchausen syndrome. Extensive psychotherapy may be helpful with some Munchausen patients. If Munchausen syndrome coexists with other mental disorders, such as a personality disorder, the underlying disorder is typically treated first. Children who develop the syndrome may respond more favorably to therapy than adults, particularly if they are diagnosed at an early age.

Children who are victims of Munchausen syndrome by proxy are usually removed from the offending caregiver immediately and placed in protective custody. Therapy may also be beneficial to these children in recovering from the emotional trauma of MSBP.

Prognosis

The infections and injuries Munchausen patients self-inflict can cause serious illness. Patients often undergo countless unnecessary surgeries throughout their lifetimes. In addition, because of their frequent hospitalizations, they have difficulty holding down a job. Further, their chronic health complaints may damage interpersonal relationships with **family** and friends.

Children victimized by sufferers of MSBP are at a real risk for serious injury and possible death. A UK study published in 1998 found that although the majority of children with MSBP studied (90 percent) were placed in child protection care at diagnosis, at two-year follow up the number had fallen to 32 percent. A reported 17 percent of children who were victims of MSBP and who were eventually returned to an abusive caregiver suffered further abuse. Those who survive physically unscathed may suffer developmental and emotional problems.

KEY TERMS

Apnea—The temporary absence of breathing. Sleep apnea consists of repeated episodes of temporary suspension of breathing during sleep.

Factitious disorder—A mental condition in which symptoms are deliberately manufactured by patients in order to gain attention and sympathy. Patients with factitious diseases do not fake symptoms for obvious financial gain or to evade the legal system.

Malingering—Pretending to be sick in order to be relieved of an unwanted duty or obtain some other obvious benefit.

Prevention

Because the cause of Munchausen syndrome is unknown, formulating a prevention strategy is difficult. Some medical facilities and healthcare practitioners have attempted to limit hospital admissions for Munchausen patients by sharing medical records. While these attempts may curb the number of hospital admissions, they do not treat the underlying disorder and may endanger Munchausen sufferers that have made themselves critically ill and require treatment. Children who are found to be victims of persons with Munchausen by proxy syndrome should be immediately removed from the care of the abusing parent or guardian.

Parental concerns

Parents who suspect that their child may be deliberately hurting themselves or falsifying symptoms should contact their pediatrician immediately for assessment. Children who are thought to pose potentially life-threatening

danger to themselves may require hospitalization, and a referral to a child psychologist or therapist will be necessary. It is important to remember that properly treating the condition requires addressing the motives and emotions behind the disorder, not simply punishing the behavior.

Muscle contractures *see* **Spasticity**

Muscle spasms and cramps

Definition

Muscle spasms and cramps are spontaneous, often painful muscle contractions.

Description

The rapid, uncontrolled muscle contraction, or spasm, happens unexpectedly, with either no stimulation or some trivially small one. The muscle contraction and **pain** last for several minutes and then slowly ease. Cramps may affect any muscle but are most common in the calves, feet, and hands. While painful, they are harmless and, in most cases, not related to any underlying disorder. Nonetheless, cramps and spasms can be manifestations of many neurological or muscular diseases.

The terms cramp and spasm can be somewhat vague, and they are sometimes used to include types of abnormal muscle activity other than sudden painful contraction. These include stiffness at rest, slow muscle relaxation, and spontaneous contractions of a muscle at rest (fasciculation). Fasciculation is a type of painless muscle spasm, marked by rapid, uncoordinated contraction of many small muscle fibers. A critical part of diagnosis is distinguishing these different meanings and allowing the patient to describe the problem as precisely as possible.

Demographics

The exact incidence of muscle cramps and spasms is not known. They are more likely to occur in older children and teenagers who are participating in organized, competitive **sports** and strenuous aerobic activities.

Causes and symptoms

Causes

Normal voluntary muscle contraction begins when electrical signals are sent from the brain through the spinal cord along nerve cells called motor neurons. These include both the upper motor neurons within the brain and the lower motor neurons within the spinal cord and leading out to the muscle. At the muscle, chemicals released by the motor neuron stimulate the internal release of calcium ions from stores within the muscle cell. These calcium ions then interact with muscle proteins within the cell, causing the proteins (actin and myosin) to slide past one another. This motion pulls their fixed ends closer, thereby shortening the cell and, ultimately, the muscle itself. Recapture of calcium and unlinking of actin and myosin allow the muscle fiber to relax.

Abnormal contraction may be caused by unusual activity at any stage in this process. Certain mechanisms within the brain and the rest of the central nervous system help regulate contraction. Interruption of these mechanisms can cause spasm. Motor neurons that are

overly sensitive may fire below their normal thresholds. The muscle membrane itself may be overly sensitive, causing contraction without stimulation. Calcium ions may not be recaptured quickly enough, causing prolonged contraction.

Structural disorders such as flat feet, hyperextended knees (genu recurvatum), and hypermobility syndrome (joints that can move beyond the normal range of motion) may predispose a person to developing leg cramps. Prolonged sitting, inappropriate leg positioning during sedentary activity, or standing on concrete flooring for prolonged periods may be associated with an increased incidence of leg cramps.

Interruption of brain mechanisms and overly sensitive motor neurons may result from damage to the nerve pathways. Possible causes include **stroke**, multiple sclerosis, **cerebral palsy**, neurodegenerative diseases, trauma, **spinal cord injury**, and nervous system poisons such as strychnine, **tetanus**, and certain insecticides. Nerve damage may lead to a prolonged or permanent muscle shortening called contracture.

Changes in muscle responsiveness may be due to or associated with the following:

- Prolonged **exercise**: Curiously, relaxation of a muscle actually requires energy to be expended. The energy is used to recapture calcium and to unlink actin and myosin. Normally, sensations of pain and fatigue signal that it is time to rest. Ignoring or overriding those warning signals can lead to such severe energy depletion that the muscle cannot be relaxed, causing a cramp. The familiar advice about not swimming after a heavy meal, when blood flow is directed away from the muscles, is intended to avoid this type of cramp.
- Exercising or participating in activities in high or humid temperatures: Copious sweating during prolonged exercise can lead to heat cramps, a condition associated with brief, painful cramps, especially in the legs, sweating, and mild **fever**, usually less than 102°F. Heat cramps are more likely to occur when the child has not taken in enough fluids before, during, and after the activity. Exercising in high temperatures without adequate fluid intake may increase the risk of **dehydration**.
- Dehydration and salt depletion: This condition may be brought on by repeated bouts of **vomiting** or **diarrhea** or by copious sweating during prolonged exercise. Loss of fluids, salts, and minerals—especially sodium, potassium, magnesium, and calcium—can disrupt ion balances in both muscle and nerves. This imbalance can prevent the muscles and nerves from responding and recovering normally and can lead to cramping.
- Metabolic disorders that affect the energy supply in muscle: These are inherited diseases in which particular muscle enzymes are deficient. They include deficiencies of myophosphorylase (McArdle's disease), phosphorylase b kinase, phosphofructokinase, phosphoglycerate kinase, and lactate dehydrogenase.
- Myotonia: Myotonias include **myotonic dystrophy**, myotonia congenita, paramyotonia congenita, and neuromyotonia. These conditions cause stiffness due to delayed relaxation of the muscle but do not cause the spontaneous contraction usually associated with cramps. However, many patients with myotonia do experience cramping from exercise. Symptoms of myotonia are often worse in cold temperatures.

Fasciculation may be due to fatigue, cold, medications, metabolic disorders, nerve damage, or neurodegenerative disease, including amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig's disease). Most people experience brief, mild fasciculation from time to time, usually in the calves.

Symptoms

The pain of a muscle cramp is intense, localized, and often debilitating. Coming on quickly, it may last for minutes and fade gradually. Contractures develop more slowly, over days or weeks, and may be permanent if untreated. Fasciculation may occur at rest or after muscle contraction and may last several minutes.

Exercising in high temperatures can lead to dehydration. Dehydration should be suspected if these symptoms are present: dry mouth or tongue, increased or excessive thirst, few or no tears when crying, decreased urination, dark yellow urine, irritability, low energy, lightheadedness or fainting, severe weakness, and sunken abdomen, eyes and cheeks.

When to call the doctor

Prompt medical attention is required if the child has any of the symptoms associated with dehydration, as listed above. Prompt medical attention also is required if the child has a high fever—temperature of 102°F or 38.9°C, or above. Parents also should call the child's pediatrician if the following symptoms are present:

- acute pain associated with the muscle cramp or spasm
- prolonged muscle contractions
- cramps or spasms that cause twisting and repetitive movement or abnormal posture
- apparent development of muscle contractures (prolonged joint flexion in an abnormal position)

Diagnosis

A usual bout of muscle cramps should not require a visit to the doctor. However, medical treatment is essential if the child has any symptoms of dehydration associated with the muscle cramps. In addition, any abnormal contractions or frequent muscle cramps or spasms that cause concern should be evaluated by a physician. Abnormal muscle contractions are diagnosed through a careful medical history, as well as a physical and neurological examination. In some cases when a structural abnormality is suspected, x rays may be performed.

The medical history helps the physician evaluate the presence of other conditions or disorders that might contribute to or cause the abnormal contractions. Records of previous diagnoses, surgeries, and treatments are reviewed. The child's **family** medical history is evaluated to determine if there is a history of muscular or neurological disorders.

Questions about the child's medical history may include:

- When were the symptoms first noticed?
- How long have the symptoms lasted?
- Are the symptoms always present?
- What muscles are affected?
- What makes the symptoms improve?
- What specific treatments or techniques have been tried?
- What makes the symptoms worse?
- Do certain activities, emotions, or events seem to aggravate the symptoms?
- Are other symptoms present?

The physical and neurological exams may include an evaluation of the child's motor reflexes including muscle tone, mobility, strength, balance, and endurance; heart and lung function; cranial nerve function; and an examination of the child's abdomen, spine, throat, and ears. The child's height and weight and blood pressure also are checked and recorded.

When a neurological cause is suspected, a multi-disciplinary team may be consulted to provide an accurate diagnosis, so the proper treatment can be planned. Occupational and physical therapy evaluations may be helpful to determine upper and lower extremity movement patterns and passive range of motion.

In some cases, nerve conduction studies with electromyography of the affected muscles may be performed to evaluate an underlying neuromuscular disorder. These tests are useful in evaluating a child's muscular activity and provide a comprehensive **assessment** of nerve and muscle function.

In both tests, the examiner uses a computer, monitor, amplifier, loudspeaker, stimulator, and high-tech filters to see and hear how the muscles and nerves are responding during the test. In the nerve conduction study, small electrodes are placed on the skin over the muscles to be examined. A stimulator delivers a very small electrical current (that does not cause damage to the body) through the electrodes, causing the nerves to fire. In the electromyogram, a very thin, sterilized needle is inserted into various muscles, usually those affected most by **spasticity** symptoms. The needle is attached by wires to a recording machine. The patient is asked to relax and contract the muscles being examined. The electrical signals produced by the nerves and muscles during these tests are measured and recorded by a computer and displayed as electrical waves on the monitor. The test results are interpreted by a specially trained physician.

Treatment

Most cases of simple cramps require no treatment other than patience and stretching. When heat cramps occur, the child should stop the activity, move to a cool or shady place, remove excess clothing, drink cool water or a sports drink with electrolytes, such as Gatorade, and rest. If the child appears nauseous or is feeling dizzy, he should lie down, with feet slightly elevated. Directing a fan on the child will help cool the child. Gently and gradually stretching and massaging the affected muscle may ease the pain and hasten recovery.

Briefly applying cold packs to cramped muscles, for about ten minutes, may help ease pain.

Acetaminophen (such as Tylenol) or ibuprofen (such as Advil or Motrin) should be used sparingly for relief of discomfort. Ask the child's doctor for specific guidelines. More prolonged or regular cramps may be treated with prescribed medications.

If the child has any signs of dehydration, generous amounts of fluids and an oral rehydrating solution containing glucose and electrolytes should be given. Oral rehydrating solutions, including brands such as Pedialyte, Infalyte, Ceralyte, and Oralyte, are available at most grocery stores and drug stores. They are essential for replacing fluids, **minerals**, and salts. Dehydration can upset the body's electrolyte balance, leading to potentially life-threatening problems such as heart beat abnormalities (arrhythmia). Prolonged, severe dehydration requires medical treatment with intravenous (IV) fluids and may require **hospitalization**.

Treatment of underlying metabolic or neurologic diseases, when possible, may help relieve symptoms.

KEY TERMS

Active motion—Spontaneous; produced by active efforts. Active range of motion exercises are those that are performed by the patient without assistance.

Acupuncture—Based on the same traditional Chinese medical foundation as acupressure, acupuncture uses sterile needles inserted at specific points to treat certain conditions or relieve pain.

Anoxia—Lack of oxygen.

Ataxia—A condition marked by impaired muscular coordination, most frequently resulting from disorders in the brain or spinal cord.

Biofeedback—A training technique that enables an individual to gain some element of control over involuntary or automatic body functions.

Central nervous system—Part of the nervous system consisting of the brain, cranial nerves, and spinal cord. The brain is the center of higher processes, such as thought and emotion and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system, that is the nerves present in the rest of body.

Cerebral palsy—A nonprogressive movement disability caused by abnormal development of or damage to motor control centers of the brain.

Clonic—Referring to clonus, a series of muscle contractions and partial relaxations that alternate in some nervous diseases in the form of convulsive spasms.

Contraction—A tightening of the uterus during pregnancy. Contractions may or may not be painful and may or may not indicate labor.

Contracture—A tightening or shortening of muscles that prevents normal movement of the associated limb or other body part.

Dystonia—Painful involuntary muscle cramps or spasms.

Fasciculations—Small involuntary muscle contractions visible under the skin.

Genu recurvatum—Hyperextension of the knee.

Hyperactive reflexes—Reflexes that persist too long and may be too strong. For example, a hyperactive grasp reflex may cause the hand to stay clenched in a tight fist.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Hypertonia—Having excessive muscular tone or strength.

Idiopathic—Refers to a disease or condition of unknown origin.

Motor neuron—A nerve cell that specifically controls and stimulates voluntary muscles.

Multiple sclerosis—A progressive, autoimmune disease of the central nervous system characterized by damage to the myelin sheath that covers nerves. The disease, which causes progressive paralysis, is marked by periods of exacerbation and remission.

Muscle spasm—Localized muscle contraction that occurs when the brain signals the muscle to contract.

Myoclonus—Involuntary contractions of a muscle or an interrelated group of muscles. Also known as myoclonic seizures.

Neurologist—A doctor who specializes in disorders of the nervous system, including the brain, spinal cord, and nerves.

Neurosurgeon—Physician who performs surgery on the nervous system.

Nocturnal leg cramps—Cramps that may be related to exertion and awaken a person during sleep.

Occupational therapist—A healthcare provider who specializes in adapting the physical environment to meet a patient's needs. An occupational therapist also assists patients and caregivers with activities of daily living and provide instructions on wheelchair use or other adaptive equipment.

Orthopedist—A doctor specializing in treatment of the musculoskeletal system.

Passive movement—Movement that occurs under the power of an outside source such as a clinician. There is no voluntary muscular contraction by the individual who is being passively moved.

Periodic limb movement disorder—A disorder characterized by involuntary flexion of leg muscles, causing twitching and leg extension or kicking during sleep.

Peripheral nerves—Nerves outside the brain and spinal cord that provide the link between the body and the central nervous system.

Physiatrist—A physician who specializes in physical medicine and rehabilitation.

Physical therapist—A healthcare provider who teaches patients how to perform therapeutic exercises to maintain maximum mobility and range of motion.

KEY TERMS (contd.)

Range of motion (ROM)—The range of motion of a joint from full extension to full flexion (bending) measured in degrees like a circle.

Restless legs syndrome (RLS)—A disorder in which the patient experiences crawling, aching, or other disagreeable sensations in the calves that can be relieved by movement. RLS is a frequent cause of difficulty falling asleep at night.

Rigidity—A constant resistance to passive motion.

Spinal cord injury—Injury to the spinal cord, via blunt or penetrating trauma.

Stroke—Interruption of blood flow to a part of the brain with consequent brain damage. A stroke may be caused by a blood clot or by hemorrhage due to a burst blood vessel. Also known as a cerebrovascular accident.

Alternative treatment

Alternative and complementary therapies include approaches that are considered to be outside the mainstream of traditional health care. In adults, alternative treatments for cramps include gingko (*Ginkgo biloba*) or Japanese quince (*Chaenomeles speciosa*). Supplements of vitamin E, niacin, calcium, and magnesium may also help to relieve the likelihood of night cramps, especially when taken at bedtime. Indications for these treatments in children have not been documented.

There are several alternative therapies that can be useful when treating **movement disorders**. Among the therapies that may be helpful are acupuncture, homeopathy, touch therapies, postural alignment therapies, and biofeedback. The progress made will depend on the individual and his/her condition.

Biofeedback training may be used to teach older children how to consciously reduce muscle tension. Biofeedback uses an electrical signal that indicates when a spastic muscle relaxes. The patient may be able to use biofeedback to learn how to consciously reduce muscle tension and possibly reduce symptoms.

Before learning or practicing any particular technique, it is important for the parent or caregiver and child to learn about the therapy, its safety and effectiveness, potential side effects, and the expertise and qualifications of the practitioner. Although some practices are beneficial, others may be harmful to certain patients. Alternative therapies should not be used as a substitute for medical therapies prescribed by a doctor. Parents should discuss these alternative treatments with the child's doctor to determine the techniques and remedies that may be beneficial for the child.

Prognosis

Occasional cramps are common and have no special medical significance.

Prevention

The likelihood of developing cramps may be reduced with regular exercise to build up energy reserves in the muscles. Avoiding exercising in extreme heat helps prevent heat cramps. Heat cramps can also be avoided by drinking plenty of water before and during exercise in extreme heat. Practicing proper body mechanics while sitting (sitting with both feet on the floor, back straight and legs uncrossed) can help prevent the development of leg cramps. Taking a warm bath before bedtime may increase circulation to the legs and reduce the incidence of nighttime leg cramps.

Nutritional concerns

The likelihood of developing cramps may be reduced by eating a well-balanced, healthy diet with appropriate levels of minerals. A registered dietitian can work with parents to identify a child's specific calorie needs and develop an individualized meal plan.

Fluids should be encouraged during all strenuous activities, especially in warm weather. People should aim for two to four eight-ounce glasses of fluid per hour of activity.

If an underlying neurological disorder has been identified, dietary guidelines are individualized, based on the child's age, diagnosis, overall health, caloric and energy needs, and level of functioning. Early identification, treatment, and correction of specific feeding problems will improve the health and nutritional status of the patient.

Parental concerns

Occasional muscle cramps are common. The most important concern is preventing dehydration, especially when the child is exercising in high or humid temperatures. Make sure the child drinks enough fluids before, during, and after sports and other activities. Pack a water bottle and/or sports drink for the child to have at sports practices, games, and other physical activities. Make

sure the coach provides time out for water breaks. After the activity, encourage the child to continue drinking water to replace lost fluids.

If a movement disorder has been diagnosed, parents should work closely with the child's therapists and doctors to create an effective treatment plan. It is important for parents to communicate their treatment goals with the health care team. Parents should take an active role in the child's exercise program.

Raising a child with a movement disorder can be challenging. There are several support groups available to provide information and assistance.

Muscular dystrophy

Definition

Muscular dystrophy is the name for a group of inherited disorders in which strength and muscle bulk gradually decline. Nine types of muscular dystrophies are generally recognized.

Description

The muscular dystrophies include:

- Duchenne muscular dystrophy (DMD), which affects young boys, causing progressive muscle weakness, usually beginning in the legs. It is the most severe form of muscular dystrophy.
- Becker muscular dystrophy (BMD), which affects older boys and young men, following a milder course than DMD
- Emery-Dreifuss muscular dystrophy (EDMD), which affects young boys, causing contractures and weakness in the calves, weakness in the shoulders and upper arms, and problems in the way electrical impulses travel through the heart to make it beat (heart conduction defects). Female carriers of EDMD are at risk for heart block.
- Limb-girdle muscular dystrophy (LGMD), which begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles around the hips and shoulders. It is the most variable of the muscular dystrophies, and there are as of 2004 several different forms of the disease recognized. Many people with suspected LGMD have probably been misdiagnosed in the past; therefore, the prevalence of the disease is difficult to estimate.
- Facioscapulohumeral muscular dystrophy (FSH), also known as Landouzy-Dejerine disease, which begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles of the face, shoulders, and upper arms. The hips and legs may also be affected.
- **Myotonic dystrophy**, also known as Steinert's disease, which affects both men and women, causing generalized weakness first seen in the face, feet, and hands. It is accompanied by the inability to relax the affected muscles (myotonia). Symptoms may begin any time from birth through adulthood.
- Oculopharyngeal muscular dystrophy (OPMD), which affects adults of both sexes, causing weakness in the eye muscles and throat
- Distal muscular dystrophy (DD), which begins in middle age or later, causing weakness in the muscles of the feet and hands
- Congenital muscular dystrophy (CMD), which is present from birth, results in generalized weakness, and usually progresses slowly. A subtype, called Fukuyama CMD, also involves **mental retardation**. Both are rare.

Demographics

DMD occurs in about one in 3,500 male births and affects approximately 8,000 boys and young men in the United States. A milder form occurs in very few female carriers.

BMD occurs in about one in 30,000 male births.

Fewer than 300 cases of EDMD have been identified.

The number of people affected with LGMD in the United States may be in the low thousands.

FSH occurs in about one out of every 20,000 people and affects approximately 13,000 people in the United States.

Myotonic dystrophy is the most common form of muscular dystrophy, affecting more than 30,000 people in the United States.

OPMD is most common among French Canadian families in Quebec and in Spanish-American families in the southwestern United States.

DD is most common in Sweden and rare in other parts of the world.

Fukuyama CMD is most common in Japan.

Causes and symptoms

Causes

Several of the muscular dystrophies, including DMD, BMD, CMD, and most forms of LGMD, are due to defects in the genes for a complex of muscle proteins. This complex spans the muscle cell membrane to unite a fibrous network on the interior of the cell with a fibrous network on the outside. As of 2004 the theory was that by linking these two networks, the complex acts as a "shock absorber," redistributing and evening out the forces generated by contraction of the muscle, thereby preventing rupture of the muscle membrane. Defects in the proteins of the complex lead to deterioration of the muscle. Symptoms of these diseases set in as the muscle gradually exhausts its ability to repair itself. Both DMD and BMD are caused by flaws in the gene for the protein called dystrophin. The flaw leading to DMD prevents the formation of any dystrophin, while that of BMD allows some protein to be made, accounting for the differences in severity and onset between the two diseases. Differences among the other diseases in the muscles involved and the ages of onset are less easily explained.

The causes of the other muscular dystrophies are not as well understood:

- One form of LGMD is caused by defects in the gene for a muscle enzyme, calpain. The relationship between this defect and the symptoms of the disease is unclear.
- EDMD is due to a defect in the gene for a protein called emerin, which is found in the membrane of a cell's nucleus, but whose exact function is unknown.
- Myotonic dystrophy is linked to gene defects for a protein that may control the flow of charged particles within muscle cells. This gene defect is called a triple repeat, meaning it contains extra triplets of DNA code. It is possible that this mutation affects nearby genes as well, and that the widespread symptoms of myotonic dystrophy are due to a range of genetic disruptions.
- The gene for OPMD appears to also be mutated with a triple repeat. The function of the affected protein may involve translation of genetic messages in a cell's nucleus.
- The cause of FSH is unknown. The genetic region responsible for it has been localized on its chromosome, however.
- The gene responsible for DD has not yet been found.

Genetics and patterns of inheritance

The muscular dystrophies are genetic diseases, meaning they are caused by defects in genes. Genes, which are linked together on chromosomes, have two functions. They code for the production of proteins, and they are the material of inheritance. Parents pass along genes to their children, providing them with a complete set of instructions for making their own proteins.

Because both parents contribute genetic material to their offspring, each child carries two copies of almost every gene, one from each parent. For some diseases to occur, both copies must be flawed. Such diseases are called autosomal recessive diseases. Some forms of LGMD and DD exhibit this pattern of inheritance, as does CMD. A person with only one flawed copy, called a carrier, will not have the disease but may pass the flawed gene on to children. When two carriers have children, the chances of having a child with the disease is one in four for each pregnancy.

Other diseases occur when only one flawed gene copy is present. Such diseases are called autosomal dominant diseases. Other forms of LGMD exhibit this pattern of inheritance, as do DM, FSH, OPMD, and some forms of DD. When a person affected by the disease has a child with someone not affected, the chances of having an affected child is one in two.

Because of chromosomal differences between the sexes, some genes are not present in two copies. The chromosomes that determine whether a person is male or female are called the X and Y chromosomes. A person with two X chromosomes is female, while a person with one X and one Y is male. While the X chromosome carries many genes, the Y chromosome carries almost none. Therefore, a male has only one copy of each gene on the X chromosome, and if it is flawed, he will have the disease that defect causes. Such diseases are said to be X-linked. X-linked diseases include DMD, BMD, and

EDMD. Women are not usually affected by X-linked diseases, since they will likely have one unaffected copy between the two chromosomes. Some female carriers of DMD suffer a mild form of the disease, probably because their one unaffected gene copy is shut down in some of their cells.

Women carriers of X-linked diseases have a one-in-two chance of passing the flawed gene on to each child born. Daughters who inherit the disease gene are carriers. A son born without the disease gene is free of the disease and cannot pass it on to his children. A son born with the defect has the disease. He will pass the flawed gene on to each of his daughters, who will then be carriers, but to none of his sons (because they inherit his Y chromosome).

Not all genetic flaws are inherited. As many as one-third of the cases of DMD are due to new mutations that arise during egg formation in the mother. New mutations are less common in other forms of muscular dystrophy.

Symptoms

All of the muscular dystrophies are marked by muscle weakness as the major symptom. The distribution of symptoms, age of onset, and progression differ significantly. **Pain** is sometimes a symptom of each, usually due to the effects of weakness on joint position.

DMD A boy with Duchenne muscular dystrophy usually begins to show symptoms as a preschooler. The legs are affected first, making walking difficult and causing balance problems. Most affected persons walk three to six months later than expected and have difficulty running. Later on, the boy with DMD will push his hands against his knees to rise to a standing position, to compensate for leg weakness. About the same time, his calves will begin to swell, though with fibrous tissue rather than with muscle and feel firm and rubbery; this condition gives DMD one of its alternate names, pseudohypertrophic muscular dystrophy. The boy will widen his stance to maintain balance and walk with a waddling gait to advance his weakened legs. Contractures (permanent muscle tightening) usually begin by age five or six, most severely in the calf muscles. This pulls the foot down and back, forcing the boy to walk on tip-toes, called equinus, and further decreases balance. Frequent falls and broken bones are common beginning at this age. Climbing stairs and rising unaided may become impossible by age nine or ten, and most boys use a wheelchair for mobility by the age of 12. Weakening of the trunk muscles around this age often leads to **scoliosis** (a side-to-side spine curvature) and kyphosis (a front-to-back curvature).

The most serious weakness of DMD is weakness of the diaphragm, the sheet of muscles at the top of the abdomen that perform the main work of breathing and coughing. Diaphragm weakness leads to reduced energy and stamina and increased lung infection because of the inability to **cough** effectively. Young men with DMD often live into their twenties and beyond, provided they have mechanical ventilation assistance and good respiratory hygiene.

About one third of boys with DMD experience specific learning disabilities, including trouble learning by ear rather than by sight and trouble paying attention to long lists of instructions. Individualized educational programs usually compensate well for these disabilities.

BMD The symptoms of BMD usually appear in late childhood to early adulthood. Though the progression of symptoms may parallel that of DMD, the symptoms are usually milder, and the course more variable. The same pattern of leg weakness, unsteadiness, and contractures occurs later for the young man with BMD, often allowing independent walking into the twenties or early thirties. Scoliosis may occur but is usually milder and progresses more slowly. Heart muscle disease (cardiomyopathy) occurs more commonly in BMD. Problems may include irregular heartbeats (arrhythmias) and congestive heart failure. Symptoms may include fatigue, shortness of breath, chest pain, and **dizziness**. Respiratory weakness also occurs and may lead to the need for mechanical ventilation.

EDMD This type of muscular dystrophy usually begins in early childhood, often with contractures preceding muscle weakness. Weakness affects the shoulder and upper arm originally, along with the calf muscles, leading to foot-drop. Most men with EDMD survive into middle age, although a defect in the heart's rhythm (heart block) may be fatal if not treated with a pacemaker.

LGMD While there are at least six genes that cause the various types of LGMD, two major clinical forms of LGMD are usually recognized. A severe childhood form is similar in appearance to DMD but is inherited as an autosomal recessive trait. Symptoms of adult-onset LGMD usually appear in a person's teens or twenties and are marked by progressive weakness and wasting of the muscles closest to the trunk. Contractures may occur, and the ability to walk is usually lost about 20 years after onset. Some people with LGMD develop respiratory weakness that requires use of a ventilator. Lifespan may be somewhat shortened. (Autosomal dominant forms usually occur later in life and progress relatively slowly.)

FSH FSH varies in its severity and age of onset, even among members of the same **family**. Symptoms most commonly begin in the teens or early twenties, though infant or childhood onset is possible. Symptoms tend to be more severe in those with earlier onset. The disease is named for the regions of the body most severely affected by the disease: muscles of the face (facio-), shoulders (scapulo-), and upper arms (humeral). Hips and legs may be affected as well. Children with FSH often develop partial or complete deafness.

The first symptom noticed is often difficulty lifting objects above the shoulders. The weakness may be greater on one side than the other. Shoulder weakness also causes the shoulder blades to jut backward, called scapular winging. Muscles in the upper arm often lose bulk sooner than those of the forearm, giving a "Popeye" appearance to the arms. Facial weakness may lead to loss of facial expression, difficulty closing the eyes completely, and inability to drink through a straw, blow up a balloon, or whistle. A person with FSH may not develop strong facial wrinkles. Contracture of the calf muscles may cause foot-drop, leading to frequent tripping over curbs or rough spots. People with earlier onset often require a wheelchair for mobility, while those with later onset rarely do.

MYOTONIC DYSTROPHY Symptoms of myotonic dystrophy include facial weakness and a slack jaw, drooping eyelids (ptosis), and muscle wasting in the forearms and calves. A person with this dystrophy has difficulty relaxing his grasp, especially if the object is cold. Myotonic dystrophy affects heart muscle, causing arrhythmias and heart block, and the muscles of the digestive system, leading to motility disorders and **constipation**. Other body systems are affected as well: myotonic dystrophy may cause cataracts, retinal degeneration, low IQ, frontal balding, skin disorders, testicular atrophy, **sleep** apnea, and insulin resistance. An increased need or desire for sleep is common, as is diminished motivation. Severe disability affects most people with this type of dystrophy within 20 years of onset, although most do not require a wheelchair even late in life.

OPMD OPMD usually begins in a person's thirties or forties, with weakness in the muscles controlling the eyes and throat. Symptoms include drooping eyelids, difficulty swallowing (dysphagia), and weakness progresses to other muscles of the face, neck, and occasionally the upper limbs. Swallowing difficulty may cause aspiration or the introduction of food or saliva into the airways. **Pneumonia** may follow.

DD DD usually begins in the twenties or thirties with weakness in the hands, forearms, and lower legs. Difficulty with fine movements such as typing or fastening buttons may be the first symptoms. Symptoms progress slowly, and the disease usually does not affect life span.

CMD CMD is marked by severe muscle weakness from birth, with infants displaying "floppiness" and very little voluntary movement. Nonetheless, a child with CMD may learn to walk, either with or without some assistive device, and live into young adulthood or beyond. In contrast, children with Fukuyama CMD are rarely able to walk and have severe mental retardation. Most children with this type of CMD die in childhood.

When to call the doctor

A doctor should be consulted whenever muscle development is thought to be abnormal or slow.

Diagnosis

Diagnosis of muscular dystrophy involves a careful medical history and a thorough physical exam to determine the distribution of symptoms and to rule out other causes. Family history may give important clues, since all the muscular dystrophies are genetic conditions (though no family history will be evident in the event of new mutations).

Lab tests may include the following:

- Blood level of the muscle enzyme creatine kinase (CK). CK levels rise in the blood due to muscle damage and may be seen in some conditions even before symptoms appear.
- Muscle biopsy, in which a small piece of muscle tissue is removed for microscopic examination. Changes in the structure of muscle cells and presence of fibrous tissue or other aberrant structures are characteristic of different forms of muscular dystrophy. The muscle tissue can also be stained to detect the presence or absence of particular proteins, including dystrophin.
- Electromyogram (EMG). EMG is used to examine the response of the muscles to stimulation. Decreased response is seen in muscular dystrophy. Other characteristic changes are seen in DM.
- Genetic tests. Several of the muscular dystrophies can be positively identified by testing for the presence of the mutated gene involved. Accurate genetic tests are available for DMD, BMD, DM, several forms of LGMD, and EDMD.
- Other specific tests as necessary. For EDMD and BMD, for example, an electrocardiogram may be nee-

MD patient Sarah Schwegel with Jerry Lewis at the Muscular Dystrophy Telethon, which raises money for research for the cure and treatment of muscular dystrophy. *(Muscular Dystrophy Association.)*

ded to test heart function, and hearing tests are performed for children with FSH.

For most forms of muscular dystrophy, accurate diagnosis is not difficult when done by someone familiar with the range of diseases. There are exceptions, however. Even with a muscle biopsy, it may be difficult to distinguish between FSH and another muscle disease, polymyositis. Childhood-onset LGMD is often mistaken for the much more common DMD, especially when it occurs in boys. BMD with an early onset appears very similar to DMD, and a muscle biopsy may be needed to accurately distinguish them. The muscular dystrophies may be confused with diseases involving the motor neurons, such as **spinal muscular atrophy**; diseases of the neuromuscular junction, such as myasthenia gravis; and other muscle diseases, as all involve generalized weakening of varying distribution.

Treatment

Drugs

As of 2004 there were no cures for any of the muscular dystrophies. Prednisone, a corticosteroid, has been shown to delay the progression of DMD somewhat, for reasons that as of 2004 are still unclear. Prednisone is also prescribed for BMD.

Treatment of muscular dystrophy is mainly directed at preventing the complications of weakness, including decreased mobility and dexterity, contractures, scoliosis, heart defects, and respiratory insufficiency.

Physical therapy

Physical therapy, in particular regular stretching, is used to maintain the range of motion of affected muscles and to prevent or delay contractures. Braces are used as well, especially on the ankles and feet to prevent equinus. Full-leg braces may be used in DMD to prolong the period of independent walking. Strengthening other muscle groups to compensate for weakness may be possible if the affected muscles are few and isolated, as in the earlier stages of the milder muscular dystrophies. Regular, nonstrenuous **exercise** helps maintain general good health. Strenuous exercise is usually not recommended, since it may damage muscles further.

Surgery

When contractures become more pronounced, tenotomy surgery may be performed. In this operation, the tendon of the contractured muscle is cut, and the limb is braced in its normal resting position while the tendon regrows. In FSH, surgical fixation of the scapula can help compensate for shoulder weakness. For a person with OPMD, surgical lifting of the eyelids may help compensate for weakened muscular control. For a person with DM, sleep apnea may be treated surgically to maintain an open airway. Scoliosis surgery is often needed in DMD but much less often in other muscular dystrophies. Surgery is recommended at a much lower degree of curvature for DMD than for scoliosis due to other conditions, since the decline in respiratory function in DMD makes surgery at a later time dangerous. In this surgery, the vertebrae are fused together to maintain the spine in the upright position. Steel rods are inserted at the time of operation to keep the spine rigid while the bones grow together.

When any type of surgery is performed in people with muscular dystrophy, anesthesia must be carefully selected. People with MD are susceptible to a severe reaction, known as malignant hyperthermia, when given halothane anesthetic.

Occupational therapy

The occupational therapist suggests techniques and tools to compensate for the loss of strength and dexterity. Strategies may include modifications in the home, adaptive utensils and dressing aids, compensatory movements and positioning, wheelchair accessories, or communication aids.

Nutrition

Good **nutrition** helps to promote general health in all the muscular dystrophies. No special diet or supplement has as of 2004 been shown to be of use in any of

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one of the two copies of an autosomal gene must be abnormal for a genetic condition or disease to occur. An autosomal gene is a gene that is located on one of the autosomes or non-sex chromosomes. A person with an autosomal dominant disorder has a 50 percent chance of passing it to each of their offspring.

Autosomal recessive—A pattern of inheritance in which both copies of an autosomal gene must be abnormal for a genetic condition or disease to occur. An autosomal gene is a gene that is located on one of the autosomes or non-sex chromosomes. When both parents have one abnormal copy of the same gene, they have a 25 percent chance with each pregnancy that their offspring will have the disorder.

Becker muscular dystrophy (BMD)—A type of muscular dystrophy that affects older boys and men and usually follows a milder course than Duchenne muscular dystrophy.

Contracture—A tightening or shortening of muscles that prevents normal movement of the associated limb or other body part.

Distal muscular dystrophy (DD)—A form of muscular dystrophy that usually begins in middle age or later, causing weakness in the muscles of the feet and hands.

Duchenne muscular dystrophy (DMD)—The most severe form of muscular dystrophy, DMD usually affects young boys and causes progressive muscle weakness, usually beginning in the legs.

Dystrophin—A protein that helps muscle tissue repair itself. Both Duchenne muscular dystrophy and Becker muscular dystrophy are caused by flaws in the gene that tells the body how to make this protein.

Facioscapulohumeral muscular dystrophy (FSH)—This form of muscular dystrophy, also known as Landouzy-Dejerine disease, begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles of the face, shoulders, and upper arms.

Limb-girdle muscular dystrophy (LGMD)—A form of muscular dystrophy that begins in late childhood to early adulthood and affects both men and women. It causes weakness in the muscles around the hips and shoulders.

Myotonic dystrophy—A form of muscular dystrophy, also known as Steinert's disease, that affects both men and women. It is characterized by delay in the ability to relax muscles after forceful contraction (myotonia) and wasting of muscles, as well as other abnormalities.

Oculopharyngeal muscular dystrophy—A type of muscular dystrophy that affects adults of both sexes, causing weakness in the eye muscles and throat.

the conditions. The weakness in the throat muscles seen especially in OPMD and later DMD may necessitate the use of a gastrostomy tube, inserted in the stomach to provide nutrition directly.

Cardiac care

The arrhythmias of EDMD and BMD may be treatable with antiarrhythmia drugs such as mexiletine or nifedipine. A pacemaker may be implanted if these do not provide adequate control. Heart transplants are increasingly common for men with BMD.

Respiratory care

People who develop weakness of the diaphragm or other ventilatory muscles may require a mechanical ventilator to continue breathing deeply enough. Air may be administered through a nasal mask or mouthpiece or through a tracheostomy tube, which is inserted through a surgical incision through the neck and into the windpipe. Most people with muscular dystrophy do not need a tracheostomy, although some may prefer it to continual use of a mask or mouthpiece. Supplemental oxygen is not needed. Good hygiene of the lungs is critical for health and long-term survival of a person with weakened ventilatory muscles. Assisted cough techniques provide the strength needed to clear the airways of secretions; an assisted cough machine is also available and provides excellent results.

Experimental treatments

Two experimental procedures aiming to cure DMD have attracted a great deal of attention. In myoblast transfer, millions of immature muscle cells are injected into an affected muscle. The goal of the treatment is to promote the growth of the injected cells, replacing the

defective host cells with healthy new ones. Despite continued claims to the contrary by a very few researchers, this procedure is widely judged a failure.

Gene therapy introduces good copies of the dystrophin gene into muscle cells. The goal is to allow the existing muscle cells to use the new gene to produce the dystrophin it cannot make with its flawed gene. Problems have included immune rejection of the virus used to introduce the gene, loss of gene function after several weeks, and an inability to get the gene to enough cells to make a functional difference in the affected muscle. Nonetheless, after a number of years of refining the techniques in mice, researchers began human trials in 1998. These trials are ongoing.

Prognosis

The expected life span for a male with DMD has increased significantly since the 1970s. Most young men live into their early or mid-twenties. Respiratory infections become an increasing problem as their breathing becomes weaker, and these infections are usually the cause of death.

The course of the other muscular dystrophies is more variable; expected life spans and degrees of disability are hard to predict but may be related to age of onset and initial symptoms. Prediction is made more difficult because, as new genes are discovered, it becomes clear that several of the dystrophies are not uniform disorders but rather symptom groups caused by different genes.

People with dystrophies with significant heart involvement (BMD, EDMD, Myotonic dystrophy) may nonetheless have almost normal life spans, provided that cardiac complications are monitored and treated aggressively. The respiratory involvement of BMD and LGMD similarly require careful and prompt treatment.

Prevention

As of 2004 there was no way to prevent any of the muscular dystrophies in a person who has the genes responsible for these disorders. Accurate genetic tests, including prenatal tests, are available for some of the muscular dystrophies. Results of these tests may be useful for purposes of family planning.

Nutritional concerns

There is no known link between nutrition and the onset of muscular dystrophy.

Parental concerns

Prospective parents with first-degree relatives (parents, siblings, or other children) who have been diagnosed with muscular dystrophy should consider including counseling in their family planning process.

Mutism

Definition

Mutism is a rare childhood condition characterized by a consistent failure to speak in situations where talking is expected.

Description

In mutism, the child has the ability to converse normally and does so, for example, in the home, but consistently fails to speak in specific situations such as at school or with strangers. The condition is also called selective mutism, to differentiate it from children who are physically unable to speak. Experts believe that this selective problem is associated with **anxiety** and **fear** in social situations such as in school or in the company of adults. It is, therefore, often considered a type of social phobia. This is not a communication disorder because the affected children can converse normally in some situations. It is not a developmental disorder because their ability to talk, when they choose to do so, is appropriate for their age level. This problem has been linked to anxiety, and one of the major ways in which both children and adults attempt to cope with anxiety is by avoiding whatever provokes the anxiety. Affected children are typically shy and are especially so in the presence of strangers and unfamiliar surroundings or situations. However, the behaviors of children with this condition go beyond **shyness**.

These children understand language and are able to talk normally in settings where they are comfortable, secure and relaxed. Over 90 percent of children with mutism also have social phobia or social anxiety, and some experts view mutism as a symptom of social anxiety. Others view it as a separate, but related, disorder. It is not yet understood why some individuals develop typical symptoms of social anxiety, like reluctance to speak in front of a group of people or feeling embarrassed easily, while others experience the inability to speak that characterizes mutism. What is clear is that children and adolescents with mutism have an actual fear of speaking and of social interactions where there is an expectation to talk. They may also be unable to communicate nonverbally, may be unable to make eye contact, and may stand motionless with fear as they are confronted with specific social settings. This can be quite heart wrenching to watch and is often very debilitating for the child as well as frustrating for parents and teachers.

A child meets the criteria for mutism if the following are true:

- The child does not speak in certain selected places such as school or at particular social events.
- The child speaks normally in at least one environment, usually in the home, but a small percentage of children with mutism are mute at home.
- The child's inability to speak interferes with his or her ability to function in school and/or social settings.
- The mutism has persisted for at least one month.
- The mutism is not caused by a communication disorder (such as **stuttering**) and does not occur as part of other mental disorders (such as **autism**).

Demographics

It is estimated that one in every 1,000 school-age children are affected by mutism.

Causes and symptoms

Mutism is believed to arise from anxiety experienced in social situations where the child may be called upon to speak. Refusing to speak or speaking in a whisper spares the child from the possible humiliation or embarrassment of saying the "wrong" thing. When asked a direct question by teachers, for example, the affected child may act as if they are unable to answer. Some children may communicate via gestures, nodding, or very brief utterances. Additional features may include excessive shyness, oppositional behavior, and impaired learning at school.

The majority of children with mutism have a genetic predisposition to anxiety. In other words, they have inherited the tendency to be anxious from **family** members and may be vulnerable to the development of an anxiety disorder. Very often, these children show signs of anxiety, such as difficulty separating from parents, moodiness, clinging behavior, inflexibility, **sleep** problems, frequent **tantrums** and crying, and extreme shyness starting in infancy. When they reach the age when they begin to interact socially outside the family environment, their persistent fear of speaking or communicating begins to manifest in symptoms like freezing, lack of response, stiff posture, blank facial expression, lack of smiling, and mutism. Studies have shown that some children are born with inhibited temperaments, which means that even as infants, they are more likely to be fearful and wary of new situations. There is reason to believe that many or most children with mutism were born with this inhibited personality type.

Research has also shown that these behaviorally inhibited children have a decreased threshold of

excitability in the area of the brain called the amygdala. The normal function of the amygdala is to receive and process signals of potential danger and set off a series of reactions that will help individuals protect themselves, such as the fight-or-flight response. In anxious individuals, the amygdala seems to overreact and set off these responses even when the individual is not really in danger. In the case of selectively mute children, the anxiety responses are triggered by social interactions in settings such as school, the playground, or social gatherings. Over time, a child with selective mutism becomes mute because of an inability to cope with fearful feelings that occur when he or she is expected to speak. When the child does not respond, the pressure is usually removed and the child feels relief from fear.

Besides genetics and biological factors, researchers believe that other factors may contribute to the development of selective mutism. A significant number of children with mutism also have expressive **language disorders**, and a fairly large number come from a bilingual environment, which may add to a child's vulnerability to mutism. Anxiety is still the root cause of the mutism, and it is theorized that these language difficulties may make the child more self-conscious about his or her speaking skills and thus may increase the fear of being judged by others. These risk factors are probably additive; in other words, if a child has genetic risk of anxiety, plus a bilingual environment or a speech disorder, the likelihood of that child developing selective mutism becomes higher with each added factor.

When to call the doctor

If selective mutism persists for more than a month, parents should discuss this pattern with their child's teachers, family physician, or pediatrician. The doctor may refer the child to a speech therapist, psychiatrist or psychologist.

Diagnosis

The diagnosis of mutism is fairly easy to make because the signs and symptoms are clear-cut and easily observable. However, other social disorders effecting social speech, such as autism or **schizophrenia**, must be considered in the diagnosis. The average age of diagnosis is between three and eight years of age; however, in retrospect many parents will say that their child displayed signs of excessive shyness and inhibition since infancy. It is not until children enter school, where there is an expectation to perform, interact, and speak, that mutism becomes more apparent. Often a parent suspects during the **preschool** years that there is a problem, but lack of knowledge about selective mutism makes it difficult to find help. It is all too common for parents to question their child's pediatrician about the child's inability to speak in public and be told that the child is just shy and will outgrow the behavior. Once a child enters school, though, teachers often point out the severity of the problem to the parents. Some parents are also reluctant to have their child evaluated and treated.

Treatment

Since selective mutism is an anxiety disorder, successful treatment focuses on methods to lower anxiety, increase **self-esteem**, and increase confidence and communication in social settings. The emphasis should never be on "getting a child to talk," nor should the goal of treatment be for the child to speak to the therapist. Progress outside the clinic or doctor's office is much more important than whether the child speaks during the therapy session. Initially, all expectations for verbalization should be removed. As the child's anxiety is lowered and confidence increases, verbalization usually follows. If it does not occur spontaneously, techniques can later be added to help encourage progress. A professional should devise an individualized treatment plan for each child and allow the child, family, and school to have a great deal of input into the treatment process. Therapy usually involves some combination of behavioral therapy, cognitive behavioral therapy, **play therapy**, or psychoanalytic therapy, medication, and in some cases, **family therapy**.

Behavioral therapy

The primary types of behavioral therapy used for selective mutism are desensitization, fading, and positive reinforcement techniques. Desensitization means exposing a child to something that is feared in a gradual way, in order to help the child overcome the fear. Fading therapy is a type of desensitization that creates a series of events or exposures that starts with a situation that is comfortable for the child, such as being alone in the classroom with a parent and playing a board game. New variables that are progressively more difficult are gradually added. For example, having the teacher walk past the room and overhear the child speaking to the parent, and then having the teacher enter the room, and eventually have the child interacting with the teacher in the classroom. Positive reinforcement, or the use of rewards for changes in behavior, should only be introduced after anxiety is lowered and the child is ready to begin working on goals. It is also important to realize that there are many intermediate steps between being mute and being verbal. During the early stages of treatment, nonverbal communication such as pointing, nodding, and use of pictures to express needs, can be encouraged and

rewarded. Though some may fear that allowing nonverbal communication will enable the mutism to continue, many therapists believe it is a necessary step for most children with mutism to overcome their communication anxiety in a step-by-step manner.

Cognitive behavioral therapy

Cognitive behavioral therapy (CBT) helps children change their thoughts (the cognitive part) and their actions (the behavioral part). CBT therapists recognize that anxious children tend to exaggerate the frightening aspects of certain situations, so they help the children gain a more realistic perspective in order to decrease anxiety. They also know that anxious children avoid situations they fear or (in the case of selectively mute children) avoid speech in anxiety-provoking situations. Avoidance makes anxiety worse. Therefore, CBT helps the child overcome avoidance by gradually facing what is feared with lots of praise and positive reinforcement for doing so. Parents, teachers, and other adults around the child can be very helpful in this process. Cognitive strategies for the selectively mute child aim to reduce the social anxiety that is often part of the disorder. Cognitive strategies help the child challenge negative expectations and replace them with more realistic ones. This process is combined with behavioral strategies that focus on helping the selectively mute child to talk in increasingly challenging situations. The therapist carefully collects information on where and with whom the child already speaks and then helps the child choose a goal to work on in a situation that is just slightly more challenging.

Play therapy

Play therapy is an adaptation of psychoanalytic therapy, which is a psychological treatment based on helping people understand their unconscious thoughts. This field of psychology includes Freudian theories but also many other modern theories about how our minds work. Play therapy refers to the use of play as communication; therapists who are trained in these techniques observe and participate in play activities with the child and interpret the child's actions as a form of subconscious communication. There is not a lot of evidence for play therapy being effective in the treatment of mutism; however, a well trained play therapist might be able to help a child with mutism better understand and express emotions and may be a part of an overall treatment plan. It may be especially useful when a stressful event or environment is a factor. For some children there may be contributing factors such as the death of a parent or other loved one, a **divorce**, or a move. Play therapists may be able to help a child to express and better understand the emotions that they are experiencing in these situations.

Family therapy

Since there is no evidence of family pathology being the cause of most cases of mutism, this type of therapy is not necessary in most cases. However, if there are unusual circumstances or a highly stressful family environment, then it may be advisable for families to participate in more intensive family therapy.

Prognosis

The prognosis for mutism is good. Sometimes it disappears suddenly on its own. The negative impact on learning and school activities may, however, persist into adult life.

Prevention

Mutism cannot be prevented because the cause is not known. However, family conflict or problems at school contribute to the seriousness of the symptoms.

Parental concerns

Parents should remove all pressure and expectations for the child to speak, conveying to their child that they understand he or she feels "scared" to speak or has difficulty speaking at times. Many parents report that simply removing the pressure and letting the child know that they understand can help to improvement the child's symptoms. Parents should also reassure their child that they will help him or her through this difficult time. The child's accomplishments and efforts should be praised, and support and understanding should be offered when the child has difficulties and frustrations. Parents should read as much information as they can to become well informed about selective mutism.

It is important for family members to be educated and informed about selective mutism and to be included in the child's treatment plan in order to provide a supportive environment for the child's recovery. The stress of dealing with the child's mutism may have created various imbalances in family dynamics, and parents may need help in coming to terms with their own emotions and becoming more consistent in their parenting styles. It is also common for parents to begin to recognize their own anxiety as they are learning to help their child. Many times they will seek help in overcoming social anxiety to improve their ability to advocate for their child's needs and to become a positive role model for their child.

KEY TERMS

Amygdala—An almond-shaped brain structure in the limbic system that is activated in stressful situations to trigger the emotion of fear. It is thought that the emotional overreactions in Alzheimer's patients are related to the destruction of neurons in the amygdala.

Autism—A developmental disability that appears early in life, in which normal brain development is disrupted and social and communication skills are retarded, sometimes severely.

Behavior modification—A form of therapy that uses rewards to reinforce desired behavior. An example would be to give a child a piece of chocolate for grooming appropriately.

Cognitive-behavioral therapy—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Family therapy—A type of therapy in which the entire immediate family participates.

Play therapy—A type of psychotherapy for young children involving the use of toys and games to build a therapeutic relationship and encourage the child's self-expression.

Myers-Briggs Type Indicator

Definition

The Myers-Briggs Type Indicator (MBTI) is a widely used personality inventory, or test, employed in vocational, educational, and psychotherapy settings to evaluate personality type in adolescents and adults age 14 and older.

Purpose

In an educational setting, the MBTI may be performed to assess student learning style. In a classroom setting, the MBTI may be used to help teens and young adults better understand their learning, communication, and social interaction styles. Guidance counselors also might use the test to help teens determine which occupational field or college major they might be best suited for.

Because the MBTI is also a tool for self-discovery, mental health professionals may administer the test in counseling sessions to provide their patients with insight into their behavior. Among adults, the MBTI is also used in organizational settings to assess management skills and facilitate teamwork and problem solving.

Description

In 2000, an estimated two million people took the MBTI, making it the most frequently used personality inventory available. First introduced in 1942, the test was the work of mother and daughter Katharine C. Myers Briggs and Isabel Briggs. There are now several different versions of the test available. Form M, which contains 93 items and is a self-scoring **assessment**, is the most commonly used. It can be used in a classroom or other group setting, and takes approximately 15 to 25 minutes to complete.

The Myers-Briggs inventory is based on Carl Jung's theory of types, outlined in his 1921 work *Psychological Types*. Jung's theory holds that human beings are either introverts or extraverts, and their behavior follows from these inborn psychological types. He also believed that people take in and process information in different ways, based on their personality traits.

The Myers-Briggs evaluates personality type and preference based on the four Jungian psychological types:

- extraversion (E) or introversion (I)
- sensing (S) or intuition (N)
- thinking (T) or feeling (F)
- judging (J) or perceiving (P)

A derivative version of the MBTI, developed by Elizabeth Murphy and Charles Meisgeier, is available for children age seven through 13 (grades two through eight). The assessment, called the Murphy-Meisgeier Type Indicator for Children (MMTIC) uses the same four psychological types as the MBTI, but is written for a second grade reading level.

Precautions

The MBTI should only be administered, scored, and interpreted by a professional trained in its use (except in the case of Form M, which can be self-scored but should still be administered and interpreted by a professional). Cultural and language differences in the test subject may affect performance and may result in inaccurate test results. The test administrator should be informed before testing begins if the test taker is not fluent in English and/or he or she has a unique cultural background.

Preparation

Prior to the administration of the MBTI, the test subject should be fully informed about the nature of the test and its intended use. He or she should also receive standardized instructions for taking the test and any information on the confidentiality of the results.

KEY TERMS

Multi-tasking—Performing multiple duties or taking on multiple responsibilities and roles simultaneously.

Vocational—Relating to an occupation, career, or job.

Normal results

Myers-Briggs results are reported as a four-letter personality type (e.g., ESTP, ISFJ). Each letter corresponds to an individual's preference in each of the four pairs of personality indicators (i.e., E or I, S or N, T or F, and J or P). There are a total of sixteen possible combinations of personality types on the MBTI.

- Letter One: E or I: Extraverts focus more on people and things, introverts on ideas.
- Letter Two: S or N: Sensing-dominant personalities prefer to perceive things through sight, sound, taste, touch, and smell, while intuition-dominant types look to past experience and are more abstract in their thinking.
- Letter Three: T or F: The third subtype is a measure of how people use judgment. Thinking types use logic to judge the world, while feeling types tend to view things on the basis of what emotions they invoke.
- Letter Four: J or P: Everyone judges and perceives, but those who are judging dominant are said to be more methodical and results-oriented, while perceiving dominant personalities are good at multi-tasking and are flexible.

Risks

There are no risks involved with the Myers-Briggs Type Indicator test.

Parental concerns

When interpreting test results, the test administrator will review what the test evaluates, its precision in evaluation and any margins of error involved in scoring, and what the individual scores mean in the context of overall norms for the test and the background of the adolescent.

Myopathies

Definition

Myopathies are diseases of skeletal muscle that are not caused by nerve disorders. These diseases cause the skeletal or voluntary muscles to become weak or shrunken (atrophied).

Description

There are many different types of myopathies. Some are inherited, some inflammatory, and some caused by endocrine or metabolic problems. Myopathies usually are not fatal. Typically they cause muscle weakness and movement problems. The shoulders and thigh muscles are usually, but not always, affected earlier than the muscles of the hands and feet. Most myopathies are degenerative, meaning they become more pronounced over time. Some weaknesses are transitory. Only rarely do individuals become dependent on a wheelchair. However, **muscular dystrophy** (technically a myopathy) is far more severe. Some types of muscular dystrophy are fatal in early adulthood.

Causes and symptoms

There is great variety among myopathies, but what they all share are effects on the skeletal muscles. The main causes of myopathies are genetic, inflammatory (caused by infection), endocrine (hormonal), and metabolic (errors in how cells function). Often the cause of the myopathy is not known (idiopathic disease).

Genetic myopathies

Among their many functions, genes are responsible for overseeing the production of proteins important in maintaining healthy cells. Muscle cells produce thousands of proteins. With each of the inherited myopathies, a genetic defect is linked to a lack of, or defect in, one of the proteins needed for normal muscle cell function.

There are several different kinds of myopathy caused by defective genes:

- central core disease
- centronuclear (myotubular) myopathy
- myotonia congenita
- nemaline myopathy
- paramyotonia congenita
- periodic paralysis (hypokalemic and hyperkalemic forms)
- mitochondrial myopathies

Most, but not all, of these genetic myopathies are inherited through an autosomal dominant pattern of inheritance. In this pattern of inheritance, one copy of each gene comes from each parent. Only one of these two copies needs to have the mutation (change) or defect in order for the child to have the disease. The parent with the defective gene has the disease, and each of this parent's children has a 50 percent chance of inheriting the disease. This percentage is not changed by results of other pregnancies. With this pattern of inheritance, male and female children are equally at risk of developing the disease.

However, for a child to have one type of myotonia congenita and some forms of nemaline myopathy, two defective genes must be inherited—one from each parents. This is called an autosomal recessive pattern of inheritance. Neither parent may have symptoms of the disease, but each carries a recessive defective gene for it. Each child of such parents has a 25 percent chance of inheriting both genes and showing signs of the disease, and a 50 percent chance of inheriting one defective gene

from only one parent. If the child has inherited just one defective gene, he or she will be a carrier of the disease and can pass the gene on to his or her offspring, while showing no signs of the disease himself.

A few forms of centronuclear myopathy develop primarily in males. Females who inherit the defective gene are usually carriers without symptoms, like their mothers, but they can pass on the disease to their sons. Mitochondrial myopathies are inherited only through the mother, since sperm do not contain mitochondria.

The major symptoms associated with the genetic myopathies are:

- Central core disease: mild weakness of voluntary muscles, especially in the hips and legs; hip displacement; delays in reaching developmental motor milestones; problems with running, jumping, and climbing stairs develop in childhood.
- Centronuclear myopathy: weakness of voluntary muscles, including those on the face, arms, legs, and trunk; drooping upper eyelids; facial weakness; foot drop; affected muscles almost always lack reflexes.
- Myotonia congenita: voluntary muscles of the arms, legs, and face stiff or slow to relax after contracting (myotonia); stiffness triggered by fatigue, stress, cold, or long rest periods, such as a night's **sleep**; stiffness can be relieved by repeated movement of the affected muscles.
- Nemaline myopathy: moderate weakness of voluntary muscles in the arms, legs, and trunk; mild weakness of facial muscles; delays in reaching developmental motor milestones; decreased or absent reflexes in affected muscles; long, narrow face; high-arched palate; jaw projects beyond upper part of the face.
- Paramyotonia congenita: stiffness of voluntary muscles in the face, hands, and forearms; attacks spontaneous or triggered by cold temperatures; stiffness made worse by repeated movement; episodes of stiffness last longer than those seen in myotonia congenita.
- Periodic paralysis: attacks of temporary muscle weakness (muscles work normally between attacks); in the hypokalemic (low potassium) form, attacks triggered by vigorous **exercise**, heavy meals high in carbohydrates, insulin, stress, alcohol, infection, pregnancy; in the hyperkalemic (high potassium) form, attacks triggered by vigorous exercise, stress, pregnancy, missing a meal, steroid drugs, high potassium intake.
- Mitochondrial myopathies: symptoms vary quite widely with the form of the disease and may include progressive weakness of the eye muscles (ocular myopathy), weakness of the arms and legs, or multi-system problems primarily involving the brain and muscles.

Endocrine-related myopathies

In some cases, myopathies can be caused by a malfunctioning endocrine gland that produces either too much or too little of the chemical messengers called hormones. Hormones travel through the bloodstream. One of their many functions is to help regulate muscle activity. Problems in producing hormones can lead to muscle weakness.

Hyperthyroid myopathy and hypothyroid myopathy affect different muscles in different ways. Hyperthyroid myopathy occurs when the thyroid gland produces too much of the hormone thyroxine, leading to muscle weakness, some muscle wasting in hips and shoulders, and, sometimes, problems with eye muscles. The hypothyroid type of myopathy occurs when too little hormone is produced, leading to stiffness, cramps, and weakness of arm and leg muscles.

Inflammatory myopathies

Some myopathies are caused by inflammation. Inflammation is a protective response of injured tissues characterized by redness, increased heat, swelling, and/or **pain** in the affected area. Examples of this type of myopathy include **dermatomyositis**, polymyositis, and myositis ossificans.

Dermatomyositis is a disease of the connective tissue that also involves weak, tender, inflamed muscles. Muscle tissue loss may be so severe that the individual may be unable to walk. Skin inflammation is also present. The cause of dermatomyositis is as of 2004 unknown, but viral infection and antibiotic use are associated with the condition. In some cases, dermatomyositis is associated with rheumatologic disease or **cancer**. Polymyositis involves inflammation of many muscles, usually accompanied by deformity, swelling, sleeplessness, pain, sweating, and tension. It, too, may be associated with cancer. Myositis ossificans is a rare inherited disease in which muscle tissue is replaced by bone, beginning in childhood.

Muscular dystrophies

While considered a separate group of diseases, the muscular dystrophies also involve muscle wasting and can be described as myopathies. Symptoms of muscular dystrophy (MD) diseases usually appear during childhood and **adolescence**. These are genetic disorders that result in defects in the production of specific proteins. The forms of muscular dystrophy differ according to the way they are inherited, the age at which symptoms begin, the muscles they affect, and how fast they progress.

Demographics

Myopathies are not common. About 14 percent of myopathies are inherited. Worldwide the rate of inflammatory myopathies is about five to ten individuals per 100,000. These myopathies are more often seen in women. MD is found in about 63 of every 1 million individuals, but the rates vary widely depending on the type of MD. The most common type is Duchenne MD, affecting one in every 3,300 boys. Other more common types of MD are Becker's, **myotonic dystrophy**, limb-girdle MD, and facioscapulohumeral MD. MD is more common in boys. The rate of metabolic and endocrine myopathies was, as of 2004, not known.

When to call the doctor

Parents should let the doctor know as soon as possible if there is a **family** history of muscle weakness or muscle wasting disease. Otherwise, they should contact their pediatrician if the child is showing any signs of delayed or abnormal growth or unexplained muscle weakness.

Diagnosis

Early diagnosis of myopathy is important in order to provide the best care possible. An experienced physician can diagnose a myopathy by evaluating a child's medical history and by performing a thorough physical examination. Diagnostic tests can help differentiate among the different types of myopathies, as well as between myopathy and other neuromuscular disorders. If the doctor suspects a genetic myopathy, a thorough family history will also be taken. Genetic tests are available for a few myopathies.

Diagnostic tests the doctor may order include: measurements of potassium, (K) creatine kinase,(CK) lactic dehydrogenase (LDH) and pyruvate kinase (PK) and certain antibodies in the blood; muscle tissue biopsy; and electromyogram (EMG).

Treatment

As of 2004, there was no cure for many myopathies. Treatment depends on the specific type of myopathy the person has and is aimed at controlling symptoms. Specific treatment approaches for specific forms of myopathies are as follows:

- periodic paralysis: medication and dietary changes
- hyperthyroid or hypothyroid myopathy: treatment of the underlying thyroid abnormality
- myositis ossificans: medication to help prevent abnormal bone formation, but there is no cure following onset

KEY TERMS

Electrooculography (EOG)—A diagnostic test that records the electrical activity of the muscles that control eye movement.

Hyperkalemia—An abnormally high level of potassium in the blood.

Hypokalemia—A condition characterized by a deficiency of potassium in the blood.

Inflammation—Pain, redness, swelling, and heat that develop in response to tissue irritation or injury. It usually is caused by the immune system's response to the body's contact with a foreign substance, such as an allergen or pathogen.

Mitochondria—Spherical or rod-shaped structures of the cell. Mitochondria contain genetic material (DNA and RNA) and are responsible for converting food to energy.

Voluntary muscles—Muscles that can be moved by conscious thought.

- central core disease: no treatment
- nemaline myopathy: no treatment
- centronuclear (myotubular) myopathy: no treatment
- paramyotonia congenita: treatment often unnecessary
- myotonia congenita: drug treatment (if necessary), but drugs do not affect the underlying disease, and attacks may still occur

General treatments aim at supporting the individual's functioning and independence. Physical therapy can help preserve or increase strength and flexibility in muscles. Ankle and wrist braces can support weakened limbs. Occupational therapy is used to develop tools and techniques to compensate for loss of strength and dexterity. A speech-language pathologist can provide retraining for weakness in the muscles controlling speech and swallowing.

Prognosis

The prognosis for patients with myopathy depends on the type and severity of the individual's disease. In most cases, the myopathy symptoms can be successfully treated, but in others, the disease can be fatal in childhood or adolescence.

Muscular dystrophy is generally a more serious disease than many other types of myopathies. Duchenne's

MD is usually fatal by the late teens; Becker's MD is less serious and may not be fatal until the 50s.

Prevention

As of 2004 there is no way to prevent the genetic mutations that cause myopathies, nor are there ways to prevent metabolic and endocrine failures that result in myopathies. Inflammatory myopathies often occur as a result of exposure to viruses or drugs, but it is almost impossible to predict their development.

Parental concerns

Individuals with known myopathies who wish to become parents may want to seek genetic counseling before attempting to have children.

Myopia

Definition

Myopia, or nearsightedness, is a condition in which objects in the distance are blurred either because the eye is too long or too strong. It is the result of both environmental and genetic factors.

Description

The degree to which one is myopic depends on the powers of the cornea and the lens of the eye and the length of the eyeball. In a normal eye the incoming visual images meet on the retina in the back of the eye. If these visual images converge in front of the retina instead of on the retina, then one is myopic.

There are several types of myopia, of which simple myopia is the most common. Individuals with simple myopia have eyes that are either too long or too powerful. Congenital myopia develops in infants. Individuals with high myopia, greater than six diopters, can develop pathological changes in the retina, called degenerative myopia. Nocturnal myopia, another type of myopia sometimes referred to as "night blindness," is blurred vision only in darkness. Myopia can also be induced by co-existing medical problems and drug exposure.

A child's refractive status or power of the eye when he or she begins school is a good indicator of whether the child will become nearsighted. Most children are hyperopic, or far-sighted, at birth and experience a decrease in far-sightedness throughout early childhood. Myopia is less likely to develop by age 13 if a child still has at least 0.75 diopters of hyperopia at age eight. But if a child has become at least 0.25 diopters myopic at this age then there is a 60 percent chance that the child will require spectacle correction for nearsightedness by age 13.

Myopia does decreases in later life. This appears not to be related to a decrease in close work as is often suggested but rather due to some factor intrinsically related to ageing. It has been hypothesized the power of the lens of the eye changes in later life.

High myopia has been associated with various syndromes: Ehlers-Danlos, Marfan, Down, and Stickler syndromes. Myopia is often observed in retinopathy of **prematurity** (ROP). ROP is seen in 68 percent of infants with low birth weights and over 80 percent of infants born with ROP will be myopic. The myopia associated with ROP increases through age five, after which it stabilizes.

Transmission

Although no gene for myopia has been isolated, heredity is believed to play a role in myopia. If both parents are myopic, then the odds that the child will be myopic are as high as 60 percent. This drops to at most 40 percent when only one parent is nearsighted, and for 15 percent of myopic children, neither parent has myopia. High myopia is especially likely to have a genetic component.

Demographics

Overall, 25 percent of those living in the United States are myopic. Myopia is slightly more prevalent among females than males, and among those with advanced academic training. Less than 5 percent of five year olds are myopic, but this percentage increases to 25 percent by late teens and to approximately 35 percent for young adults and to 42 percent of those middle-aged. These percentages decrease to 20 percent by age 65 and to less than 13 percent by age 80.

Myopia is more prevalent in Asian countries; as much as 70 percent of the Chinese population is nearsighted.

Causes and symptoms

Congenital myopia develops because of an obstruction along the visual pathway such as cataract. The eye becomes elongated in response to blur these causes, creating a myopic eye.

A first sign that a child might have myopia is difficulty in seeing things in the distance, such as the chalkboard. The child may not see things in the distance as well as a classmate or sibling.

For the 2 percent of the population who are extremely nearsighted, an inherently weak sclera, whose fibers are not held together tightly, causes the eye to stretch. This stretching can continue into adulthood, increasing myopia.

Other causes of increasing nearsightedness include difficulty with converging, the process through which the eyes move inwardly together when reading, and esophoria, the condition in which the eyes are more comfortable positioned close to the nose. Doing a lot of close work, such as playing **video games** and using the computer for extended periods, may increase myopia for these children.

Causes of induced myopia include cataracts and elevations of blood sugar in diagnosed or undiagnosed diabetics. Some drugs, such as corticosteroids, **antihistamines**, and some **antibiotics**, including **sulfonamides**, can induce myopia.

Another cause of increasing myopia is the over wearing of **contact lenses**. Swelling of the cornea can occur if the eye does not have sufficient oxygen causing a transient increase in myopia. Silicone contact lenses allow a marked increase in oxygen to reach the eye decreasing the probability of myopic increases.

For the child with diabetes, fluctuations in blood sugars can cause swelling of the cornea of the eye, leading to transient increases in myopia, which stabilize once the diabetes is controlled. But the child may independently become more myopic later in life.

In the early 2000s, it has been suggested that insulin resistance, which accompanies type 2 diabetes and prediabetes, may increase myopia in children and adolescents. The level of insulin-like growth factor binding protein 3 (IGFBP-3), a hormone that works with insulin to lower blood glucose levels, is low in individuals who are insulin resistant. This decreased level, in turn, decreases the sensitivity of ocular tissue to another compound called retinoic acid, which prevents increases in the length of the eye. Thus, if insulin levels are higher than normal, the risk of myopia may be increased.

Asthenopia or a feeling of eye strain is not common in myopia. If a child complains of eye strain, then usually there is another cause of the eye strain, including an astigmatism, a condition in which the eye is football shaped; anisometropia, a condition in which the eyes are of different powers; or difficulty with focusing.

When to call the doctor

There are many reasons why a child cannot see well in the distance. Myopia is the most common cause of distance blur, and since much of what a child learns comes from vision and visual cues, correction of myopia is important. Also, problems with vision may be a sign of a more serious ocular problem, such as cataracts, or of a medical problem, such as diabetes.

Diagnosis

Myopia is diagnosed by determining a child's unaided vision and is confirmed objectively by the eye care practitioner with various techniques, including retinoscopy and refraction.

The type and extent of myopia is determined by additional testing. These tests include an evaluation of the child's binocular vision, his eye movements, his ability to converge and focus on objects close-up, and his ocular health. Dilation of the eye allows the doctor to check for complications of ROP, diabetes, or degenerative myopia. Since children are capable of over focusing, dilation can help the eye care practitioner determine a child's true prescription because the drugs used to dilate also impair this tendency to over focus. Over focusing can cause a child to appear to be myopic when he or she is actually not.

Treatment

Myopia is most commonly treated with spectacles or glasses. Myopia in **preschool** children does not need to be corrected with glasses, unless either anisometropia, a condition in which there is a difference of more than 1.00 diopters between the two eyes, or **amblyopia**, a condition in which a child cannot be corrected to 20/20 with spectacles, is present. As the child enters school, distance vision becomes critical for learning, and children with prescriptions of at least 1.00 diopter of myopia or who have 20/40 vision or worse should be given glasses. Once a child is diagnosed with myopia, he or she should be examined every six months to a year, and each eye should be corrected to 20/20 at each visit. The glasses are then usually worn full time, except for children with difficulty with convergence (esophoria), who may remove their glasses for close work.

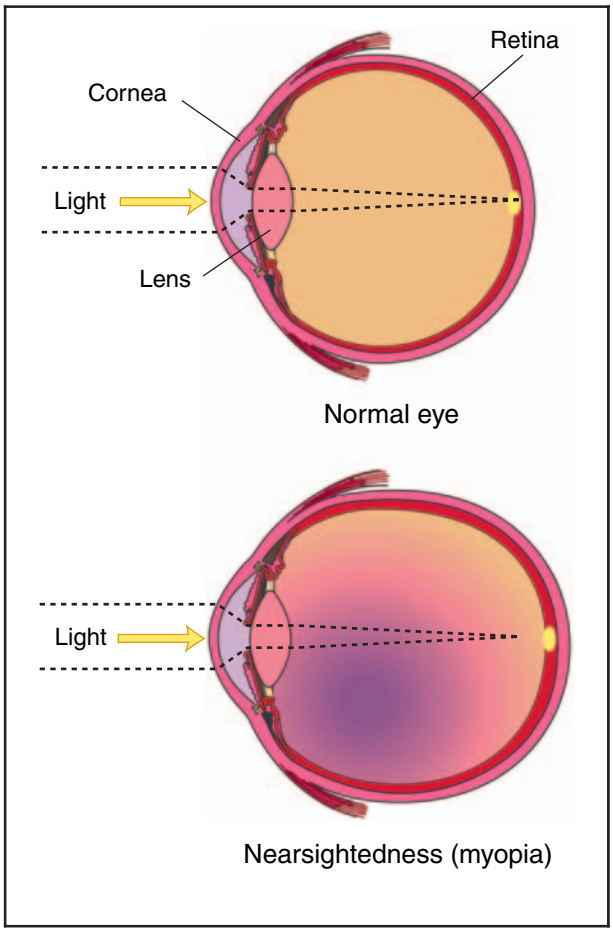
Some adolescents may want to wear contact lenses. Wearing contact lenses can improve appearance. Peripheral vision is improved with contact lenses, especially for those with high degrees of myopia or who have anisometropia.

Rigid gas permeable (RGPs) contact lenses are used to correct myopia. The rate at which myopia increases may be slowed by RGP lenses. RGPs are also employed in orthokeratology, a technique in which RGP lenses of gradually decreasing flatness are worn for specified amounts of time. These lenses, called ortho-K lenses, flatten the cornea, changing the power of the cornea over time and decreasing myopia. This effect of ortho-K lenses is not permanent and an ortho-K lens must be worn periodically or the original myopia reappears. For some individuals—for example, those with keratoconnus, a disease of the cornea—RGPs may offer the only way to correct vision.

For some children the development of myopia may be slowed with reading glasses or bifocals. If bifocals are prescribed, then either progressive or no-lines, or a lined bifocal may be given. If a lined bifocal is prescribed, then the line is always placed higher for the child than for the adult. This is done to encourage use of the power of the bifocal.

Refractive surgery is also used to correct myopia, but only on fully grown individuals. A child's eyes change and the **safety** of these procedures have not been established in the growing eye.

The most common surgical procedure performed to correct myopia is laser in situ keratomileusis (LASIK). Other techniques to correct myopia include photorefractive keratectomy (PRK), radial keratomy (RK), laser epithelial keratomileusis (LASEK), intraocular lens implants and intrastromal corneal rings. Inflammation of the eye, increased dryness of the eye, and cataracts are some of the risks associated with refractive surgery.



Myopia, or nearsightedness, is a condition of the eye in which objects are seen more clearly when close to the eye while distant objects appear blurred or fuzzy. *(Illustration by Electronic Illustrators Group.)*

Alternative treatment

Cycloplegic drugs, such as atropine, may decrease myopia, but they may hinder the child's ability to see up close. As of 2004 pirenzepine, which has shown to decrease the rate of myopia in children without sacrificing the ability of the child to do close work, is in clinical trial.

Prognosis

Most infants are born far-sighted and eventually reach emmetropia or normal vision, by age six. Over one third of children go on to become myopic as adults.

KEY TERMS

Accommodation—The ability of the lens to change its focus from distant to near objects and vice versa. It is achieved through the action of the ciliary muscles that change the shape of the lens.

Anisometropia—An eye condition in which there is an inequality of vision between the two eyes. There may be unequal amounts of nearsightedness, farsightedness, or astigmatism, so that one eye will be in focus while the other will not.

Astigmatism—An eye condition in which the cornea doesn't focus light properly on the retina, resulting in a blurred image.

Cataract—A condition in which the lens of the eye turns cloudy and interferes with vision.

Convergence—The natural movement of the eyes inward to view objects close-up.

Cornea—The clear, dome-shaped outer covering of the eye that lies in front of the iris and pupil. The cornea lets light into the eye.

Diopter (D)—A unit of measure for describing the refractive power of a lens.

Emmetropia—Normal vision.

Retina—The inner, light-sensitive layer of the eye containing rods and cones. The retina transforms the image it receives into electrical signals that are sent to the brain via the optic nerve.

Sclera—The tough, fibrous, white outer protective covering of the eyeball.

Patients with high myopia, greater than 6.00 diopters, have an increased risk of developing a retinal tear, hole, or detachment; a posterior staphyloma; a posterior vitreous detachment; or glaucoma. Rarely are these pathological changes of myopia seen in children or adolescents. Retinal detachments and tears are possible, however, in highly myopic children or adolescents who play contact **sports**. If a retinal problem is diagnosed or suspected, referral to a retinal specialist is necessary.

Prevention

For individuals who have difficulty with convergence or focusing or who are esophoric, close work may increase myopia. Children diagnosed with these problems would benefit from frequent breaks while doing close work. Increases in myopia for these children may be slowed with bifocals and/or removal of glasses for reading and homework.

Nutritional concerns

Since elevated levels of insulin may be associated with increased myopia; a diet low in those foods that increase insulin secretion, such as refined carbohydrates, may help decrease myopia.

Parental concerns

Children rely on their vision in their learning processes; if they have difficulty seeing this handicap affects academic performance. Thus, any vision problem should be corrected promptly. Once myopia is diagnosed, it typically increases through childhood and vision correction is needed for classroom work and for sports. If a child is not corrected fully and continues to have blurred vision, the eye may elongate in response to blur, perpetuating the myopia.

Myopia cannot be diagnosed by school screenings or by simply reading eye chart at the pediatrician's office. A comprehensive eye exam as given by an ophthalmologist or an optometrist is needed, if myopia is suspected. Most cases of myopia result from changes within the eye, but the condition can be a manifestation of other more serious problems, such as cataract or diabetes.

Myotonic dystrophy

Definition

Myotonic dystrophy is a progressive disease in which the muscles are weak and slow to relax after contraction.

Description

Myotonic dystrophy (DM), also called dystrophia myotonica, myotonia atrophica, or Steinert disease, is a common form of **muscular dystrophy**. DM is an inherited disease. It causes general weakness, usually beginning in the muscles of the hands, feet, neck, or face. It slowly progresses to involve other muscle groups, including the heart and a wide variety of other organ systems.

There are four types of DM as determined by when symptoms appear. These are:

- Congenital: Severe symptoms are apparent at birth.
- Juvenile: Symptoms appear between birth and adolescence.
- Adult: Symptoms appear in individuals ages 20–40.
- Late onset: Mild symptoms appear after age 40.

Transmission

DM is an inherited disease. It is passed from parent to child through an autosomal dominant pattern of inheritance. In the case of DM, one copy of each gene is inherited from each parent. In an autosomal dominant pattern of inheritance, only one of these two copies needs to have the mutation (change) or defect in order for the child to have DM. Therefore, there is a 50 percent chance that a parent who has DM will pass it onto each child. This percentage is not changed by results of other pregnancies. In each pregnancy, a parent with DM has a 50% chance of having a child with DM.

Demographics

Myotonic dystrophy is an uncommon disease occurring in about one out of every 8,000 individuals. It is found worldwide. The congenital form of DM is much rarer, occurring in only about one out of every 100,000 births. DM affects males and females approximately equally.

Causes and symptoms

The most common type of DM is called DM1, which is caused by a mutation in a gene called myotonic dystrophy protein kinase (DMPK). The DMPK gene is located on chromosome 19. The specific mutation that causes DM1 is called a trinucleotide repeat expansion. In people who have DM1, a particular unit of the gene is repeated too many times—more than the normal range of five to 38 times—and thus this section of the gene is too big and is unstable. The enlarged section of the gene is called a trinucleotide repeat expansion.

People who have repeat numbers in the normal range will not develop DM1 and cannot pass it to their children. Having more than 50 repeats causes DM1. People who have 38–49 repeats have what is called a premutation. They do not develop DM1, but can pass DM1 on to their children.

Myotonic dystrophy has an effect called "anticipation." This means that when a person with repeat numbers in the affected or premutation range (above 38) has children, the expansion grows larger, and the child has more of the repeated genetic unit (a higher repeat number). As a result, symptoms of the disease tend to appear at an earlier age in children than in their affected parent. Anticipation happens more often when a mother, rather than the father, passes DM1 to children. Occasionally, repeat sizes stay the same or even get smaller when they are passed to a person's children.

In general, the more repeats above 38 an individual has, the earlier the age of onset of symptoms and the more severe the symptoms. Having repeat numbers greater than 1,000 causes congenital myotonic dystrophy. However, this is a general rule. It is not possible to look at a person's repeat number and predict at what age

he or she will begin to have symptoms or how the condition will progress.

Some families with symptoms of DM do not have a mutation in the DMPK gene. Instead, they have a mutation in a gene on chromosome 3 that causes four units within the gene to be repeated. This genetic defect is called DM2 or proximal myotonic myopathia (PROMM). Symptoms of DM2 are almost never apparent at birth. This defect has only been decoded since 2001; therefore, less is known about how it functions.

Symptoms of DM vary in severity, and not everyone will have all of the symptoms. In general, myotonic dystrophy causes weakness and delayed muscle relaxation called myotonia. Exactly how the repeat of genetic information causes myotonia, the inability to relax muscles, is not yet understood. The disease somehow blocks the flow of electrical impulses across the muscle cell membrane. Without proper flow of charged particles, the muscle cannot return to its relaxed state after it has contracted.

The most severe form of DM, congenital myotonic dystrophy, may appear in newborns of mothers who have DM1. Congenital myotonic dystrophy is marked by severe weakness, poor sucking and swallowing responses, respiratory difficulty, delayed motor development, and **mental retardation**. Death in infancy is common in babies with congenital DM.

Symptoms of juvenile and adult onset DM include facial weakness and a slack jaw, drooping eyelids called ptosis, and muscle wasting in the forearms and calves. A person with DM has difficulty relaxing his or her grasp, especially in the cold. DM affects the heart muscle, causing irregularities in the heartbeat. It also affects the muscles of the digestive system, causing **constipation** and other digestive problems. DM may cause cataracts in the eye, retinal degeneration, low IQ, early frontal balding, skin disorders, atrophy of the testicles, and diabetes. It can also cause **sleep** apnea, a condition in which normal breathing is interrupted during sleep. DM increases the need for sleep and decreases motivation. Often, severe disabilities do not set in until about 20 years after symptoms begin. Most people with myotonic dystrophy maintain the ability to walk, even late in life.

Some people who have a trinucleotide repeat expansion in their DMPK gene do not have DM symptoms or have very mild symptoms that go unnoticed. It is not unusual for a woman to be diagnosed with DM after she has an infant with congenital myotonic dystrophy.

When to call the doctor

Parents should let the doctor know as soon as possible if there is a **family** history of DM. Otherwise, they should contact their pediatrician if the child shows any signs of delayed or abnormal growth, or unexplained muscle weakness.

Diagnosis

Diagnosis of DM is not difficult once the disease is considered. However, the diagnosis may be masked because symptoms can begin at any age, can be mild or severe, and can occur with a wide variety of associated complaints. Diagnosis of DM begins with a careful medical history and a thorough physical examination to determine the distribution of symptoms and to rule out other causes. A family history of DM or unexplained weakness helps to establish the diagnosis.

Genetic testing, usually using a blood sample, establishes a definitive diagnosis of DM. The DNA in the blood cells is examined and the number of repeats in the affected gene is determined. Other tests may be done to help establish the diagnosis, but only rarely would other testing be needed. An electromyogram (EMG) is a test used to examine how muscles respond to stimulation. Characteristic changes revealed by this test, and seen in DM, help distinguish it from other muscle diseases. Removing a small piece of muscle tissue for microscopic examination is called a muscle biopsy. DM is marked by characteristic changes in the structure of muscle cells that can be seen on a muscle biopsy. An electrocardiogram could be performed to detect abnormalities in heart rhythm associated with DM. These symptoms often appear later in the course of the disease.

If genetic testing in a family has identified a DMPK mutation, it is possible to test a fetus during pregnancy. Testing can be done at 10–12 weeks gestation by a procedure called chorionic villus sampling (CVS) that involves removing a tiny piece of the placenta and analyzing DNA from its cells. It can also be done by **amniocentesis** after 14 weeks gestation by removing a small amount of the amniotic fluid surrounding the fetus and analyzing the cells in the fluid. Each of these procedures carries a small risk of miscarriage. Those who are interested in learning more should check with their doctor or genetic counselor.

Treatment

Myotonic dystrophy cannot be cured, and no treatment can delay its progression. However, many of its symptoms can be treated. Physical therapy can help

KEY TERMS

Electrocardiagram (ECG, EKG)—A record of the electrical activity of the heart, with each wave being labeled as P, Q, R, S, and T waves. It is often used in the diagnosis of cases of abnormal cardiac rhythm and myocardial damage.

Electromyography (EMG)—A diagnostic test that records the electrical activity of muscles. In the test, small electrodes are placed on or in the skin; the patterns of electrical activity are projected on a screen or over a loudspeaker. This procedure is used to test for muscle disorders, including muscular dystrophy.

Muscular dystrophy—A group of inherited diseases characterized by progressive wasting of the muscles.

Sleep apnea—A sleep disorder characterized by periods of breathing cessation lasting for 10 seconds or more.

Trinucleotide repeat expansion—A sequence of three nucleotides that is repeated too many times in a section of a gene.

preserve or increase strength and flexibility in muscles. Ankle and wrist braces can support weakened limbs. Occupational therapy is used to develop tools and techniques to compensate for loss of strength and dexterity. A speech-language pathologist can provide retraining for weakness in the muscles controlling speech and swallowing.

Irregularities in heartbeat may be treated with medication or a pacemaker. A yearly electrocardiogram is usually recommended. **Diabetes mellitus** in DM is treated in the same way that it is in the general population. A high-fiber diet can help prevent constipation. Sleep apnea may be treated with surgical procedures to open the airways or with nighttime ventilation. Treatment of sleep apnea may reduce drowsiness. Lens replacement surgery is available when cataracts develop.

Prognosis

The course of myotonic dystrophy varies. When symptoms appear earlier in life, disability tends to become more severe. Occasionally people with DM may require a wheelchair later in life. Children with congenital DM often die in infancy. If they survive, they usually require special educational programs and physical and occupational therapies. Respiratory infections pose a danger if weakness becomes severe.

Prevention

There is no way to prevent the genetic mutations that cause DM. However, it is possible to test someone who is at risk for developing DM1 before symptoms arise, to see whether he or she inherited an expanded trinucleotide repeat. This is called predictive testing. Predictive testing cannot determine the age at which someone will begin to have symptoms or the course of the disease.

Another procedure, called preimplantation diagnosis, allows a couple to have a child that does not have the genetic condition. This procedure is still experimental. Those interested in learning more about the procedure should check with their doctor or genetic counselor.

Parental concerns

Pregnant woman should be cared for by an obstetrician familiar with the particular problems of DM because complications can occur during pregnancy, labor, and delivery.

It is advisable for children or adults with DM to wear a medical alert bracelet. Some emergency medications may have dangerous effects on the heart rhythm in a person with DM. Adverse reactions to general anesthesia may also occur.

Myringotomy and ear tubes

Definition

Myringotomy is a surgical procedure in which a small incision is made in the eardrum (the tympanic membrane), usually in both ears. The word comes from *myringa*, modern Latin for drum membrane, and *tomē*, Greek for cutting. It is also called myringocentesis, tympanotomy, tympanostomy, or paracentesis of the tympanic membrane. The doctor can withdraw fluid from the middle ear through the incision.

Ear tubes, or tympanostomy tubes, are small tubes open at both ends that are inserted into the incisions in the eardrums during a myringotomy. The tubes come in various shapes and sizes and are made of plastic, metal, or both. They are left in place until they fall out by themselves or until they are removed by a doctor. Ear tubes are also sometimes called ventilation tubes.

Purpose

Myringotomy with the insertion of ear tubes is an optional treatment for inflammation of the middle ear with fluid collection (effusion), also called glue ear, that lasts more than three months (chronic **otitis media** with effusion) and does not respond to drug treatment. Myringotomy is the recommended treatment if the condition lasts four to six months. Effusion is the collection of fluid that escapes from blood vessels or the lymphatic system. In this case, the effusion collects in the child's middle ear.

Initially, acute inflammation of the middle ear with effusion is treated with one or two courses of antibiotic drugs. **Antihistamines** and **decongestants** have also been used to treat otitis media, but they have not been proven effective unless the child also has hay fever or some other allergic inflammation that contributes to the ear problem. Myringotomy with or without the insertion of ear tubes is *not* recommended as the initial treatment for otherwise healthy children with middle ear inflammation with effusion.

In about 10 percent of children, the ear effusion lasts for three months or longer; at that point the condition is considered chronic. Systemic steroids may help children with chronic ear infections, but the evidence that these drugs are beneficial is not clear, and there are risks associated with steroid use.

Myringotomy with insertion of ear tubes becomes an option when medical treatment does not stop the effusion after three months in a child who is one to three years old, is otherwise healthy, and has hearing loss in both ears. If the effusion lasts for four to six months, myringotomy with insertion of ear tubes may be recommended. Although doctors in the past sometimes removed the child's tonsils or adenoids to treat recurrent otitis media with effusion, this practice is not recommended as of the early 2000s.

Myringotomy may be performed to relieve the **pain** and other symptoms of otitis media; to restore the child's hearing; to take a sample of the fluid to examine in the laboratory in order to identify any microorganisms present; or to insert ventilation tubes.

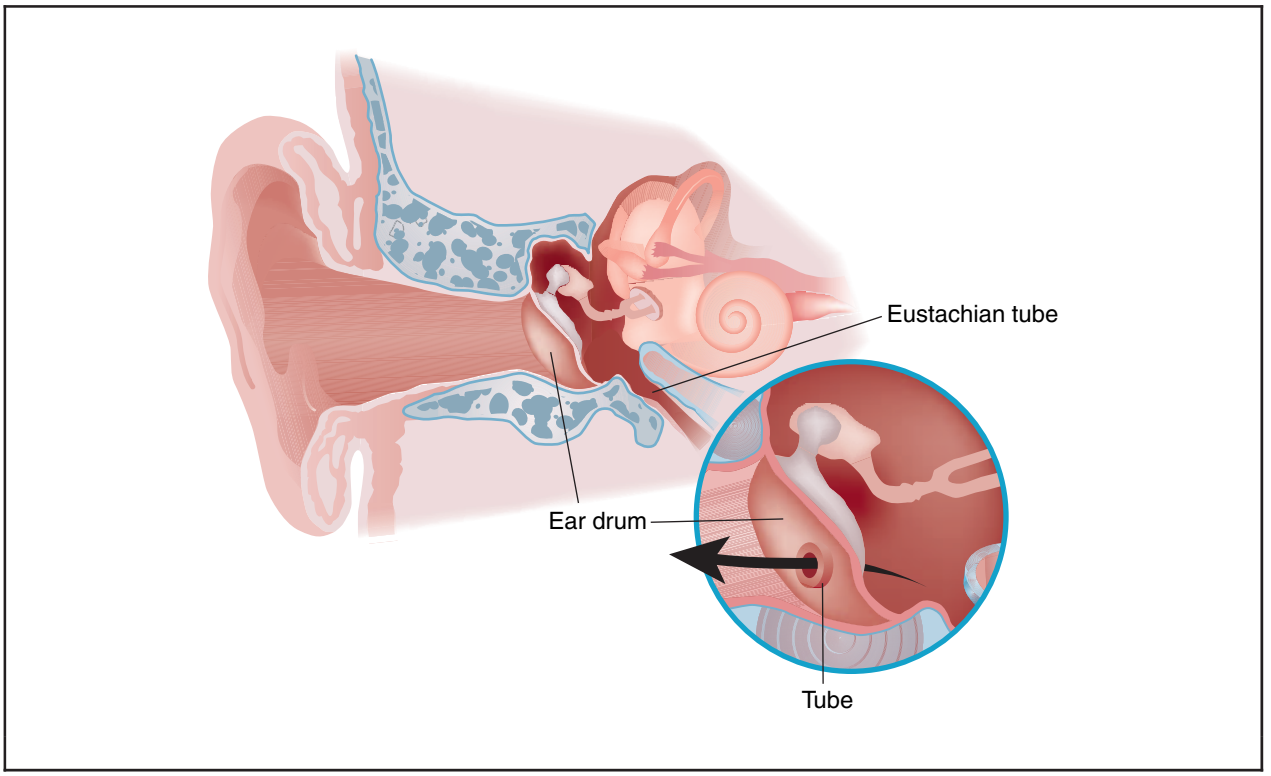
Ear tubes can be inserted into the incision during a myringotomy and left there. The eardrum heals around them, securing them in place. They usually fall out on their own in six to 12 months or are removed by a doctor.

While in place, the tubes keep the incision from closing, forming an open channel between the middle ear and the outer ear. This channel allows fresh air to reach the middle ear, allows fluid to drain out, and prevents pressure from building up in the middle ear. The patient's hearing returns to normal immediately and the risk of recurrence diminishes.

Parents often report that children talk better, hear better, are less irritable, **sleep** better, and behave better after myringotomy with the insertion of ear tubes.

Description

The procedure is usually performed in an ambulatory surgical unit under general anesthesia, although some physicians do it in the office with sedation and local anesthesia, especially in older children. Most primary care physicians prefer to refer children who need a myringotomy and tube placement to an otolaryngologist.



The insertion of ear tubes in the eardrum helps to alleviate chronic middle ear infections. *(Illustration by Argosy, Inc.)*

The ear is washed, a small incision made in the eardrum, the fluid sucked out, a tube inserted, and the ear packed with cotton to control bleeding.

Carbon dioxide lasers may also be used to perform the myringotomy. Laser-assisted myringotomy can be performed in a doctor's office with only a local anesthetic. It has several advantages over the older technique: it is less painful; less frightening to children; and minimizes the need for tube insertion because the hole in the eardrum produced by the laser remains open longer than an incision made with a scalpel. On the other hand, laser-assisted myringotomies have a higher rate of recurrence of infection.

Another technique to keep the incision in the eardrum open without the need for tube insertion is application of a medication called mitomycin C, which was originally developed to treat bladder **cancer**. The mitomycin prevents the incision from sealing over. As of the early 2000s, however, this technique is still in its experimental stages.

Some researchers have designed ear tubes that are easier to insert or to remove or that stay in place longer.

Precautions

As of 2004 clinical practice guidelines emphasized the importance of watchful waiting and medical treatment before performing a myringotomy and the importance of distinguishing between children at risk for speech or hearing problems from otitis media from others with chronic ear infections.

Preparation

A child scheduled for a myringotomy should not have food or water for four to six hours before being given anesthesia. **Antibiotics** are usually not needed before the procedure.

Aftercare

The use of antimicrobial drops after a myringotomy is controversial. Water should be kept out of the ear canal until the eardrum is intact. A doctor should be notified if the tubes fall out.

An additional element of postoperative care is the recommendation by many doctors that the child use ear plugs to keep water out of the ear during bathing or swimming to reduce the risk of infection and discharge.

KEY TERMS

Acute otitis media—Inflammation of the middle ear with signs of infection lasting less than three months.

Chronic otitis media—Inflammation of the middle ear with signs of infection lasting three months or longer.

Effusion—The escape of fluid from blood vessels or the lymphatic system and its collection in a cavity.

Middle ear—The cavity or space between the eardrum and the inner ear. It includes the eardrum, the three little bones (hammer, anvil, and stirrup) that transmit sound to the inner ear, and the eustachian tube, which connects the inner ear to the nasopharynx (the back of the nose).

Tympanic membrane—The eardrum, a thin disc of tissue that separates the outer ear from the middle ear. It can rupture if pressure in the ear is not equalized during airplane ascents and descents.

Tympanostomy tube—An ear tube. A tympanostomy tube is small tube made of metal or plastic that is inserted during myringotomy to ventilate the middle ear.

Risks

The risks of a myringotomy and ear tube placement include the following:

- cutting the outer ear
- formation of granular nodes due to inflammation at the site of the myringotomy
- formation of a cholesteatoma, which is a mass of skin cells and cholesterol in the middle ear that can grow and damage the surrounding bone
- permanent perforation of the eardrum
- hearing loss in late **adolescence** or early adulthood
- a 13 percent risk of persistent discharge from the ear (otorrhea)

If the procedure is repeated, structural changes in the eardrum can occur, such as loss of tone (flaccidity), shrinkage or retraction, or hardening of a spot on the eardrum (tympanosclerosis). The risk of hardening is 51 percent; its effects on hearing were not known as of 2004, but they are probably insignificant.

It is also possible that the incision will not heal properly, leaving a permanent hole in the eardrum, which can cause some hearing loss and increases the risk of infection.

It is also possible that the ear tube will move inward and get trapped in the middle ear rather than move out into the external ear, where it either falls out on its own or can be retrieved by a doctor. The exact incidence of tubes moving inward is not known, but this possibility could increase the risk of further episodes of middle-ear inflammation, inflammation of the eardrum or the part of the skull directly behind the ear, formation of a mass in the middle ear, or infection due to the presence of a foreign body.

The surgery may not be a permanent cure. As many as 30 percent of children undergoing myringotomy with insertion of ear tubes need to undergo another procedure within five years.

The other risks include the usual risks associated with sedatives or general anesthesia.

Parental concerns

Parental concerns with regard to a myringotomy and tube insertion are usually related to the risks associated with the procedure itself, such as the child's reaction to the anesthetic, the possibility that the procedure will have to be repeated at a later date, and the risk of eventual mild hearing loss. These potential complications against the risks of **language delay**, possible learning problems, or hearing loss resulting from chronic otitis media.

Nail-patella syndrome

Definition

Nail-patella syndrome is a genetic disease of the connective tissue that produces defects in the fingernails, bone joints, and kidneys.

Description

Patients who have nail-patella syndrome may show a variety of physical defects. The most common features of this syndrome are missing or poorly developed fingernails, toenails, and patellae (kneecaps). Other common abnormalities include elbow deformities, abnormally shaped pelvis bone (hip bone), and kidney (renal) disease.

Less common medical findings include defects of the upper lip, the roof of the mouth, and unusual skeletal abnormalities. Skeletal abnormalities may include poorly developed shoulder blades (scapulae), sideways bent fingers (clinodactyly), **clubfoot**, **scoliosis**, and unusual neck bones. There are also other effects, such as thickening of the basement membrane in the skin and tiny clusters of capillaries (glomeruli) in the kidney. Nail-patella syndrome is associated with open-angle glaucoma, which, if untreated, may lead to blindness. Patients may also have cataracts, drooping eyelids (ptosis), or corneal problems such as glaucoma. In addition, scientists have recognized an association between nail-patella syndrome and colon **cancer**.

People with nail-patella syndrome may display only a few or many of the recognized signs of this disease, with symptoms varying widely from person to person. Symptoms even vary within a single **family** with multiple affected members.

Nail-patella syndrome is also known as Fong disease, hereditary onycho-osteodysplasia (HOOD), Iliac Horn syndrome, and Turner-Kieser syndrome.

Demographics

Nail-patella syndrome is a rare genetic disease. The incidence of nail-patella syndrome is approximately one in 50,000 births. This disorder affects males and females equally. It is found throughout the world and occurs in all ethnic groups. The strongest risk factor for nail-patella syndrome is a family history of the disease.

Causes and symptoms

Nail-patella syndrome has been recognized as an inherited disorder for over a hundred years. It is caused by mutations in a gene known as LIM Homeobox Transcription Factor 1-Beta (LMX1B), located on the long arm of chromosome 9. The LMX1B gene codes for a protein that is important in organizing embryonic limb development. Mutations in this gene have been detected in many unrelated people with nail-patella syndrome. Scientists have also been able to interrupt this gene in mice to produce defects similar to those seen in human nail-patella syndrome.

Nail-patella syndrome is inherited in an autosomal dominant manner. This means that possession of only one copy of the defective gene is enough to cause disease. When a parent has nail-patella syndrome, each of the children has a 50 percent chance to inherit the disease-causing mutation.

A new mutation causing nail-patella syndrome can also occur, causing disease in a child with no family history of the syndrome. This is called a sporadic occurrence and accounts for approximately 20 percent of cases of nail-patella syndrome. The children of a person with sporadic nail-patella syndrome are also at a 50 percent risk of inheriting the disorder.

Medical signs of nail-patella syndrome vary widely between patients. Some patients with this disorder do not display symptoms. These patients are discovered to have the nail-patella syndrome only when genetic studies are conducted to trace their family history.

The most obvious sign associated with nail-patella syndrome is absent, poorly developed, or unusual fingernails. Fingernail abnormalities are found in about 98 percent of children with this disorder. Abnormalities may be found in one or more fingernails. Only rarely are all fingernails affected. This disease most commonly affects the fingernails of the thumbs and index fingers. The pinky fingernail is least likely to be affected. Fingernails may be small and concave with pitting, ridges, splits, and/or discoloration. Toenails are less often affected.

Kneecap abnormalities, present in about 92 percent of children with this disorder, are the second most common sign associated with this disorder. Either or both kneecaps may be missing or poorly formed. If present, kneecaps are likely to be dislocated. The knees of people with nail-patella syndrome may have a square appearance. Besides the kneecap, other support structures including bones, ligaments, and tendons may also be malformed. Since these support structures stabilize the knee, patients with some leg malformations may have difficulty in walking. There may also be some hip bone anomaly or other skeletal symptoms, for example, clubfoot.

Kidney disease is present in about 30 to 50 percent of people with nail-patella syndrome. Kidney disease has been reported in children with nail-patella syndrome, but renal involvement more commonly develops during adulthood, usually during the fourth decade of life.

Eye problems may be present and vary from person to person. Nail-patella syndrome is thought to be associated with open-angle glaucoma, a condition caused by blockage of the outflow of fluid (aqueous humor) from the front chamber of the eyes. Nail-patella syndrome has also been associated with abnormalities of the cornea, cataracts, and astigmatism. Additionally, the irises of the eye may be multicolored.

When to call the doctor

The doctor should be called if a parent detects the symptoms of nail-patella syndrome in a child previously not diagnosed with the syndrome.

Diagnosis

Genetic testing for nail-patella syndrome is usually available only at research institutions that are working to further characterize this disorder. However, genetic testing cannot predict which signs of the disease will develop nor predict the severity of disease symptoms.

Diagnosis of this disease is most often made on visual medical symptoms such as the characteristic abnormalities of the fingernails and kneecaps. Diagnosis is confirmed by x-ray images of the affected bones and, when indicated, kidney biopsy. The bony pelvic spurs found in children with nail-patella syndrome are not associated with any other disease.

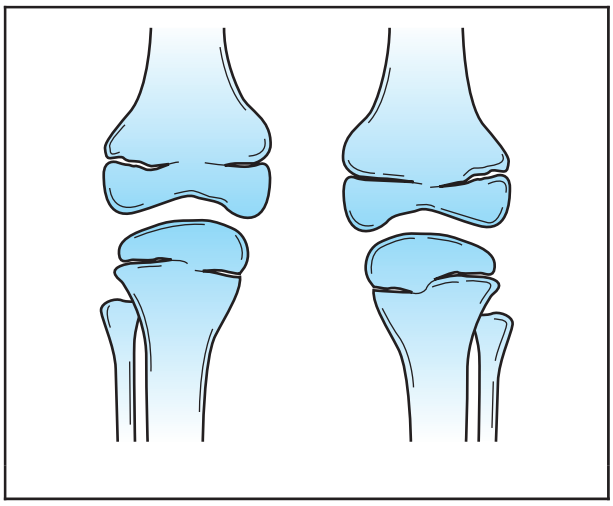

Illustration of bones around the knees showing absence of the patella in nail-patella syndrome. *(Illustration by Argosy, Inc.)*

Treatment

Treatment for children affected by nail-patella syndrome depends on the child's specific symptoms.

A wheelchair may be required if walking becomes painful due to bone, tendon, ligament, or muscle defects. Orthopedic surgery may be necessary for congenital clubfoot deformity. Manipulation or surgery may be required to correct hip dislocation. Cataracts are also surgically treated. Medical treatment at early signs of glaucoma prevents progression of the disease to blindness.

Controlling blood pressure may slow the rate of deterioration of kidney function. Severe kidney disease can be treated with dialysis or a kidney transplant. Children receiving kidney transplants do not develop nail-patella-type renal complications in their new kidney.

Because many possible manifestations of nail-patella syndrome exist, parents are advised to obtain extra medical care for their child with nail-patella syndrome, including regular urinalysis to monitor blood and protein levels to detect kidney disease as well as eye exams to detect glaucoma. Children with nail-patella syndrome should be periodically screened for scoliosis and lordosis.

KEY TERMS

Chorionic villus sampling—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of the chorionic membrane. These cells are then tested for chromosome abnormalities or other genetic diseases.

Glaucoma—A common eye disease characterized by increased fluid pressure in the eye that damages the optic nerve, which carries visual impulses to the brain. Glaucoma can be caused by another eye disorder, such as a tumor or congenital malformation, or can appear without obvious cause, but if untreated it generally leads to blindness.

Glomerulus—Plural, glomeruli; a network of capillaries located in the nephron of the kidney where wastes are filtered from the blood.

Hematuria—The presence of blood in the urine.

Hypnogogic hallucination—A vivid, dream-like hallucination, such as the sensation of falling, that occurs at the onset of sleep.

Patella—The kneecap.

Proteinuria—Abnormally large quantites of protein in the urine.

Prognosis

Symptoms vary from person to person and for one person through time. The long-term prognosis is extremely variable. One person may exhibit mild symptoms, while another person may become wheelchair-bound or require a kidney transplant.

Survival among patients with nail-patella syndrome is not decreased unless they exhibit renal complications. It is estimated that 8 percent of individuals with nail-patella syndrome who come to medical attention eventually die of kidney disease.

Prevention

Genetic counseling can be offered to persons who have the disease. Parents with this disease have a 50 percent chance of passing it to each of their children.

Parental concerns

Families may wish to seek counseling regarding the effects on relationships within the family after the birth of a child with nail-patella syndrome, for many people respond with guilt, **fear**, or blame when a genetic disorder is manifested within a family. Support groups are often good sources of information about nail-patella syndrome and can offer emotional and psychological support.

Narcolepsy

Definition

Narcolepsy is a disorder of the nervous system marked by excessive daytime sleepiness, uncontrollable **sleep** attacks, and cataplexy (a sudden loss of muscle tone, usually lasting up to half an hour). The American Psychiatric Association (APA) classifies narcolepsy as a sleep disorder in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM-IV*. The National Institute of Neurological Disorders and Stroke (NINDS) defines narcolepsy as a "disorder caused by the brain's inability to regulate sleep-wake cycles normally." The disorder is sometimes called Gélineau's syndrome because it was first identified in 1880 by the French neurologist Jean-Baptiste Gélineau. The word *narcolepsy* itself comes from two Greek words that together mean "seized by sleepiness."

Description

Narcolepsy is the second-leading cause of excessive daytime sleepiness (after obstructive sleep apnea). Persistent sleepiness and sleep attacks are the hallmarks of this condition. The sleepiness has been compared to the

feeling of trying to stay awake after not sleeping for two or three days. It is not correct, however, to describe people with narcolepsy as sleeping longer or spending more time asleep in a 24-hour period than people without the disorder. Although patients with narcolepsy experience drowsiness and sleep attacks during the daytime, they also wake up frequently during the nighttime hours. For this reason, narcolepsy is more accurately described as a disorder of the normal boundaries between sleep and wakefulness.

People with narcolepsy fall asleep suddenly—anywhere, at any time, maybe even in the middle of a conversation. These sleep attacks can last from a few seconds to more than an hour. Depending on where they occur, they may be mildly inconvenient or even dangerous. Some people continue to function outwardly during the sleep episodes, such as talking or putting things away. But when they wake up, they have no memory of the event.

Narcolepsy is related to the deep, dreaming part of sleep known as rapid eye movement (REM) sleep. Normally when people fall asleep, they experience 80 to 100 minutes of non-REM sleep, which is then followed by about 20 minutes of REM sleep. People with narcolepsy, however, enter REM sleep immediately. In addition, REM sleep occurs inappropriately throughout the day in patients with narcolepsy.

Demographics

There has been considerable debate in the early 2000s over the incidence of narcolepsy. Some researchers think the disorder is underdiagnosed. According to NINDS, the disorder affects one American in every 2000, or about 135,000 people in the general United States population. However, the rates in other countries vary considerably, from one in 600 people in Japan to one in 500,000 in Israel. The reasons for these variations in different ethnic groups are not yet fully understood.

Males and females seem to experience this disorder at about the same rate.

Narcolepsy is a somewhat unusual disorder in terms of age distribution. Although the disorder has been identified in children as young as three years of age, most patients with narcolepsy are diagnosed either between the ages of ten and 25 or between the ages of 40 and 45. It is uncommon for a person to develop the signs of narcolepsy for the first time after age 55.

Causes and symptoms

Causes

In 1999 researchers identified the gene that causes narcolepsy on chromosome 12. The gene allows cells in the hypothalamus (the part of the brain that regulates sleep behavior) to receive messages from other cells. When this gene is abnormal, cells cannot communicate properly, and abnormal sleeping patterns develop. However, not everyone who has the gene develops narcolepsy; between 12 percent and 35 percent of the United States population is thought to carry the gene but only 0.02 percent develop the disorder. Narcolepsy sometimes clusters in families; first-degree relatives of a person diagnosed with the disorder have a 1 percent to 2 percent risk of developing narcolepsy themselves, or about 10 to 40 times the risk of a person in the general population.

In the late 1990s, three independent research groups discovered a neuropeptide system in the hypothalamus, the part of the brain that regulates body temperature and appetite. The newly discovered system, which has been called the hypocretinergic system, regulates sleep and wakefulness. The nerve cells, or neurons, in this part of the hypothalamus secrete substances known as hypocretins or orexins, which regulate the sleep/wake cycle in humans. There are two of these compounds, known as orexin-A and orexin-B, or as hypocretin-1 and hypocretin-2. As of the early 2000s, narcolepsy is thought to be an orexin deficiency syndrome; that is, it develops when a person's hypothalamus does not secrete enough orexins to keep the person from falling asleep at inappropriate times. Samples of cerebrospinal fluid taken from patients with narcolepsy contain little or no orexins. MRI scans of these patients indicate that there is some loss of brain tissue in the hypothalamus itself, suggesting that the neurons responsible for secreting orexins have died.

In a few cases, the first signs of narcolepsy are triggered by traumatic damage to the part of the brain that governs REM sleep or from a rapidly growing tumor that puts pressure on this region of the brain. It is also thought that the hormonal changes of **puberty** may affect this region of the brain in some people.

Symptoms

Narcolepsy is defined by four major symptoms:

- Excessive daytime sleepiness (EDS).
- Cataplexy, the most dramatic symptom of narcolepsy, affecting 75 percent of people with the disorder. During an attack of cataplexy, the person's knees buckle and the neck muscles go slack. In extreme cases, the person may become paralyzed and

fall to the floor. This loss of muscle tone is temporary, lasting from a few seconds to half an hour, but it is frightening to other **family** members or friends. Attacks of cataplexy can occur at any time but are often triggered by such strong emotions as anger, joy, or surprise.

- Hypnagogic hallucinations, intense and sometimes terrifying experiences that occur as the person is falling asleep. The hallucinations may be either visual or auditory. They are thought to represent an intrusion of REM sleep/dreaming into the wakeful state.
- Sleep paralysis, a frightening inability to move shortly after awakening or dozing off.

When to call the doctor

The symptoms of narcolepsy in children below the age of ten are somewhat different from the classical signs of the disorder in adolescents and adults. They may include the following (in addition to cataplexy and daytime sleepiness):

- unexplained falls or dropping of objects
- night terrors
- moodiness and abrupt episodes of irritability
- restlessness and hyperactivity
- difficulty waking up in the morning

Children between the ages of ten and 12 frequently report falling asleep in school or being unable to pay attention during class. In some cases a sudden drop in the child's academic performance is the first indication of narcolepsy.

Parents who suspect that their child may have narcolepsy should consult a specialist (usually a pediatric neurologist) and have the child tested in a sleep clinic. Children with narcolepsy have often been misdiagnosed as having attention-deficit hyperactivity disorder, while adolescents have sometimes been misdiagnosed as having substance abuse or **personality disorders**. The sooner narcolepsy is correctly identified, the better the child's chances of maintaining normal academic and social development.

Diagnosis

Narcolepsy is a complex disorder, and it is not always easy to identify. It takes ten years on average for an individual to be correctly diagnosed. The diagnosis of younger patients is additionally complicated by the fact that children with narcolepsy rarely have all four of the classical symptoms of the disorder as described in adults. Most often, the first symptom in children is an overwhelming feeling of fatigue. After several months or years, cataplexy and the other classical symptoms of the disorder may appear.

The child's doctor will not be able to diagnose narcolepsy on the basis of a routine physical examination. If the child has experienced both excessive daytime sleepiness and cataplexy, a tentative diagnosis may be made on the basis of the patient's history. In addition, the doctor may give the child or adolescent a short self-administered list of eight questions known as the Epworth Sleepiness Scale (ESS). First published by an Australian doctor in 1991, the ESS asks the person to rate how likely they are to doze off or fall asleep in eight different situations from everyday life. A score above ten (maximum score is 24) generally indicates that the doctor should consider laboratory testing for narcolepsy.

Imaging studies are not helpful in diagnosing narcolepsy, although in some cases the doctor may order an MRI or CT scan to rule out a brain tumor or other abnormality in brain structure. Laboratory tests used to evaluate a person for narcolepsy include an overnight polysomnogram (a test in which sleep is monitored with electrocardiography, a video camera, and respiratory parameters). A multiple sleep latency test, which measures sleep latency (onset) and how quickly REM sleep occurs, may also be used. People who have narcolepsy usually fall asleep much more rapidly that people without the disorder, often in less than five minutes.

If the diagnosis is still questionable, a genetic blood test can reveal the existence of certain substances in people who have a tendency to develop narcolepsy. Positive test results suggest but do not prove that the person has narcolepsy. As of the early 2000s, the diagnosis of narcolepsy also can be confirmed by taking a sample of the patient's cerebrospinal fluid by a spinal tap and testing it for the presence of hypocretin-1. Patients with narcolepsy have no hypocretin-1 in their spinal fluid.

Treatment

There is no cure for narcolepsy. The disorder is neither progressive nor fatal, but it is chronic. The symptoms, however, can be managed with a combination of medications and lifestyle adjustments. Amphetamine-like **stimulant drugs** are often prescribed to control drowsiness and sleep attacks. Patients who do not like taking high doses of stimulants may choose to take smaller doses and make adjustments in their lifestyles, such as napping every couple of hours, to relieve daytime sleepiness. **Antidepressants** are also often effective in treating symptoms of abnormal REM sleep.

Newer nonamphetamine wake-promoting drugs are available to treat narcolepsy. These medications lack the unpleasant side effects of amphetamines, particularly jitteriness and **anxiety**. Modafinil (Provigil) is the most commonly prescribed of the newer psychostimulants. As of 2004, however, researchers do not know exactly how modafinil prevents the drowsiness associated with narcolepsy. Its most common side effect is **headache**. A study published in 2003 reported that modafinil appears to be safe for use in children.

With discovery of the gene that causes narcolepsy, researchers are hopeful that therapies can eventually be designed to relieve the symptoms of the disorder.

Alternative treatment

The botanical remedy yohimbe (*Pausinystalia yohimbe*) may be useful in promoting alertness. As with any herbal preparation or medication, however, individuals should check with their healthcare professional before taking the remedy to treat narcolepsy.

Nutritional concerns

Children with narcolepsy sometimes fall asleep while eating, but the disorder itself does not cause or lead to **malnutrition**. Adolescents should be advised to avoid tobacco, **caffeine**, and alcoholic beverages, as these substances can increase daytime sleepiness in patients with narcolepsy.

Prognosis

The symptoms of narcolepsy are more severe when they develop in children than when they emerge in adult life. Narcolepsy is not a degenerative disease, however, and patients do not develop other neurologic symptoms. In fact, older patients often report that their symptoms decrease in severity after age 60. Apart from falls or other accidents, narcolepsy does not affect a person's life expectancy. It can, however, severely interfere with a young person's ability to study, **play**, participate in **sports** and other social activities, and develop close relationships with others. The sooner it is diagnosed and treated, the better the child's outlook for a happy and productive adult life.

Prevention

There is no way to prevent narcolepsy as of the early 2000s.

KEY TERMS

Cataplexy—A symptom of narcolepsy in which there is a sudden episode of muscle weakness triggered by emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to minutes.

Hypocretins—Chemicals secreted in the hypothalamus that regulate the sleep/wake cycle.

Hypothalamus—A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Orexin—Another name for hypocretin, a chemical secreted in the hypothalmus that regulates the sleep/wake cycle. Narcolepsy is sometimes described as an orexin deficiency syndrome.

Sleep paralysis—An abnormal episode of sleep in which the patient cannot move for a few minutes, usually occurring on falling asleep or waking up. Often found in patients with narcolepsy.

Parental concerns

Narcolepsy can affect a family in a number of ways before it is diagnosed. Younger children are at risk of injuring themselves by falling, and adolescents with driving privileges are at high risk of automobile accidents. Poor performance in school and difficulty making friends as a result of irritability or embarrassment over sleep attacks can have a lasting impact on a child's chances of preparation for college or the choice of a challenging and satisfying line of work. In many cases the child is accused of being lazy or stupid, which can have devastating effects on his or her **self-esteem**. Misdiagnoses can lead to inappropriate treatment and psychological depression for the affected child. In addition, sleep attacks and cataplexy can be frightening to other family members who witness them.

Narcolepsy can be particularly stressful for a family when the affected child reaches **adolescence**, because of **peer pressure** to experiment with **smoking** and recreational drugs, and because of resentment about restrictions on learning to drive or use of the family car. Families with a child diagnosed with narcolepsy should consider joining a support group for people affected by the disorder.

Narcotic drugs

Definition

Narcotics are addictive drugs that reduce the user's perception of **pain** and induce euphoria (a feeling of exaggerated and unrealistic well-being). The English word narcotic is derived from the Greek *narkotikos*, which means "numbing" or "deadening." Although the term can refer to any drug that deadens sensation or produces stupor, it is commonly applied to the opioids—that is, to all natural or synthetic drugs that act like morphine.

Description

Historical background

Narcotics are the oldest as well as the strongest **analgesics**, or pain-relieving drugs, known to humans. Ancient Sumerian and Egyptian medical texts dated as early as 4000 B.C. mention the opium poppy (*Papaver somniferum*) as the source of a milky fluid (opium latex) that could be given to relieve coughs and insomnia as well as ease pain. Traditional Chinese medicine recommended the opium poppy, known to Chinese physicians as *ying su ke*, for the treatment of **asthma**, severe **diarrhea**, and dysentery as well as chronic pain and insomnia. Opium latex contains between 10 and 20 percent morphine, which in its purified form is a white crystalline powder with a bitter taste.

Narcotics are central nervous system depressants that produce a stuporous state in the person who takes them. These drugs often induce a state of euphoria or feeling of extreme well-being, and they are powerfully addictive. The body quickly builds a tolerance to narcotics in as little as two to three days, so that greater doses are required to achieve the same effect. Because of the addictive qualities of these drugs, most countries in the

twenty-first century have strict laws regarding the production and distribution of narcotics. These laws became necessary when opium **addiction** in the nineteenth century became a widespread social problem in the developed countries. Opium, which was the first of the opioids to be widely used, had been a common folk remedy for centuries that often led to addiction for the user; in fact, many popular Victorian patent medicines for ''female complaints'' actually contained opium. The invention of the hypodermic needle in the mid-nineteenth century, however, increased the number of addicts because it allowed opioids to be delivered directly into the bloodstream, thereby dramatically increasing their effect.

Classification of narcotics

As of the early 2000s, narcotics are commonly classified into three groups according to their origin:

- Natural derivatives of opium: Narcotics in this group include morphine itself and codeine.
- Partially synthetic drugs derived from morphine: These drugs include heroin, oxycodone (OxyContin), hydromorphone (Dilaudid), and oxymorphone (Numorphan).
- Synthetic compounds that resemble morphine in their chemical structure: Narcotics in this group include fentanyl (Duragesic), levorphanol (Levo-Dromoran), meperidine (Demerol), methadone, and propoxyphene (Darvon).

Narcotics are available in many different forms, ranging from oral, intramuscular, and intravenous preparations to patches that can be applied to the skin (fentanyl). Illegal street heroin can be taken by inhalation as well as by injection.

How narcotics work

The central nervous system in humans and other mammals contains five different types of opioid receptor proteins, located primarily in the brain, spinal cord, and digestive tract. When a person takes an opioid medication, the drug attaches to these opioid receptors in the brain and spinal cord and decreases the person's perception of pain. Narcotics do not, however, reduce or eliminate the cause of the pain.

Some of the opioid receptors (known as mu and sigma receptors) influence a person's perception of pleasure. When a narcotic medication stimulates these receptor proteins, the person typically experiences intense sensations of euphoria or well-being. The speed with which these drugs take effect depends on the method of administration; IV narcotics reach their peak effectiveness within ten minutes, while oral narcotics take about an hour and a half, and skin patches take between two and four hours.

Overdoses of narcotics can cause drowsiness, unconsciousness, and even death because these drugs suppress respiration.

General use

Narcotics have several legitimate uses:

- Analgesic: Doctors frequently prescribe oral codeine and propoxyphene (alone or in combination with aspirin) for pain control after oral surgery, for severe menstrual cramps, and for temporary pain relief after other outpatient surgical procedures. Intravenous narcotics may be given for several days after major surgery to relieve the patient's discomfort. Subsequent methods of administering opioids following surgery include a sustained-release injected form of morphine sulfate (DepoMorphine) and a patient-controlled transdermal system (E-TRANS) that releases doses of fentanyl when the patient pushes a button attached to the arm or upper chest. Intravenous narcotics may also be used for palliative care, to relieve the pain of patients diagnosed with terminal **cancer**.
- Antitussive: Antitussives are medications given to control coughing. Codeine is often effective in relieving severe coughs and is a common ingredient in prescription **cough** mixtures.
- Antidiarrheal: Paregoric, a liquid preparation containing powdered opium, anise oil, and glycerin, is sometimes prescribed for severe diarrhea. The opium in paregoric works to control diarrhea because it slows down the rhythmic contractions of the intestines that ordinarily move food through the digestive tract. Lomotil, another antidiarrheal medication, contains a synthetic opioid known as diphenoxylate; it is often recommended for treating cancer patients with diarrhea caused by radiation therapy.

Precautions

In the United States, opioids are as of 2004 classified as Schedule II drugs under the Controlled Substances Act of 1970. Drugs in this category are described by the government as having a high potential for abuse and a liability for dependence and yet an approved medical use in **pain management**. The corresponding Canadian legislation, the Controlled Drugs and Substances Act of 1997, classifies medications containing any narcotic under the heading (N) but specifies varying levels of regulation ranging from strict controls for highly addictive single-drug products to lesser controls on drugs combin-

ing a narcotic with non-narcotic substances. As both countries' legal controls indicate, narcotics should be used cautiously, for as short a period of time as possible, and only under a doctor's supervision. In particular, they should never be used together with certain other categories of prescription drugs or herbal preparations.

Side effects

In addition to the risk of dependency or addiction, narcotics have a number of physical side effects, including the following:

- **constipation**
- drowsiness
- withdrawal symptoms after extended use (tearing, sweating, diarrhea, **vomiting**, gooseflesh, muscle twitching, runny nose, loss of appetite, and hot or cold flashes)

Interactions

Narcotics can be dangerous because of their potential for deadly interactions with other medications as well as their potential for dependence and addiction. Narcotics should never be combined with other types of drugs that depress the central nervous system. These categories of drugs include the following:

- alcohol
- benzodiazepine tranquilizers, including such drugs as diazepam (Valium), alprazolam (Xanax), and chlordiazepoxide (Librium)
- barbiturates, used to treat insomnia and **anxiety**, including such medications as pentobarbital (Nembutal) and mephobarbital (Mebaral)
- antihistamines, even over-the-counter cold or allergy medications, which can interact with narcotics to intensify drowsiness and repress breathing

Narcotics can also interact with certain herbal preparations to cause central nervous system depression. Anyone taking narcotics for pain relief should avoid using herbal preparations containing kava kava (*Piper methysticum*), valerian (*Valeriana officinalis*), chamomile (*Matricaria recutita*), or lemon balm (*Melissa officinalis*), as these herbs intensify the tendency of opioids to cause drowsiness and slow down breathing. Ginseng (*Panax ginseng*) should also be avoided because it interferes with the pain-relieving qualities of opioid medications.

Prevention

Scientists have attempted to develop ways to use the pain-killing properties of narcotics while counteracting their addictive qualities. Substances known as narcotic or opioid antagonists are drugs that block the actions of narcotics and are used to reverse the side effects of narcotic abuse or an overdose. A class of drugs, a mixture of opioids and opioid antagonists, has been developed so that patients can be relieved of pain without the addictive or other unpleasant side effects associated with narcotics.

Parental concerns

One minor concern that parents may have if the doctor prescribes narcotic medications for their child is that such side effects as constipation or sleepiness are more common and more severe in children younger than 18 years of age.

Far more seriously, narcotic drugs are among those substances used illegally or abused by adolescents. Some researchers estimate that as many as 90 percent of adult drug addicts began a pattern of substance abuse during **adolescence**. Teenagers are particularly likely to begin experimenting with narcotics in the form of prescription cough syrup and such pain relievers as Darvon or OxyContin and to combine narcotics with alcohol or other drugs of abuse. Moreover, although opioid medications account for fewer cases of drug abuse than cocaine, alcohol, or several other drugs, they still account for 4 to 5 percent of emergency room visits. In addition, the death rate of opioid abusers is proportionately significantly higher than the mortality of people who abuse PCP or cocaine.

The American Academy of Child and Adolescent Psychiatry (AACAP) lists opiates as common drugs of abuse among teenagers and notes that children as young as 12 may be using narcotics. In many cases, children can obtain these drugs at home in the form of medications prescribed for other **family** members. Children who are abusing opioid medications may show the following signs:

- euphoria or "feeling no pain"
- constipation
- slurred speech
- shallow breathing
- itching or flushing of the skin
- mental confusion and poor judgment
- bloodshot eyes with small pupils
- nausea and vomiting
- unusual drowsiness

KEY TERMS

Analgesics—A class of pain-relieving medicines, including aspirin and Tylenol.

Antitussive—A drug used to suppress coughing.

Euphoria—A feeling or state of well-being or elation.

Morphine—The principal alkaloid derived from the opium poppy for use as a pain reliever and sedative. In its purified form, it is a white, bitter-tasting crystalline powder.

Narcotic—A drug derived from opium or compounds similar to opium. Such drugs are potent pain relievers and can affect mood and behavior. Long-term use of narcotics can lead to dependence and tolerance. Also known as a narcotic analgesic.

Opium latex—The milky juice or sap of the opium poppy, used to produce morphine.

Palliative—Referring to a drug or a form of care that relieves pain without providing a cure. Persons in severe pain from terminal cancer are often prescribed narcotics as palliative care.

Stupor—A trance-like state that causes a person to appear numb to their environment.

Parents who suspect that their children are abusing opioids, either alone or in combination with other drugs, should get help as soon as possible.

Rebecca Frey, PhD

Nasal trauma

Definition

Nasal trauma is defined as any injury to the nose or related structure that may result in bleeding, a physical deformity, a decreased ability to breathe normally

because of obstruction, or an impaired sense of smell. The injury may be either internal or external.

Description

The human nose is composed of bone, soft tissue, and cartilage. It serves as a passageway for air to flow from the outside environment into the lower respiratory tract and lungs. At the same time the nasal passages warm and humidify the air that enters the body.

Internal injuries to the nose typically occur when a foreign object is placed in the nose or when a person takes in drugs of abuse (inhalants or cocaine) through the nose. External injuries to the nose are usually blunt force injuries related to **sports** participation, criminal violence, **child abuse**, or automobile or bicycle accidents. This type of injury may result in a nasal fracture. The nasal bones are the most frequently fractured facial bones due to their position on the face, and they are the third most common type of bone fracture in general after **fractures** of the wrist and collarbone. A force of only 30 g is required to break the nasal bones, compared to 70 g for the bones in the jaw and 200 g for the bony ridge above the eyes. The pattern of the fracture depends on the direction of the blow to the nose, whether coming from the front, the side, or above the nose. Although not usually life-threatening by itself, a fractured nose may lead to difficulties in breathing as well as facial disfigurement.

Fractures resulting from trauma to the nose may involve the bones of the septum (the partition of bone and cartilage dividing the two nostrils) as well as the bones surrounding the eyes. These bones include the nasal, maxilla, lacrimal, and frontal bones. Direct trauma to the bridge of the nose may also result in damage to a part of the base of the skull known as the cribriform plate. This injury in turn may allow cerebrospinal fluid to leak out of the skull and leave the body through the nose. Fractures may also damage the membranes that line the nasal passages, leading to possible formation of scar tissue, obstruction of the airway, and damage to the child's sense of smell.

In addition to fractures, external injuries of the nose include soft-tissue injuries resulting from **bites** (human and animal), insect **stings**, cuts, or scrapes. Penetrating injuries to the nasal area caused by air gun or BB pellets were as of 2004 also reported with increasing frequency in older children and adolescents. When fired at close range, these pellets can penetrate the skin and cheekbone and lodge in the nasal septum or the sinuses near the nose.

Lastly, nose **piercing** as a fashion trend is a type of intentional injury to the nose that has several possible complications, including infections of the cartilage and soft tissues in the nose; blockage of the airway due to a loosened stud or other nose ornament; and gastrointestinal emergencies caused by accidental swallowing of nose jewelry.

If a patient's nasal trauma leads doctors to suspect child abuse, the incident must be reported to the police.

Demographics

The demographics of nasal trauma vary according to the type of injury. Internal nasal injuries are unusual in infants but occur fairly frequently in toddlers and young children as a result of playfulness or curiosity. Children often insert small hard objects (buttons, coins, watch batteries, dried peas or beans, plastic parts from **toys**, etc.) in their nostrils. One Japanese study of children brought to the emergency room for removal of foreign bodies from the respiratory and digestive tracts found that the nose was the most common location (39.4% of patients) of these objects. Sixty-seven percent of the children treated were between one and four years of age, with two-year-olds the most common age group. Another common cause of injury to the nasal passages in children is scratching or picking the inside of the nose, often as a reaction to dry and **itching** nasal membranes during the heating season in colder climates.

In older children and adolescents, however, the single most common cause of internal nasal injuries is inhalant abuse or ingesting cocaine through the nose ("snorting"). Inhalants include such substances as toluene (paint thinner, nail polish remover, rubber cement, airplane glue), butane (lighter fluid, spray paint, room fresheners, hair spray), chlorinated hydrocarbons (dry cleaning fluid, spot removers, typewriter correction fluid), and acetone (rubber cement, permanent markers, nail polish remover). According to the American Academy of Family Practice (AAFP) and the U.S. Department of Health and Human Services, nearly 20 percent of children in the United States have used inhalants at least once by the time they are in eighth grade. The average age of children experimenting with inhalants is 13, with Hispanic and Caucasian youth more likely to abuse these substances than African Americans. With regard to cocaine, figures from the National Institute on Drug Abuse (NIDA) from the late 1990s indicate that that 3.2 percent of all eighth graders in the United States have used cocaine at least once, although young adults between the ages of 18 to 25 are the age group with the highest usage of the drug.

Nose piercing as a fashion statement is most common among adolescents and young adults. One study of

undergraduates at a university in upstate New York found that 51 percent had body piercing, with the nose and ears the most common sites. Seventeen percent of these students reported medical complications from the piercing, ranging from skin or cartilage infections to periodic bleeding from the nose. A less common cause of internal injuries to the nose in older children and adolescents is the use of magnetized jewelry as a substitute for body piercing. The external piece of jewelry is held in place on the outside of the nostril by a small magnet placed inside the nose. Displacement of these magnets has been reported to cause bleeding and perforation of the nasal septum, while accidental swallowing of these magnets may require emergency surgery. One British hospital reported no fewer than 24 such cases over an eight-week period.

With regard to nasal fractures, one group of American researchers estimates that they account for about 24 percent of all facial fractures. The most common single cause is assault, accounting for 41 percent of nasal fractures. The second most common cause is automobile accidents (27%), followed by **sports injuries** (11%). Falls account for most other nasal fractures in children, although dog bites are reported with increasing frequency as a cause of nasal fractures in children below 16 years of age. Adolescents who have had plastic surgery on the nose (rhinoplasty) are at increased risk of nasal fractures in later life.

As many as 10 percent of nasal injuries in younger children, however, result from physical abuse. Doctors in the early 2000s are advised to consider abuse as a possible diagnosis when evaluating nasal fractures in children under six years of age. Suspected child abuse must be reported to police.

Causes and symptoms

Causes

External trauma to the nose may be accidental (transportation accidents, animal bites, air gun injuries, and sports injuries) or intentional (fights, criminal assault, domestic violence, nose piercing). Nasal injuries from athletic activities may result from contact with equipment (being hit in the face by a baseball, hockey ball, or other small ball hit at high speed, or by the bat or stick itself) or the bodies of other players (football, boxing, martial arts, rugby). Nasal injuries from piercing include bacterial infections of the skin and nasal cartilage, allergic reactions to the jewelry, tissue damage, and periodic bleeding. Direct trauma and/or delayed type hypersensitivity reaction to nickel may occur from nasal rings and jewelry, facial adornments which as of 2004 are increasingly popular.

In a few cases, external trauma to the nose may also be iatrogenic, or caused by medical care. Most of these injuries result from medical examination of the nose—particularly in emergency circumstances—or as complications of plastic surgery.

Internal injuries to the nose may be either mechanical (caused by **foreign objects** in the nose or by picking or scratching the tissues lining the nose) or chemical (caused by environmental irritants or substance abuse).

Chemical injuries to the nose are caused by accidental or purposeful breathing or sniffing of irritating substances. These may include tobacco smoke; household cleaners (ammonia and chlorine bleach) and furniture polish; ozone and other air pollutants; cocaine; and glue, paint thinners, solvents, and similar household products that produce toxic vapors. An increasingly common form of chemical injury to the nasal membranes in toddlers is alkali **burns** caused by leakage from small batteries placed in the nose. While chemical damage to the nose is usually accidental in younger children, it is more often the result of substance abuse in adolescents. Taking cocaine through the nose (''snorting'') or inhalant abuse (''sniffing'' or ''huffing'') are the most common causes of chemical damage to the nose in older children or teenagers.

Symptoms

The symptoms of physical trauma to the nose may include the following:

- flattening or other deformation of the shape of the nose
- infections of the cartilage or soft tissue
- epistaxis, or bleeding from the nose
- crepitus, or the crackling or crunching sound heard when the ends of a fractured bone are rubbed together
- pain and tissue swelling
- airway blockage from bleeding, fluid discharge, or tissue swelling
- **rhinitis** or inflammation of the mucous membranes lining the nose (In the case of a fracture, rhinitis may lead to increased tear production in the eyes and a runny nose.)
- septal hematoma, a mass of blood from torn tissue that may collect within the cartilage that divides the two nostrils (It may become infected and form an abscess that eventually destroys the cartilage.)
- bruising or discoloration (ecchymosis) of the tissues around the eye

- leakage of cerebrospinal fluid through the nostrils

Chemical trauma to the nose may result in the following:

- runny nose and watering of the eyes
- pain
- loss of the sense of smell
- nasal congestion and sneezing
- reddening and swelling of the mucous membranes lining the nose
- eventual destruction of the cartilage in the nasal septum and the tissues lining the nose

When to call the doctor

Parents should call the doctor at once in the event of a nose injury when the following conditions are apparent:

- The child is bleeding profusely from the nose.
- The child is having difficulty breathing normally.
- The injury involves an air gun, BB gun, or animal or human bites.
- The child is seeing double, has other visual disturbances, or staggers when trying to walk.
- The child's nasal discharge is watery as well as bloody.
- The child is known to have inserted a battery into the nose or to have swallowed such a battery or piece of nose jewelry.
- The child's appearance or behavior suggests inhalant or cocaine abuse. Some danger signals are: a chemical odor on the child's breath; constant runny nose; unusual or excessive use of nose drops or **decongestants**; sores inside or around the mouth; stains on the fingernails; dazed appearance; **anxiety**, **sleep** disturbances, **nausea and vomiting**; slurred speech; visual disturbances; and loss of physical coordination.

Diagnosis

History and physical examination

In many cases the diagnosis of an injury to the child's nose is obvious to the doctor from taking a history, particularly if the parent witnessed the accident or saw the child putting something in his nose. The physical examination depends in part on the history. If the child's nose is bleeding without a history of a fall, blow to the face, or other obvious cause, the doctor gently examines inside the nose with a handheld speculum of the type used to examine the ears, in order to see where the nasal bleeding originates. Bleeding from the lower part of the nose is more common and usually less serious. In most cases the doctor is able to tell whether there is a foreign object in the nose or whether the child has been scratching or picking at the nose. Bleeding from the upper part of the nose closer to the throat is more serious because it can block the airway and because it may indicate that the child has a bleeding disorder rather than a traumatic injury. The doctor may then examine the child's throat for signs of blood from the upper nose trickling down into the throat. He or she will remove any blood clots from the nose with suction.

In the case of a known accident, sports injury, or assault, the doctor begins with the ABCs, which means that he or she will check the child's *airway*, *breathing*, and *circulation*. The doctor will usually have the child sit upright or lie on one side, and will remove blood clots, broken teeth, or other foreign bodies from the nose or throat. He or she will then carry out a systematic examination of the child's face and head. The most common pattern of examination moves from the inside of the nose and mouth to the outside of the face and from the bottom of the face to the top.

The doctor looks for signs of bruising and tissue swelling as well as bleeding and gently palpates, or touches, the various facial bones for movement and stability. If the doctor suspects that the nose itself is fractured, he or she will listen for crepitus when the nose is gently moved and will look for evidence of a dislocated septum or a septal hematoma, which will appear as a bluish bulging mass within the nasal septum. The child's teeth will be examined for looseness, and the muscles and nerves of the face will be evaluated. If there is a discharge from the nose, the doctor will look at it to see whether it contains cerebrospinal fluid, which would indicate damage to the bones of the skull as well as the nasal bones. Lastly, the doctor examines the child's eyes to make sure that the pupils are responding normally to light and that the child is not seeing double or having other visual problems that might indicate nerve damage or damage to the eye itself.

In cases involving animal bites or other tearing or crushing injuries to the skin and external tissues of the nose, the doctor carefully cleanses the broken skin with soap and water or disinfectants such as benzalkonium chloride as well as checks for fractured facial bones.

Many of the early signs of inhalant or cocaine abuse are not specific to these disorders; however, a careful history-taking and examination of the child's eyes, nose, and throat may lead the doctor to ask the child or adolescent appropriate questions about his or her use of inhalants or cocaine.

Imaging studies and laboratory tests

Computed tomography (CT) scans are the type of imaging study most commonly done to evaluate suspected nasal fractures. X-ray studies may be ordered to identify the location of a foreign body if it is metal, such as a pellet from a BB gun or air gun, or to evaluate the nasal area for evidence of repeated fractures when abuse is suspected. A blood test will be performed prior to surgery in order to determine the child's blood type, clotting time, and complete blood count. In some cases the doctor may order a filter paper or glucose content test of nasal secretions to check for the presence of cerebrospinal fluid.

In some cases, the physician may ask the child's parents for photographs taken prior to the injury in order to determine the extent of deformity or other injuries to the nose. Photographs may also be taken for documentation if abuse is suspected and also for documentation of injuries for later plastic surgery.

Drug-specific blood or urine tests may be ordered for children or adolescents suspected of abusing inhalants or cocaine.

Treatment

Timing

Nasal injuries should be treated as promptly as possible to lower risk of infection. If the child has been bitten by an animal, the injury must be cleansed as soon as possible to lower the risk of **rabies**. Batteries placed in the nose should be removed as soon as possible, preferably within four hours to avoid serious burns from their contents. If a septal hematoma has developed, the doctor must remove it as quickly as possible to prevent infection or eventual death of the tissues in the nasal septum.

Treatment of nasal fractures is best performed during the first three hours after the injury. If this is impossible, management of a nasal fracture should be done within three to seven days. Timing is of utmost importance when treating nasal fractures because delays longer than seven to 10 days may allow the broken bones to set without proper alignment or lead to such complications as scar tissue formation and airway obstruction. Poorly set nasal fractures usually require surgical correction.

Specific procedures

Foreign objects in the nose can be removed by nasal suction in most cases. Most nosebleeds are treated by five to 30 minutes of direct pressure on the nostrils, with the child's head placed in an upright position. The doctor may also pack the child's nose with gauze coated with petroleum jelly. If the bleeding does not stop or if it appears to originate in the upper nose, the doctor will consult a head and neck surgeon or an otolaryngologist for specialized evaluation of the bleeding.

Air gun or BB pellets that have penetrated the nose or nearby sinuses are generally removed with the help of an endoscope, which is a slender tubular instrument that allows the doctor to examine the inside of a body cavity.

Treatment of nasal fractures depends on the extent of the injury; the most difficult fractures to treat are those that involve the nasal septum. The doctor will usually reduce the fracture, which means that he or she will restore the damaged bones to their proper position and alignment. Although local anesthesia is usually sufficient for treating nasal fractures in adults and older teenagers, general anesthesia is usually given when treating these injuries in younger children.

Reductions of nasal fractures may be either open or closed. A closed reduction involves manipulation of the bones without cutting into the overlying skin. This type of reduction is performed for fractures of the nasal bones that are limited in size and complexity. Open reductions are performed for more complex nasal fractures. In an open reduction, the nasal bones are moved back to their original location after the surgeon has made an incision in the overlying skin. This procedure is done for fractures involving dislocation of the septum as well as the nasal bones. In addition, an open reduction is necessary if the child has a septal hematoma or an open fracture in which the skin has been perforated. If a septal hematoma is present, the doctor will drain it and pack the nose to prevent subsequent accumulation of blood. The nasal bones are held in the proper position with external splints as well as the internal packing, and the splints are kept in place for seven to ten days. The child is given **antibiotics** to lower the risk of infection and may be referred to an otolaryngologist or plastic surgeon for further evaluation. Ice packs or cold compresses can be applied at home to reduce swelling and ease the child's discomfort.

In the case of animal bites, the child may be given passive or active immunization against rabies if there is a chance that the dog or other animal is rabid. This precaution is particularly important for animal bites on the nose or other parts of the face, as the incubation period of the rabies virus is much shorter for bites on the head and neck than for bites elsewhere on the body.

Prognosis

Most types of nasal trauma have a good prognosis. Nosebleeds or tissue damage caused by scratching or picking at the nose usually clear completely once the

child stops these habits. Infections or allergic reactions caused by foreign objects in the nose or piercing usually clear up promptly once the object or piece of jewelry is removed. Nasal fractures that do not involve the nasal septum or other facial bones and receive prompt treatment generally heal without deformities of the nose, cartilage destruction, or other complications. More extensive facial fractures, however, may require a second operation to correct the positioning of the bones and restore the appearance of the nose.

The prognosis for soft-tissue injuries to the nose depends on the cause and extent of the injuries. Such tearing or crushing injuries as those caused by bites take longer to heal than simple cuts and may require plastic surgery at a later date to restore the appearance of the nose.

Damage to the tissues lining the nose caused by exposure to tobacco smoke or other irritants in the environment is usually reversible once the child is removed from contact with the irritating substance. Erosion or destruction of the nasal cartilage as a result of inhalant or cocaine abuse, however, usually requires surgical treatment.

Prevention

Preventive strategies for nasal trauma depend on the child's age group. For younger children, parents should take the following precautions:

- Keep such small objects as coins, disk batteries, and buttons in childproof drawers or cabinets and throw out broken toys or toy parts.
- Use a humidifier during heating season to prevent drying and itching of the nasal membranes and coat the inside of the child's nose with petroleum jelly.
- Quit **smoking** completely or stop smoking inside the house.
- Open windows or otherwise ventilate the room when using ammonia, chlorine bleach, oven cleaner, degreasers, spray paints, dry cleaning fluid, furniture polish, or other household products that give off strong vapors at room temperature. Keep all such products in a childproof cabinet or closet.
- Teach the child basic rules of **safety** in playing with household pets as well as in dealing with large dogs and other animals outside the house. Have pet dogs or cats immunized against rabies.
- Drive safely and make sure the child is using an age-appropriate protective seat or seat belt.
- Make sure that the child understands basic safety precautions and traffic laws before allowing him or her to ride a bicycle in the street.

KEY TERMS

Crepitus—A crackling sound.

Dorsum—The medical term for the bridge of the nose.

Ecchymosis—The medical term for a bruise, or skin discoloration caused by blood seeping from broken capillaries under the skin.

Epistaxis—The medical term used to describe a bleeding from the nose.

Hematoma—A localized collection of blood, often clotted, in body tissue or an organ, usually due to a break or tear in the wall of blood vessel.

Iatrogenic—A condition that is caused by the diagnostic procedures or treatments administered by medical professionals. Iatrogenic conditions may be caused by any number of things including contaminated medical instruments or devices, contaminated blood or implants, or contaminated air within the medical facility.

Otolaryngologist—A doctor who is trained to treat injuries, defects, diseases, or conditions of the ear, nose, and throat. Also sometimes known as an otorhinolaryngologist.

Reduction—The restoration of a body part to its original position after displacement, such as the reduction of a fractured bone by bringing ends or fragments back into original alignment. The use of local or general anesthesia usually accompanies a fracture reduction. If performed by outside manipulation only, the reduction is described as closed; if surgery is necessary, it is described as open. Also describes a chemical reaction in which one or more electrons are added to an atom or molecule.

Rhinitis—Inflammation and swelling of the mucous membranes that line the nasal passages.

Rhinoplasty—Plastic surgery of the nose to repair it or change its shape.

Septum—A wall or partition. Often refers to the muscular wall dividing the left and right heart chambers or the partition in the nose that separates the two nostrils. Also refers to an abnormal fold of tissue down that center of the uterus that can cause infertility.

- Check the home for safety hazards that might lead to falls (for example, loose carpeting, poorly lit stairwells, and toys allowed to lie on the floor after play).
- Teach the child to deal with quarrels with other children without physical fighting and set the child a good example in relationships with others.

For older children and adolescents, parents should take the following steps:

- Set a good example of safe driving and make sure that teenagers have a mature attitude toward driving before they acquire a driver's license.
- Inform themselves about such problems as drug abuse, bullying, or violence in dating relationships, and learn to identify the signs of these problems in their children.
- Make sure that their child's sports teams use the appropriate safety equipment, that the equipment is in good condition, and that the teams have appropriate adult supervision.
- Discourage the child from nose piercing and similar fads or at least make certain that he or she has the procedure done at a reputable business that follows Food and Drug Administration (FDA) guidelines for cleanliness and sterilization of equipment.
- Teach safe and responsible use of BB guns and air guns.

Parental concerns

Parental concerns regarding nasal trauma depend on the cause and severity of the injury. Minor nosebleeds and uncomplicated fractures of the nose caused by accidents generally heal without problems and are quickly absorbed into the family's routine. Complex fractures or other injuries requiring a second operation may require explanation or discussion with the child. Nasal injuries related to the neighborhood environment (street crime, chemical pollution), lifestyle choices (body piercing, smoking in the home), or family dysfunction (substance abuse, domestic violence), however, suggest the need for professional counseling and changes in the family's structure, geographical location, or increased level of functioning.

Rebecca Frey, PhD

Nausea and vomiting

Definition

Nausea is the sensation of being about to vomit. Vomiting, or emesis, is the expelling from the stomach of undigested food through the mouth.

Description

Nausea is a reaction to a number of causes that include overeating, infection, or irritation of the throat or stomach lining. Persistent or recurrent nausea and vomiting should be checked by a doctor.

A doctor should be called if nausea and vomiting occur in the following instances:

- after eating rich or spoiled food or taking a new medication
- repeatedly or for 48 hours or longer
- following intense dizziness

It is important to see a doctor if nausea and vomiting are accompanied by the following:

- yellowing of the skin and whites of the eyes
- **pain** in the chest or lower abdomen
- trouble with swallowing or urination
- **dehydration** or extreme thirst
- drowsiness or confusion
- constant, severe abdominal pain
- a fruity breath odor

Demographics

Nausea and vomiting are commonly experienced. There are no distinctive patterns of age, gender, or race.

Causes and symptoms

Persistent, unexplained, or recurring nausea and vomiting can be symptoms of a variety of serious illnesses. They can be caused by overeating or drinking too much alcohol. These symptoms can be due to stress, certain medications, or illness. For example, people who are given morphine or other opioid medications for pain relief after surgery sometimes feel nauseated by the drug. Such poisonous substances as arsenic and other heavy metals cause nausea and vomiting. Morning sickness is a consequence of pregnancy-related hormone changes. **Motion sickness** can be induced by traveling in a vehicle, plane, or on a boat. Many people experience nausea after eating spoiled food or foods to which they are allergic. Individuals who suffer migraine **headache** often experience nausea. **Cancer** patients receiving **chemotherapy** are often nauseated. Gallstones, **gastroenteritis**, and stomach ulcer may cause nausea and vomiting. These symptoms should be evaluated by a physician.

Nausea and vomiting may also be psychological in origin. Some people vomit under such conditions of emotional stress as **family** arguments, academic tests, airplane travel, losing a job, and similar high-stress situations. In addition, some eating disorders are characterized by self-induced vomiting.

When to call the doctor

A doctor should be notified if vomiting is heavy and/or bloody, if the vomitus looks like feces, or if the affected person has been unable to keep food down for 24 hours. Most vomiting episodes should stop in eight to 12 hours of onset. The pediatrician should be consulted if vomiting continues beyond that time, if the child shows signs of dehydration, seems extremely lethargic, or if the child is a very young infant.

An ambulance or emergency response number should be called immediately if the following occurs:

- The child's mouth and tongue are very dry.
- The child has very rapid heartbeat and breathing.
- The child cries but has no tears.
- The child has sunken eyes.
- Diabetic shock is suspected.
- Nausea and vomiting continue after other symptoms of viral infection have subsided.

- The person has a severe headache.
- The person is sweating and having chest pain and trouble breathing.
- The person is known or suspected to have swallowed a drug overdose or poisonous substance.
- The person has a high body temperature, **muscle cramps**, and other signs of heat exhaustion or heat stroke.
- Nausea, vomiting, and breathing problems occur after exposure to a known allergen.

Diagnosis

Diagnosis is based on the severity, frequency, and duration of symptoms, and other factors that could indicate the presence of a serious illness.

Diagnosis is based on a careful medical history that includes foods recently eaten, travel, and occupation. In some cases, the doctor may order laboratory tests or imaging studies to determine the presence of drugs or poisonous substances in the person's blood or urine, or evidence of head injuries or abnormalities in the digestive tract. If the nausea and vomiting appear to be related to **anxiety**, stress, or an eating disorder, the doctor may refer the person to a psychiatrist for further evaluation.

Treatment

Getting a breath of fresh air or getting away from whatever is causing the nausea can solve the problem. Eating olives or crackers or sucking on a lemon can calm the stomach by absorbing acid and excess fluid. Cola syrup is another proven remedy.

Vomiting relieves nausea quickly but can cause dehydration. Sipping clear juices, weak tea, and some sports drinks helps replace lost fluid and **minerals** without irritating the stomach. Infants and small children under age two do best with an oral rehydration solution like Pedialyte. The solution should be given a teaspoon at a time, at frequent intervals, starting 30–60 minutes after vomiting has ceased. Food should be reintroduced gradually, several hours after vomiting stops, beginning with small amounts of dry, bland food like crackers and toast.

Medications that are given to relieve nausea and vomiting are called antiemetics. Meclizine (Bonine), a medication for motion sickness, also diminishes the feeling of queasiness in the stomach. Dimenhydrinate (Dramamine), another motion-sickness drug, is not effective on other types of nausea and may cause drowsiness.

Other drugs that have been developed to treat post-operative or post-chemotherapy nausea and vomiting include ondansetron (Zofran) and granisetron (Kytril). Intravenous administration of supplemental fluid before the operation can lower the risk of nausea after surgery.

Alternative treatment

Advocates of alternative treatments suggest biofeedback, acupressure and the use of herbs to calm the stomach. Biofeedback uses **exercise** and deep relaxation to control nausea. Acupressure (applying pressure to specific areas of the body) can be applied by wearing a special wristband or by applying firm pressure to the following:

- the back of the jawbone
- the webbing between the thumb and index finger
- the top of the foot
- the inside of the wrist
- the base of the rib cage

Acupuncture is an alternative treatment found to be effective in relieving nausea. A few people, however, experience nausea as a side effect of acupuncture.

Chamomile (*Matricaria recutita*) or lemon balm (*Melissa officinalis*) tea may relieve symptoms. Ginger (*Zingiber officinale*), another natural remedy, can be ingested as tea or taken as candy, cookies, or powdered capsules.

Prognosis

Most instances of nausea and vomiting respond well to appropriate treatment, including removing any substance or condition that precipitates the nausea.

Prevention

Massage, meditation, **yoga**, and other relaxation techniques can help prevent stress-induced nausea. Anti-nausea medication taken before traveling can prevent motion sickness. Sitting in the front seat, focusing on the horizon, and traveling after dark can also minimize symptoms.

Food should be fresh, properly prepared, and eaten slowly. Overeating, tight-fitting clothes, and strenuous activity immediately after a meal should be avoided.

Vomiting related to emotional upsets may be avoided by forms of psychotherapy that teach people to manage stress in healthier ways.

KEY TERMS

Antiemetic drug—A medication that helps control nausea; also called an antinausea drug.

Dehydration—An excessive loss of water from the body. It may follow vomiting, prolonged diarrhea, or excessive sweating.

Diabetic coma—A life-threatening, reduced level of consciousness that occurs in persons with uncontrolled diabetes mellitus.

Emesis—An act or episode of vomiting.

Nutritional concerns

Prolonged vomiting can lead to fluid and electrolyte depletion. Nausea can curtail appetite. Over time, this can lead to nutritional problems.

Parental concerns

Parents should be especially concerned about prolonged vomiting in children younger than two years of age. This concern intensifies if the vomiting is accompanied by **diarrhea** that accelerates fluid and electrolyte depletion. Parents should consult a pediatrician for treatment options if an infant younger than six months of age vomits multiple times within several hours.

Near-drowning

Definition

Near-drowning is the term for survival after suffocation caused by submersion in water or other fluid. Some experts exclude from this definition cases of temporary survival that end in death within 24 hours, which they prefer to classify as drownings.

Description

Drowning is always fatal, but near-drowning may result in survival with no long-lasting effects; survival with permanent damage, usually to the brain; or death after a 24-hour survival period. Near drowning sets into motion a collection of reactions in the body that ultimately can damage the lungs and lead to an absence of oxygen in tissues, even when individuals have been removed from the water and begun breathing either on their own or with mechanical help.

Near-drowning happens very quickly. Within three minutes of submersion, most people are unconscious, and within five minutes the brain begins to suffer from lack of oxygen. Abnormal heart rhythms (cardiac dysrhythmias) often occur in near-drowning cases, and the heart may stop pumping (cardiac arrest). The blood may increase in acidity (acidosis) and, under some circumstances, near drowning can cause a substantial increase or decrease in the volume of circulating blood. If not rapidly reversed, these events cause permanent damage to the brain.

Demographics

About 1,500 children drown every year in the United States. Drowning is the second leading cause of injury-related deaths in children ages one month to 14 years of age in the United States as a whole, and the first leading cause of injury-related deaths in California, Arizona, and Florida. The rate of near drowning is much higher, as not all near drownings are reported. It is estimated that for every drowning, there are four additional hospitalizations and 14 additional emergency room visits due to near drowning.

Children under age four and between 15 and 19 years of age are at highest risk of drowning or near drowning. Most young children drown in swimming pools and bathtubs, while teens drown in natural bodies of water. Teen drownings are often associated with boating accidents, alcohol consumption, and illicit drug use. Boys are 12 times more likely to drown than girls, especially during **adolescence**, when risk-taking behavior is more pronounced in males. However, even in younger age groups, except in bathtub drownings, substantially more boys drown than girls.

Causes and symptoms

The circumstances leading to near-drownings and drownings are varied. Rarely do they involve nonswimmers accidentally entering deep water. In older children and adults, near-drownings are often secondary to an event such as or a head or spinal injury or (in adults) a heart attack that causes unconsciousness and prevents a diver from resurfacing.

Near-drownings can occur in shallow as well as deep water. Small children have drowned or almost drowned in bathtubs, toilets, industrial-size cleaning buckets, and washing machines. Bathtubs are especially dangerous for infants six months to one year of age, who can sit up straight in a bathtub but may lack the ability to pull themselves out of the water if they slip under the surface. One 2004 study found that 88 percent of children who drowned were under the supervision of another person, usually a **family** member. Seventy-seven percent of these children were under age ten. The most common occurrence was that the supervising adult knew the child was in or near the water but was distracted long enough for the child to drown.

A reduced concentration of oxygen in the blood (hypoxemia) is common to all near-drownings. When drowning begins, the larynx (a part of the air passage) closes involuntarily, preventing both air and water from entering the lungs. In 10 to 20 percent of cases, hypoxemia results because the larynx spasms and stays closed.

This is called "dry drowning," and no water is breathed into the lungs. Hypoxemia also occurs in "wet drowning," when the larynx relaxes and water enters the lungs. Individuals who are close to drowning can also regurgitate their stomach contents and breathe these into the lungs.

The physiological mechanisms that produce hypoxemia in wet drowning are different for freshwater and saltwater, but only a small amount of either kind of water is needed to damage the lungs and interfere with lung's ability to remove oxygen from the air.

The signs and symptoms of near-drowning can differ from person to person depending in part on how long the individual has been submerged, the person's age, and the temperature of the water. Upon rescue, some victims are alert but agitated or disoriented, while others are comatose. Breathing and heartbeat may have stopped, or the victim may be gasping for breath. Bluish skin (cyanosis), coughing, **vomiting**, and frothy pink sputum (material expelled from the respiratory tract by coughing) are often observed. Rapid breathing (tachypnea) and a rapid heart rate (tachycardia) are common during the first few hours after rescue. The victim may experience hypothermia (drop in core body temperature).

When to call the doctor

Emergency medical aid should be sought with any near drowning incident. Even a child who appears to have recovered should be checked by a physician, since some internal reactions to near drowning can be delayed.

Diagnosis

Diagnosis relies on a physical examination of the victim, reports of observers, and a wide range of tests and other procedures. Blood is taken to measure oxygen levels and to determine electrolyte balances. Pulse oximetry, another way of assessing oxygen levels, involves attaching a device called a pulse oximeter to the patient's finger. An electrocardiograph is used to monitor heart activity. X rays can detect head and neck injuries and fluid in the lungs.

Treatment

Treatment begins with removing the victim from the water and performing **cardiopulmonary resuscitation** (CPR) as needed to restore heartbeat and provide oxygen until the individual is able to breath without assistance. When emergency medical help arrives, 100 percent oxygen is administered to the victim. If the victim's breathing has stopped or is otherwise impaired, a tube is inserted into the windpipe (trachea) to maintain the airway (endotracheal intubation). The victim is also checked for head, neck, and other injuries, and intravenously fluids may be started. Hypothermia from submersion in very cold water requires special handling to protect the heart.

On arriving at the emergency room, the individual continues receiving oxygen until blood tests show a return to normal. About one-third of near-drowning victims are intubated and initially need mechanical support to breathe. Treatment is administered as needed for cardiac arrest or cardiac dysrhythmias. Slow rewarming is undertaken when hypothermia is present. Individuals are observed for the development of acute **respiratory distress syndrome** (ARDS) or multi-organ failure, both of which can develop after near drowning. Lung problems can develop 12 or more hours after submersion.

Based on symptoms, individuals may be admitted to the hospital or discharged from the emergency department after four to six hours, if their blood oxygen level is normal and no signs or symptoms of near-drowning are present. Discharged individuals must understand that should complications arise, they must immediately seek additional medical care. Admission to a hospital for at least 24 hours for further observation and treatment is necessary for patients who do not appear to fully recover in the emergency department.

Prognosis

Recovery is directly related to the amount of time the body was without adequate oxygen (hypoxia). Brain damage is the major long-term concern in the treatment of near-drowning victims. Patients who arrive at an emergency department awake and alert usually survive with brain function intact, although they may initially have respiratory complications. **Pneumonia** is common following near drowning and often develops within the first 24 hours.

Death or permanent neurological damage is very likely when patients arrive at the emergency room comatose or without a heartbeat. Of these patients, 35 to 60 percent die in the emergency department, while almost all of those who survive have permanent disabilities. Early rescue of near-drowning victims (within five minutes of submersion) and prompt CPR (within less than ten minutes of submersion) seem to be the best guarantees of a complete recovery. However, in a phenomenon that is not well understood, extremely cold water (less than 41°F or 5°C) seems to protect individuals from some of the neurological damage that occurs with near drowning. Some hypothermic near-drowning victims

KEY TERMS

Cyanosis—A bluish tinge to the skin that can occur when the blood oxygen level drops too low.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Hypothermia—A serious condition in which body temperature falls below 95°F (35 °C). It is usually caused by prolonged exposure to the cold.

Hypoxemia—A condition characterized by an abnormally low amount of oxygen in the arterial blood. It is the major consequence of respiratory failure, when the lungs no longer are able to perform their chief function of gas exchange.

Hypoxia—A condition characterized by insufficient oxygen in the cells of the body

have been revived after they appeared dead and have experienced few permanent disabilities.

Prevention

Drowning and near drowning are almost always preventable. Prevention depends on educating adults and children about water **safety**. Children cannot be left in or near water without adult supervision even for a short time. Unsupervised young children are at risk around swimming pools, bathtubs, toilets, buckets, and natural bodies of water. Pools and spas need to be enclosed with a fence at least 5 ft (1.5 m) high and have a self-closing and self-locking gate. Adults and teens should consider learning CPR. No one should swim alone or **play** along flooded streams or streets. Teens and adults should be educated to understand that alcohol and illicit drug use substantially increase the chances of a drowning accident. Boat owners need to participate in boat safety classes, and children should wear approved life preservers when boating, water skiing, or riding on a jet ski.

Parental concerns

Parents should be aware that physicians are required to consider the possibility of **child abuse** in every drowning or near drowning involving a child under the age of one year.

Necrotizing enterocolitis

Definition

Necrotizing enterocolitis (NEC) is a serious bacterial infection in the intestine, primarily affecting sick or premature newborn infants. It can cause the death (necrosis) of intestinal tissue and progress to blood poisoning (septicemia).

Description

Necrotizing enterocolitis is a serious infection that can produce complications in the intestine itself such as ulcers, perforations or holes in the intestinal wall, and tissue necrosis. It can also progress to life-threatening septicemia. Necrotizing enterocolitis most commonly affects the ileum, the lower portion of the small intestine. It is less common in the colon and upper small bowel.

Demographics

It is estimated that narcotizing enterocolitis affects 2 percent of all newborns, but it is more frequently seen in very low birth weight infants, affecting as many as 13.3 percent of these babies. It has a high mortality rate, especially among very low birth weight babies. Some 20 to 40 percent of these infants die. It does not appear that male or females are more susceptible to this condition, and no one race or nationality has a higher incidence.

Causes and symptoms

The cause of necrotizing enterocolitis is not clear. It is believed that the infection usually develops after the bowel wall has already been weakened or damaged by a lack of oxygen, predisposing it to bacterial invasion. Bacteria grow rapidly in the bowel, causing a deep infection that can kill bowel tissue and spread to the bloodstream.

Necrotizing enterocolitis almost always occurs in the first month of life. Infants who require tube feedings may have an increased risk for the disorder. A number of other conditions also make newborns susceptible, including **respiratory distress syndrome**, congenital heart problems, and episodes of apnea (cessation of breathing). The primary risk factor, however, is **prematurity**. Not only is the immature digestive tract less able to protect itself, but premature infants are subjected to many stresses on the body in their attempt to survive.

Early symptoms of necrotizing enterocolitis include an intolerance to formula, distended and tender abdomen, **vomiting**, and blood (visible or not) in the stool. One of the earliest signs may also be the need for mechanical support of the infant's breathing. If the infection spreads to the bloodstream, infants may develop lethargy, fluctuations in body temperature, and may periodically stop breathing.

Diagnosis

The key to reducing the complications of this disease is early detection by the physician. A series of x rays of the bowel often reveals the progressive condition, and blood tests confirm infection.

Treatment

Over two-thirds of infants can be treated without surgery. Aggressive medical therapy with **antibiotics** is begun as soon as the condition is diagnosed or even suspected. Tube feedings into the gastrointestinal tract (enteral **nutrition**) are discontinued, and tube feedings into the veins (parenteral nutrition) are used instead until the condition has resolved. Intravenous fluids are given for several weeks while the bowel heals.

Some infants are placed on a ventilator to help them breathe, and some receive transfusions of platelets, which help the blood clot when there is internal bleeding. Antibiotics are usually given intravenously for at least 10 days. These infants require frequent evaluations by the physician, who may order multiple abdominal x rays and blood tests in order to monitor their condition during the illness.

Sometimes, necrotizing enterocolitis must be treated with surgery. This is often the case when an infant's condition does not improve with medical therapy or there are signs of worsening infection.

The surgical treatment depends on the individual patient's condition. Patients with infection that has caused serious damage to the bowel may have portions of the bowel removed. It is sometimes necessary to create a substitute bowel by making an opening (ostomy) into the abdomen through the skin, from which waste products are discharged temporarily. But many physicians avoid this and operate to remove diseased bowel and repair the defect at the same time.

Postoperative complications are common, including wound infections and lack of healing, persistent sepsis and bowel necrosis, and a serious internal bleeding disorder known as disseminated intravascular coagulation.

Prognosis

Necrotizing enterocolitis is the most common cause of death in newborns undergoing surgery. The average mortality is 30 to 40 percent, even higher in severe cases.

Early identification and treatment are critical to improving the outcome for these infants. Aggressive nonsurgical support and careful timing of surgical intervention have improved overall survival; however, this condition can be fatal in about one third of cases. With the resolution of the infection, the bowel may begin functioning within weeks or months. But infants need to be carefully monitored by a physician for years because of possible future complications.

About 10 to 35 percent of all survivors eventually develop a stricture, or narrowing, of the intestine that occurs with healing. This can create an intestinal obstruction that requires surgery. Infants may also be more susceptible to future bacterial infections in the gastrointestinal tract and to a delay in growth. Infants with severe cases may also suffer neurological impairment.

The most serious long-term gastrointestinal complication associated with necrotizing enterocolitis is short-bowel, or short-gut, syndrome. This refers to a condition that can develop when a large amount of bowel must be removed, making the intestines less able to absorb certain nutrients and enzymes. These infants gradually evolve from tube feedings to oral feedings, and medications are used to control the malabsorption, **diarrhea**, and other consequences of this condition.

Prevention

In very small or sick premature infants, the risk for necrotizing enterocolitis may be diminished by beginning parenteral nutrition and delaying enteral feedings for several days to weeks.

Breast-fed infants have a lower incidence of necrotizing enterocolitis than formula-fed infants; however, conclusive data showing that breast milk may be protective was as of 2004 not available. A large multicenter trial showed that steroid drugs given to women in preterm labor may protect their offspring from necrotizing enterocolitis.

Sometimes necrotizing enterocolitis occurs in clusters, or outbreaks, in hospital newborn (neonatal) units. Because there is an infectious element to the disorder, infants with necrotizing enterocolitis may be isolated to avoid infecting other infants. Persons caring for these infants must also employ strict measures to prevent spreading the infection.

Parental concerns

Approximately 75 percent of all babies with necrotizing enterocolitis survive. After discharge from the hospital, these infants return home still requiring special care. Many have an ostomy. This is an external opening for the intestinal contents to exit the body while the affected part of the intestine heals. Parents and caregivers need instruction on how to care for the ostomy. Many sources advise parents to room in with the baby prior to discharge from the hospital so that they can learn how to care for the special health needs of infants recovering from necrotizing enterocolitis. Additionally, many of these infants have a condition called short-gut syndrome, which results from the removal of a large part of the small intestine. The small bowel will grow in time, but for as long as two years in some cases, the child will require careful monitoring of his or her nutritional intake to insure that he is receiving adequate levels of **vitamins**, **minerals**, and calories. These children will require tube feedings, and parents will need proper instruction in this type of feeding.

KEY TERMS

Enteral nutrition—Liquid nutrition provided through tubes that enter the gastrointestinal tract, usually through the mouth or nose.

Necrosis—Localized tissue death due to disease or injury, such as a lack of oxygen supply to the tissues.

Ostomy—A surgically-created opening in the abdomen for elimination of waste products (urine or stool).

Parenteral nutrition—Liquid nutrition usually provided intravenously.

Sepsis—A severe systemic infection in which bacteria have entered the bloodstream or body tissues.

Neonatal jaundice

Definition

Neonatal **jaundice** is the term used when a newborn has an excessive amount of bilirubin in the blood. Bilirubin is a yellowish-red pigment that is formed and released into the bloodstream when red blood cells are broken down. Jaundice comes from the French word

jaune, which means yellow; thus a jaundiced baby is one whose skin color appears yellow due to bilirubin.

Description

Normally, small amounts of bilirubin are found in everyone's blood. It is formed and released into the bloodstream when red blood cells are broken down. It is then carried to the liver where it is processed and eventually excreted from the body. When too much bilirubin is made, the excess is discarded into the bloodstream and deposited in tissues for temporary storage. In the neonate, however, there is more bilirubin than can be handled due to immature liver functioning and extra red blood cells that break down. Thus, the extra bilirubin remains in the tissues. Neonatal jaundice affects 60 percent of full-term infants and 80 percent of preterm infants in the first three days after birth.

Demographics

Infants of East Asian and Native American descent have higher levels of bilirubin than white infants, who in turn have higher bilirubin levels than infants of African descent. There is an enzyme, glucose-6-phosphate dehydrogenase (G6PD), deficiency that is more prevalent in infants of East Asian, Greek, and African descent which causes neonatal jaundice to appear at approximately the same time as physiological jaundice. **Sickle cell anemia** does not predispose newborn infants to jaundice.

Causes and symptoms

Typically, neonatal jaundice occurs in otherwise healthy infants for two reasons. First, infants have too many red blood cells and it is a natural process for the body to break down these excess red blood cells to form a large amount of bilirubin. It is this bilirubin that causes the skin to take on a yellowish color. Second, the newborn's liver is immature and cannot process bilirubin as quickly as the infant will be able to when older. This slow processing of bilirubin has nothing to do with liver disease. It merely means that the baby's liver is not as fully developed as it will be; thus, there is some delay in eliminating the bilirubin.

Breastfeeding is an important risk factor for hyperbilirubinemia in healthy infants and is related to inadequate maternal milk supply in the first few days, decreased caloric intake and delayed passage of meconium. Nonetheless, this is not a reason to give formula or stop breastfeeding. The breastfeeding mother just needs to nurse the baby more frequently and for longer periods of time to enhance the production of breastmilk. Other factors that cause neonatal jaundice are ABO incompatibility and Rh incompatibility. Both of these conditions result in a very fast breakdown of red blood cells. It is also possible for jaundice to appear in infants with physical defects in the organs that work to eliminate bilirubin from the body. An abnormal increase in red blood cells is frequently seen in infants who are large or small for their gestational age, as well as in trisomy syndromes, twin-to-twin transfusion syndrome, maternal-fetal transfusion, use of oxytocin in labor, Asian male babies, presence of bruising and cephalohematoma, and a **family** history of neonatal jaundice.

As the excess bilirubin builds up in the newborn, jaundice appears first in the face and upper body and progresses downward toward the toes. Most babies with jaundice have physiologic jaundice, which is the type caused by the natural process of breaking down red blood cells. If the baby's jaundice is caused by any other conditions, however, the healthcare giver will provide the parents with additional information for caring for the baby.

When to call the doctor

With short neonatal hospital stays, jaundice will not have peaked or become apparent at the time of hospital discharge. Therefore, infants at risk for severe hyperbilirubinemia should be identified so they can be observed closely both while in the hospital and after discharge. The parents need to be instructed on how to evaluate the infant for jaundice. They should look for it first in the face and upper body and if it progresses downward this means the concentration is getting too high and it is time to call the pediatrician. If there is an area of their living quarters that gets sunlight, it helps to let the baby lie there in only a diaper for a short period of time each day.

Diagnosis

Jaundice can be observed with the naked eye, but it is too difficult to estimate the variation in levels of bilirubin in that manner. Thus, if an infant begins to appear jaundiced, bilirubin levels will be ordered to determine the severity. Jaundice usually becomes apparent when total bilirubin levels exceed 5 mg/dL; however, the clinical significance of bilirubin levels depends on postnatal age in hours. A bilirubin level of 12 mg/dL may be pathologic in an infant younger than 48 hours but is benign in an infant older than 72 hours. In the determination of cause, it is suggested that laboratory testing be reserved for infants with nonphysiologic jaundice. In up to 50 percent of infants with severe jaundice, breast-

feeding and lower gestational age were the only causes identified despite extensive workups.

Treatment

The mainstay in treatment of hyperbilirubinemia is phototherapy, which is safe and widely available. Its effectiveness was demonstrated in a study by the National Institute of Child Health and Human Development. Multiple factors can influence the effectiveness of phototherapy, including the type and intensity of the light and the extent of skin surface exposure. Special blue fluorescent light has been shown to be most effective, although many nurseries use a combination of daylight, white, and blue lamps. In the early 2000s, fiberoptic blankets have been developed that emit light in the blue-green spectrum, which is light at a wavelength of 425–475 nm. Light at this wavelength converts bilirubin to a water-soluble form that can be excreted in the bile or urine. The intensity of light delivered is inversely related to the distance between the light source and the skin surface. Since phototherapy acts by altering the bilirubin that is deposited in the tissue, the area of the skin exposed to phototherapy should be maximized. This has been made more practical with the development of fiberoptic phototherapy blankets that can be wrapped around an infant.

Home-based care for neonatal jaundice has become more prevalent than hospital care, and the availability of fiberoptic blankets has made it possible. Infants receiving home phototherapy need daily visits by a nurse, who performs a physical examination and measures the total serum bilirubin level. If bilirubin levels continue to rise, hospital readmission should be considered. Discontinuation of home phototherapy is safe once the total serum bilirubin level has decreased to less than 15 mg/dL in healthy full-term infants older than four days. Office evaluation within two to three days of discontinuing home phototherapy is recommended.

Potential side effects of phototherapy used for elevated bilirubin levels, include watery **diarrhea**, increased water loss, skin rash, and transient bronzing of the skin. Many infants who are readmitted to the hospital because of hyperbilirubinemia are mildly to moderately dehydrated. Breastfeeding should be increased to every two to two and a half hours. Increased feedings can increase peristalsis and meconium passage, decreasing bilirubin resorption into circulation.

Full-term infants rarely require an exchange transfusion if intense phototherapy is initiated in a timely manner. It should be considered if the total serum bilirubin level is approaching 20 mg/dL and continues to rise despite intense in-hospital phototherapy. Exchange transfusion corrects anemia associated with the destruction of red blood cells and is effective in removing sensitized red blood cells before they are destroyed. It also removes about 60 percent of bilirubin from the plasma, resulting in a clearance of about 30 percent to 40 percent of the total bilirubin. If a transfusion is not performed and bilirubin levels get higher, the infant progresses through three phases. In the first two to three days the infant is lethargic, has muscle weakness, and sucks weakly. Progression is marked by a tensing of the muscles, arching, **fever**, seizures, and high-pitched crying. In the final phase, the patient is hypotonic for several years.

A newborn baby undergoes phototherapy with visible blue light to treat his jaundice. *(Photograph by Ron Sutherland. Photo Researchers, Inc.)*

Prognosis

The prognosis for physiological neonatal jaundice is generally very good. Very few infants ever have bilirubin levels greater than 20 mg/dL, which is the level that is correlated with kernicterus (an abnormal accumulation

KEY TERMS

ABO incompatability—The reaction that occurs with blood groups that are of a different type.

Cephalohematoma—A benign swelling of the scalp in a newborn due to an effusion of blood beneath the connective tissue that surrounds the skull, often resulting from birth trauma.

Kernicterus—A potentially lethal disease of newborns caused by excessive accumulation of the bile pigment bilirubin in tissues of the central nervous system.

Meconium—A greenish fecal material that forms the first bowel movement of an infant.

Oxytocin—A hormone that stimulates the uterus to contract during child birth and the breasts to release milk.

Peristalsis—Slow, rhythmic contractions of the muscles in a tubular organ, such as the intestines, that move the contents along.

Rh incompatability—A factor of blood classified as negative or positive and related to the reaction that occurs between different types.

Trisomy—An abnormal condition where three copies of one chromosome are present in the cells of an individual's body instead of two, the normal number.

of bile pigment in the brain and other nerve tissue that causes yellow staining and tissue damage). It rarely occurs with bilirubin levels lower than 20 mg/dL but typically occurs when levels exceed 30 mg/dL. Levels between 20 and 30 mg/dL associated with **prematurity** and hemolytic disease may increase the risk of kernicterus. There are long-term neurological problems when this occurs. Affected children have marked developmental and motor delays in the form of **cerebral palsy** and **mental retardation** may also be present.

Prevention

Elevated bilirubin in the neonate is the most common reason for hospital readmission in the first two weeks of life. Kernicterus is still relatively uncommon but has been on the rise with the mandated early postnatal discharge policies. Bilirubin-induced complications can be prevented by introducing a neonatal jaundice protocol to identify infants at risk for significant bilirubin increases, by ensuring adequate parental education and providing for follow-up care.

Parental concerns

Parents of a newborn need to be vigilant in monitoring changes in their infant. If the mother is breastfeeding, she should nurse the baby at least once every three hours to ensure the onset of milk production and to maintain hydration, which can also be evaluated by the number of wet diapers. Many pediatricians recommend seeing the infant at two weeks but if the parents feel it should be sooner due to alterations in the newborn's physical status, they should take the infant in for a visit.

Neonatal reflexes

Definition

Neonatal reflexes or primitive reflexes are the inborn behavioral patterns that develop during uterine life. They should be fully present at birth and are gradually inhibited by higher centers in the brain during the first three to 12 months of postnatal life. These reflexes, which are essential for a newborn's survival immediately

after birth, include sucking, swallowing, blinking, urinating, hiccupping, and defecating. These typical reflexes are not learned; they are involuntary and necessary for survival.

Description

A normal birth is considered full term if the delivery occurs during the thirty-seventh to fortieth week after conception. Developmentally, the baby is considered a neonate for the first 28 days of life. At birth, the neonate must immediately make five major adjustments:

- Transition from an aquatic environment to a world of air. The first breath begins even before the umbilical cord is cut.
- Eat and digest his or her own food since the circulatory relationship between mother and baby stops with the severance of the umbilical cord.
- Excrete his or her own wastes.
- Maintain his or her own body temperature.
- Adjust to intermittent feeding since food is now only available at certain intervals.

Under normal developmental conditions, these neonatal reflexes represent important reactions of the nervous system and are only observable within a specific period of time over the first few months of life. The following reflexes are normally present from birth and are part of a normal newborn evaluation:

- The Moro reflex (or startle reflex) occurs when an infant is lying in a supine position and is stimulated by a sudden loud noise that causes rapid or sudden movement of the infant's head. This stimulus results in a symmetrical extension of the infant's extremities while forming a C shape with the thumb and forefinger. This is followed by a return to a flexed position with extremities against the body. Inhibition of this reflex occurs from the third to the sixth month. An asymmetrical response with this reflex may indicate a fractured clavicle or a birth injury to the nerves of the arm. Absence of this reflex in the neonate is an ominous implication of underlying neurological damage.
- Asymmetrical tonic neck reflex (sometimes called the tonic labyrinthine reflex) is activated as a result of turning the head to one side. As the head is turned, the arm and leg on the same side will extend while the opposite limbs bend, in a pose that mimics a fencer. The reflex should be inhibited by six months of age in the waking state. If this reflex is still present at eight to nine months of age, the baby will not be able to support its weight by straightening its arms and bringing its knees beneath its body.
- Symmetrical tonic neck reflex occurs with either the extension or flexion of the infant's head. Extension of the head results in extension of the arms and flexion of the legs, and a flexion of the head causes flexion of the arms and an extension of the legs. This reflex becomes inhibited by the sixth month to enable crawling.
- Grasping reflex occurs as the palmar reflex when a finger is placed in the neonate's palm and the neonate grasps the finger. The palmar reflex disappears around the sixth month. Similarly, the plantar reflex occurs by placing a finger against the base of the neonate's toes and the toes curl downward to grasp the finger. This reflex becomes inhibited around the ninth to tenth month.
- Rooting reflex is stimulated by touching a finger to the infant's cheek or the corner of the mouth. The neonate responds by turning the head toward the stimulus, opening the mouth and searching for the stimulus. This is a necessary reflex triggered by the mother's nipple during breastfeeding. It is usually inhibited by the third to fourth month.
- Sucking reflex is triggered by placing a finger or the mother's nipple in the infant's mouth. The neonate will suck on the finger or nipple forcefully and rhythmically and the sucking is coordinated with swallowing. Like the rooting reflex, it is inhibited by the third to fourth month.
- Babinski or plantar reflex is triggered by stroking one side of the infant's foot upward from the heel and across the ball of the foot. The infant responds by hyperextending the toes; the great toe flexes toward the top of the foot and the other toes fan outward. It generally becomes inhibited from the sixth to ninth month of post natal life.
- Blink reflex is stimulated by momentarily shining a bright light directly into the neonate's eyes causing him or her to blink. This reflex should not become inhibited.
- Pupillary reflex occurs with darkening the room and shining a penlight directly into the neonate's eye for several seconds. The pupils should both constrict equally; this reflex should not disappear.
- Galant reflex is stimulated by placing the infant on the stomach or lightly supporting him or her under the abdomen with a hand and, using a fingernail, gently stroking one side of the neonate's spinal column from the head to the buttocks. The response occurs with the neonate's trunk curving toward the stimulated side. This reflex can become inhibited at any time between the first and third month.
- Stepping reflex is observed by holding the infant in an upright position and touching one foot lightly to a flat

Neonatal reflexes

Reflex	Stimulation	Response	Duration
Babinski	Sole of foot stroked	Fans out toes and twists foot in	Disappears at nine months to a year
Blinking	Flash of light or puff of air	Closes eyes	Permanent
Grasping	Palms touched	Grasps tightly	Weakens at three months; disappears at a year
Moro	Sudden move; loud noise	Startles; throws out arms and legs and then pulls them toward body	Disappears at three to four months
Rooting	Cheek stroked or side of mouth touched	Turns toward source, opens mouth and sucks	Disappears at three to four months
Stepping	Infant held upright with feet touching ground	Moves feet as if to walk	Disappears at three to four months
Sucking	Mouth touched by object	Sucks on object	Disappears at three to four months
Swimming	Placed face down in water	Makes coordinated swimming movements	Disappears at six to seven months
Tonic neck	Placed on back	Makes fists and turns head to the right	Disappears at two months

(Table by GGS Information Services.)

surface, such as the bed. The infant responds by making walking motions with both feet. This reflex will disappear at approximately two months of age.

- Prone crawl reflex can be stimulated by placing the neonate prone (face down) on a flat surface. The neonate will attempt to crawl forward using the arms and legs. This reflex will be inhibited by three to four months of age.
- Doll's eye reflex can be noted with the infant supine (lying on the back) and slowly turning the head to either side. The infant's eyes will remain stationary. This reflex should disappear between three to four months of age.

Common problems

The presence and strength of a reflex is an important indication of neurological functioning. Within the first 24 hours after birth, a healthcare provider evaluates an infant's neurological functioning and development by testing and observing these reflexes. If a reflex is absent or abnormal in an infant, this may suggest significant neurological problems. In normal development, the primary reflex system is inhibited or transformed in the first year of life and a secondary or postural reflex system emerges. The secondary system forms the basis for later adult coordinated movement. Absence or presence of a reflex is a symptom, not a disorder.

Severe persistence of primary reflexes indicates predominantly persistent physical problems. Relatively milder persistence, however, is associated with less severe disorders that include specific reading difficulties.

The process of inhibition of these reflexes in the earliest months of life remains unknown but it has been assumed that this process cannot occur after early childhood because neonatal movement is largely stereotypical and follows the patterns of the primary reflex system. Thus, the early movements of the fetus and newborn were previously viewed as passive byproducts of the central nervous system. They are viewed as interactive and having a reciprocal effect on the underlying central nervous system structure and functioning. This implies that the actual rehearsal and repetition of primary reflex movements play a role in the inhibition process itself.

Parental concerns

An evaluation of neonatal reflexes is performed during well-baby examinations. The abnormal presence of infantile reflexes in an older child can be discovered during a neurological examination. **Assessment** of neonatal reflexes is a screening tool for at-risk children with neurological difficulties. Primary reflexes may persist for certain children beyond their normal time span causing a disruption in subsequent development. Children with neurological damage will have a common denomi-

KEY TERMS

Palmar—Referring to the palm of the hand.

Plantar—Relating to the sole of the foot.

Postural—Pertaining to the position of the head, neck, trunk and lower limbs in relation to the ground and the vertical.

Prone—Lying on the stomach with the face downward.

Supine—Lying on the back with the face upward.

Visuosensory—Pertaining to the perception of visual stimuli.

nator of prolonged neonatal reflexes. Since recent studies have demonstrated that repetition of these reflexes seems to eventually inhibit them, parents can work with the infant by assisting with the repetition of persistent reflexes.

When to call the doctor

Persistence of neonatal reflexes is not threatening to life and, therefore, can be discussed with the pediatrician during normal well-baby visits.

Neurofibromatosis

Definition

Neurofibromatosis (NF) is a genetic disease in which multiple soft tumors (neurofibromas) develop under the skin and throughout the nervous system. Various sized tumors may grow on the nerves in or leading away from the brain and spinal cord (peripheral nerves) and in the vascular system (veins and arteries) and other organ systems. There are two types of NF: NF-1, also called vonRecklinghausen NF, and NF-2, also called acoustic NF (sometimes bilateral acoustic NF or BAN). NF-1 is more common, representing 90 percent of all cases, while NF-2 is diagnosed in 10 percent of NF cases.

Description

Neural crest cells are primitive cells that are present as part of the nervous system during fetal development. These cells eventually turn into the following:

- cells that form nerves throughout the brain, spinal cord, and body
- cells that serve as coverings around the nerves throughout the body
- pigment cells that provide color to body structures
- meninges, the thin, membranous coverings of the brain and spinal cord
- cells that ultimately develop into the bony structures of the head and neck

In both types of NF, a genetic defect causes these neural crest cells to develop abnormally, resulting in numerous tumors and malformations of the nerves, bones, and skin.

NF-1 affects nerves throughout the body, occurring as groups of soft, fibrous swellings that grow on nerves in the skin, brain, and spinal cord (central nervous system), muscles, and bone. Severe disfigurement can result from the development of these tumors as the disease progresses and bone deformities may occur as well.

NF-2 is a rare type of NF in which multiple tumors grow on the cranial (head) and spinal nerves and other growths can occur in the brain and spinal cord. Tumor growth (schwannoma) on the nerves to the ears (auditory nerves) is most characteristic of NF-2. Disfigurement does not occur although hearing and visual problems are typical.

Demographics

NF-1 is a common genetic disorder that occurs in about one of every 4,000 births worldwide. NF-2 is rare, occurring in one of every 40,000 births. Children with a **family** history of neurofibromatosis are at highest risk for having either form of the condition.

Causes and symptoms

Both forms of neurofibromatosis are caused by a defective gene. NF-1 is due to a defect on chromosome 17; NF-2 results from a defect on chromosome 22. Both of these disorders are inherited in a dominant fashion, which means that anyone who receives just one defective gene will have the disease. However, a family pattern of NF is only evident for about half of all cases of NF. The other cases of NF occur due to a spontaneous mutation (a permanent change in the structure of a specific gene). Once such a spontaneous mutation has been established in an individual, however, it can then be passed on to any offspring. The chance of a person with NF passing on the NF gene to a child is 50 percent.

NF-1 has a number of possible signs and can be diagnosed if any two of the following are present:

- The presence of coffee-colored spots. These are patches of tan or light brown skin, usually about 5 to 15 mm in diameter. Nearly all patients with NF-1 will display these spots.
- Multiple freckles in the armpit or groin area.
- Ninety percent of patients with NF-1 have tiny tumors called Lisch nodules in the iris (colored area) of the eye.
- Soft tumors (neurofibromas) are the hallmark of NF-1. They occur under the skin, often located along nerves or within the gastrointestinal tract. Neurofibromas are small and rubbery, and the skin overlying them may be somewhat purple in color.
- Skeletal deformities, such as a twisted spine (**scoliosis**), curved spine (humpback), or bowed legs.
- Tumors along the optic nerve, causing vision disturbances in about 20 percent of those affected.
- The presence of NF-1 in a child's parent or sibling.

Very high rates of speech impairment, learning disabilities, and attention deficit disorder occur in children with NF-1. Other complications include the development of a **seizure disorder** or the abnormal accumulation of fluid within the brain (**hydrocephalus**). A number of cancers are more common in individuals who have NF-1. These include various types of malignant brain tumors, as well as leukemia and cancerous tumors of certain muscles (rhabdomyosarcoma), the adrenal glands (pheochromocytoma), or the kidneys (**Wilms' tumor**).

Patients with NF-2 do not necessarily have the same characteristic skin symptoms that appear in NF-1. The characteristic symptoms of NF-2 are due to tumors along the acoustic nerve that result in nerve dysfunction and the loss of hearing. The tumor may also spread to neighboring nervous system structures, causing weakness of the muscles of the face, **headache**, **dizziness**, poor balance, and uncoordinated walking. Cloudy areas on the lens of the eye (cataracts) frequently develop at an unusually early age. As in NF-1, the chance of brain tumors developing is unusually high.

When to call the doctor

A history of either form of NF in the child's parent or sibling is reason to consult a physician. The presence of any of the symptoms associated with NF-1 or NF-2 should be investigated by a physician as well, particularly spots on the skin or small movable lumps under the skin and visual disturbances, memory loss, or difficulty maintaining balance. Hearing loss may be the first sign of NF-2 but can also be due to other unrelated conditions.

Diagnosis

Diagnosis is based on characteristic symptoms and physical examination. Diagnosis of NF-1 requires that at least two of the characteristic signs are present. Diagnosis of NF-2 requires the presence of either a nodule or mass (tumor) on the acoustic nerve or another distinctive nervous system tumor, which may only be identifiable

through imaging studies. An important diagnostic clue for either NF-1 or NF-2 is the known presence of the disorder in a child's parent or sibling. Gene studies may be done to detect abnormalities on chromosomes 17 and 22.

Diagnosis of NF-1 will be confirmed by manipulation of the skin to reveal moveable, small, solid lumps (nodules) and the presence of coffee-colored spots on the skin of the trunk and pelvis. The spots may appear in childhood and typically become more noticeable in young adults. Two or more nodules and six or more discolored spots are usually definitive for a diagnosis of NF-1. Curvature of the spin (scoliosis) may be present, elevated blood pressure, and abnormalities in height, weight, and head size may also be noticed on physical examination.

Diagnosis of NF-2 also relies on manipulation of the skin to indicate the presence of nodules and evaluation of hearing and vision to determine any impairment.

X rays, CT scans, and MRI scans are performed to track the development/progression of tumors in the brain and along the nerves. Auditory evoked potential testing (the electric response evoked in the cerebral cortex by stimulation of the acoustic nerve) may be helpful to determine involvement of the acoustic nerve, and EEG (**electroencephalogram**, a record of electrical currents in the brain) may be needed for children who have possible seizures. As the disease progresses, hearing and vision are carefully monitored and imaging studies of the bones are frequently done to watch for the development of deformities.

Treatment

There is no standard treatment for either type of neurofibromatosis. To some extent, the symptoms of NF-1 and NF-2 can be treated individually. Skin tumors can be surgically removed. Some brain tumors and tumors along the nerves, can be surgically removed or treated with chemotherapeutic drugs or x-ray treatments (radiation therapy). Twisting or curving of the spine and bowed legs may be corrected to some degree by surgical treatment or the wearing of a special brace. Social adjustment problems are common among young children with physical deformities caused by the condition.

Prognosis

NF of either type is progressive, and the clinical outcome is not predictable. Prognosis varies depending on the types of tumors that develop. As tumors grow, they begin to destroy surrounding nerves and structures. Ultimately, this destruction can result in blindness, deafness, increasingly poor balance, and increasing difficulty with the coordination necessary for walking. Deformities of the bones and spine can also interfere with walking and other kinds of movement. When cancers develop as a result of NF, prognosis worsens according to the specific type of **cancer**. Successful surgical removal of neurofibromas has a survival rate of 50 to 90 percent.

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease. This change can be transmitted to offspring.

Neurofibroma—A soft tumor usually located on a nerve.

Tumor—A growth of tissue resulting from the uncontrolled proliferation of cells.

Prevention

There is no known way to prevent NF cases that occur as a result of spontaneous change in the genes (mutation). New cases of inherited NF can be prevented with careful genetic counseling. Parents with NF can be encouraged to understand that each of his or her offspring has a 50 percent chance of also having NF. When a parent has NF, and the specific genetic defect causing the parent's disease has been identified, tests can be performed on the fetus (developing baby) during pregnancy. Procedures such as **amniocentesis** or chorionic villus sampling allow small amounts of the baby's cells to be removed for examination. The tissue can then be examined for the presence of the parent's genetic defect. Some families choose to use this information in order to prepare for the arrival of a child with a serious medical problem. Other families may choose not to continue the pregnancy.

Parental concerns

Parents may worried about the development of deformities associated with NF-1. Social workers and psychologists can be consulted about possible counseling for children with the disease, helping them to cope with changes in their bodies that may be hard to accept. Hearing loss and visual disturbances associated with NF-2 are usually not reversible and specialists can be consulted about possible therapies to improve functioning in existing sight or hearing senses. Surgery to remove tumors may require the provision of educational information for both parents and children so that the procedure and possible complications are understood ahead of time.

Neurologic exam

Definition

A neurological examination is an essential component of a comprehensive physical examination. It is a systematic examination that surveys the functioning of nerves delivering sensory information to the brain and carrying motor commands (peripheral nervous system) and impulses back to the brain for processing and coordinating (central nervous system).

Purpose

A careful neurological evaluation can help to determine the cause of impairment and help a clinician begin to localize the problem. Symptoms that occur unexpectedly suggest a blood vessel or seizure problem. Those that are not so sudden suggest a possible tumor. Symptoms that have a waning course with recurrences and worsen over time suggest a disease that destroys nerve cells. Others that are chronic and progressive indicate a degenerative disorder. In cases of trauma, symptoms may be evident upon inspection and causes may be explained by third party witnesses. Some patients may require extensive neurological screening examination (NSE) and/or neurological examination (NE) to determine the cause. The NE will assist the clinician in diagnosing illnesses as diverse as seizure disorders, **narcolepsy**, migraine disorders, **dizziness**, and dementia.

Description

A neurological screening is an essential component of every comprehensive physical examination. In cases of neurological trauma, disease, or psychological disorders, patients are usually given an in-depth neurological examination. The examination is performed in a systematic manner, which means that there is a recommended order for procedures.

Neurological screening examination

The NSE is basic procedure, especially in patients who have a general neurological complaint or symptoms. The NSE consists of six areas of **assessment**:

- mental status: assessing normal orientation to time, place, space, and speech
- cranial nerves: checking the eyes with a special light source (ophthalmoscope) and also assessing facial muscles strength and functioning
- motor: checking for tone, drift, and heel and toe walking
- sensory: cold and vibration testing
- coordination: observing the patient walk and finger to nose testing
- reflexes: using a special instrument the clinician taps an area above a nerve to emit a reflex (usually movement of muscle groups)

Neurological examination

The NE should be performed on a patient suspected of having neurological trauma, or neurological or psychological diseases. The NE is performed in a systematic and comprehensive manner. It consists of several comprehensive and in-depth assessments of mental status, cranial nerves, motor abilities, reflexes, sensory acuity, and posture and walking (gait) abilities.

MENTAL STATUS EXAMINATION (MSE) There are two types of MSE, informal and formal. The informal MSE is usually done as clinicians are obtaining historical information from a patient. The formal MSE is performed for a patient suspected of a neurological problem. The patient is commonly asked his/her name, the location, the day, and date. Determining the number of digits that can be repeated in sequence can assess retentive memory capability and immediate recall. Recent memory is typically examined by testing recall potential of a series of objects after defined times, usually within five and 15 minutes. Asking the patient to review in a coherent and chronological fashion his or her illness or personal life events can provide the opportunity for assessment of remote memory. Patient recall of common historical or current events can be used to assess general knowledge. Brain processing capabilities can be assessed by spontaneous speech, repetition, reading, naming, writing, and comprehension. Modifications can be made based on the age and maturity of the child. The child may be asked to perform tasks such as identification of fingers, whistling, saluting, brushing teeth motions, combing hair, drawing, and tracing figures. These procedures allow for assessment of dominant (left-sided brain) functioning or higher cortical function.

The MSE is particularly important in psychotherapy. Psychotherapists recommend an in-depth MSE for all patients with possible organic (physiologica) or psychotic disorders. This examination is also performed in a systematic and orderly manner. It is divided into several categories:

- Appearance determines the child's presentation, i.e., how the child looks (clothes posture, grooming, and alertness).
- Behavior assesses the patient's motor activity (movements) such as walking, gestures, muscular twitching, and impulse control.
- Speech can be examined concerning volume, rate of speech, and coherence. Individuals who exhibit latent or delayed speech may be depressed, while those who have rapid or pressured speech may suffer from mania or **anxiety**.
- Mood and affect indicate attitude or feeling. Normal mood (euthymia) is healthy. Variations in mood include: flat, labile, blunted, constructed, or inappropriate mood. The child can also be euphoric (elevated) or dysphoric (on the down side).
- Thought processes and content is typically assessed by determining word usage (can indicate brain disease), thought stream (slow, restricted, blocked, or overabundant), continuity of thought (associations among ideas), and content of thought (delusional as opposed to reality-bound).
- Perception assessment examines the individual's sensory ability to hear, see, touch, taste, and smell. Certain psychological states may cause hearing and visual hallucinations. Impairments of smell and touch usually have medical (organic) causes or are side effects of certain medications.
- Attention and concentration assessment indicates the child's ability to focus on a specific task or activity. Abnormalities in attention and concentration can indicate problems related to anxiety or hallucinations.
- Orientation assessment determines if the child has a normal sense of time, place, and identification of self (can state his or her own name). Disturbances in orientation can be due to a medical condition (other than psychological), substance abuse, or to a side effect of certain medications such as those used to treat depression, anxiety, or psychosis, since these medications usually have a sedative affect.
- Memory assessment includes determining the child's remote, recent, and immediate memory capabilities. Remote and recent memory can be assessed by the patient's ability to recall historical and current events. Immediate memory can be tested by naming three objects and asking the child to repeat the named objects immediately, then after five and 15 minute intervals.
- Judgment assessment evaluates the individual's ability to exercise appropriate judgment. It also determines whether the individual has an understanding of consequences associated with their actions. This evaluation pertains primarily to older children.
- **Intelligence** and information measurement can be obtained by administering specialized intelligence tests, However, a preliminary assessment of intelligence can be made based on the child's fund of age-appropriate information, general knowledge, awareness of current events, and the ability for abstract thinking.
- Insight assessment pertains to determining the patient's awareness of their problem that prompted them to seek professional examination. Insight concerning the present illness can range from denial to fleeting admission of current illness.

CRANIAL NERVES (CN) Cranial nerves are nerves that originate in the brain and connect to specialized structures such as the nose, eyes, muscles in the face, scalp, ear, and tongue.

- CN I: This nerve checks for visual capabilities. Patients are usually given the Snellen Chart (a chart

with rows of large and small letters). Patients read letters with one eye at a time.

- CN III, IV, and VI: These nerves examine the pupillary (the circular center structure of the eye that light rays enter) reaction. The pupils get smaller, normally when exposed to the light. The eyelids are also examined for drooping or retraction. The eyeball is also checked for abnormalities in movement.
- CN V: The clinician can assess the muscles on both sides of the scalp muscles (the temporalis muscle). Additionally the jaw can be tested for motion resistance, opening, protrusion, and side-to-side mobility. The cornea located is a transparent tissue covering the eyeball and can be tested for intactness by lightly brushing a wisp of cotton directly on the outside of the eye.
- CN VII: Examination of CN VII assesses asymmetry of the face at rest and during spontaneous movements. The patient is asked to raise eyebrows, wrinkle forehead, close eyes, frown, smile, puff cheeks, purse lips, whistle, and contract chin muscles. Taste for the front and middle portions of the tongue can also be examined.
- CN VIII: Testing for this CN deals with hearing. The clinician usually uses a special instrument called a tuning fork and tests for air conduction and structural problems which can occur inside the ear.
- CN IX and X: These tests evaluate certain structures in the mouth. The clinician will usually ask the patient to say ''aah'' and can detect abnormal positioning of certain structures such as the palatel-uvula. The examiner will also assess the sensation capabilities of the pharynx, by stimulating the area with a wooden tongue depressor, causing a gag reflex.
- CN XI: This nerve is usually examined by asking the patient to shrug shoulders (testing a muscle called the trapezius) and rotating the head to each side (testing a muscle called the sternocleidomastoid). These muscles are responsible for movement of the shoulders and neck. The test is usually done with resistance, meaning the examiner holds the area while the patient is asked to move. This is done to assess patient's strength in these areas.
- CN XII: This nerve tests the bulk and power of the tongue. The examiner looks for tongue protrusion and/or abnormal movements.

MOTOR EXAMINATION The motor examination assesses the patient's muscle strength, tone, and shape. Muscles could be larger than expected (hypertrophy) or smaller due to tissues destruction (atrophy). It is important to assess if there is evidence of twitching or abnormal movements. Involuntary movements due to **tics** can be observed. Additionally, movements can be abnormal during maintained posture in some neurological disorders. Muscle tone is usually tested by applying resistance to passive motion of a relaxed limb. Power is assessed for movements at each joint. Decreases or increases in muscle tone can help the examiner localize the affected area.

REFLEXES The patient's reflexes are tested by using a special instrument that looks like a little hammer. The clinician taps the rubber triangular shaped end in several different areas in the arms, knee, and Achilles heel area. The clinician will ask the patient to relax and gently tap the area. If there is a difference in response from the left to right knee, then there may be an underlying problem that merits further evaluation. A difference in reflexes between the arms and legs usually indicates of a lesion involving the spinal cord. Depressed reflexes in only one limb, while the other limb demonstrates a normal response usually indicates a peripheral nerve lesion.

SENSORY EXAMINATION Although an essential component of the NE, the sensory examination is the least informative and least exacting since it requires patient concentration and cooperation. Five primary sensory categories are assessed: vibration (using a tuning fork), joint position (examiner moves the limb side-to-side and in a downward position), light touch, pinprick, and temperature. Patients who have sensory abnormalities may have a lesion above the thalamus. Spinal cord lesions or disease can possibly be detected by pinprick and temperature assessment.

COORDINATION The patient is asked to repetitively touch his nose using his index finger and then to touch the clinician's outstretched finger. Coordination can also be assessed by asking the patient to alternate tapping the palm then the back of one hand on the thigh. For coordination in the lower extremities (legs), the patient lies on his or her back and is asked to slide the heel of each foot from the knee down the shin of the opposite leg and to raise the leg and touch the examiner's index finger with the big toe.

WALKING (GAIT) Normal walking is a complex process and requires use of multiple systems such as power, coordination, and sensation, all working together in a coordinated fashion. The examination of gait can detect a variety of disease states. Decreased arm swinging on one side is indicative of corticospinal tract disease. A high-stepped, slapping gait may be the result of a peripheral nerve disease.

Precautions

A neurologic examination is not invasive and there are no risks or dangers associated with these tests. The results and validity of this exam may be affected by the child's age and ability to cooperate.

Preparation

The MSE is the first step in a continuous assessment to determine the diagnosis. A psychotherapist should take a detailed medical history in the process of ruling out a general medical condition. Little preparation is needed for this assessment, but parents should explain to young children what will happen in order to encourage their cooperation.

Aftercare

For suspected neurological diseases, the doctor uses information gained from the NE for ordering further tests. These tests may include a complete blood analysis, liver function tests, kidney function tests, hormone tests, and a lumbar puncture to determine abnormalities in cerebrospinal fluid. In trauma cases (e.g. car accident, **sports** injury), the NE is a quick and essential component of emergency assessment. Once a diagnosis is determined, emergency measures may include further tests and/or surgery.

In psychological cases the treatment may include therapy and/or medication. In cases of an acute insult such as trauma, the patient is usually admitted to the hospital for appropriate treatment. Some neurological diseases are chronic and require conservative medical treatment and frequent follow-up visits for monitoring and stability or progression of the disease.

Risks

The MSE and NE are good diagnostic tools. There are no risks associated with initial neurologic assessment.

Parental concerns

Parental concerns center on the cause of the medical disease or psychological disorder, rather than around the procedure, which is straightforward and non-threatening.

Night terrors

Definition

Childhood night terrors are a parasomnia, or partial-sleep disorder, common in young children. They occur in the deepest stage of **sleep** and are characterized by an abrupt arousal, usually within the first hour of sleep. The child may sit bolt upright in acute terror, screaming inconsolably. Night terrors are a confusional arousal resulting from immature sleep patterns with an intense activation of the flight or fight emotion.

Description

Night terrors are not a dream or typical nightmare. They occur in non-REM, slow-wave sleep. The panicked screaming, kicking, thrashing, and flailing is alarming in its intensity. Sleepwalking, another parasomnia disorder, may also occur in as many as one third of children with night terrors. While experiencing the night terror the child is extremely disoriented and may stare straight ahead, eyes wide open, with the dark centers (pupils) enlarged. There is profuse sweating, the heartbeat is rapid, the breathing fast, and the blood pressure is elevated. As the child is not fully awake, she is unable to see or recognize her parent or caretaker and cannot be easily awakened. The night terror may last from one to 15 minutes or more and is usually followed by a return to deep sleep. Afterwards the child may have no memory of the experience.

Night terrors appear to run in families, though there is no scientific evidence of genetic factors. They are a developmental process and not typically a result of mental or physical illness.

Demographics

Childhood night terrors occur more frequently in boys. Children between the ages of three and five years of age are most likely to experience such nocturnal episodes. Such confusional arousals rarely persist beyond childhood, and they are significantly less frequent or cease entirely after age 12.

Causes and symptoms

Childhood night terrors appear to be a normal physiological process of the immature and developing nervous system. These confusional arousals can be triggered by stressful circumstances such as when a child is overly tired, when there is a loud noise or other unusual disruption, a change in the child's regular sleep-wake schedule, or even a full bladder. Night terrors occurring in **adolescence** and adult life may be more severe and are often linked with trauma and post-traumatic stress disorders.

When to call the doctor

Consult a pediatrician for night terrors if any of the following occur:

- Episodes occur more than once a week.
- Episodes persist after a schedule of preventive awakenings.
- Episodes last more than 45 minutes.
- The child exhibits drooling, jerking, and stiffening of the body.
- The child is physically endangered during an episode.
- Episodes occur later during the sleep cycle, more than two hours after going to sleep.
- The child has fears that persist throughout the day.

Diagnosis

Diagnosis is based on observation of the following characteristic symptoms:

- recurring episodes of abrupt and partial awakening from deep sleep with panicked screaming and disorientation
- increased heart rate, rapid breathing, and profuse sweating during an episode
- child is unresponsive to efforts to arouse or console during an episode
- child has little or no memory of the event after a full awakening

Treatment

Parents should not attempt to awaken a child experiencing a night terror. Efforts to console may be futile, though holding the child firmly and speaking with soothing words may facilitate the return to deep sleep. The primary effort should be to protect the child from possible harm to herself and others and ease them back to sleep.

In some severe cases, a pediatrician may prescribe a benzodiazepine tranquilizer, such as diazepam, known to suppress the stage four level of deep sleep. Though tranquilizers may be used for short-term control of night terrors, the result is uncertain and not generally advised.

Alternative treatment

Hypnosis, biofeedback, and various relaxation techniques have been used with some success to reduce or eliminate occurrence of childhood night terrors. Calming music or bedtime stories can help lull a child into deep sleep. Maintaining a quiet home without sudden disruptive noise will minimize some of the external stimuli that may trigger night terrors.

Nutritional concerns

Unusually heavy or spicy meals should be avoided before bedtime as indigestion might act as a trigger for night terror arousals.

KEY TERMS

Benzodiazepine—One of a class of drugs that have a hypnotic and sedative action, used mainly as tranquilizers to control symptoms of anxiety. Diazepam (Valium), alprazolam (Xanax), and chlordiazepoxide (Librium) are all benzodiazepines.

Confusional arousal—A partial arousal state occurring during the fourth stage of deepest sleep. Childhood night terrors are a form of confusional arousal.

Parasomnia—A type of sleep disorder characterized by abnormal changes in behavior or body functions during sleep, specific stages of sleep, or the transition from sleeping to waking.

Rapid eye movement (REM) sleep—A phase of sleep during which the person's eyes move rapidly beneath the lids. It accounts for 20–25% of sleep time. Dreaming occurs during REM sleep.

Prognosis

Childhood night terrors are usually outgrown by the age of seven and rarely persist beyond adolescence.

Prevention

Some pediatricians suggest that parents maintain a sleep diary and observe the child throughout several night terror episodes, noting the amount of time following sleep when the night terror begins. After the sleep-wake pattern is determined, a series of 15–20 minutes prior to the usual occurrence of the night terror and keep the child awake and out of bed for a full five minutes. This may help to break the disruptive sleep pattern that has resulted in the night terrors.

Children often experience night terrors during the toilet-training years. The night terror might be triggered by a full bladder. Assisting the child to the toilet prior to bedtime and even during the course of a night-terror might be beneficial in reducing reoccurrence.

Parental concerns

Childhood night terrors are alarming to witness. Parents may find it particularly difficult when efforts to console the child fail and the child does not recognize them even though his or her eyes may be wide open. The screaming, flailing, and kicking that accompany a night terror may frighten parents who **fear** the child is having a seizure. It is not a seizure unless the behavior includes eyes rolling back in the head, stiffening of the body, and drooling. Most childhood night terrors will last about 10 minutes.

Nightmares

Definition

Nightmares are a type of **sleep** disruption, or parasomnia, characterized by frightening psychological

content. Nightmares provoke a feeling of imminent physical danger with a sensation of being trapped or suffocated. These frightening dreams occur during rapid eye movement sleep (REM), or dream-time sleep, and trigger a partial or full awakening. Nightmares are a universal human experience occurring throughout the lifespan. They are especially common in early childhood and involve activation of the limbic brain, particularly the area that mediates negative emotion.

Description

Nightmares are greatly influenced by the particular stressors and anxieties present in the child's waking life. Typical childhood nightmares include dreams of **abandonment**; of being lost; of falling; or being chased, bitten, or eaten by a monster or hostile animal. Dream researchers have observed a developmental progression in the content and frequency of children's nightmares. A two-year-old dreamer may recall a fearful dream, but be unable to give form to the source of the threat. By the age of five, the frightened young dreamer may identify the attacker as a monster or wild animal. Older children who have developed more of an understanding of real-life dangers report dreams of pursuit by mean or bad people.

Children gradually develop the ability to understand the difference between dreams and reality. Very young children have great difficulty believing that the dream is not real. By three to four years of age, however, most children can distinguish between the nightmare content and their waking reality.

When a child is awakened by a nightmare she will soon become fully alert and able to remember the scary dream in elaborate detail, expressing emotions appropriate to the dream content. The frightened child will resist returning to bed and often seek the comfort and reassurance of a parent or caretaker. Nightmares are different than the non-dream sleep disturbance known as a night terror, which causes only a partial arousal from deep sleep and occurs during the first period of sleep known as slow-wave sleep (SWS). A child experiencing a night terror will be difficult to awaken or comfort, will not recognize her parent or caretaker, and will usually have no memory of the terrifying emotions that caused the sleep disturbance.

Demographics

Although infants spend most of their sleep time in the REM stage where dreams are known to occur, there is no reliable way to determine if dreaming actually takes place prior to the development of language and the reflective ability to think in images. Sleep researchers and developmental psychologists generally agree that nightmares first occur in children from 18 months to two years of age. By age three, more than half of all children will report having experienced a nightmare. The incidence of these frightening dreams increases considerably in elementary school children.

In a study of the dreams of four- to 12-year-old children published in the *Journal of Clinical Child Psychology* in 2000, researchers found that 67.7 percent of four to six year olds, 95.7 percent of seven to nine year olds, and 76.3 percent of ten to 12-year olds reported having had a nightmare experience. Nightmares are common throughout childhood, changing somewhat in content and frequency as children move through different developmental phases and acquire more skills to cope with the changing realities and stresses in their lives.

Causes and symptoms

Childhood nightmares are a normal maintenance function of the developing brain. They are a means of integrating recent and past learning and of establishing psychological equilibrium. Children who have not yet developed sufficient coping mechanisms to deal with many normal childhood fears and problems may feel overwhelmed and insecure. These distressing emotions provide the basis for nightmares. Common stressful events include moving to a different neighborhood or school, encountering a schoolyard bully, watching a horror movie or a violent television or video program, the birth of a sibling, ongoing conflict with siblings, parental marital problems, or any of numerous other stressful situations that may add to a child's sense of vulnerability or powerlessness.

Nightmares may increase and intensify following particularly traumatic events such as the death of a parent, a sibling, or other loved one; parental **divorce** or separation; an injury, illness, or other medical crises; or witnessing or being subjected to physical or verbal violence or sexual abuse. Children who have been traumatized may suffer ongoing post-traumatic stress and express it through recurring nightmares.

Certain medications used to treat **asthma**, **allergies**, and seizures can be a causal factor in the onset of sleep disturbances and nightmares. Abrupt withdrawal from drugs or medications, including barbiturates and benzodiazepines, can also induce these sleep disturbances. Illness with high **fever** may bring about delirium with frightening episodes of nighttime awakening. The following behaviors are usually present in a normal nightmare episode:

- Child awakens during the last third of her sleep period.
- Child is frightened and becomes fully alert.
- Child can describe the frightening dream in detail.
- Child seeks and responds to comfort and reassurance from a parent or caretaker.
- Child fears a recurrence of the frightful dream and may resist a return to bed.

When to call the doctor

If a child's nightmares increase in frequency and intensity, it is important to consult a physician or pediatrician to determine if the sleep disruption is due to any injury, illness, or infection, or if it might be caused by the use of or change in medications. Disturbed sleeping patterns in children are also present in some cases of juvenile rheumatoid arthritis, **autism**, and fibromyalgia.

Nightmares usually diminish in frequency and intensity over time. Recurring nightmares may indicate an ongoing problem that the child is having difficulty resolving. A child who is losing sleep and whose fears persist during day-time hours may benefit from the help of a pediatric psychotherapist in developing coping strategies for the stress and **anxiety** expressed through the dreams.

Diagnosis

Parental observation of the child's sleeping patterns and careful record-keeping of symptoms of any sleep disruption through use of a sleep journal will usually reveal any parasomnia patterns that may require professional **assessment**.

Treatment

Parents or caretakers should take into account the age and developmental maturity of their child when responding to the fears and anxieties that a nightmare brings to the surface. The child's ability to understand that the nightmare is not real and that it is an event happening only within their own mind increases with age. The nightmare reflects real fears and stressful circumstances present in the child's waking life. A parent's willingness to listen to and sympathize with a child's fears provides a necessary validation of the child's experience and helps to calm the child's anxiety. Very young children who lack the verbal skills to describe the frightening dream may require more reassurances that they are safe and more time in the comforting presence of a parent or caretaker before they are ready to return to bed.

Anne Sayre Wiseman, writing in her book *Nightmare Help: A Guide for Parents and Teachers*, suggests that parents approach the nightmare as a dream story with a problem to be solved. Parents who act as dream guides can help their children to find their own solution to the dream problem. The parents' goal, Wiseman counsels, is to "encourage autonomy so the child learns to empower themselves at whatever level they can handle."

Alan Siegel and Kelly Bulkeley, writing in their book, *Dreamcatching: Every Parent's Guide to Exploring and Understanding Children's Dreams and Nightmares*, suggest four beneficial remedies to help a child cope with disturbing nightmares. "The Four R's" of nightmare relief are:

- Reassurance: Provide physical and emotional reassurance and a listening ear so the frightened child will feel safe enough to share the dream images.
- Rescripting: Discuss the dream images with the child and work together with the frightened dreamer to imagine changes in the outcome. Encourage the child to express the images through artwork, fantasy, drama, and writing.
- Rehearsal: Encourage the child to imagine how the various alternative dream endings might change and assist the child in working through the different outcomes to find those that restore a sense of control and safety.
- Resolution: Work with the child to help her discover and acknowledge the life problems and stressful circumstances that may be reflected in the nightmare.

Nightmares are a common childhood parasomnia and medication is rarely indicated. Other parasomnias, such as **night terrors** and night walking, may call for medication if other interventions and treatments fail to relieve seriously disruptive symptoms.

Alternative treatment

Teaching the child simple relaxation skills through guided imagery will provide a valuable self-help resource that may minimize bed-time anxiety. Older children can be encouraged to connect with an "inner guide" as a source of strength when they are awakened by frightening dreams. Inner guides may take the form of a loving voice within that the child can listen for during times of **fear** or a beloved animal that they may call upon as a companionable inner helper when dealing with problems presented in scary dreams.

Nightmares

Preventing Nightmares

Have the child go to bed about the same time every day.
Avoid eating or exercising before bed.
Avoid scary books or movies before bed.
Put the child to sleep with a favorite stuffed toy or special blanket.
Keep a nightlight on in the child's room.
Keep the door to the child's room open.

(Table by GGS Information Services.)

Nutritional concerns

Nightmares are a sleep disturbance that is part of a normal adaptive mechanism of the developing child. They are usually not caused by a child's diet. However fatty foods or spicy meals that may bring about digestive distress at bedtime may trigger sleep disturbances and awaken a child out of an otherwise peaceful slumber.

Prognosis

Childhood nightmares are a normal process of coping with new challenges and integrating new life experiences into the child's understanding of the world. With guidance from a sensitive parent, a child's nightmares can provide an opportunity for parents and children to gain a deeper understanding of, and find solutions to childhood anxieties and insecurities.

Prevention

Nightmares are part of the normal developmental process that literally provide a "wake-up" call to both parent and child to pay attention to strong feelings and problems that may require some resolution. Nightmares diminish as children feel more confidence and control in their lives. If nightmares persist and intensify they may indicate a situation in the child's life that needs to be changed rather than worked through with dream problem-solving.

Establishing a regular bedtime schedule and routine, including a calming-down period prior to sleep, will help reduce the number of sleep disruptions. Eliminating the stimulation of television or **video games** at bedtime, particularly violent television shows, movies, and games may reduce the nightmares brought about by these unnecessary and sometimes disturbing stimulations.

Parental concerns

Sleep disruptions throughout childhood also cause disruptions for the entire **family**, particularly parents who must attend to the frightened child and soothe the child back to sleep. Childhood sleep disruptions that persist over time may interfere with the normal sleep-wake cycle of the caregivers. Loss of sleep has a cumulative impact on the well being of both children and adults. Parents may become anxious in sympathy with the child and lie awake in worry long after the frightened dreamer has returned to sleep. There are many good books available to help a parent understand the normal sleep-wake cycles of children and the common parasomnias that all children experience. This knowledge can bring much needed peace of mind and help the parent determine when professional assessment and assistance is appropriate.

KEY TERMS

Limbic system—A group of structures in the brain that includes the hypothalamus, amygdala, olfactory bulbs, and hippocampus. The limbic system plays an important part in regulation of human moods and emotions. Many psychiatric disorders are related to malfunctioning of the limbic system.

Parasomnia—A type of sleep disorder characterized by abnormal changes in behavior or body functions during sleep, specific stages of sleep, or the transition from sleeping to waking.

Rapid eye movement (REM) sleep—A phase of sleep during which the person's eyes move rapidly beneath the lids. It accounts for 20–25% of sleep time. Dreaming occurs during REM sleep.

Slow-wave sleep (SWS)—Stage of deepest sleep characterized by absence of eye movements, decreased body temperature, and involuntary body movements. Night terrors and sleepwalking occur during this stage of sleep.

Nonsteroidal anti-inflammatory drugs

Definition

Nonsteroidal anti-inflammatory drugs are medicines that relieve **pain**, swelling, stiffness, and inflammation.

Description

Nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed for a variety of painful conditions, including arthritis, bursitis, tendonitis, gout, menstrual cramps, **sprains**, **strains**, and other injuries.

Although the NSAIDs are often discussed as a group, not all are approved for use in children. As of 2004, the following drugs are approved for pediatric use:

- Ibuprofen (Advil, Motrin, Nuprin).
- Indomethicin (Indocin), not recommended for children under the age of 14 except in circumstances that warrant the risk. Indomethicin has special application in some infants born with heart problems.
- Ketoprofen (Orudis, Oruvail), not given to children under the age of 16 unless directed by a physician.
- Ketorolac tromethamine (Toradol), not approved for use in children but has been reported safe by some pediatric authorities.
- Meclofenamate sodium, safety and efficacy in children under 14 years of age has not been established.
- Mefenamic acid (Ponstel), safety and efficacy in children under 14 years of age has not been established.
- Naproxen (Aleve, Anaprox, Naprosyn), safety and efficacy in children under two years of age has not been established.
- Tolmetin sodium (Tolectin), safety and efficacy in children under two years of age has not been established.

Other NSAIDs have been used in pediatric therapy, but should not be considered as first choice for treatment of children or adolescents.

A new class of NSAIDs, called COX-2 inhibitors, have a lower risk of causing ulcers than do the traditional NSAIDs. These drugs may be appropriate for use in older teenagers but have not been approved for use in younger children, and there is some evidence that they are inappropriate for infants.

General use

Nonsteroidal anti-inflammatory drugs relieve pain, stiffness, swelling, and inflammation, but they do not cure the diseases or injuries responsible for these problems. Two drugs in this category, ibuprofen and naproxen, also reduce **fever**. Some nonsteroidal anti-inflammatory drugs can be bought without a prescription; others are available only with a prescription from a physician or dentist.

Precautions

Children with certain medical conditions and those who are taking some other medicines can have problems if they take nonsteroidal anti-inflammatory drugs. Before giving children these drugs, parents need to let the physician know about any of the following conditions.

Allergies

The physician needs to know about any **allergies** to foods, dyes, preservatives, or other substances. For children who have had reactions to nonsteroidal anti-inflammatory drugs in the past, parents should check with a physician before having these drugs prescribed again.

Pregnancy

Teens and young women who are pregnant or who plan to become pregnant should check with their physicians before taking these medicines. Whether nonsteroidal anti-inflammatory drugs cause birth defects in people is unknown, but some do cause birth defects in laboratory animals. If taken late in pregnancy, these drugs may prolong pregnancy, lengthen labor time, cause problems during delivery, or affect the heart or blood flow of the fetus.

Breastfeeding

Some nonsteroidal anti-inflammatory drugs pass into breast milk. Women who are breastfeeding their babies should check with their physicians before taking these drugs.

Other medical conditions

A number of medical conditions may influence the effects of nonsteroidal anti-inflammatory drugs. Parents of children and teens who have any of the conditions listed below should tell their physician about the condition before having nonsteroidal anti-inflammatory drugs prescribed.

- stomach or intestinal problems, such as colitis or Crohn's disease
- liver disease
- current or past kidney disease or current or past kidney stones
- heart disease
- high blood pressure
- blood disorders, such as anemia, low **platelet count**, low white blood cell count
- bleeding problems
- diabetes mellitus
- hemorrhoids, rectal bleeding, or rectal irritation
- asthma
- epilepsy
- systemic lupus erythematosus
- diseases of the blood vessels, such as polymyalgia rheumatica and temporal arteritis
- fluid retention
- alcohol abuse
- mental illness

Side effects

The most common side effects are stomach pain or cramps, **nausea**, **vomiting**, indigestion, **diarrhea**, heartburn, **headache**, **dizziness** or lightheadedness, and drowsiness. As the patient's body adjusts to the medicine, these symptoms usually disappear. If they do not, the physician who prescribed the medicine should be contacted.

Serious side effects are rare, but do sometimes occur. If any of the following side effects occur, patients should stop taking the medicine and get emergency medical care immediately:

- swelling or puffiness of the face
- swelling of the hands, feet, or lower legs
- rapid weight gain
- fainting
- breathing problems
- fast or irregular heartbeat
- tightness in the chest

Other side effects do not require emergency medical care, but should have medical attention. If any of the following side effects occur, patients should stop taking the medicine and the physician who prescribed the medicine should be called as soon as possible:

- severe pain, cramps, or burning in the stomach or abdomen
- convulsions
- fever
- severe nausea, heartburn, or indigestion
- white spots or sores in the mouth or on the lips
- rashes or red spots on the skin
- any unusual bleeding, including nosebleeds and spitting up or vomiting blood or dark material
- black, tarry stool

- chest pain
- unusual bruising
- severe headaches

A number of less common, temporary side effects are also possible. They usually do not need medical attention and will disappear once the body adjusts to the medicine. If they continue or interfere with normal activity, the physician should be contacted. Among these side effects are:

- gas, bloating, or constipation
- bitter taste or other taste changes
- sweating
- restlessness, irritability, anxiety
- trembling or twitching

Interactions

Nonsteroidal anti-inflammatory drugs may interact with a variety of other medicines. When interaction occurs, the effects of the drugs may change, and the risk of side effects may be greater. Physicians prescribing this drug should know all other medicines the patient is already taking. Among the drugs that may interact with nonsteroidal anti-inflammatory drugs are:

- blood thinning drugs, such as warfarin (Coumadin)
- other nonsteroidal anti-inflammatory drugs
- heparin
- tetracyclines
- cyclosprorine
- digitalis drugs
- lithium
- phenytoin (Dilantin)
- zidovudine (AZT, Retrovir)

NSAIDs may also interact with certain herbal preparations sold as dietary supplements. Among the herbs known to interact with NSAIDs are bearberry (*Arctostaphylos uva-ursi*), feverfew (*Tanacetum parthenium*), evening primrose (*Oenothera biennis*), and gossypol, a pigment obtained from cottonseed oil and used as a male contraceptive. In most cases, the herb increases the tendency of NSAIDs to irritate the digestive tract. It is just as important for doctors to know which herbal remedies the patient is taking on a regular basis as it is for doctors to know the other prescription medications which are being taken.

KEY TERMS

Anemia—A lack of hemoglobin, the compound in blood that carries oxygen from the lungs throughout the body and brings waste carbon dioxide from the cells to the lungs, where it is released.

Bursitis—Inflammation of the tissue around a joint.

Colitis—Inflammation of the colon (large bowel).

COX-2 inhibitors—A class of newer NSAIDs that are less likely to cause side effects in the digestive tract. COX-2 inhibitors work by inhibiting the production of cyclooxygenase-2, an enzyme involved in inflammation.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Salicylates—A group of drugs that includes aspirin and related compounds. Salicylates are used to relieve pain, reduce inflammation, and lower fever.

Tendonitis—Inflammation of a tendon, which is a tough band of tissue that connects muscle to bone.

Prevention

Many serious digestive system effects of NSAIDs can be prevented by taking mysoprostol (Cytotec), but this drug is only appropriate for patients with a high risk of ulcers. It is not called for when the NSAID is being used for a short period of time or in patients with other risk factors. Stomach upset can often be prevented by taking NSAIDs with food or milk.

Parental concerns

NSAIDs are very safe when used properly over a short period of time. They should not be used for longer periods or in larger doses than indicated on the label. If NSAIDs are to be used for prolonged periods, as in juvenile rheumatoid arthritis, there is a risk of potentially serious stomach and intestinal problems.

Nosebleed

Definition

A nosebleed, also called epistaxis, is a loss of blood from any blood vessel in the nose. It usually appears in only one nostril.

Description

Although unexpected or persistent bleeding from anywhere is a warning sign of **cancer** and should be investigated, nosebleeds are rarely a sign of serious illness. They are usually the result of minor injury or irritation.

Nosebleeds most often come from the front of the septum, the cartilage that separates the nose into two nostrils. These anterior nosebleeds comprise 80 percent of all nosebleeds. A mass of blood vessels, called Kiesselbach's plexus, lie on either side of the septum. These blood vessels are easy to injure and bleeding can occur.

Posterior nosebleeds, which come from the back of the nose, are less common and much harder to manage. Bleeding usually begins in the upper part of the nose and flows toward the throat and mouth where it is swallowed. It is difficult to determine how much blood is lost in these nosebleeds.

Demographics

Though it is a common misconception that children are more susceptible to nosebleeds than adults, research has found that nosebleeds are more prevalent in older adults and more often are a sign of other health problems. Nosebleeds do, however, occur frequently in childhood. About 30 percent of children up to five years of age have had spontaneous nosebleeds that appeared without apparent injury to the nose. Of children six to ten years of age, 56 percent have had them and 64 percent of preadolescents and adolescents from 11 to 15 have as well. Moreover, over half of adults with recurring nosebleeds had them as children. Only about 10 percent of children with frequent nosebleeds have been found to have a previously undiagnosed bleeding disorder.

Rarely, menstruating women, even adolescents, who have endometriosis, a condition in which tissues resembling the lining of the uterus occur abnormally in other parts of the pelvic cavity and sometimes in other parts of the body, can have cyclical nosebleeds with their menstrual periods.

Causes and symptoms

Causes

The most common cause of nosebleeds is injury from picking or blowing the nose. People with respiratory **allergies**, hay fever, and sinus infections have swollen nasal membranes that are fragile and more likely to bleed. Physical injury to the nose from falls, **sports**, or fighting can also cause nosebleeds. Chemical irritants such as cleaning products, aerosols, and paint can irritate the nose, sometimes resulting in nosebleeds. In addition, some drugs, such as cocaine, inflame the nose, causing it to bleed. Children with deviated septums or crooked noses are also prone to nosebleeds.

Nosebleeds occur more frequently in the winter when the air is cold outside and homes are filled with dry air from furnaces and other heating sources. Changes from cold to warm air or dry to humid air stress the delicate membranes of the nose and make it vulnerable to

injury and bleeding. Also, flu, colds, and other respiratory illnesses seem to occur more often in the winter. These also stress the nasal passages and make injury more likely. Bleeding from the nose, therefore, usually follows these seasonal stresses.

A nosebleed can also be an indication of illness. Certain blood disorders, such as **hemophilia**, can cause the nose to bleed. In this case, medical help should be sought immediately. Some head injuries produce nosebleeds. Uncontrolled high blood pressure, liver disease, leukemia, and tumors of the nasal passages and the brain can also cause the nose to bleed.

Even some medications can cause nosebleeds. Anticoagulants, medications used to thin the blood, including aspirin, can cause spontaneous bleeding from the nose. Overuse of nasal sprays can also produce nosebleeds. In addition, nosebleeds can be a side effect of alcohol abuse.

Nosebleeds in children can sometimes be caused by children putting objects into their noses. The object can tear the delicate membranes of the nose. Objects inserted into the nose can also cause obstruction of airflow and may need to be removed by a doctor.

Symptoms

Bleeding from one or both nostrils may be a trickle or a flood. Sometimes, it accompanies direct injury to the nose as in a sports injury or in picking the nose or too vigorous nose blowing. Children may experience frequent swallowing or a sensation of fluid in the back of the nose and throat.

When to call the doctor

If the bleeding does not stop after 20 minutes, it is necessary to seek medical help. Also, if there is a known or suspected **head injury** accompanying the nosebleed, there may be a skull fracture or brain disorder. In this case, the child should be taken to the emergency room immediately. In addition, if the nose is misshapen, especially after an accident, fall, or injury, it may be broken and will need to be evaluated by a doctor. Frequent nosebleeds, especially if they are occurring more often and are not due to colds, allergies, or trauma, will need to be seen by a doctor as well.

It may be a medical emergency if the bleeding is rapid or if there is a lot of blood. If the child feels faint or weak during a nosebleed, it may be do to blood loss and the child should see the doctor immediately.

Diagnosis

Bleeding from the nose is the obvious determinant of a nosebleed. The severity of it, however, may require blood work to look for bleeding disorders, diseases of the blood, or infections. X rays may be taken to determine if there has been a head injury or abnormalities within the structure of the nose. To further examine the nose, the doctor may perform a nasal endoscopy, a procedure that involves inserting a tiny camera into the nose to look at blood vessels and nasal structures.

Treatment

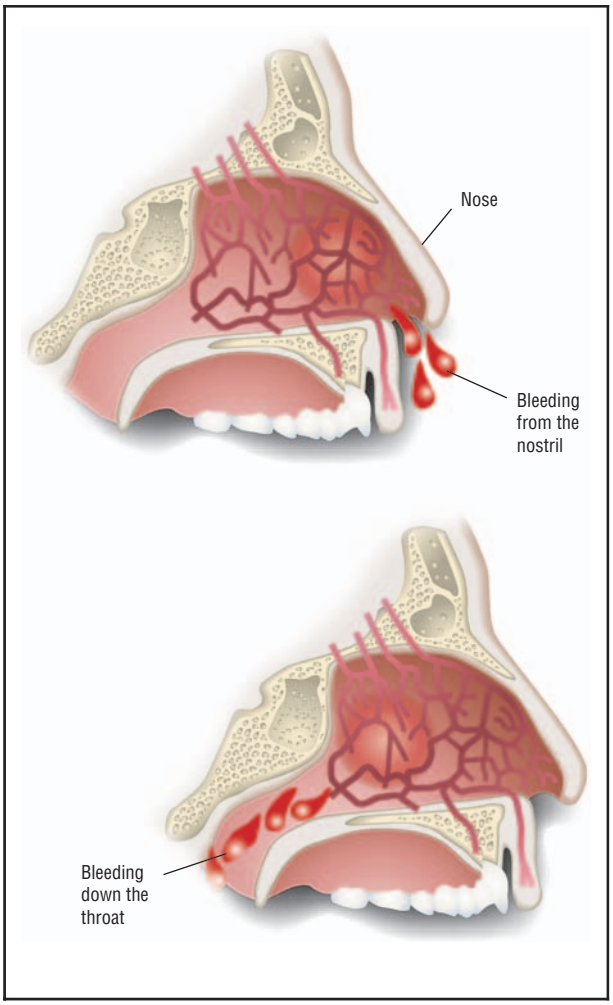
The first line of treatment is to gently pinch the nostrils together with the thumb and forefinger, while sitting upright and breathing through the mouth, for five to ten minutes. Leaning forward will prevent the child from swallowing blood. After at least five minutes, the parent or child can check to see if the bleeding has stopped. If it has not, then the pinching of the nose should be resumed and the child or parent should wait another five minutes. Most nosebleeds will stop within this time period, especially if the child is encouraged to remain calm. **Anxiety** or panic will cause blood to flow more rapidly and can hinder this self-healing process. It is very important for the child not to lie down while having a nosebleed.

Sometimes, a cold compress or crushed ice in a washcloth or plastic bag can be placed across the bridge of the nose and cheeks to encourage clotting. It is important not to pack the inside of the nose with gauze since this might further injure the nose.

In 2004, a new over-the-counter product was introduced for a quick home treatment for simple nosebleed. Called Nosebleed QR (Quick Relief), the product is composed of a hydrophilic polymer, a synthetic powder that absorbs blood, and potassium salt that aids in scab formation. The parent or child sprinkles the product onto a swab and coats the nostril then pinches the nose for 15 to 20 seconds. The product stops bleeding within one minute. However, it does sting and may not be a comfortable product to use with children.

Alternative treatment

Estrogen cream, the same preparation used to revitalize vaginal tissue, can toughen fragile blood vessels in the anterior septum and forestall the need for cauterization. Botanical medicines known as stiptics, which slow down and can stop bleeding, may be taken internally or applied topically. Some of the plants used are achillea (yarrow), trillium, geranium, and shepherd's purse (*Capsella bursa*).



Anatomical sideview of a nosebleed. *(Illustration by GGS Information Services)*

KEY TERMS

Deviated septum—A shift in the position of the nasal septum, the partition that divides the two nasal cavities.

Endometriosis—A condition in which the tissue that normally lines the uterus (endometrium) grows in other areas of the body, causing pain, irregular bleeding, and frequently, infertility.

Hemophilia—Any of several hereditary blood coagulation disorders occurring almost exclusively in males. Because blood does not clot properly, even minor injuries can cause significant blood loss that may require a blood transfusion, with its associated minor risk of infection.

Kiesselbach's plexus—The mass of blood vessels on either side of the septum.

Nasal endoscopy—A procedure that involves inserting a tiny camera into the nose in order to look at blood vessels and nasal structures.

Otorhinolaryngologist—An ear, nose, and throat specialist.

Septum—A wall or partition. Often refers to the muscular wall dividing the left and right heart chambers or the partition in the nose that separates the two nostrils. Also refers to an abnormal fold of tissue down that center of the uterus that can cause infertility.

Homeopathic remedies can be one of the quickest and most effective treatments for nosebleeds. One well known remedy is phosphorus.

Another natural treatment includes swabbing the nose with vitamin E oil for three days. If nosebleeds recur within that time, it is recommended to take 500 mg of bioflavonoids twice a day. Bioflavonoids are antioxidants found in citrus fruits that help strengthen blood vessels.

Prognosis

Most common nosebleeds are easily managed and can be prevented. Children usually recover quickly. Serious nosebleeds need further investigation but are usually controlled by treating the underlying cause.

Prevention

Keeping the home cooler in winter and using a humidifier help keep the nasal passages moist and reduce the risk of nosebleeds due to dry air. Some doctors also recommend using a nasal saline spray to enhance moisture in the nose.

Also, before sending children out to **play** on cold, dry days, parents can put a bit of petroleum jelly on a cotton swab and wipe it just inside their children's nostrils. This keeps the nose from drying out and producing surface cracks which can damage blood vessels in the lining of the nose and cause bleeding. Some parents routinely apply a thin layer of A & D ointment, petroleum jelly, or a mentholated salve around their children's noses at night as well as when they go outside.

Gently blowing the nose and not picking it will also prevent nosebleeds. This is especially important for several hours after nasal bleeding has stopped. In some cases,

strong sniffing is also discouraged to reduce further stress on the delicate tissues of the nose. Keeping the mouth open when sneezing can also reduce stress on the nose.

Treatment of hay fever and other respiratory allergies decreases sneezing and nasal inflammation. If a child is prone to sinus infections, some doctors may also use prophylactic or preventative treatment similar to allergy management.

Parental concerns

Nosebleeds can be frightening for children. Seeing any amount of blood may cause some children to panic or even faint. It is important to treat the nosebleed matter-of-factly as any parent would handle any other childhood scrape or wound. The parent's calm helps the child remain calm while waiting for the natural blood clotting mechanisms of the body to work. Parents should also be aware of any abnormal amount of blood during a nosebleed and make note of any recent falls or head injuries. These observations will inform parents about when to seek medical or emergency help.

Numbness and tingling

Definition

Numbness and tingling are decreased or abnormal sensations caused by altered sensory nerve function.

Description

The feeling of having a foot "fall asleep" is a familiar one. This same combination of numbness and tingling can occur in any region of the body and may be caused by a wide variety of disorders. Sensations such as these, which occur without any associated stimulus, are called paresthesias. Other types of paresthesias include feelings of cold, warmth, burning, **itching**, and skin crawling.

Demographics

People of all ages experience episodes of numbness and tingling. These generally become more common as people age. Episodes of numbness and tingling are more common among people with diabetes, **hypothyroidism**, **alcoholism**, **malnutrition**, or who experience mechanical trauma, especially to their limbs, neck or spine.

Causes and symptoms

Causes

Sensation is carried to the brain by neurons (nerve cells) running from the outer parts of the body to the spinal cord in bundles called nerves. In the spinal cord, these neurons make connections with other neurons that run up to the brain. Paresthesias are caused by disturbances in the function of neurons in the sensory pathway. This disturbance can occur in the central nervous system (the brain and spinal cord), the nerve roots that are attached to the spinal cord, or the peripheral nervous system (nerves outside the brain and spinal cord).

Peripheral disturbances are the most common cause of paresthesias. "Falling asleep" occurs when the blood supply to a nerve is cut off—a condition called ischemia. Ischemia usually occurs when an artery is compressed as it passes through a tightly flexed joint. Sleeping with the arms above the head or sitting with the legs tightly crossed frequently cause numbness and tingling.

Direct compression of the nerve also causes paresthesias. Compression can be short-lived, as when a heavy backpack compresses the nerves passing across the shoulders. Compression may also be chronic. Chronic nerve compression occurs in entrapment syndromes. The most common example is carpal tunnel syndrome, which occurs when the median nerve is compressed as it passes through a narrow channel in the wrist. Repetitive motion or prolonged vibration can cause the lining of the channel to swell and press on the nerve. Chronic nerve root compression, or radiculopathy, can occur in disk disease or spinal arthritis.

Other causes of paresthesias related to disorders of the peripheral nerves include the following:

- metabolic or nutritional disturbances, including diabetes, hypothyroidism (a condition caused by too little activity of the thyroid gland), alcoholism, malnutrition, and vitamin B_{12} deficiency
- trauma, including injuries that crush, sever, or pull on nerves
- inflammation
- connective tissue disease, including arthritis, systemic lupus erythematosus (a chronic inflammatory disease that affects many systems of the body, including the nervous system), polyarteritis nodosa (a vascular disease that causes widespread inflammation and ischemia of small and medium-size arteries), and Sjögren's syndrome (a disorder marked by insufficient moisture in the tear ducts, salivary glands, and other glands)
- toxins, including heavy metals (metallic elements such as arsenic, lead, and mercury which can, in large amounts, cause **poisoning**), certain medications **antibiotics** and **chemotherapy** agents, solvents, and overdose of pyridoxine (vitamin B_6)
- malignancy
- infections, including **Lyme disease**, human **immunodeficiency** virus (HIV), and leprosy
- hereditary disease, including **Charcot-Marie-Tooth disease** (a disorder that causes wasting of the leg muscles, resulting in malformation of the foot), porphyria (a group of disorders in which there is abnormally increased production of substances called porphyrins), and Denny-Brown's syndrome (a disorder of the nerve root)

Paresthesias can also be caused by central nervous system disturbances, including **stroke**, transient ischemic attack (TIA), tumor, trauma, multiple sclerosis, or infection.

Symptoms

Sensory nerves supply or innervate particular regions of the body. Determining the distribution of symptoms is an important way to identify the nerves involved. For instance, the median nerve innervates the thumb, the first two fingers, half of the ring finger, and the part of the hand to which they connect. The ulnar nerve innervates the other half of the ring finger, the little finger, and the remainder of the hand. Distribution of symptoms may also aid diagnosis of the underlying disease. Diabetes usually causes a symmetrical glove-and-stocking distribution in the hands and feet. Multiple sclerosis may cause symptoms in several, widely separated areas.

Other symptoms may accompany paresthesias, depending on the type and severity of the nerve disturbance. For instance, weakness may accompany damage to nerves that carry both sensory and motor neurons. (Motor neurons are those that carry messages outward from the brain.)

When to call the doctor

A healthcare professional should be consulted when instances of numbness or tingling last for more than a few hours.

Diagnosis

A careful history of the affected individual is needed for a diagnosis of paresthesias. The medical history should focus on the onset, duration, and location of symptoms. The history may also reveal current related medical problems and recent or past exposure to drugs, toxins, infection, or trauma. The **family** medical history may suggest a familial disorder. A work history may reveal repetitive motion, chronic vibration, or industrial chemical exposure.

The physical and neurological examination tests for distribution of symptoms and alterations in reflexes, sensation, or strength. The distribution of symptoms may be mapped by successive stimulation over the affected area of the body.

Lab tests for paresthesia may include blood tests and urinalysis to detect metabolic or nutritional abnormalities. Other tests are used to look for specific suspected causes. Nerve conduction velocity tests, electromyography, and imaging studies of the affected area may be employed. Nerve biopsy may be indicated in selected cases.

Treatment

Treatment of paresthesias depends on the underlying cause. For limbs that have "fallen asleep," restoring circulation by stretching, exercising, or massaging the affected limb can quickly dissipate the numbness and tingling. Physical therapy can also be helpful. If the paresthesia is caused by a chronic disease such as diabetes or occurs as a complication of treatments such as chemotherapy, most treatments are aimed at relieving symptoms. Anti-inflammatory drugs such as aspirin or ibuprofen are recommended if symptoms are mild. In more difficult cases, antidepressant drugs such as amitriptyline (Elavil) are sometimes prescribed. These drugs

are given at a much lower dosage for this purpose than for relief of depression. They are thought to help because they alter the body's perception of **pain**. In severe cases, opium derivatives such as codeine can be prescribed. In the early 2000s trials are being done to determine whether treatment with human nerve growth factor will be effective in regenerating the damaged nerves.

Several alternative treatments are available to help relieve symptoms of paresthesia. Nutritional therapy includes supplementation with B complex **vitamins**, especially vitamin B_{12} (intramuscular injection of vitamin B_{12} is most effective). Vitamin supplements should be used cautiously, however. Overdose of Vitamin B_6 is one of the causes of paresthesias. People experiencing paresthesia should also avoid alcohol. Acupuncture and massage are said to relieve symptoms. Self-massage with aromatic oils is sometimes helpful. The application of topical ointments containing capsaicin, the substance that makes hot peppers hot, provides relief for some. It may also be helpful to wear loosely fitting shoes and clothing. None of these alternatives should be used in place of traditional therapy for the underlying condition.

Prognosis

Treating the underlying disorder may reduce the occurrence of paresthesias. However, paresthesias resulting from damaged nerves may persist throughout or even beyond the recovery period. The overall prognosis depends on the cause.

Prevention

Preventing the underlying disorder may reduce the incidence of paresthesias. For those with frequent paresthesias caused by ischemia, changes in posture may help.

Nutritional concerns

Vitamin supplements should be used with caution as an overdose of vitamin B_6 is one of the causes of paresthesias. People experiencing paresthesia should avoid alcohol.

Parental concerns

Parents should monitor children who complain of numbness or tingling that lasts for more than a few minutes and fails to improve. They should recommend stretching and **exercise** and if relief does not come quickly, investigate other causes, such as clothing that is too tight.

KEY TERMS

Electrooculography (EOG)—A diagnostic test that records the electrical activity of the muscles that control eye movement.

Motor nerve—Motor or efferent nerve cells carry impulses from the brain to muscle or organ tissue.

Nerve condition velocity (NCV)—Technique for studying nerve or muscle disorders, measuring the speed at which nerves transmit signals.

Nerve growth factor—A protein resembling insulin that affects the growth and maintenance of nerve cells

Peripheral nervous system—The part of the nervous system that is outside the brain and spinal cord. Sensory, motor, and autonomic nerves are included.

Sensory nerves—Sensory or afferent nerves carry impulses of sensation from the periphery or outward parts of the body to the brain and spinal cord.

Nursemaid's elbow

Definition

Nursemaid's elbow is an injury to the ligament (strong band of tissue) that keeps the two bones of the forearm in the correct place.

Description

The two bones in the forearm are the radius and the ulna. The radius is on the thumb side of the forearm. The upper end of the radius is called the radius head. The radial head is held in place by a ligament called the annular ligament. When the annular ligament is torn, a part of it slides upward and becomes trapped in the elbow joint, which is very painful condition. The child holds the arm with the palm facing inward and the elbow bent. This injury is uncommon after the ages of three to four, due to stronger joints and ligaments. Also, youngsters are less likely to be in situations where this injury might occur.

Nursemaid's elbow is also called subluxation of the radial head, pulled elbow, slipped elbow, or toddler elbow.

Demographics

Nursemaid's elbow is a common occurrence in children from the ages of one to four or five. It is rarely seen after the age of six.

Causes and symptoms

Nursemaid's elbow is caused by a strong force on the elbow, such as a sudden pulling or yanking on the hand or forearm. This can occur when a child falls, when an adult pulls up a child's arm, to assist the child up a curb or step or to hurry the child along, or when a child falls away from an adult while being held by the arm. Swinging toddlers from the arms while playing can cause this injury. It can also occur when an infant rolls himself or herself over.

Symptoms of nursemaid's elbow include immediate **pain** in the injured arm, refusal or inability to move the injured arm, creating a condition called pseudo-paralysis, persistent crying, refusal to **play**, and **anxiety**. However each child may experience symptoms differently. These symptoms may also resemble other conditions or medical problems, so a physician should be consulted for a diagnosis.

Swinging a young child by the arms can cause nursemaid's elbow. *(© Raoul Minsart/Corbis.)*

When to call the doctor

The doctor should be called or the child should be taken to an emergency room when a child does not use the arm that has been injured, when the child seems to be in a lot of pain, or when there is a suspicion that someone has deliberately harmed the child.

After treatment for nursemaid's elbow, the doctor should be called if the child still refuses to use the arm six hours after it is put back into place; the child still has pain after 24 hours; the child's fingers get numb and tingly; or the child's elbow comes out of the socket again.

Diagnosis

The diagnosis of nursemaid's elbow is made through a physical examination by the child's physician. X rays of the elbow are usually not necessary.

Treatment

The child's arm should not be straightened or its position changed before the doctor examines it. An ice pack can be used, and the arm splinted in the position in which it is found. The area both above and below the elbow should be immobilized, including the shoulder and wrist if possible.

The physician or health care provider will move the bone and ligament back to their correct positions. This is an easy procedure that can be done in the office by supinating (externally rotating) the forearm (turning the thumb out with palm up), and then gently flexing the arm at the elbow (pushing the forearm up into the biceps). The ligament needs time to heal, so the child's arm should be treated gently after the procedure. The arm may be immobilized in a sling for one or two days, if desired.

Once the ligament and the radial head are returned to their proper position, the child can usually begin to use his or her arm again within a few minutes. Sometimes there is a short period of crying for a minute or two after the release. The earlier after the injury that the child is treated, the more rapid will be the recovery. Alternatively, if the problem has existed for some days, then relief from pain may not be so rapid. Bracing and **immo-**

KEY TERMS

Elbow—Hinged joint between the forearm and upper arm.

Ligament—A type of tough, fibrous tissue that connects bones or cartilage and provides support and strength to joints.

Nursemaid's elbow—An injury to the ligament (strong band of tissue) that keeps the two bones of the forearm in the correct place.

Radius—The bone of the forearm which joins the wrist on the same side as the thumb.

Ulna—One of the two bones of the forearm. Two pivot joints join it to the radius, one near the elbow, one near the wrist.

bilization is usually not required if this is the first occurrence of this condition. For repeat injuries, however, a posterior splint may be applied for several days. A few children may have swelling or pain in the joint. Regular doses of ibuprofen or other over-the-counter pain killers for a few days will help with the swelling and the pain.

If the child fails to use the arm after 15 minutes, the elbow should be x rayed to determine if it was fractured. If no fracture is found, the arm should be splinted and put into a sling, and the condition re-evaluated after 24 hours.

Prognosis

The child should be able to use the elbow after the injury has healed. However, once an elbow has been injured, it is more likely that it will happen again in the future if care is not taken to prevent further injury.

Prevention

A child should not be lifted or swung by the arms or hands nor should a child's arm be pulled hard. A small child should be lifted from under the arms.

Parental concerns

Parents should be aware of the damage to the ligament structures of the elbow and should not lift the child by the arm, as the pulled-elbow condition can reoccur up. Recurrence is especially likely for three to four weeks following the injury.

Unfortunately, nursemaid's elbow commonly occurs when an obstinate child is forcibly pulled along or lifted by the forearm by a parent or older sibling. For example, the injury might occur in a shopping center where a young child, typically two or three years old, is intent on pursuing a course or selecting an item somewhat different from the intentions of the parent. Another scenario that might result in nursemaid's elbow is when a parent or caregiver and a child are crossing the street where the parent or caregiver is forced to pull the child along quickly to avoid an approaching vehicle or to make it to the other curb before the traffic lights change. Care should also be taken to control anger or impatience to prevent re-injury in the future.

Nutrition

Definition

The process by which humans take in and use food in their bodies; also the study of diet as it relates to health.

Description

Good nutrition in childhood lays the foundation for good health throughout a person's lifetime. With the proliferation of fast food restaurants, the number of junk food commercials on television, and the increased trend toward eating out, it is more difficult than ever for parents to ensure that their children maintain a nutritious diet. Across the last decades of the twentieth century, increasing affluence and the widespread availability of vitamin-enriched foods have shifted the focus of nutritional

concerns in the United States from obtaining minimum requirements to cutting down on harmful elements in one's diet. Parents need to be as concerned about high levels of fat, cholesterol, sugar, and salt, as well as adequate intake of **vitamins**, **minerals**, and other nutrients.

The American Academy of Pediatrics, the National Academy of Sciences, the American Heart Association, and other health-care organizations agree that fat should not account for more than 30 percent of the calorie intake of children over the age of two, and saturated fat should account for under 10 percent. The main dietary sources in children's diets of saturated fat are whole milk, cheese, hot dogs, and luncheon meats. Recommendations for dietary change include switching to 1 percent or skim milk, low-fat cheese, and meats from which the fat can be trimmed. Since fat is important for growth, experts also caution that fat intake should not be under 25 percent of daily calorie intake and that parents of children under age two should not restrict fat in their diets.

The amount of refined sugar in children's diets—typically accounting for 14 percent of calorie intake by adolescence—is another cause for concern. Although sugar is known to cause **tooth decay** and also may be associated with behavior problems, the greatest danger in consuming foods high in added sugar is that these "empty calories" may replace the more nutritious foods that children need in order to maintain good health. (Soft drinks, perhaps the single greatest source of refined sugar in the diet of children and teenagers, get virtually all their calories from sugar and offer no nutrients.) This high intake of fat can lead to excess weight and, potentially, **obesity**.

Another element that needs to be restricted in children's diets is the intake of sodium through salted foods. Sodium has been closely linked to **hypertension** (high blood pressure), which increases a person's risk of heart disease and **stroke**. It has been determined that 18-year-olds need only 500 milligrams of sodium daily. In addition to limiting the amounts of fat, cholesterol, salt, and sugar in their children's diets, health authorities also recommend that parents concerned about nutrition ensure that children obtain a generous supply of complex carbohydrates (found in such foods as beans, potatoes, whole-grain products, and pasta) and have at least five servings of fresh fruits and vegetables daily.

Infancy

The first nutritional decision that must be made for a child by a parent or primary caregiver is whether to breastfeed or bottle feed. Breast milk is generally considered the best food for an infant up to the age of six to nine months. It has virtually all the nutrients that babies need and in the right balance. In addition, it contains important antibodies that help protect infants from infection at a time when their own immune systems are not yet fully developed.

The composition of breast milk actually changes during the first two weeks after a baby is born. Initially, it consists largely of colostrum, a substance that has more protein than complete breast milk and lower amounts of fat and sugar. It is also rich in the antibody immunoglobin A, which helps protect against infections. By the tenth day after birth, the regular breast milk, containing more carbohydrates and fat and less protein, is produced. The amounts of carbohydrates and fat gradually continue to increase, as will the quantity of the milk itself, to match the needs of the growing baby. Although most full-term infants get all the necessary nutrients from breastfeeding, some may need supplements of vitamins D and K.

Women who are either unable to breastfeed or who choose not to do so usually feed their babies formula made from processed cow's milk, generally reconstituted skim milk with vegetable oils added to substitute for the missing butterfat, which is difficult for infants to digest. Lactose (milk sugar) is also added, and some formulas contain whey protein as well. For infants who demonstrate sensitivity to cow's milk, formulas based on soy protein are available.

Breast milk or formula provides all the nutrients an infant needs up to the age of four to six months. Contrary to past beliefs, it has been found that not only do babies not need solid foods before then, introducing solids too early may lead to **food allergies** or overfeeding. Regular grocery-store cow's milk, which cannot be adequately digested by infants and can cause gastrointestinal bleeding, should not be introduced until a child is a year old. As the first solid food, pediatricians often recommend cereal made from a grain other than wheat, such as rice. The first solid foods may be either commercial baby food or strained foods prepared at home. Once solid foods have been introduced, infants still need to receive most of their nourishment from either breast milk or formula during their first year.

Toddlerhood

During children's second year, their growth rate slows dramatically compared to the prior period. In the first year, their birth weight triples, their length increases by 50 percent, and the size of their brain doubles. After that first year, it takes several years for their weight to even double. They will grow in spurts, with each spurt followed by a period of weight gain. This decreased

A child should eat a variety of foods every day for good health and proper growth. *(© Brian Leng/Corbis.)*

growth leads to a decreased demand for food, often manifested in a newfound pickiness. As long as a child consumes an adequate, varied diet over a period of several days, parents are cautioned against becoming unduly concerned over a single day of unbalanced eating. Toddlers need to eat more than three times a day, either five or six small meals or three major ones with snacks in between.

Preschool

Preschoolers are still growing relatively slowly. Their weight increases about 12 percent between the ages of three and five, although their appearance changes considerably as they lose the baby fat of infancy and toddlerhood. They are still picky eaters, generally eating less—and less consistently—than their parents would like. Although their fat requirement is not as high as that of infants, preschoolers still require more fat and fewer carbohydrates than adults. Fat is needed both for growth and for regulation of body temperature. Also, preschoolers need more than twice as much protein as adults. If the nutritional recommendations of the National Academy of Sciences are followed, a preschooler's diet will consist of 40 percent carbohydrates, 35 percent fats, 20 percent protein, and 5 percent fiber.

Between the ages of three and five, children's tastes expand considerably, and they are willing to consider foods they would have refused as toddlers. Four-year-olds can generally eat whatever foods the rest of the **family** is having. Preschoolers still cannot eat enough at three meals to meet their nutritional needs, and nutritious snacks are important. By this age, children's food choices can be strongly influenced by others. They will imitate good eating habits they see practiced by their parents, but they can also be easily swayed by television commercials for junk food.

School age

The diet of young school-age children, like that of preschoolers, should contain, in order of importance, carbohydrates, fat, and protein. A recommended proportion of these nutrients is 55 percent of the daily calorie intake from carbohydrates, 30 percent from fats, and 15 percent from protein. Once children begin spending a full day in school, a substantial, nutritious breakfast becomes more important than ever. Breakfast has been shown to affect the concentration and performance of elementary school children. Ideally, a balanced breakfast for a school-age child contains food high in protein as well as fruit and bread or another form of grain.

A major change affecting the nutrition of school-age children is the growth of opportunities to eat outside the home. The carefully packed homemade lunch may be traded for a salty snack or cupcake, and parts of it may be discarded. Vending machines and stores offer more temptations. In addition, school lunch programs differ widely in quality; even the nutritional value of a single food, such as a hamburger, can vary significantly depending on how it is prepared and what ingredients are used.

Adolescence brings its own set of nutritional needs and challenges. Beginning with the pre-teen years, children undergo their most intensive period of physical growth since infancy and need more food than at any other stage of life, particularly if they participate in **sports**. Teenagers, especially boys, are notorious for being able to empty the refrigerator of food, usually without gaining excess weight. Early adolescence in particular is a time of increased nutritional requirements for girls, who experience their greatest growth spurt at this time and also begin menstruating. It is difficult for weight-conscious teenage girls to eat enough to satisfy their minimum daily iron requirement of 18 milligrams, and they should try to eat either foods that are naturally rich in iron, such as turkey, beef, liver, and beans, or foods made from iron-enriched cereals. Adequate calcium intake is essential for the rapidly growing bones of teenagers, but milk has often been replaced by soft drinks as the beverage of choice among this age group. Parents should encourage adolescents, especially girls, to eat other foods rich in calcium, such as cheese, salmon, and broccoli.

As adolescents grow more independent, the number of meals and snacks eaten away from home increases as they spend more time with friends and take increased responsibility for arranging their own meals, with fast foods, soft drinks, and sweets often prominent on the menu. In addition to the natural appeal of these foods, **peer pressure** contributes to the choice of a diet soft drink over milk or juice, or pizza over broccoli. Although parents cannot control the eating habits of their teenagers, they can influence them by consistently making nutritious foods available at home and, at least in some cases, by discussing the benefits of good nutrition with them, especially if a relative or friend has had an illness, such as heart disease or colon **cancer**, that has known links to diet.

Common problems

A special problem that may affect childhood nutrition is the presence of food **allergies**, which are more common in children than in adults. They are most likely to begin when a child is very young and the immune system is still sensitive, usually in infancy. Food allergies also tend to run in families: if one parent has food allergies, a child has a 40 percent likelihood of developing one. This figure rises to 75 percent if both parents have food allergies. Common symptoms of food allergies include **hives** and **rashes**; swelling of the eyes, lips, and mouth; respiratory symptoms; and digestive problems. Foods that most often produce allergic reactions in infants are cow's milk, soy products, and citrus fruits. Other common childhood allergens include wheat, nuts, chocolate, strawberries, tomatoes, corn, and seafood. In time, childhood food allergies are often outgrown. Feeding a child with food allergies is a challenging but not impossible task for parents. A variety of foods can be substituted for those to which a child is allergic: soy products for milk and other dairy products; carob for chocolate; and, in the case of wheat allergies, products or flour made from grains such as rice or oats.

Parental concerns

Vegetarian kids

About 2 percent of Americans ages six to 17 (about 1 million) are vegetarian, the same percentage as among American adults, and 0.5 percent are vegan, according to a 2002 survey by the Vegetarian Resource Group (VRG). Six percent of six- to 17-year-olds do not eat meat but eat fish and/or poultry. Teens who follow a vegetarian diet are more likely to meet recommendations for total fat, saturated fat, and number of servings of fruits and vegetables as compared to non-vegetarians. They also have higher intakes of iron, vitamin A, fiber, and diet soda, and lower intakes of vitamin B12, cholesterol, and fast food. Most teens, whether they are vegetarian or not, do not meet recommendations for calcium, according to the VRG survey. The study concluded that rather than viewing adolescent **vegetarianism** as a phase or fad, the diet could be viewed as a healthy alternative

KEY TERMS

Colostrum—Milk secreted for a few days after birth and characterized by high protein and antibody content.

Essential fatty acid (EFA)—A fatty acid that the body requires but cannot make. It must be obtained from the diet. EFAs include omega-6 fatty acids found in primrose and safflower oils, and omega-3 fatty acids oils found in fatty fish and flaxseed, canola, soybean, and walnuts.

Immunoglobin A—A sugar protein with a high molecular weight that acts like an antibody and is produced by white blood cells during an immune response.

to the traditional American meat-based diet. The study also said that vegetarian diets in adolescence could lead to lifelong health-promoting dietary practices. The study was reported in the July-August 2002 issue of the VRG publication *Vegetarian Journal*.

Parents should closely monitor their vegetarian child's height, weight, and general health. A child who is not getting enough vitamins and nutrients may have symptoms such as skin rashes, fatigue, a painful and swollen tongue, irritability, pale skin, mental slowness, or difficulty breathing. The diets of vegetarian adolescents should be monitored closely to make sure they include a variety of foods, including fruits, vegetables, beans, whole grains, and non-meat protein sources. For vegetarians who do not eat fish, getting enough omega-3 essential fatty acids may be an issue, and supplements such as flaxseed oil should be considered, as well as walnuts and canola oil. Another essential fatty acid, omega-6, found in fish, can be obtained from borage oil or evening primrose oil supplements.

When to call the doctor

Parents should consult their child's pediatrician or physician if they are unsure the child's diet is nutritionally adequate. A doctor should also be consulted if a child's weight or height is not appropriate for their age.

Nystagmus

Definition

Nystagmus is a condition in which there is involuntary and rhythmic movement or oscillation of the eye. It is often caused by an underlying ocular or neurological disorder.

Description

The eye movements associated with nystagmus are varied. They can be either pendular, in which the oscillations are equal in all directions and or jerk, in which the movements may be faster in one direction than another. The frequency of the oscillation or movement and the amplitude of the oscillation also vary. The movements themselves may be vertical, horizontal, circular, or oblique in direction. Nystagmus can be sensory and develop as a result of poor vision, or it can be motor and develop as a result of a neurological problem.

Nystagmus may be congenital, or it may be acquired. Congenital, or infantile, nystagmus appears within the first few months of life. Congenital nystagmus is usually binocular and affects both eyes, is horizontal in direction, and does not occur while the child is sleeping. It decreases when the child's eyes converge or move inward. Most of these cases of nystagmus develop because of poor vision and do not have an underlying neurological cause.

Children with congenital nystagmus usually have a point in their eye movement in which the intensity of the nystagmus is decreased. This is called the null point, and the child may adopt a head tilt or rotation to help maintain his or her eyes at this position. This point is usually not in straight ahead or in a primary gaze position. Children with nystagmus who have their the null point located at a position in which the eyes are positioned inward may develop an esotropia, a form of **strabismus** or eye turn.

One variant of congenital nystagmus is spasmus nutans, which appears as a triad with accompanying head nodding and torticollis (head turn or tilt), and is seen between four months and three-and-a-half years of age and usually resolves without treatment within one to two years of onset. Rarely does it persist past age five. Usually spasmus nutans appears bilaterally, and the nystagmus is in a horizontal direction. When the nystagmus of spasmus nutans is vertical or rotary, the child does not have a head tilt.

There are various types of nystagmus. Downbeat nystagmus is characterized by a nystagmus that is more pronounced when the child looks down, especially when looking to the side, or in lateral gaze. An accentuated oscillation when looking up is seen in upbeat nystagmus. Seesaw nystagmus is an unusual type of in which one eye moves in and down and the other out and up. A periodic alternating nystagmus (PAN) is observed in primary gaze when the patient is looking straight ahead and is characterized by eye movements that continuously change direction and speed. Peripheral vestibular nystagmus may be accompanied by vertigo, **nausea**, and tinnitus, or ringing in the ears. This type of nystagmus is not always apparent but can be seen by a doctor when he or she looks in the back of the eye with a direct ophthalmoscope.

Latent nystagmus appears only when one eye is covered. This is a congenital nystagmus caused by an ocular motor disturbance rather than visual deprivation. It is often accompanied by strabismus or an eye turn. A child with latent nystagmus will not see well when one eye is covered.

Gaze evoked nystagmus occurs only when one is looking to the side in extreme lateral gaze. This type of nystagmus can be caused by ethanol and recreational drug use, but is seen in myasthenia gravis and thyroid disease as well.

Some types of nystagmus are normal. If one looks at an object in extreme gaze for a long period of time, endpoint nystagmus may be noted. Optokinetic nystagmus (OKN) is a nystagmus that can be elicited involuntarily when a rapidly moving striped object is passed in front of an individual's eyes.

Transmission

Congenital nystagmus may be transmitted genetically, either as an autosomal recessive or dominant, or as an X-linked recessive trait. It can also be associated with other conditions that are genetically transmitted. For example, Leber's amaurosis is an autosomal dominant trait and **albinism** is X-linked.

Demographics

Congenital nystagmus occurs twice as frequently in males than in females. The prevalence of nystagmus in the pediatric population is .015 percent. Eighty percent of nystagmus is congenital, and the remaining 20 percent is acquired.

Causes and symptoms

The eyes of an individual with nystagmus cannot remain still and oscillate in some position of gaze. Those

with nystagmus usually have decreased vision and poor depth perception, although those born with nystagmus, may not realize that their vision is poor. Those with acquired nystagmus may experience double vision or oscillopsia, or that objects in their visual space appear to move. An acquired nystagmus may be accompanied by other symptoms such **dizziness**, difficulty with balance, hearing loss, poor coordination, and **numbness**. If an individual with nystagmus experiences oscillopsia, then the nystagmus is acquired.

The primary cause of congenital nystagmus is visual deprivation, and the causes of visual deprivation in an infant include cataracts, oculoalbinism, glaucoma, retinal detachments, Leber's amaurosis, developmental abnormalities of the optic nerve such as a coloboma, and achromatopsia, a condition in which the infant cannot see color.

Acquired nystagmus can be caused by demyelination of nerve fibers, such as occurs in multiple sclerosis, lesions or tumors of the vestibular or visual pathways, strokes of the central nervous system, and drug use, both recreational as well as a side effect of prescribed drugs, such as those used to treat seizures and depression. Other causes of acquired nystagmus are Arnold-Chiari malformations, vitamin deficiencies, syphilis, Wernicke's encephalopathy, Behcet's syndrome, and Meniere's disease.

When to call the doctor

Since nystagmus can be caused by tumors, **stroke**, and trauma or neurological disorder, any type of nystagmus must be evaluated by a qualified practitioner. The nystagmus can be a sign of a serious problem. For example, a type of tumor called chiasmal glioma has signs and symptoms similar to spasmus nutans.

Diagnosis

Diagnosis of nystagmus is made primarily by patient history as reported by a parent, the age of onset, and observation of any accompanying signs such as a head turn, tilt or tremor, or oscillopsia. If possible, the infant or child's best visual acuity is determined. If the onset is acute, then usually the nystagmus is acquired.

The type of nystagmus can accurately be determined by eye movement recordings, which map direction, frequency, null point, and amplitude of the nystagmus. For the infant with congenital nystagmus, evoked response potential (EVR) and electroretinogram (ERG) give the doctor objective information about visual potential, and **magnetic resonance imaging** (MRI) can determine if and where a lesion is located. For the infant or young child, some of these tests may be done under anesthesia.

Treatment

The treatment for nystagmus, once the etiology is determined and treated, includes optical devices such as **contact lenses** and glasses, medication, and surgery.

For individuals with nystagmus correction of refractive error with glasses or contact lenses is the first step in treating the condition. For 85 percent of children with nystagmus, a spectacle prescription improves vision significantly. For those with congenital nystagmus, prism may be put in glasses to help position the eye at its null point or to help the eyes converge. For some people contact lenses are prescribed. Contact lenses slow down eye movements, and because the optical center of the prescription is always centered on the eye with the contact lens, vision improves. Low vision aids such as telescopes assist those whose vision cannot be fully corrected with spectacles and contact lenses alone. Tinting of the glasses or sunglasses may decrease the nystagmus of individuals with albinism. For the patient with oscillopsia, grinding prism into the spectacles may move the visual field to a point of decreased oscillopsia.

Congenital nystagmus, when due to a visual deprivation, is rarely improved by surgery. But when a head tilt or head turn accompanies nystagmus, surgery to correct a muscle imbalance may improve nystagmus and visual acuity. Surgery on the extraocular muscles of the eye may be helpful when the child's null point is in not in primary gaze but located at least 30 degrees from straight-ahead vision. When a tumor or stroke has caused an acquired nystagmus, then neurosurgery, if indicated for the underlying cause, may lead to resolution of the nystagmus. When surgery is considered, the risks of anesthesia must also be considered.

If oscillopsia is a co-existing symptom, then drugs can be given to reduce the ocular oscillations. Vestibular nystagmus can be treated by diazepam or scopolamine. Drugs called GABA agonists, such as baclofen and carbamazepine, are useful in treatment of seesaw nystagmus and PAN, if the nystagmus is acquired and not congenital. Baclofen cannot be given to children.

Botox (*Botulinum* toxin) injections can temporarily control the eye movements, but because of side effects such as double vision and ptosis or drooping of the eyelid, and because it is not a permanent solution, Botox is not used often.

KEY TERMS

Acupuncture—Based on the same traditional Chinese medical foundation as acupressure, acupuncture uses sterile needles inserted at specific points to treat certain conditions or relieve pain.

Albinism—An inherited condition that causes a lack of pigment. People with albinism typically have light skin, white or pale yellow hair, and light blue or gray eyes.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Binocular—Affecting or having to do with both eyes.

Biofeedback—A training technique that enables an individual to gain some element of control over involuntary or automatic body functions.

Coloboma—A birth defect in which part of the eye does not form completely.

Lesion—A disruption of the normal structure and function of a tissue by an injury or disease process. Wounds, sores, rashes, and boils are all lesions.

Strabismus—A disorder in which the eyes do not point in the same direction. Also called squint.

X-linked—A gene carried on the X chromosome, one of the two sex chromosomes.

If the nystagmus is due to drug toxicity, then reducing or discontinuing the drug eventually resolves the problem.

Alternative treatment

Acupuncture and biofeedback and vision therapy have been successful for some patients.

Prognosis

Congenital nystagmus is usually a benign condition. It is not curable, but its symptoms can be diminished with spectacles or contact lenses. The best corrected vision for most individuals with congenital nystagmus is between 20/40 and 20/70, but correction to 20/20 is possible for some. Nystagmus associated with spasmus nutans resolves spontaneously before the child reaches school age.

The prognosis for an acquired nystagmus depends on its cause. If the condition is due to a side effect of a drug, then decreasing or changing the treatment drug eventually resolves the nystagmus.

Prevention

In general nystagmus cannot be prevented. Since the cause of acquired nystagmus can be due to a co-existing neurological condition, prompt attention to other neurological signs that may accompany nystagmus, such as dizziness, may prevent or decrease the severity of nystagmus itself. Careful monitor of dosage of those drugs with nystagmus as a side effect may prevent the condition.

Parental concerns

Because nystagmus can be associated with many medical problems, the child with this condition must undergo a complete ocular and neurological evaluation.

Children with nystagmus are not aware that they may have a visual deficiency and as they get older must be helped with the restrictions that nystagmus places on them. For instance, driving may be restricted or not permitted. Certain occupations for which good visual correction is a requirement may be not feasible. Every effort must be made to integrate the child with nystagmus into a normal school setting in order to prepare the child for adult life, even if cosmetic concerns may instinctively lead the parent to want to protect the child.

Support for families of those with nystagmus can be found through the American Nystagmus Network.

O

Obesity

Definition

Obesity is an abnormal accumulation of body fat, usually 20 percent or more over an individual's ideal body weight. Obesity is associated with increased risk of illness, disability, and death.

The branch of medicine that deals with the study and treatment of obesity is known as bariatrics. As obesity has become a major health problem in the United States, bariatrics has become a separate medical and surgical specialty.

Description

Childhood obesity is in the early 2000s a significant health problem in the United States. Obese children and adolescents are at increased risk for developing diabetes, **hypertension**, coronary artery disease, **sleep** apnea, orthopedic problems, and psychosocial disorders.

Obesity involves excessive weight gain and fat accumulation. For children and adolescents, obesity is defined in terms of body mass index (BMI) percentile. BMI is a formula that considers an individual's height and weight to determine body fat and health risk, and it is used differently for children and adolescents than it is for adults. In adults, BMI often misrepresents obesity because it does not consider healthy weight from muscle tissue; therefore, body fat percentage is considered a more accurate method for determining obesity in adults. In children and adolescents, because body fat changes as they mature, BMI is gender- and age-specific and plotted on gender-specific growth charts to determine BMI-for-age. Curved lines on the chart (percentiles) are used by healthcare professionals to identify children and adolescents at risk for overweight and obesity. Children and adolescents with a BMI-for-age in the 85th to 95th percentile are considered overweight and at risk for obesity, and those with a BMI-for-age greater than the 95th percentile are considered obese.

Demographics

According to the American Obesity Association and the Centers for Disease Control and Prevention, 30.3 percent of children aged six to 11 years are overweight and 15.3 percent are obese, and 30.4 percent of adolescents aged 12 to 19 years are overweight and 15.5 percent are obese. From 1980 to 2004, the prevalence of obesity among children quadrupled, and the prevalence of obesity in adolescents more than doubled. Overweight and obesity is more prevalent in boys (32.7%) than girls (27.8%). Obesity is more common in African American, Hispanic American, and Native American children and adolescents, than among Caucasians of the same ages.

Causes and symptoms

Although obesity can be a side effect of certain hormonal disorders or use of certain medications, the primary cause of obesity in children and adolescents is excess calorie consumption coupled with a sedentary lifestyle. Children and adolescents living in the twenty-first century are the most inactive generation ever. The majority of schools no longer offer daily physical education classes; and active leisure activities, such as bicycle riding, have been replaced by sedentary activities, such as television watching and playing computer games. Studies have documented dramatic changes in childhood food consumption from the 1970s to 2004. Fast foods and foods eaten at other restaurants have increased by 300 percent since 1977, and soft drink consumption has also increased significantly. In addition, standard meal portion sizes and snacking have increased.

Obesity is the result of a complex interaction of genetics and environmental factors. Genetics influence how the body regulates appetite and metabolism, while certain environmental factors encourage excess calorie

consumption. The body requires a certain amount of energy for basic metabolism and to support additional physical activity. When calories consumed from food and beverages equal calories expended during physical activity, body weight is maintained. When calories consumed exceed calories expended, weight gain results. To gain one pound, 3,500 additional calories must be consumed. In American society, excess calories are easily consumed just by drinking soft drinks and eating "supersized" fast food meals. A sedentary lifestyle results in far fewer calories being burned daily.

The major symptoms of obesity are excessive weight gain and the presence of large amounts of fatty tissue. Obesity can cause a number of other conditions, including type 2 diabetes, hypertension, **high cholesterol**, joint **pain**, **asthma**, **hypothyroidism**, and gallstones. Type 2 diabetes, previously referred to as adult-onset diabetes, has increased dramatically in children, and this increase has been directly linked to obesity.

When to call the doctor

Overweight and obese children should be evaluated by a physician for diabetes, hypertension, high cholesterol, and other medical conditions that are influenced by excessive weight gain. Primary care physicians can be consulted for weight management counseling to help children lose weight.

Diagnosis

Obesity in children and adolescents is diagnosed using the BMI-for-age formula described above, which is used to define obesity. Comorbid conditions, such as diabetes and high cholesterol, are diagnosed using medical laboratory tests.

Treatment

As of 2004, no weight loss drugs were approved for use in children, although some drugs used to treat obesity are approved for use in adolescents age 16 years and older. A few drugs are under investigation for use in children. Although no drugs are specifically approved for pediatric weight loss, some physicians may prescribe them "off-label." Because the side effects of these medications in children are unknown, children should not use adult weight loss drugs.

For extremely obese adolescents, surgical procedures—called bariatric surgery—may be performed, but only rarely. These procedures involve significant surgical alteration of the digestive tract and require substantial modification of diet after the surgery to much less than 1,000 calories per day. The long-term effects on growth and development from severe post-operative calorie restriction are not unknown, and weight loss surgery should only be performed on adolescents as a last resort.

The most effective treatment for obese children and adolescents is behavior and lifestyle modification under the guidance of a physician or weight management specialist experienced in dealing with children and adolescents. Behavior and lifestyle modification involves the following:

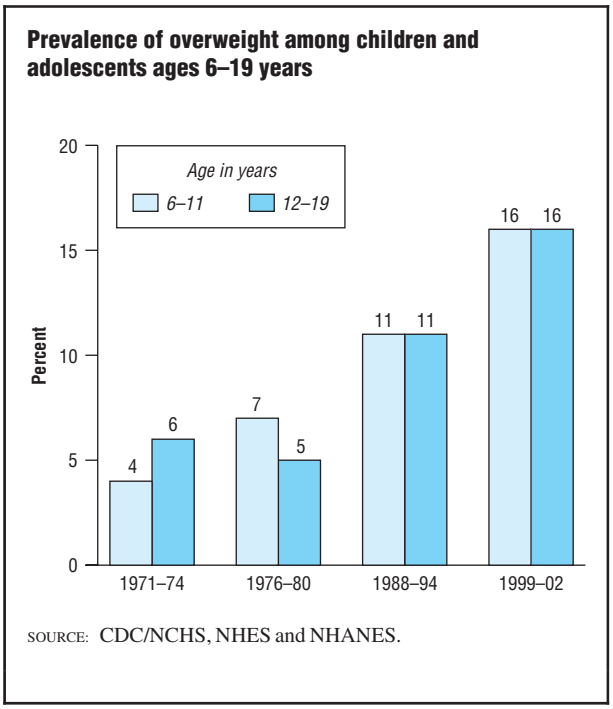
- **assessment** of child's and family's eating habits
- implementation of a regular, safe **exercise** program and increasing active leisure activities
- limiting television viewing and other sedentary activities
- setting reasonable goals and monitoring goal achievement using positive, non-food-related incentives
- counseling regarding how to keep a food/activity diary to track progress
- extensive support by involving entire **family** and/or joining a weight loss group of peers

Alternative treatment

Alternatives for weight loss involve the use of ephedra-containing drugs or herbal preparation or the use of diuretics and **laxatives**. Both of these practices are unsafe, especially for children and adolescents. Because ephedra can cause severe cardiac side effects, the Food and Drug Administration has issued warnings against its use. Diuretics and laxatives can result in severe **dehydration** and improper absorption of nutrients.

Acupressure and acupuncture can suppress food cravings. Visualization and meditation can create and reinforce a positive self-image that enhances the patient's determination to lose weight. By improving physical strength, mental concentration, and emotional serenity, **yoga** can provide the same benefits.

Given the drastic increase in childhood obesity, special summer programs and therapeutic schools have been formed to help children lose weight. Summer camp programs that focus on healthy eating and exercise habits are available for overweight and obese children. In addition, in early 2004, the first **alternative school** for overweight and obese children, which operates like other private and charter schools, but with a focus on healthy weight loss and maintenance, was established.



This graph shows the increasing numbers of overweight children in the United States. *(Illustration by GGS Information Services.)*

Prognosis

Obese and overweight children and adolescents are more likely to be obese or overweight as adults. According to the American Obesity Association, obese children aged 10 to 13 have a 70 percent chance of remaining obese for the rest of their lives. Obese individuals are at increased risk for many other diseases and early death. Behavior and lifestyle modification programs involving positive goal-setting, increased exercise, and group support can help children and adolescents successfully and safely lose weight.

Prevention

Obesity can be prevented by instilling healthy eating and regular exercise habits in children at an early age. Minimizing and structuring daily time for sedentary activities like television viewing and encouraging outdoor activities such as bicycle riding, walking, running, and active **play**, and active indoor activities such as dancing can help increase physical activity. Dietary modifications to help prevent obesity include limiting soft drink and fast food consumption, monitoring food portion sizes, and providing a well-balanced diet.

KEY TERMS

Adipose tissue—Fat tissue.

Bariatrics—The branch of medicine that deals with the prevention and treatment of obesity and related disorders.

Ghrelin—A peptide hormone secreted by cells in the lining of the stomach. Ghrelin is important in appetite regulation and maintaining the body's energy balance.

Hyperlipidemia—A condition characterized by abnormally high levels of lipids in blood plasma.

Hyperplastic obesity—Excessive weight gain in childhood, characterized by an increase in the number of new fat cells.

Hypertension—Abnormally high arterial blood pressure, which if left untreated can lead to heart disease and stroke.

Hypertrophic obesity—Excessive weight gain in adulthood, characterized by expansion of already existing fat cells.

Ideal weight—Weight corresponding to the lowest death rate for individuals of a specific height, gender, and age.

Leptin—A protein hormone that affects feeding behavior and hunger in humans. As of 2004 it is thought that obesity in humans may result in part from insensitivity to leptin.

Nutritional concerns

Nutrition is a primary factor for weight management of obese children and adolescents. Poor nutrition and dietary habits can lead to weight gain and obesity. Dietary modification is important for helping children lose weight and prevent obesity.

The following nutritional guidelines can help in the management of obesity:

- Limit soft drink consumption to one per day or less. One 12-ounce can of soda has 120 calories or more. Often, children and adolescents consume "super-size" sodas that may contain up to 1,000 calories.
- Limit fast food restaurant visits to one per week, and choose healthy options like grilled chicken and smaller sized portions of high-calorie items.
- Monitor food serving sizes.
- Increase consumption of fruits, vegetables, high-fiber foods, and whole-grain foods.

- Be aware that "low-fat" foods often substitute sugar for fat, and calories may actually be the same as the regular or high-fat version.

Parental concerns

Parents of obese children and adolescents should be concerned for their current and future health, since obesity can result in diabetes, hypertension, and coronary artery disease. Losing weight can be very difficult for obese children, and parental support is essential for success. Because children model behavior after their parents, obesity often affects both parents and children. Parents should strive to have healthy eating habits and exercise regularly to be effective role models for their children. Making healthy eating and exercise a family priority is better for everyone and helps reinforce positive changes in behavior for the obese child.

Obese children and adolescents are more susceptible to eating disorders, negative **self-esteem** and body image, and depression due to peer influences. Counseling, peer group therapy, and **family therapy** may be required to support lifestyle modifications for obese children and adolescents.

Obsessive-compulsive disorder

Definition

Obsessive-compulsive disorder (OCD) is a type of **anxiety** disorder. Anxiety disorder is the experience of prolonged, excessive worry about circumstances in one's life. OCD is characterized by distressing repetitive thoughts, impulses, or images that are intense, frightening, absurd, or unusual. These thoughts are followed by

ritualized actions that are usually bizarre and irrational. These ritual actions, known as compulsions, help reduce anxiety caused by the individual's obsessive thoughts. Often described as the "disease of doubt," the sufferer usually knows the obsessive thoughts and compulsions are irrational but, on another level, fears they may be true.

Description

Most people with obsessive-compulsive disorder have both obsessions and compulsions, but occasionally a person will have just one or the other. The degree to which this condition can interfere with daily living also varies. Some people are barely bothered, while others find the obsessions and compulsions to be profoundly traumatic and spend much time each day in compulsive actions. Because the symptoms are so distressing, sufferers often hide heir fears and rituals but cannot avoid acting on them. OCD sufferers are often unable to decide if their fears are realistic and need to be acted upon.

Obsessions are intrusive, irrational thoughts that keep popping up in a person's mind, such as the urgency to wash one's hands again. Typical obsessions include fears of dirt, germs, contamination, and violent or aggressive impulses. Other obsessions include feeling responsible or others' **safety** or an irrational **fear** of hitting a pedestrian with a car. Additional obsessions can involve excessive religious feelings or intrusive sexual thoughts. The patient may need to confess frequently to a religious counselor or may fear **acting out** the strong sexual thoughts in a hostile way. People with obsessive-compulsive disorder may have an intense preoccupation with order and symmetry or may be unable to throw anything out.

Compulsions usually involve repetitive rituals such as excessive washing (especially hand washing or bathing), cleaning, checking and touching, counting, arranging, and/or hoarding. As the person performs these acts, he may feel temporarily better, but there is no long-lasting sense of satisfaction or completion after the act is performed. Often, a person with obsessive-compulsive disorder believes that if the ritual is not performed, something dreadful will happen. While these compulsions may temporarily ease stress, short-term comfort is purchased at a heavy price—time spent repeating compulsive actions and a long-term interference with life.

The difference between OCD and other compulsive behavior is that while people who have problems with gambling, overeating, or with substance abuse may appear to be compulsive, these activities also provide pleasure to some degree. The compulsions of OCD, on the other hand, are never pleasurable.

OCD may be related to some other conditions, such as the continual urge to pull out body hair (**trichotillomania**); fear of having a serious disease (hypochondriasis); or preoccupation with imagined defects in personal appearance disorder (body dysmorphia). Some people with OCD also have **Tourette syndrome**, a condition featuring **tics** and unwanted vocalizations (such as swearing). OCD is often linked with depression and other anxiety disorders.

Demographics

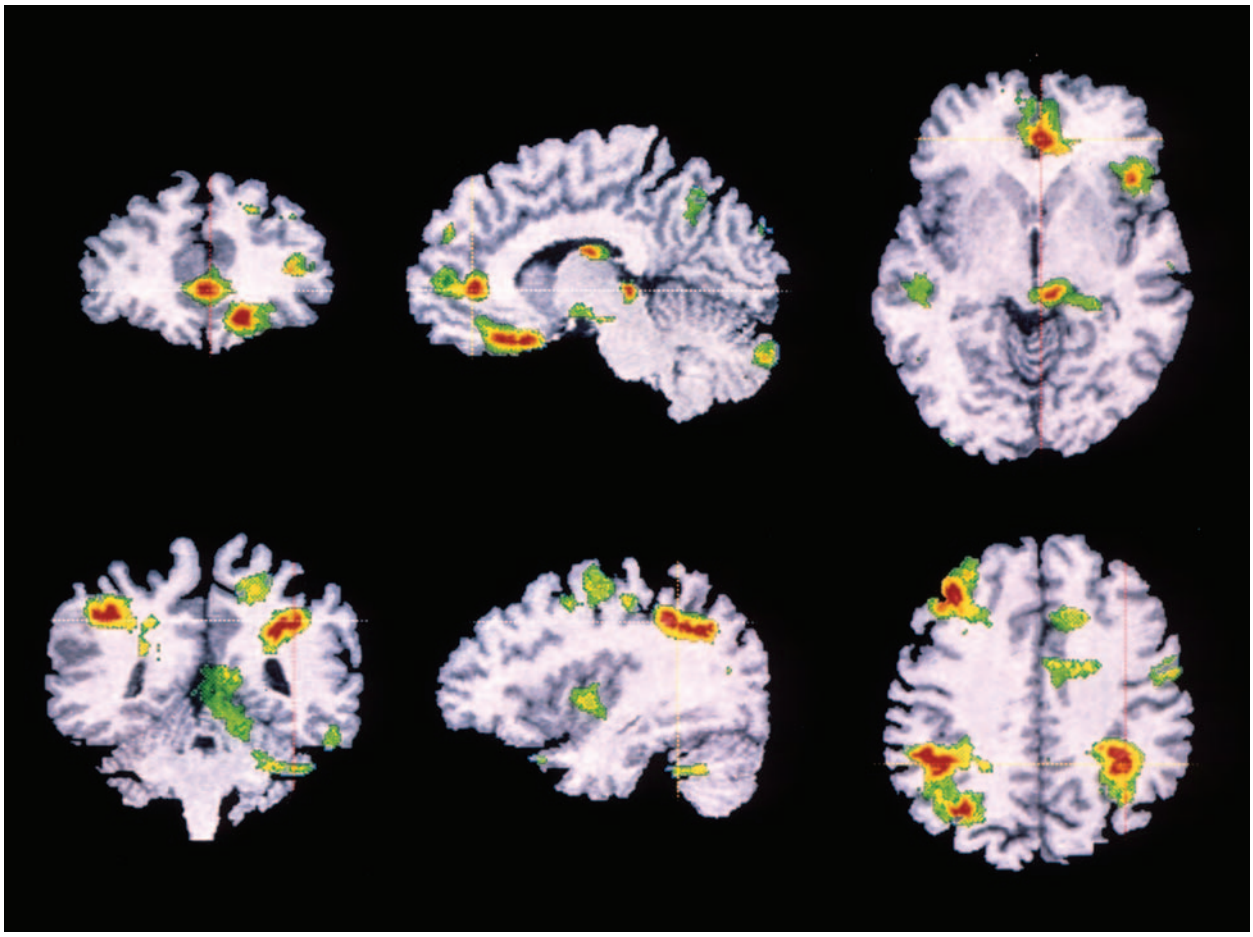
Almost one out of every 40 people suffers from obsessive-compulsive disorder at some time in their lives. The condition is two to three times more common than either **schizophrenia** or manic depression and strikes men and women of every ethnic group, age, and social level.

If one person in a **family** has obsessive-compulsive disorder, there is a 25 percent chance that another immediate family member has the condition. It also appears that stress and psychological factors may worsen symptoms, which usually begin during **adolescence** or early adulthood.

Causes and symptoms

Research suggests that the tendency to develop obsessive-compulsive disorder is inherited. There are several theories behind the cause of OCD. OCD may be related to a chemical imbalance within the brain that causes a communication problem between the front part of the brain (frontal lobe) and deeper parts of the brain responsible for the repetitive behavior. The orbital cortex located on the underside of the brain's frontal lobe is overactive in OCD patients. This may be one reason for the feeling of alarm that pushes the patient into compulsive, repetitive actions. It is possible that people with OCD experience overactivity deep within the brain that causes the cells to get "stuck," much like a jammed transmission in a car damages the gears. This could lead to the development of rigid thinking and repetitive movements common to the disorder. The fact that drugs which boost the levels of serotonin, a brain messenger substance linked to emotion and many different anxiety disorders, in the brain can reduce OCD symptoms may indicate that to some degree OCD is related to levels of serotonin in the brain.

There may also be a link between childhood episodes of **strep throat** and the development of OCD. In some vulnerable children, strep antibodies attack a certain part of the brain. Antibodies are cells that the body produces to fight specific diseases. That attack results in



PET scans of a brain showing active areas in obsessive-compulsive disorder; positive correlations (activity increases as symptoms get stronger), top row; negative correlation (activity decreases as symptoms strengthen), bottom. *(Wellcome Department of Cognitive Neurology/SPL/Photo Researchers, Inc.)*

the development of excessive washing or germ **phobias**. A phobia is a strong but irrational fear. In this instance the phobia is fear of disease germs present on commonly handled objects. These symptoms would normally disappear over time, but some children who have repeated infections may develop full-blown OCD. Treatment with **antibiotics**, immunoglobulin, or blood cleansing procedures can decrease the circulating anti-strep antibodies in the blood, thus lessening the OCD symptoms in some of these children.

Diagnosis

People with obsessive-compulsive disorder feel ashamed of their problem and often try to hide their symptoms. They avoid seeking treatment. Because they can be very good at keeping their problem from friends and family, many sufferers do not get the help they need until the behaviors are deeply ingrained habits and hard to change. As a result, the condition is often misdiagnosed or underdiagnosed. All too often, it can take more than a decade between the onset of symptoms and proper diagnosis and treatment.

OCD appears to be related to a disruption in serotonin levels, there is no blood test for the condition. Instead, doctors diagnose OCD after evaluating a person's symptoms and history.

Treatment

Obsessive-compulsive disorder can be effectively treated by a combination of cognitive-behavioral therapy and medication that regulates the brain's serotonin levels. Drugs that are approved to treat obsessive-compulsive disorder include fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft), all selective serotonin reuptake inhibitors (SSRIs) that

affect the level of serotonin in the brain. Older drugs include the antidepressant clomipramine (Anafranil), a widely studied drug in the treatment of OCD, but one that carries a greater risk of side effects. Drugs should be taken for at least 12 weeks before a person decides whether they are effective.

Cognitive-behavioral therapy (CBT) teaches patients how to confront their fears and obsessive thoughts by making the effort to endure or wait out the activities that usually cause anxiety without compulsively performing the calming rituals. Eventually their anxiety decreases. People who are able to alter their thought patterns in this way can lessen their preoccupation with the compulsive rituals. At the same time, the patient is encouraged to refocus attention elsewhere, such as on a hobby.

In a few very severe cases in which patients have not responded to medication or behavioral therapy, brain surgery may be tried as a way of relieving the unwanted symptoms. Surgery can help up to one third of patients with the most severe form of OCD. The most common operation involves removing a section of the brain called the cingulate cortex. The serious side effects of this surgery for some patients are seizures, personality changes, and less ability to plan.

Prognosis

Obsessive-compulsive disorder is a chronic disease that, if untreated, can last for decades, fluctuating from mild to severe and worsening with age. When treated by a combination of drugs and behavioral therapy, some patients go into complete remission. Unfortunately, not all patients have such a good response. About 20 percent of people cannot find relief with either drugs or behavioral therapy. **Hospitalization** may be required in some cases.

Despite the crippling nature of the symptoms, many successful doctors, lawyers, business people, performers, and entertainers function well in society despite their condition. Nevertheless, the emotional and financial cost of obsessive-compulsive disorder can be quite high.

Parental concerns

Some people have referred to obsessive-compulsive disorder as "the great pretender," because its symptoms can mimic a number of other disorders. Furthermore, children may become skilled at hiding the more embarrassing features of their condition. Because of these characteristics of the disorder, obsessive-compulsive disorder may go undiagnosed for some time.

KEY TERMS

Anxiety disorder—A mental disorder characterized by prolonged, excessive worry about circumstances in one's life. Anxiety disorders include agoraphobia and other phobias, obsessive-compulsive disorder, post-traumatic stress disorder, and panic disorder.

Cognitive-behavioral therapy—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Compulsion—A repetitive or ritualistic behavior that a person performs to reduce anxiety. Compulsions often develop as a way of controlling or "undoing" obsessive thoughts.

Obsession—A persistent image, idea, or desire that dominates a person's thoughts or feelings.

Selective serotonin reuptake inhibitors (SSRIs)—A class of antidepressants that work by blocking the reabsorption of serotonin in the brain, thus raising the levels of serotonin. SSRIs include fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil).

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

Oligomenorrhea

Definition

Medical dictionaries define oligomenorrhea as infrequent or very light **menstruation**. But physicians typically apply a narrower definition, restricting the diagnosis of oligomenorrhea to women whose periods were regularly established before they developed problems with infrequent flow. With oligomenorrhea, menstrual periods occur at intervals of greater than 35 days, with only four to nine periods in a year.

Description

True oligomenorrhea cannot occur until a young woman's menstrual periods have been established. In the United States, 97.5 percent of women have begun normal menstrual cycles by age 16. The complete absence of menstruation (menstrual periods never started or they stopped after having been established) is called **amenorrhea**. Oligomenorrhea can be redefined as amenorrhea if menstruation stops for six months or more; however, there is no universally agreed-upon cutoff point or timeline.

It is quite common for women at the beginning and end of their reproductive lives to miss periods or have them at irregular intervals. This variation is normal and is usually the result of imperfect coordination between the hypothalamus, the pituitary gland, and the ovaries. For no apparent reason, a few women menstruate (with ovulation occurring) on a regular schedule as infrequently as once every two months. For them that schedule is normal and not a cause for concern.

Women with polycystic ovary syndrome (PCOS) are also likely to suffer from oligomenorrhea. PCOS is a condition in which the ovaries become filled with small cysts. Women with PCOS show menstrual irregularities that range from oligomenorrhea and amenorrhea to very heavy and irregular periods. PCOS affects about 6 percent of premenopausal women and is related to excess androgen production.

Other physical and emotional factors also cause a woman to miss periods. These include the following:

- emotional stress
- chronic illness
- poor nutritional status
- such eating disorders as **anorexia nervosa**
- excessive **exercise**
- estrogen-secreting tumors
- abnormalities in the structure of the uterus or cervix that obstruct the outflow of menstrual fluid
- illicit use of anabolic steroid drugs to enhance athletic performance

Professional ballet dancers, gymnasts, and ice skaters are especially at risk for oligomenorrhea because they combine strenuous physical activity with a diet intended to keep their weight down. Menstrual irregularities are known to be one of the three disorders comprising the so-called "female athlete triad," the other disorders being disordered eating and osteoporosis. The triad was first formally named at the annual meeting of the American College of Sports Medicine in 1993, but doctors were aware of the combination of bone mineral loss, stress **fractures**, eating disorders, and participation in women's **sports** for several decades before the triad was named. Women's coaches have become increasingly aware of the problem since the early 1990s and are encouraging female athletes to seek medical advice.

Demographics

By definition, oligomenorrhea is a health concern only for women. It is estimated that about 5 percent of women in the United States in their childbearing years experience an episode of oligomenorrhea each year. This percentage appears to be constant across racial and ethnic groups.

Oligomenorrhea related to the female athlete triad is more common in this group of women than in the general female population. One study at the University of California at San Francisco found that 11 percent of female

marathon runners had amenorrhea or oligomenorrhea. Although precise data are difficult to obtain because many athletes with the triad try to hide their symptoms from others, disordered eating and menstrual irregularities have been estimated to run as high as 62 percent of female athletes at the college level, with 4 percent to 39 percent meeting the criteria for anorexia nervosa or **bulimia nervosa** as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM-IV*.

Causes and symptoms

Causes

Oligomenorrhea that occurs in adolescents is often caused by immaturity or lack of synchronization between the hypothalamus, pituitary gland, and ovaries. The hypothalamus is the part of the brain that controls body temperature, cellular metabolism, and such basic functions as appetite for food, the sleep/wake cycle, and reproduction. The hypothalamus also secretes hormones that regulate the pituitary gland.

The pituitary gland is then stimulated to produce hormones that affect growth and reproduction. At the beginning and end of a woman's reproductive life, some of these hormone messages may not be synchronized, resulting in menstrual irregularities.

Oligomenorrhea in PCOS is thought to be caused by inappropriate levels of both female and male hormones. Male hormones are produced in small quantities by all women, but in women with PCOS, levels of male hormone (androgens) are slightly higher than in other women. Some researchers hypothesize that the ovaries of women with PCOS are abnormal in other respects. In 2003, a group of researchers in London reported that there are fundamental differences between the development of egg follicles in normal ovaries and follicle development in the ovaries of women with PCOS.

In athletes, models, actresses, dancers, and women with anorexia nervosa, oligomenorrhea occurs because body fat drops too low compared to weight. Emotional stress related to performance anxiety may also be a factor in oligomenorrhea in these women.

Symptoms

Women with oligomenorrhea may have the following symptoms:

- menstrual periods at intervals of more than 35 days
- unusually light menstrual flow
- irregular menstrual periods with unpredictable flow
- difficulty conceiving

Young women whose oligomenorrhea is associated with the female athlete triad may have such other symptoms of the triad as frequent stress fractures, particularly in the bones of the hips, spine, or lower legs; abnormal eating patterns or extremely restrictive diets; and abnormal heart rhythms or low blood pressure.

When to call the doctor

A young woman should see her doctor as soon as she notices that a previously regular menstrual pattern has become irregular; it is not necessary to wait six months or longer to have oligomenorrhea investigated. A common rule is to consult the doctor after three missed periods.

Diagnosis

History and physical examination

Diagnosis of oligomenorrhea begins with the patient informing the doctor about infrequent periods. The doctor will ask for a detailed description of the problem and take a history of how long it has existed and any patterns the patient has observed. A woman can assist the doctor in diagnosing the cause of oligomenorrhea by keeping a record of the time, frequency, length, and quantity of bleeding. She should also tell the doctor about any recent illnesses, including longstanding conditions such as **diabetes mellitus**. The doctor may also inquire about the patient's diet, exercise patterns, sexual activity, contraceptive use, current medications, or past surgical procedures.

The doctor will then perform a physical examination to evaluate the patient's weight in proportion to her height, to check for signs of normal sexual development, to make sure the heart rhythm and other vital signs are normal, and to palpate (feel) the thyroid gland for evidence of swelling.

In the case of female athletes, the doctor may need to establish a relationship of trust with the patient before asking about such matters as diet, practice and workout schedules, and the use of such drugs as steroids or ephedrine. The presence of stress fractures in young women should be investigated. In some cases, the doctor may give the patients the Eating Disorder Inventory (EDI) or a similar screening questionnaire to help determine whether the patient is at risk for developing anorexia or bulimia.

Laboratory tests

After taking the young woman's history, the gynecologist or **family** practitioner does a pelvic examination and Pap smear. To rule out specific causes of oligomenorrhea, the doctor may also order a pregnancy test in sexually active women and blood tests to check the level of thyroid hormone. Based on the initial test results, the doctor may want to perform additional tests to determine the level of other hormones that play a role in reproduction.

As of 2003, more sensitive monoclonal assays had been developed for measuring hormone levels in the blood serum of women with PCOS, thus allowing earlier and more accurate diagnosis.

Imaging studies

In some cases the doctor may order an ultrasound study of the pelvic region to check for anatomical abnormalities or x rays or a bone scan to check for bone fractures. In a few cases the doctor may order an MRI to rule out tumors affecting the hypothalamus or pituitary gland.

Treatment

Treatment of oligomenorrhea depends on the cause. In adolescents and women near menopause, oligomenorrhea usually needs no treatment. For some athletes, changes in training routines and eating habits may be enough to return the woman to a regular menstrual cycle.

Most patients suffering from oligomenorrhea are treated with birth control pills. Other women, including those with PCOS, are treated with hormones. Prescribed hormones depend on which particular hormones are deficient or out of balance. When oligomenorrhea is associated with an eating disorder or the female athlete triad, the underlying condition must be treated. Consultation with a psychiatrist and nutritionist is usually necessary to manage an eating disorder. Female athletes may require physical therapy or rehabilitation as well.

Alternative treatment

As with conventional medical treatments, alternative treatments are based on the cause of the condition. If a hormonal imbalance is revealed by laboratory testing, hormone replacements that are more "natural" for the body (including tri-estrogen and natural progesterone) are recommended. Glandular therapy can assist in bringing about a balance in the glands involved in the reproductive cycle, including the hypothalamus, pituitary, thyroid, ovarian, and adrenal glands.

Since homeopathy and acupuncture work on deep, energetic levels to rebalance the body, these two forms of therapy may be helpful in treating oligomenorrhea. Western and Chinese herbal medicines also can be very effective. Herbs used to treat oligomenorrhea include dong quai (*Angelica sinensis*), black cohosh (*Cimicifuga racemosa*), and chaste tree (*Vitex agnus-castus*). Herbal preparations used to bring on the menstrual period are known as emmenagogues. For some women, meditation, guided imagery, and visualization can play a role in the treatment of oligomenorrhea by relieving emotional stress.

Nutritional concerns

Diet and adequate **nutrition**, including adequate protein, essential fatty acids, whole grains, and fresh fruits and vegetables are important for every woman, especially if deficiencies are present or if she regularly exercises very strenuously. Female athletes at the high school or college level should consult a nutritionist to make sure that they are eating a well-balanced diet that is adequate to maintain a healthy weight for their height. Girls participating in dance or in sports that emphasize weight control or a slender body type (gymnastics, track and field, swimming, and cheerleading) are at higher risk of developing eating disorders than those that are involved in such sports as softball, weight lifting, or basketball. In some cases the athlete may be given calcium or vitamin D supplements to lower the risk of osteoporosis.

Prognosis

Many women, including those with PCOS, are successfully treated with hormones for oligomenorrhea. They have more frequent periods and begin ovulating during their menstrual cycle, restoring their fertility.

For women who do not respond to hormones or who continue to have an underlying condition that causes oligomenorrhea, the outlook is less positive. Women who have oligomenorrhea as teenagers may have difficulty becoming pregnant and may receive fertility drugs. The absence of adequate estrogen increases the risk of osteoporosis, repeated bone fractures, and cardiovascular disease in later life. Female athletes who develop bone loss or osteoporosis in their late teens or early twenties are at increased risk of developing arthritis as they grow older. Women who do not have regular periods also are more likely to develop uterine **cancer**. Oligomenorrhea can become amenorrhea at any time, increasing the chance of having these complications.

KEY TERMS

Amenorrhea—The absence or abnormal stoppage of menstrual periods.

Anorexia nervosa—An eating disorder marked by an unrealistic fear of weight gain, self-starvation, and distortion of body image. It most commonly occurs in adolescent females.

Cyst—An abnormal sac or enclosed cavity in the body filled with liquid or partially solid material. Also refers to a protective, walled-off capsule in which an organism lies dormant.

Emmenagogue—A type of medication that brings on or increases a woman's menstrual flow.

Female athlete triad—A combination of disorders frequently found in female athletes that includes disordered eating, osteoporosis, and oligo- or amenorrhea. The triad was first officially named in 1993.

Osteoporosis—Literally meaning "porous bones," this condition occurs when bones lose an excessive amount of their protein and mineral content, particularly calcium. Over time, bone mass and strength are reduced leading to increased risk of fractures.

Prevention

Oligomenorrhea is preventable only in women whose low body fat to weight ratio is keeping them from maintaining a regular menstrual cycle. Adequate nutrition and less vigorous training schedules for female athletes will normally prevent oligomenorrhea. When oligomenorrhea is caused by hormonal factors, however, it is not preventable, but is usually treatable.

Parental concerns

Oligomenorrhea in teenagers who have only recently begun to menstruate is not usually a cause for parental concern, particularly if the girl's development during **puberty** has been otherwise normal or if there is a family history of oligomenorrhea. Oligomenorrhea in an adolescent should be investigated, however, if the girl is heavily involved in athletics or if she is otherwise at risk for developing an eating disorder. One way that parents can help college-age athletes is to be affectionate and emotionally supportive of their daughter, as girls who are away from home for the first time or who are "loners" are particularly at risk for developing the female athlete triad during their freshman year.

Oppositional defiant disorder

Definition

Oppositional defiant disorder (ODD) is a childhood mental disorder characterized by a pattern of angry, antagonistic, hostile, negative, irritable, and/or vindictive behavior lasting at least six months and occurring more frequently than is typically observed for the child's age and developmental stage. Children diagnosed with ODD do not meet the clinical diagnostic criteria for **conduct disorder**.

Description

Oppositional defiant disorder (ODD), a relatively new clinical classification, involves an ongoing pattern of antagonistic, defiant, and hostile behavior toward parents and other authority figures. Children and adolescents with ODD often have frequent temper **tantrums**, blame others for their misbehavior, argue excessively with adults, actively refuse to comply with adult rules and requests, deliberately defy adults and attempt to annoy or upset them, and are easily annoyed by others.

Demographics

Before **puberty**, ODD is more common in boys than girls; however, after puberty ODD occurrence rates are about equal in boys and girls. The disorder typically begins by the age of eight. According to the American Academy of Child and Adolescent Psychiatry, approximately 5 to 15 percent of all school-aged children have ODD.

Causes and symptoms

Although the specific causes of ODD are unknown, genetics and environment are thought to play a role in its development. As of 2004 several theories about the causes of oppositional defiant disorder are being investigated. ODD may be related to the following:

- the child's **temperament** and the family's response to that temperament
- an inherited predisposition to the disorder in certain families
- a neurological cause, such as a head injury
- a chemical imbalance in the brain (especially with the brain chemical serotonin)

ODD appears to be more common in families in which at least one parent has a history of a mood disorder, conduct disorder, attention deficit hyperactivity disorder (ADHD), **antisocial personality disorder**, or a substance abuse-related disorder. Children with one parent who is alcoholic or who has been in trouble with the law are almost three times more likely to have ODD. Additionally, some studies suggest that mothers with a depressive disorder are more likely to have children that develop ODD. ODD can also occur in conjunction with other conditions such as ADHD, learning disabilities, **anxiety** disorders, and **mood disorders**. About 50 percent to 65 percent of children with ADHD also have ODD.

Symptoms of ODD include a pattern of negative, hostile, and defiant behavior lasting at least six months. During this time four or more of the following must be present for a child to be diagnosed with ODD:

- often loses his/her temper
- often argues with adults
- often actively defies or refuses to comply with adults' requests or rules
- often deliberately annoys people
- often blames others for his/her mistakes or misbehavior
- is often touchy or easily annoyed by others
- is often angry and resentful
- is often spiteful or vindictive
- misbehaves frequently
- swears or uses obscene language
- has a low opinion of him/herself

Additional problems may be present, including the following:

- learning problems
- a depressed mood
- hyperactivity (although ADHD must be ruled out)

- substance abuse or dependence
- dramatic and erratic behavior

When to call the doctor

Parents of children and adolescents who exhibit symptoms of ODD should see a physician as soon as possible. Usually, a referral to a psychologist, psychiatrist, or therapist will be given.

Diagnosis

ODD is diagnosed by psychological and psychiatric evaluations; interviews with **family** members, teachers, and caregivers; and observation and interviews with the child or adolescent. Diagnosis is based on clinical criteria defined in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision C (DSM-IV-TR).

ODD often has characteristics in common with other psychological disorders and often occurs in conjunction with other conditions, such as ADHD or mood disorders. Therefore, diagnosis of ODD usually depends on exclusion of other disorders. A diagnosis of ODD is not made if the symptoms occur exclusively in psychotic or mood disorders, or if the child meets clinical criteria for conduct disorder, or, if the adolescent is 18 years old or older and meets clinical criteria for antisocial personality disorder. Children and adolescents with ODD do not exhibit the more serious aggressive behaviors or physical cruelty that is common in other disorders.

Treatment

Treatment of ODD usually involves medication, and group, individual, and/or **family therapy**. Of these, individual therapy is the most common. The goal of therapy is to help provide a consistent daily schedule, support, rules, **discipline**, and limits, as well as to help train patients to get along with others by modifying behaviors. Therapy can occur in residential or day treatment facilities, in a medical setting, or on an outpatient basis. Therapy can instruct patients on how to effectively deal with ODD and help them learn how to do the following:

- use self time-outs
- identify what increases anxiety
- talk about feelings instead of acting on them
- find and use ways to calm themselves
- frequently remind themselves of their goals
- get involved in tasks and physical activities that provide a healthy outlet for energy
- learn how to talk with others
- develop a predictable, consistent, daily schedule of activity
- develop ways to obtain pleasure and feel good
- learn how to get along with other people
- find ways to limit stimulation
- learn to admit mistakes in a matter-of-fact way

Therapy can also involve the parents. Parent management training focuses on teaching parents specific and more effective techniques for handling the child's opposition and defiance. Research has shown that parent management training is more effective than family therapy.

Stimulant medication is used only when ODD co-occurs with ADHD. Occasionally, children and adolescents with ODD may also have depression or anxiety disorders, and treatment with **antidepressants** and anti-anxiety medications can help alleviate some symptoms of ODD.

Prognosis

The prognosis for ODD varies. In some children, ODD evolves into a conduct disorder or a mood disorder. ODD, if left untreated, has approximately an 80 percent chance of turning into conduct disorder as a child ages. Later in life, ODD can develop into passive-aggressive personality disorder or antisocial personality disorder. ODD can cause significant social, academic, and/or occupational impairment. Generally, with treatment and long-term participation in therapy, adjustment in social settings and in the workplace can be made in adulthood.

Prevention

As of 2004, ODD could not be prevented.

Parental concerns

Children and adolescents with ODD usually have difficulties in school and at home. In some cases, ODD can result in expulsion from school. Parents should investigate **alternative school** settings that may be able to provide counseling and group therapy integrated with academics. Assistance is available through county social or mental health services, educational consultants, and local school counselors. Family therapy may help alleviate stressful family situations and help other family members understand the disorder.

KEY TERMS

Alternative school—An educational setting designed to accommodate educational, behavioral, and/or medical needs of children and adolescents that cannot be adequately addressed in a traditional school environment.

Antisocial personality disorder—A disorder characterized by a behavior pattern that disregards for the rights of others. People with this disorder often deceive and manipulate, or their behavior might include aggression to people or animals or property destruction, for example. This disorder has also been called sociopathy.

Attention deficit hyperactivity disorder (ADHD)—A condition in which a person (usually a child) has an unusually high activity level and a short attention span. People with the disorder may act impulsively and may have learning and behavioral problems.

Conduct disorder—A behavioral and emotional disorder of childhood and adolescence. Children with a conduct disorder act inappropriately, infringe on the rights of others, and violate societal norms.

Television viewing and video/computer games can contribute to ODD behaviors. For children with ADHD or ODD, the American Academy of Pediatrics recommends limiting use of television and video/computer games to no more than two hours per day, monitoring children's use of television and computers, and viewing family-oriented television programs with their children.

Parents may find it helpful to track their child's moods and behaviors and to help children learn to track their own moods and behaviors to help identify possible stresses and causative factors.

Parents should actively participate in their child's therapy and learn positive parenting techniques that can help ODD behaviors. When parents are too restrictive, children and adolescents with ODD can rebel, and power struggles can frequently occur. Therapists specializing in ODD can help families become more effective in handling ODD behaviors in order to avoid such rebellion. The American Academy of Child and Adolescent Psychiatry recommends the following for parents with children who have ODD:

- Choose battles by setting priorities regarding child's behavior.
- Set reasonable, age-appropriate limits with consistently enforceable consequences.
- Work with teachers, coaches, and other family members for support in dealing with the child with ODD.
- Use positive reinforcement praise when the child displays desired behaviors.
- Take time to manage stress by exercising and/or relaxing away from the child.

Oral contraceptives

Definition

Oral contraceptives are medicines taken by mouth to help prevent pregnancy. They are also known as the pill, OCs, or birth control pills.

Description

Oral contraceptives, or birth control pills, contain synthetic forms of two hormones produced naturally in the body. These hormones, estrogen and progestin, regulate the female menstrual cycle. Some types of oral contraceptives use only progestational hormones, but most use a combination of estrogen and progestin. As of 2004, there were three types of oral contraceptives marketed:

- Monophasic use a fixed dose of both estrogen and progestin during the entire cycle.
- Biphasic oral contraceptives use a constant amount of estrogen during the full cycle, but the amount of progestin is lower during the first half of the cycle and increases in the second half. This shift in dosage is intended to mimic the natural ovarian cycle.
- Triphasic oral contraceptives may vary both the estrogen and progestin levels at different times during the cycle.

The goal of the biphasic and triphasic formulations is to achieve adequate control of the menstrual cycle while using lower doses of both estrogens and progestins, thereby reducing the risk of adverse effects. Reviews of controlled studies have not demonstrated a clear advantage of the newer formulations over the older monophasic drugs.

General use

When taken in the proper amounts, following a specific schedule, oral contraceptives are very effective in preventing pregnancy. Studies show that fewer than one of every 100 females who use oral contraceptives correctly becomes pregnant during the first year of use.

These pills have several effects that help prevent pregnancy. For pregnancy to occur, an egg must become mature inside a woman's ovary, be released, and travel to the fallopian tube. Sperm must travel through the reproductive track to fertilize the egg in the fallopian tube. Then the fertilized egg must travel to the woman's uterus (womb), where it lodges in the uterus lining and develops into a fetus.

The main way that oral contraceptives prevent pregnancy is by keeping an egg from ripening fully. Eggs that do not ripen fully cannot be fertilized. In addition, birth control pills thicken mucus in the woman's body through which the sperm has to swim. Thus it is more difficult for the sperm to reach the egg. Oral contraceptives also change the uterine lining so that a fertilized egg cannot lodge there to develop.

Although **contraception** is the primary use of these medications, they may also be used to treat adolescent and post-adolescent **acne** in girls. Some products have this as part of their official indications, but others may be used as well.

Precautions

No form of birth control (except abstinence from sexual intercourse) is 100 percent effective. However, oral contraceptives can be highly effective when used properly. Teens and young women who anticipate having sexual intercourse should discuss the options with a healthcare professional.

Oral contraceptives do not protect against **AIDS** or other **sexually transmitted diseases**. For some protection against such diseases, teenage males and young men need to use a latex **condom**. Also, oral contraceptives are not effective immediately after a young woman begins taking them. Physicians recommend using other forms of birth control for the first one to three weeks. Then users should follow the instructions of the physician who prescribed the medicine.

Smoking cigarettes while taking oral contraceptives greatly increases the risk of serious side effects. Females who take oral contraceptives should not smoke cigarettes.

Seeing a physician regularly while taking this medicine is very important. The physician will note unwanted side effects, and patients should follow his or her advice on how often they should be seen.

Young women who take oral contraceptives should be sure to tell the healthcare professional in charge before they undergo surgical or dental procedures, laboratory tests, or emergency treatment.

This medicine may increase sensitivity to sunlight. Females using oral contraceptives should avoid too much sun exposure and should not use tanning beds, tanning booths, or sunlamps until they know how the medicine affects them. Some females taking oral contraceptives may get brown splotches on exposed areas of their skin. These usually go away over time after the women stop taking birth control pills.

Oral contraceptives may cause the gums to become tender and swollen or to bleed. Careful brushing and flossing, gum massage, and regular cleaning may help prevent this problem. Users should check with a physician or dentist if gum problems develop.

Side effects

Serious side effects are rare in healthy females who do not smoke cigarettes. In women with certain health problems, however, oral contraceptives may cause problems such as liver **cancer**, noncancerous liver tumors, blood clots, or **stroke**. Healthcare professionals can help prospective users weigh the benefits of being protected against unwanted pregnancy against the risks of possible health problems.

The most common minor side effects are **nausea**, **vomiting**, abdominal cramping or bloating, breast **pain**, tenderness or swelling, swollen ankles or feet, tiredness, and acne. These problems usually go away as the body adjusts to the drug and do not need medical attention unless they continue or they interfere with normal activities. Other side effects should be brought to the attention of the physician who prescribed the medicine. Teens and young women should check with the physician as soon as possible if any of the following side effects occur:

- menstrual changes, such as lighter periods or missed periods, longer periods, or bleeding or spotting between periods
- headaches
- vaginal infection, **itching**, or irritation
- increased blood pressure

Women who have any of the following symptoms should get emergency help right away. These symptoms may be signs of blood clots:

- sudden changes in vision, speech, breathing, or coordination
- severe or sudden **headache**
- coughing up blood
- sudden, severe, or continuing pain in the abdomen or stomach
- pain in the chest, groin, or leg (especially in the calf)
- weakness, **numbness**, or pain in an arm or leg

The adverse effects of oral contraceptives can be impossible to predict. Other than avoiding smoking, there are no effective means of preventing side effects. All observed adverse effects should be reported to a physician promptly.

Oral contraceptives may continue to affect the menstrual cycle for some time after a young woman stops taking them. Women who miss periods for several months after stopping this medicine should check with their physicians. Other rare side effects may occur. Anyone who has unusual symptoms while taking oral contraceptives should get in touch with her physician.

A doctor explains to a teenage girl how to use birth control pills. *(© LWA-Stephen Welstead/Corbis.)*

Interactions

Oral contraceptives may interact with a number of other medicines. When interaction occurs, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes oral contraceptives should let the physician know all other medicines she is taking and should ask whether possible interactions can interfere with drug therapy.

These drugs may make oral contraceptives less effective in preventing pregnancy. Anyone who takes these drugs should use an additional birth control method for the entire cycle in which the medicine is used:

- ampicillin
- penicillin V
- rifampin (Rifadin)
- tetracyclines
- griseofulvin (Gris-PEG, Fulvicin)

KEY TERMS

Cyst—An abnormal sac or enclosed cavity in the body filled with liquid or partially solid material. Also refers to a protective, walled-off capsule in which an organism lies dormant.

Endometriosis—A condition in which the tissue that normally lines the uterus (endometrium) grows in other areas of the body, causing pain, irregular bleeding, and frequently, infertility.

Fallopian tubes—The pair of narrow tubes leading from a woman's ovaries to the uterus. After an egg is released from the ovary during ovulation, fertilization (the union of sperm and egg) normally occurs in the fallopian tubes.

Fetus—In humans, the developing organism from the end of the eighth week to the moment of birth. Until the end of the eighth week the developing organism is called an embryo.

Fibroid tumor—A non-cancerous tumor of connective tissue made of elongated, threadlike structures, or fibers, which usually grow slowly and are contained within an irregular shape. Fibroids are firm in consistency but may become painful if they start to break down or apply pressure to areas within the body. They frequently occur in the uterus and are generally left alone unless growing rapidly or causing other problems. Surgery is needed to remove fibroids.

Hormone—A chemical messenger secreted by a gland or organ and released into the bloodstream. It travels via the bloodstream to distant cells where it exerts an effect.

Jaundice—A condition in which the skin and whites of the eyes take on a yellowish color due to an increase of bilirubin (a compound produced by the liver) in the blood. Also called icterus.

Migraine—A throbbing headache that usually affects only one side of the head. Nausea, vomiting, increased sensitivity to light, and other symptoms often accompany a migraine.

Mucus—The thick fluid produced by the mucous membranes that line many body cavities and structures. It contains mucin, white blood cells, water, inorganic salts, and shed cells, and it serve to lubricate body parts and to trap particles of dirt or other contaminants.

Ovary—One of the two almond-shaped glands in the female reproductive system responsible for producing eggs and the sex hormones estrogen and progesterone.

Pelvic inflammatory disease (PID)—Any infection of the lower female reproductive tract (vagina and cervix) that spreads to the upper female reproductive tract (uterus, fallopian tubes and ovaries). Symptoms include severe abdominal pain, high fever, and vaginal discharge. PID is the most common and most serious consequence of infection with sexually transmitted diseases in women and is a leading cause of female fertility problems.

Uterus—The female reproductive organ that contains and nourishes a fetus from implantation until birth. Also called the womb.

- corticosteroids
- barbiturates
- carbamazepine (Tegretol)
- phenytoin (Dilantin)
- primidone (Mysoline)
- ritonavir (Norvir)

In addition, taking the following medicines with oral contraceptives may increase the risk of side effects or interfere with the medicine's effects:

- Theophylline: Effects of this medicine may increase, along with the chance of unwanted side effects.
- Cyclosporine: Effects of this medicine may increase, along with the chance of unwanted side effects.
- Troleandomycin (TAO): Chance of liver problems may increase. Effectiveness of oral contraceptive may also decrease, raising the risk of pregnancy.

The list above does not include every drug that may interact with oral contraceptives. Women should be sure to check with a physician or pharmacist before combining oral contraceptives with any other prescription or nonprescription (over-the-counter) medicine. As with any medication, the benefits and risks should be discussed with a physician.

Parental concerns

Parents become concerned that teens who use oral contraceptives are at risk of becoming sexually active. Although studies have been limited, they have failed to

show that availability of oral contraceptives leads to an increase in sexual activity among adolescent girls.

Oral contraceptives do not protect against sexually transmitted diseases. When used for contraception, they should be limited to monogamous relationships.

Although the list of potential side effects and adverse effects is very long and contains some severe risks, the actual frequency of these risks is low. In most cases, oral contraceptives have a very high safety margin.

Oral hygiene

Definition

Oral hygiene is the practice of keeping the mouth clean and healthy by brushing and flossing to prevent **tooth decay** and gum disease.

Purpose

The purpose of oral hygiene is to prevent the build-up of plaque, the sticky film of bacteria and food that forms on the teeth. Plaque adheres to the crevices and fissures of the teeth and generates acids that, when not removed on a regular basis, slowly eat away, or decay, the protective enamel surface of the teeth, causing holes (cavities) to form. Plaque also irritates gums and can lead to gum disease, **periodontal disease**, and tooth loss. Brushing and flossing removes plaque from teeth, and antiseptic mouthwashes kill some of the bacteria that help form plaque. Fluoride, found in toothpaste, drinking water, or dental treatments, also helps to protect teeth by binding with enamel to make it stronger. In addition to such daily oral care, regular visits to the dentist promote oral health. Preventative services that the dentist can perform include fluoride treatments, sealant application, and scaling (scraping off the hardened plaque, called tartar). The dentist can also perform such diagnostic services as x-ray imaging and such treatments as filling cavities.

Description

The Centers for Disease Control and Prevention report that dental caries are perhaps the most prevalent of infectious diseases in children. More than 40 percent of all children have cavities by the time they reach kindergarten. It is, therefore, imperative that all parents learn the importance of early oral care and that they teach their children proper oral hygiene.

Good oral hygiene should start at the very beginning of a child's life. Even before his or her first teeth emerge, certain factors can affect their future appearance and health. Pregnant and nursing mothers should be careful about using medications, as some, like the antibiotic tetracycline, can cause tooth discoloration. Even before infants have teeth, they have special oral hygiene needs about which all parents should be aware. These include making certain the child receives adequate fluoride and guarding against baby bottle decay.

Fluoride in infancy

Fluoride is beneficial for babies even before their teeth erupt. It makes the tooth enamel stronger as the teeth are developing. In most municipal water supplies, the correct amount of fluoride is added for proper tooth development. If the water supply does not contain enough fluoride or if bottled water is used for drinking and cooking, the doctor or dentist should be informed. They may prescribe fluoride supplements for the baby.

Baby bottle decay

Baby bottle decay is caused by recurring exposure over time to sugary liquids. These include milk, formula, and fruit juices. These liquids pool for prolonged periods of time as the child sleeps. This exposure can lead to cavities forming, especially in the upper and lower front teeth. For this reason, children should not be allowed to fall asleep with a bottle of juice or milk in their mouths. An alternative is to give the child a bottle filled with water or a pacifier recommended by the dentist. Even breast-fed children are at risk. They should have their gums and teeth wiped with a clean, damp washcloth or gauze pad following each feeding.

Baby teeth, also known as primary teeth, are just as important as permanent teeth. They help the child to bite and chew food, help them speak correctly, save space for the child's permanent teeth, and help guide the permanent teeth into place. That is why it is so important to initiate a program of good oral hygiene for children early on.

Brushing

Once a baby has four teeth in a row, either on top or on the bottom, parents should begin using a toothbrush two times a day. When choosing a toothbrush, make sure the bristles are soft, polished, and made of nylon. Parents should administer only a pea-size amount of fluoride toothpaste that is made especially for children. Children tend to swallow, instead of spit out, toothpaste. If the child does not like the flavor of the toothpaste, using water alone is acceptable. Parents should also continue to wipe the toothless gum areas with a washcloth or gauze.

As the child gets older, parents should demonstrate proper brushing techniques. These include brushing the inside surface of each tooth first, where plaque tends to accumulate most. Then they should clean the outer surfaces of each tooth, angling the brush along the outer gum line. Next, they should brush the chewing surface of each tooth, then using the tip of the brush, clean behind each front tooth. They should use a gentle, back and forth motion when brushing and finish by brushing the tongue.

Children will, at some point, decide they would like to try brushing their teeth themselves. This is fine and should be encouraged, but parents should remain in charge of keeping children's teeth clean until they are between six to eight years old. Children do not have the dexterity or coordination to perform brushing well until this time. Even then, it is important that parents inspect their children's teeth each time they brush. They should pay special attention to the molars, as these teeth have lots of tiny grooves and crevices where food particles can hide.

A boy flosses his teeth as part of a daily regimen for good oral hygiene. *(© Joh Feingersh/Corbis.)*

Good oral hygiene remains important as children grow into **adolescence**. In fact, adolescence can often be a time when cavities and periodontal disease happen more frequently. This higher rate is usually caused by an increased intake of junk food and sugary foods such as soft drinks, as well as inattention to oral hygiene procedures. Add to that the fact that many older children and teens wear braces, making the cleaning of teeth even more challenging. Parents should talk to their children about how important good oral hygiene is in preventing not only cavities, but teeth stains, bad breath, and an assortment of other dental problems.

Flossing

Flossing once a day helps to prevent gum disease by removing food particles and plaque at and below the gum line, as well as between teeth. Parents do not need to initiate flossing until the child has teeth that touch each other, which normally occurs in the molar areas first. Parents should continue to floss their child's teeth until they are six or seven years old. They should continue to monitor the child's techniques and consistency thereafter.

Proper flossing technique is essential in removing as much plaque as possible in a safe manner. The following procedure is recommended by dental hygienists. Wind 18 inches (45 cm) of dental floss around the middle fingers of each hand. Pinch the floss between the thumbs and index fingers, leaving about 1–2 inches (3–5 cm) length in between. Use the thumbs to direct the floss between the upper teeth. Try to keep the floss taut

between the fingers. Use the index fingers to guide floss between lower teeth. Gently guide the floss between the teeth by using a zig-zag motion. Contour the floss around the side of each tooth. Slide the dental floss up and down against the tooth surface and under the gum line. Floss each tooth thoroughly with a clean section of floss.

Dental floss comes in many varieties (waxed, unwaxed, flavored, tape) and may be chosen based on personal preference. For those who have difficulty handling floss, floss holders and other types of interdental (between the teeth) cleaning aids are available. Some floss holders have animal and cartoon characters on them, which might make flossing more appealing to a child.

Precautions

It is important that younger children only use a very small amount of fluoridated toothpaste since using too much fluoride can be toxic to infants. Though brushing and flossing are important, neither should be performed too vigorously. The rough mechanical action may irritate or damage oral tissues. Parents should change their child's toothbrush three to four times a year and after every illness to avoid bacteria and germs.

Another factor that may affect a child's oral health is the increasingly popular practice among adolescents of oral piercings involving the tongue, lips, and cheeks. These piercings have been associated with infections, tooth fractures, periodontal disease, and nerve damage. Some life-threatening complications have occurred, including bleeding and airway obstruction. The American Academy of Pediatric Dentistry strongly opposes the practice of oral piercings.

Risks

The primary risks arise from a lack of proper oral hygiene practices. These major oral health problems are plaque, tartar, gingivitis, periodontitis, and tooth decay.

Parental concerns

Parents play an important role in both modeling and teaching good oral hygiene. Parents can make sure their child sees a dentist before the age of two. This can be a frightening experience for some children, but if parents exhibit a positive attitude, most children become comfortable with dentist visits. Children who learn proper oral care at a young age benefit from those good habits for the rest of their lives.

KEY TERMS

Calculus—Plural, calculi. Any type of hard concretion (stone) in the body, but usually found in the gallbladder, pancreas, and kidneys. They are formed by the accumulation of excess mineral salts and other organic material such as blood or mucous. Calculi (pl.) can cause problems by lodging in and obstructing the proper flow of fluids, such as bile to the intestines or urine to the bladder. In dentistry, calculus refers to a hardened yellow or brown mineral deposit from unremoved plaque, also called tartar.

Cavity—A hole or weak spot in the tooth surface caused by decay.

Gingivitis—Inflammation of the gums in which the margins of the gums near the teeth are red, puffy, and bleeding. It is most often due to poor dental hygiene.

Pediatric dentistry—The dental specialty concerned with the dental treatment of children and adolescents.

Plaque—A deposit, usually of fatty material, on the inside wall of a blood vessel. Also refers to a small, round demyelinated area that develops in the brain and spinal cord of an individual with multiple sclerosis.

Orthodontics

Definition

Orthodontics is a specialized branch of dentistry that diagnoses, prevents, and treats dental and facial irregularities called malocclusions. Orthodontics includes dentofacial orthopedics, which is used to correct problems involving the growth of the jaw.

Purpose

Humans have attempted to straighten teeth for thousands of years before orthodontics became a dental specialty in 1900. Although orthodontic treatment often improves facial appearance and occasionally is performed for solely cosmetic reasons, it is used primarily to correct health problems and to ensure the proper functioning of the mouth. Properly aligned teeth, which close together correctly, simplify **oral hygiene** and enable children to chew their food efficiently. Orthodontic treatment provides the following:

- straightens teeth that are rotated, tilted, or otherwise improperly aligned
- corrects crowded or unevenly spaced teeth
- corrects bite problems
- aligns the upper and lower jaws

Malocclusions

Few children have perfectly symmetrical teeth and a perfect bite. In an ideal bite, the following are characteristics:

- All of the teeth fit easily without crowding or spacing.
- The teeth are not rotated, twisted, or leaning forward or backward.
- The teeth of the upper jaw slightly overlap those of the lower jaw.
- The points of the molars fit into the grooves of the opposite molars.

Types of malocclusions include the following:

- crowded, crooked, or misaligned teeth
- extra or missing teeth
- bite problems
- jaws that are out of alignment

Causes of malocclusion

Most malocclusions are caused by hereditary factors that affect the contours of the face and the size of the teeth and jaw. The most common cause of **malocclusion** is a disproportion in size between the jaw and teeth or between the upper and lower jaws. A child who inherits a mother's small jaw and a father's large teeth may have teeth that are too big for the jaw, causing overcrowding. Specific inherited malocclusions include:

- overcrowded teeth
- too much space between teeth
- extra or missing teeth
- various irregularities in the teeth, jaw, or face

Malocclusions can be acquired through the following:

- accidents such as a jaw fracture that causes misalignment
- prolonged sucking on thumbs, fingers, or pacifiers, particularly after the age of four
- fingernail or lip biting
- a lost tooth that causes nearby teeth to move into the empty space, throwing them out of alignment
- airways that are obstructed by tonsils or adenoids
- dental disease
- tumors in the mouth or jaw
- improperly fitted fillings, crowns, or braces
- premature loss of baby teeth or permanent teeth
- late loss of baby teeth

Symptoms of malocclusion

Occasionally children have mild, temporary symptoms of malocclusion resulting from a growth spurt. However, symptoms of malocclusion usually develop gradually beginning at the age of six. Symptoms may include the following:

- crowded or misaligned teeth
- abnormal spacing between teeth, most often occurring because teeth are small or missing or the dental arch—

the arch-shaped jawbone that supports the teeth—is very wide
- incisors (front teeth) that do not meet
- an open bite, occurring when the upper and lower incisors do not touch each other during biting, thereby putting all of the chewing pressure on the back teeth and resulting in inefficient chewing and excessive tooth wear
- an overbite or overjet, in which the upper incisors protrude, often caused by a lower jaw that is significantly shorter than the upper jaw
- a deep or closed bite, an excessive overbite in which the lower incisors bite too closely to or into the gum tissue or palate behind the upper teeth
- a crossbite, in which a protruding lower jaw that is longer than the upper jaw causes the upper front or back teeth to bite inside the lower teeth

Early intervention

Although orthodontic treatment can be performed at any age, children are easier, faster, and less expensive to treat than adults. Most often orthodontic treatment is used on older children and adolescents whose teeth are still developing. However some types of problems are corrected more readily before all of the permanent teeth have erupted and facial growth is complete. If a child's permanent lower incisors erupt behind each other, braces may be required at a young age. Crossbites are usually treated early because they can interfere with biting and chewing. Early treatment also is used when thumb- or finger-sucking has affected teeth positioning.

Early orthodontic intervention can provide the following:

- straighten crooked teeth
- preserve or create space for incoming permanent teeth
- guide erupting permanent teeth into the correct positions
- prevent impacted permanent teeth, those that remain partially covered by gum tissue or partially or completely buried in the jawbone
- correct harmful habits such as thumb- or finger-sucking
- lower the risk of accidents to protruding upper incisors

Other advantages of early orthodontic treatment include the following:

- correction of bite problems by guiding jaw growth and controlling the width of the upper and lower dental arches
- reduction or elimination of abnormal swallowing or speech problems
- shortening and simplification of later orthodontic treatment
- prevention of later tooth extractions
- improvements in appearance and self-esteem

Untreated malocclusions

Minor misalignment or crowding may not require treatment. However untreated malocclusions can cause the following:

- teeth that are partially impacted or fail to erupt
- lips, tongue, or cheeks that contact biting surfaces due to poor tooth alignment
- inefficient or uncomfortable biting, chewing, and digestion
- speech impairments
- teeth that are hard to clean, leading to cavities and gum disease
- abnormal wear of tooth surfaces
- chipped teeth
- loosening or fracturing of a misaligned tooth that is overstrained
- injury to a protruding upper incisor
- thinning and receding of bone and gums covering the roots of very crowded teeth
- accelerated gum disease and bone loss
- temporomandibular joint (TMJ) misalignments at the point where the lower jaw attaches to the skull
- stress and trauma to the teeth, gum tissue, ligaments, muscles, jawbone, and jaw joints
- premature loss of teeth
- adverse effects on facial development and appearance
- the need for surgery

Untreated malocclusions often worsen with time. TMJ problems can cause chronic headaches or **pain** in the face and neck. A deep overbite can cause significant pain and bone damage and may contribute to excessive wear on the incisors.

Description

Orthodontics in young children

Alignment problems usually become apparent as the permanent teeth begin erupting at about age six. Dentists monitor the development of a child's permanent teeth

and refer the child to an orthodontist if a problem is suspected. The American Association of Orthodontists recommends that all children be screened by an orthodontist by the age of seven.

Once a child's lower baby incisors have erupted, an orthodontist can measure the child's jaw and tooth size, project their growth rate, and possibly predict whether the child will have orthodontic problems with their permanent teeth. The orthodontist may be able to perform preventative or interceptive orthodontics that can reduce or eliminate the need for braces later.

In a procedure called selective serial extraction, the orthodontist removes one or more baby or permanent teeth. Doing so creates space for the permanent teeth, especially unerupted canine teeth that might become impacted or erupt in the wrong position. After the removal or loss of a tooth, braces or another orthodontic appliance may be used to prevent the remaining teeth from moving into the empty space. If a baby molar—that acts as a space-holder for later permanent teeth—is lost, a fixed orthodontic wire is inserted between the teeth to keep the space available.

Preparation

The orthodontist compiles pretreatment records that are used for diagnosis, determining the course of treatment, and measuring the progress of treatment. These records may include:

- a complete medical and dental history
- a clinical examination
- x rays revealing the positions of erupted and unerupted teeth, development of unerupted teeth, any missing or impacted teeth, shortened or damaged tooth roots, and the amount of bone supporting the teeth
- a facial-profile x ray or cephalometric film revealing the sizes, positions, and relationships of the teeth and jaw, as well as facial form, growth pattern, and the inclinations of tipped or tilted incisors
- plastic impressions of the bite and plaster models made from the impressions
- photographs and other measurements of the teeth and face

Based on the diagnosis the orthodontist develops a custom treatment plan and designs the appropriate corrective appliances that will gradually straighten or move the teeth. Severe overcrowding may necessitate the extraction of permanent teeth, usually the premolars, to create space prior to using braces to move teeth.

Braces and other orthodontic appliances

By applying constant gentle pressure in a specific direction, braces can slowly move teeth through the supporting bone to a new position. Springs and wires put pressure on teeth in order to straighten them. The pressure causes bone in the jaw to dissolve in front of the moving tooth as new bone grows behind the tooth. Braces and other appliances may be removable or fixed and are made of clear or colored metal, ceramic, or plastic. Removable appliances are often plastic plates that fit into the roof of the mouth and clip onto a tooth.

Fixed braces exert more pressure than removable braces and can achieve more complex movements. They consist of wires and springs that are held in place by small brackets glued to the outside surfaces of the incisors and sometimes the premolars. Lingual braces have brackets bonded to the back of the teeth. Bands encircling the molars also can be used for attachments. The wires, springs, and other devices attached to the brackets or bands put pressure on the teeth, gradually shifting them into new positions. The nickel-titanium wires are very light, and some are heat-activated. These are very flexible at room temperature and actively begin to move the teeth as they warm to body temperature. Elastic bands sometimes connect the upper and lower teeth to create tension.

Appliances used to direct jaw growth and development in growing children and adolescents include:

- Headgear attached to braces and usually worn for 10 to 12 hours at night puts pressure on the upper teeth and jaw and influences the direction and speed of upper jaw growth and upper teeth eruption.
- Herbst appliances attached to the upper and lower molars correct a severe overbite by holding the lower jaw forward, influencing jaw growth and tooth position; they force the jaw muscles to work in ways that promote forward development of the lower jaw; treatment with Herbst appliances must begin several years before the jaw stops growing and they must remain in place throughout the treatment.
- Palatal or upper jaw expansion devices can widen a narrow upper jaw and correct a crossbite within months.
- Removable bionators hold the lower jaw forward and guide tooth eruption while helping the upper and lower jaws to grow proportionately.

Headgear and Herbst appliances can significantly reduce protrusion of the four top incisors and enable the growing lower jaw to catch up with the upper jaw, eliminating swallowing problems.

Children with braces. *(Photograph by Robert J. Huffman/Field Mark Publications.)*

Duration of treatment

Orthodontic treatment usually continues until the desired outcome is reached. Active orthodontic treatment lasts an average of two years, with a range of one to three years. Some children respond to treatment faster than others and interceptive or early treatments may continue for only a few months. Appliances are adjusted periodically during treatment. Factors affecting the duration of treatment include:

- the growth of the mouth and face
- the severity of the problem
- the health of the teeth, gums, and supporting bones
- the child's level of cooperation

Precautions

Orthodontic appliances trap food, bacteria, and plaque, leading to **tooth decay**. Extra brushing with specially shaped and/or electric toothbrush and fluoride toothpaste is required around the areas where the braces or appliances attach to the teeth. Both the tops and bottoms of braces must be brushed and irrigated with a water jet directed from the top down and the bottom up. If possible, teeth should be flossed. A fluoride mouthwash may be recommended. Removable appliances should be brushed every time the teeth are brushed. Regular dental check-ups and cleanings must be continued.

Children with braces should eat raw fruits and vegetables and avoid soft, processed, and refined foods that attract bacteria, as well as hard or sticky foods, including gum, caramels, peanuts, ice chips, and popcorn. Chewing on hard items, such as fingernails or pencils, can damage braces. Children with braces should wear a protective mouth guard while playing contact **sports**.

Aftercare

After braces are removed the teeth must be stabilized in their new positions. This phase of treatment commonly takes two to three years. Occasionally it continues indefinitely. Types of retainers used for stabilization include:

KEY TERMS

Active treatment stage—The period during which orthodontic appliances or braces are used.

Bicuspid—Premolar; the two-cupped tooth between the first molar and the cuspid.

Canines—The two sharp teeth located next to the front incisor teeth in mammals that are used to grip and tear. Also called cuspids.

Crossbite—The condition in which the upper teeth bite inside the lower teeth.

Crown—The natural part of the tooth covered by enamel. A restorative crown is a protective shell that fits over a tooth.

Deep bite—A closed bite; a deep or excessive overbite in which the lower incisors bite too closely to or into the gum tissue or palate behind the upper teeth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Impacted tooth—Any tooth that is prevented from reaching its normal position in the mouth by another tooth, bone, or soft tissue.

Incisors—The eight front teeth.

Interceptive orthodontics—Preventative orthodontics; early, simpler orthodontic treatment.

Malocclusion—The misalignment of opposing teeth in the upper and lower jaws.

Molars—The teeth behind the primary canines or the permanent premolars, with large crowns and broad chewing surfaces for grinding food.

Open bite—A malocclusion in which some teeth do not meet the opposing teeth.

Orthognatic surgery—Surgery to alter the relationships of the teeth and/or supporting bones, usually in conjunction with orthodontic treatment.

Overbite—Protrusion of the upper teeth over the lower teeth.

Plaque—A sticky film of saliva, food particles, and bacteria that attaches to the tooth surface and causes decay.

Retainer—An orthodontic appliance that is worn to stabilize teeth in a new position.

Retention treatment stage—The passive treatment period following orthodontic treatment, when retainers may be used to stabilize the teeth.

Temporomandibular joint (TMJ)—One of a pair of joints that attaches the mandible of the jaw to the temporal bone of the skull. It is a combination of a hinge and a gliding joint.

- positioners, rubber-like mouthpieces that are worn at night and bitten into for a few hours during the day
- removable retainers with a plastic plate that snaps onto the roof of the mouth and wires on the outside of the teeth
- removable, clear, plastic retainers that completely cover the sides and biting surfaces of the teeth
- semi-rigid wires that are bonded onto the inside of the incisors.

Risks

Braces may cause discomfort when they are first installed or adjusted during treatment. For the first three to five days teeth may hurt during biting. Lips, cheeks, and tongue may be irritated for one to two weeks before they toughen and adapt to the braces. Some appliances may interfere with speech for the first day or two. Damaged appliances can extend the length of treatment and negatively affect the outcome.

Food particles and plaque deposits around orthodontic appliances can cause demineralization of the tooth enamel, leading to cavities and permanent whitish scars on the teeth.

Normal results

Orthodontic treatment is usually very successful at correcting malocclusions. Even a significant size discrepancy between the upper and lower jaws often can be corrected. Sometimes, particularly in adults, corrective orthognathic surgery is required to shorten or lengthen a jawbone. The height of the lower face also can be shortened or lengthened. Sometimes surgery reduces the duration of the orthodontic treatment.

Maturational change can cause teeth to gradually shift with age—at least until one's early 20s—causing crowding. Nighttime retainers can prevent maturational movement.

Parental concerns

In general the earlier an orthodontic problem is detected, the easier and less expensive it is to correct. Parents can compare their child's **dental development** with standard charts and pictures.

When to call the doctor

Children with problems involving the width or length of the jaws should be evaluated no later than age 10 for girls and age 12 for boys. For children receiving orthodontic care, the orthodontist should be notified immediately if an appliance breaks. Indications that children may need an early orthodontic examination include:

- early or late loss of baby teeth
- crowded, misplaced, or blocked-out teeth
- upper and lower teeth that do not meet normally
- thumb- or finger-sucking
- biting of the cheek or roof of the mouth
- difficulty biting or chewing
- breathing through the mouth
- jaws that shift or make noise
- jaws and teeth that are out of proportion to the rest of the face

Osgood-Schlatter disease *see* **Osteochondroses**

Osteochondroses

Definition

The term osteochondroses refers to a group of diseases of children and adolescents in which localized tissue death (necrosis) occurs, usually followed by full regeneration of healthy bone tissue. The singular term is osteochondrosis.

Description

During the years of rapid bone growth, blood supply to the growing ends of bones (epiphyses) may become insufficient resulting in necrotic bone, usually near joints. Since bone is normally undergoing a continuous rebuilding process, the necrotic areas are most often self-repaired over a period of weeks or months.

Osteochondrosis can affect different areas of the body and is often categorized by one of three locations: articular, non-articular, and physeal.

Physeal osteochondrosis is known as Scheuermann disease or juvenile kyphosis. It is a deformity of the thoracic spine (in the chest area, the vertebra to which ribs are attached) caused by abnormal centers of bone development at the intervertebral joints (physes). It is most common among children ages 13 to 16.

Articular disease occurs at the joints (articulations). One of the more common forms is Legg-Calvé-Perthes disease, which occurs at the hip joint. Other forms include Köhler disease (foot), Freiberg disease (second toe), and Panner disease (elbow). These diseases are most common during **adolescence**, although they have been found in individuals ranging in age from eight to 77.

Non-articular osteochondrosis occurs at any other skeletal location. For instance, Osgood-Schlatter disease of the tibia (the large inner bone of the leg between the knee and ankle) is relatively common. It is often the cause of knee and leg **pain** in active teens.

Osteochondritis dissecans (OCD) is a form of osteochondrosis in which loose bone fragments form in a joint. The knee is a common site for osteochondritis dissecans. The condition is found most often in people aged ten to 20, although it may occur at other ages. OCD is sometimes associated with some sort of past trauma to the joint. In about 30 to 40 percent of cases the same joint on both sides of the body is involved (e.g. both knees, both elbows).

Demographics

Osteochondroses are disorders of teens and young adults. Some are rare disorders, and in many cases, the number of individuals who have these disorders is not known, since cases many resolve on their own. Scheuermann disease is thought to occur in 0.4 to 8 percent of individuals. One Finnish study found that 13 percent of adolescents had Osgood-Schlatter disease. Freiberg disease is the one type of osteochondrosis that is more common in females than in males. OCD affects males about twice as often as females. All other osteochondrosis appear to affect the sexes equally.

Causes and symptoms

Many theories have been advanced to account for osteochondrosis, but none has proven fully satisfactory. Stress on the bone, ischemia (reduced blood supply), and trauma to the site are commonly mentioned factors. Athletic children are often affected when they overstress their developing limbs with a particular repetitive motion. Many cases are idiopathic, meaning that no specific cause is known.

The most common symptom for most types of osteochondrosis is pain, usually a dull, non-specific ache, at the affected joint. Pain is especially noticeable when pressure is applied. Locking of a joint or limited range of motion at a joint can also occur.

Scheuermann disease can (rarely) lead to serious kyphosis (hunchback condition) due to erosion of the vertebral bodies. Usually, however, the kyphosis is mild, causing no further symptoms and requiring no special treatment.

When to call the doctor

A doctor should be consulted whenever a child has a persistent joint pain that does not go away after resting the joint for a few days.

Diagnosis

Diagnosis is suspected based on history and symptoms. It can be confirmed by x-ray findings.

Treatment

Conservative treatment is usually attempted first. In many cases, resting the affected body part for a several days or weeks brings relief. A cast may be applied if needed to prevent movement of a joint.

Surgical intervention may be needed in some cases of osteochondritis dissecans to remove abnormal bone fragments in a joint. Rarely is spine curvature so pronounced in Scheuermann disease that the individual needs to wear a brace or have surgical intervention.

Prognosis

Accurate prediction of the outcome for individual adolescents is difficult with osteochondrosis. Some individuals heal spontaneously. Others heal with little treat-

KEY TERMS

Osteoblast—A bone-building cell.

Osteoclast—A large, multinuclear cell involved in the physiological destruction and absorption of bone.

ment other than keeping weight or stress off the affected limb. The earlier the age of onset, the better the prospects for full recovery. Surgical intervention is often successful in osteochondritis dissecans.

Prevention

No preventive measures are known.

Parental concerns

Persistent pain in the joint may keep children temporarily from playing **sports**.

Osteogenesis imperfecta

Definition

Osteogenesis imperfecta (OI) is a group of genetic diseases in which the bones are formed improperly, making them fragile and prone to breaking.

Description

Collagen is a fibrous protein material that serves as the structural foundation of skin, bone, cartilage, and ligaments. In osteogenesis imperfecta, the collagen produced is abnormal and disorganized, which results in a number of abnormalities throughout the body, the most notable being fragile, easily broken bones.

There are four forms of OI, types I through IV. Of these, type II is the most severe and is usually fatal within a short time after birth. Types I, III, and IV have some overlapping and some distinctive symptoms, with the hallmark symptom being fragile bones.

OI is usually inherited as an autosomal dominant condition. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 non-sex chromosomes) from either parent can cause the disease. Only one parent needs to be a carrier in order for the child to inherit the disease. The parent affected by OI will have one abnormal gene and one normal gene. A child who has one parent with the disease therefore has a 50 percent chance of also inheriting the disease.

If both parents have OI caused by an autosomal dominant gene change, there is a 75 percent chance that the child will inherit one or both OI genes. In other words, there is a 25 percent chance of inheriting a faulty gene from the mother and a normal gene from the father, a 25 percent chance of inheriting a normal gene from the mother and a faulty gene from the father, a 25 percent chance of inheriting faulty genes from both parents, and a 25 percent chance of inheriting normal genes from both parents. It is difficult to predict the severity of OI in a child who has inherited two copies of the faulty gene because of its rarity.

There is no **family** history of OI in about 25 percent of children born with the disease. This occurs as a result of a spontaneous mutation of the gene in either the sperm or egg. The cause of such mutations is not known. Called new dominant mutation, the affected child subsequently has a 50 percent of passing the abnormal gene to his or her children. The risk of normal parents having a second child with OI, or of normal siblings going on to have affected children, does not appear to be greater than that of the general population.

In studies of families into which infants with OI type II were born, most of the babies had a new dominant mutation in a collagen gene. In some of these families, however, more than one infant was born with OI. Previously, researchers had seen this recurrence as evidence of recessive inheritance of OI type II. Subsequently, however, researchers concluded that the rare recurrence

of OI to a couple with a child with autosomal dominant OI is more likely due to gonadal mosaicism. Instead of mutation occurring in an individual sperm or egg, it occurs in a percentage of the cells that give rise to a parent's multiple sperm or eggs. This mutation, present in a percentage of his or her reproductive cells, can result in more than one affected child without affecting the parent with the disorder. An estimated 2 percent to 4 percent of families into which an infant with OI type II is born are at risk of having another affected child because of gonadal mosaicism.

Demographics

OI affects equal numbers of males and females. It occurs in about one of every 20,000 births.

Causes and symptoms

Evidence suggests that OI results from abnormalities in the collagen gene COL1A1 or COL1A2 and possibly abnormalities in other genes. In OI, the genetic abnormality causes one of two things to occur. It may direct cells to make an altered collagen protein and the presence of this altered collagen causes OI type II, III, or IV. Alternately, the dominant altered gene may fail to direct cells to make any collagen protein. Although some collagen is produced by instructions from the normal gene, an overall decrease in the total amount of collagen produced results in OI type I.

Type I

OI type I is the most common and mildest type. Among the common features of type I are the following:

- Bones are predisposed to fracture, with most **fractures** occurring before **puberty**; people with OI type I typically have about 20 to 40 fractures before puberty.
- Stature is normal or near-normal.
- Joints are loose and muscle tone is low.
- Sclerae (whites of the eyes) have blue, purple, or gray tint.
- Face shape is triangular.
- Tendency toward **scoliosis** (a curvature of the spine) is present.
- Bone deformity is absent or minimal.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is a possible symptom, often beginning in early 20s or 30s.
- Structure of collagen is normal but the amount is lower than normal.

Type II

Sometimes called the lethal form, type II is the most severe form of OI. Among the common features of type II are the following:

- Frequently, OI type II is lethal at or shortly after birth, often as a result of respiratory problems.
- Fractures are numerous and bone deformity is severe.
- Stature is small with underdeveloped lungs.
- Collagen is formed improperly.

Type III

Among the common features of type III are the following:

- Bones fracture easily (Fractures are often present at birth, and x rays may reveal healed fractures that occurred before birth; people with OI type III may have more than 100 fractures before puberty.)
- Stature is significantly shorter than normal.
- Sclerae have blue, purple, or gray tint.
- Joints are loose and muscle development is poor in arms and legs.
- Rib cage is barrel-shaped.
- Face shape is triangular.
- Scoliosis (a curvature of the spine) is present.
- Respiratory problems are possible.
- Bones are deformed and deformity is often severe.
- Dentinogenesis imperfecta may occur.
- Hearing loss is possible.
- Collagen is formed improperly.

Type IV

OI type IV falls between type I and type III in severity. Among the common features of type IV are the following:

- Bones fracture easily, with most fractures occurring before puberty.
- Stature is shorter than average.
- Sclerae are normal in color, appearing white or near-white.
- Bone deformity is mild to moderate.
- Scoliosis (curvature of the spine) is likely.

- Rib cage is barrel-shaped.
- Face is triangular.
- Dentinogenesis imperfecta may occur.
- Hearing loss is possible.
- Collagen is formed improperly.

When to call the doctor

Parents should contact a healthcare professional if their child exhibits any of the symptoms of OI, particularly a tendency to fracture bones easily.

Diagnosis

It is often possible to diagnose OI solely on clinical features and x-ray findings. Collagen or DNA tests may help confirm a diagnosis of OI; test results may take several weeks to confirm. Approximately 10 to 15 percent of individuals with mild OI who have collagen testing, and approximately 5 percent of those who have genetic testing, test negative for OI despite having the disorder.

Diagnosis is usually suspected when a baby has bone fractures after having suffered no apparent injury. Another indication is small, irregular, isolated bones in the sutures between the bones of the skull (wormian bones). Sometimes the bluish sclerae serve as a diagnostic clue. Unfortunately, because of the unusual nature of the fractures occurring in a baby who is not yet mobile, some parents have been accused of **child abuse** before the actual diagnosis of osteogenesis imperfecta was reached.

Prenatal diagnosis

Testing is available to assist in prenatal diagnosis. Women with OI who become pregnant or women who conceive a child with a man who has OI may wish to explore prenatal diagnosis. Because of the relatively small risk (2–4%) of recurrence of OI type II in a family, families may opt for ultrasound studies to determine if a developing fetus has the disorder.

Ultrasound is the least invasive procedure for prenatal diagnosis and carries the least risk. Using ultrasound, a doctor can examine the fetus's skeleton for bowing of the leg or arm bones, fractures, shortening, or other bone abnormalities that may indicate OI. Different forms of OI may be detected by ultrasound in the second trimester. When OI occurs as a new dominant mutation and is found inadvertently on ultrasound, it may be difficult to confirm the diagnosis until after delivery since other genetic conditions can cause bowing and/or fractures prenatally.

Chorionic villus sampling is a procedure that obtains a sampling of cells from the placenta for testing. Examination of fetal collagen proteins in the tissue can reveal information about the quantitative or qualitative collagen defects that leads to OI. When a parent has OI, it is necessary for the affected parent to have the results of his or her own collagen test available. Chorionic villus sampling can be performed at ten to 12 weeks of pregnancy.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus, into the amniotic sac, and withdrawing a small amount of amniotic fluid. Genetic material can be extracted from the fetal cells contained in the amniotic fluid and tested for the specific mutation known to cause OI in that family. This technique is useful only when the mutation causing OI in a particular family has been identified through previous genetic testing of affected family members, including previous pregnancies involving a baby with OI. Amniocentesis is performed at 16 to 18 weeks of pregnancy.

Treatment

There are no treatments available to cure OI, nor to prevent most of its complications. Most treatments are aimed at treating the fractures and bone deformities caused by OI. Splints, casts, braces, and rods are all used. Rodding is a surgical procedure in which a metal rod is implanted within a bone (usually the long bones of the thigh and leg). This surgery is performed when bowing or repeated fractures of these bones has interfered with a child's ability to walk.

Other treatments include hearing aids and early capping of teeth. Patients may require the use of a walker or wheelchair. **Pain** may be treated with a variety of medications. **Exercise** is encouraged as a means to promote muscle and bone strength. Swimming is a form of exercise that puts a minimal amount of strain on muscles, joints, and bones. Walking is encouraged for those who are able.

Alternative treatment

Alternative treatment such as acupuncture, naturopathic therapies, hypnosis, relaxation training, visual imagery, and biofeedback have all been used to try to decrease the constant pain of fractures.

Nutritional concerns

Smoking, excessive alcohol and **caffeine** consumption, and steroid medications may deplete bone and exacerbate bone fragility.

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Ligament—A type of tough, fibrous tissue that connects bones or cartilage and provides support and strength to joints.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease. This change can be transmitted to offspring.

Sclera—The tough, fibrous, white outer protective covering of the eyeball.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Prognosis

The lifespan of people with OI types I, III, and IV is not generally shortened. The prognosis for people with these types of OI is quite variable, depending on the severity of the disorder and the number and severity of the fractures and bony deformities.

Fifty percent of all babies with OI type II are stillborn. The rest of these babies usually die within a very short time after birth. In the early 2000s, some people with type II have lived into young adulthood.

Prevention

As a congenital birth defect, OI cannot be prevented. Individuals at risk of having a child with OI should be encouraged to undergo genetic counseling to more accurately determine their chances of having a child with OI. The risk of fractures can be minimized with bone- and muscle-strengthening exercises, rehabilitative therapy, and use of leg braces.

Nutritional concerns

Because the symptoms of OI are caused by collagen abnormalities and not a calcium deficiency (such as in osteoporosis), supplementation of **vitamins** or **minerals** will not cure the disease. To prevent bone loss related to calcium deficiency, which could exacerbate the fragility of bones, it is important that children with OI consume an adequate amount of calcium (generally 500 mg for children ages one to three, 800 mg for children ages four to eight, and 1,300 mg a day for preteens and teenagers).

Parental concerns

In cases in which OI is not diagnosed at birth, a child may experience numerous fractures of seemingly unexplained cause, leading healthcare providers to suspect the child is being abused. Once a child has been diagnosed, it may be helpful for parents to carry with them a letter from the child's healthcare provider detailing the diagnosis in order to facilitate care in an emergency.

Osteopetroses

Definition

Osteopetrosis (plural osteopetroses) is a rare inherited disorder that makes bones increase in both size (mass) and fragility. It is a potentially fatal condition that can deform bone structure and distort the appearance. Osteopetrosis is also called chalk bones, ivory bones, or marble bones.

Description

In healthy individuals, bones are constantly being broken down (resorption) by cells called osteoclasts, and new bone material is constantly being formed by cells called osteoblasts. Osteopetrosis occurs when there is a failure in bone resorption. The mass of bone increases, but the new bone material that is added is porous, weak, and brittle.

There are three types of osteopetrosis. In some children with osteoporosis, bone mass begins to increase at birth, but symptoms may not become evident until adulthood. In mild cases, bone mass increases at gradual, irregular intervals until full adult height is attained. Some bones are not affected. Other forms of osteopetrosis progress at a more rapid pace and destroy bone structure, which can involve bones throughout the body, although the lower jaw is never affected.

Types of osteopetroses

Severe malignant infantile osteopetrosis (early-onset osteopetrosis) is the most severe form of osteopetrosis. It results from a child inheriting defective genes from both parents (autosomal recessive pattern of inheritance). It is most often discovered soon after birth. The ends of the long bones of the arms and legs appear widened and thickened (clubbed). Bone mass continues to increase rapidly, often filling in the hollow middle of the bone where the bone marrow, which produces red blood cells, is found. Early-onset osteopetrosis can be a fatal condition, with death occurring before the age of two. About one-third of all children with malignant infantile osteopetroses die before age ten. Although this form of osteopetrosis is called "malignant," it is not a type of **cancer**.

Intermediate osteopetrosis generally appears in children under age ten. This condition is usually less severe than early-onset or malignant infantile osteopetrosis and is not normally life-threatening.

Adult (delayed-onset) osteopetrosis may not become evident until after age 20. Albers-Schönberg disease is a mild form of this condition. People who have this disease are born with normal bone structure. Bone mass increases as they age but does not affect appearance, health, **intelligence**, or life span. Many people with adult osteopetrosis are diagnosed only when abnormalities are discovered on x rays taken for other purposes. There are two distinct types of adult osteopetrosis (types I and II). These types have different biochemical features. Individuals with type II disease have a higher risk of sustaining bone **fractures**.

Demographics

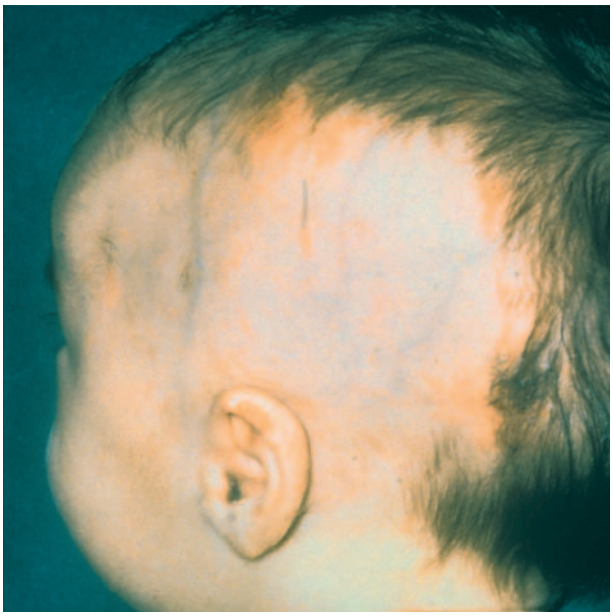
The incidence of osteopetroses is not known, although it is estimated that adult osteopetrosis occurs in about one of every 1,250 individuals. About 20,000 people in the United States have this form of the disease. Worldwide malignant infantile osteopetrosis occurs in about one in 100,000 to 500,000 births, making it exceedingly rare. Only eight to 40 children are born with this disease in the United States each year. Males and females appear to be equally affected.

Causes and symptoms

Osteopetrosis is the result of a genetic defect that causes the body to add new bone more rapidly than existing bone disintegrates. When fibrous or bony tissue invades bone marrow where red blood cells are made, the individual may develop anemia. Infection results when excess bone impairs the immune system, and hemorrhage can occur when platelet production is disrupted. When the skeleton grows so thick that nerves are unable to pass between bones, the individual may have a nerve damage, paralysis, or become blind or deaf.

Other symptoms associated with osteopetrosis include:

- bones that break easily and do not heal properly



This infant has osteopetrosis, a condition which thickens and hardens the bone. Note the unusual shape of the skull. *(Custom Medical Stock Photo Inc.)*

- bruising
- bone **pain**
- carpal tunnel syndrome
- osteoarthritis
- convulsions
- enlargement of the liver, lymph glands, or spleen
- failure to thrive (delayed growth, weight gain, and development)
- hydrocephalus (fluid on the brain)
- macrocephaly (abnormal enlargement of the head)
- paralysis or loss of control of muscles in the face or eyes

When to call the doctor

A doctor should be consulted if the child has frequent broken bones, bone pain, or failure of normal growth and development.

Diagnosis

Osteopetrosis is usually diagnosed when x rays reveal abnormalities or increases in bone density. Bone biopsy can confirm the diagnosis. Additional tests may be done to look for associated problems in vision, hearing, blood composition, and so forth.

Treatment

Interferon gamma-1b (Actimmune) is the only drug approved by the United States Food and Drug Administration (FDA) to treat osteopetrosis. Injections delay the progress of severe osteopetrosis in both children and adults.

Bone marrow transplantation (BMT) is the only therapy that can completely cure severe malignant infantile osteopetrosis. It replaces the abnormal osteoclasts with normal cells. The survival rate for children with osteopetrosis who undergo BMT is 40 to 70 percent. Because of the high risk of death, this procedure is done only with the most severely affected children where a good bone marrow match can be found.

High doses of calcitriol, an active form of vitamin D, can stimulate osteoclasts responsible for disintegration of old bone and significantly alleviate symptoms of severe disease in some individuals.

When bone overgrowth deforms the shape of the skull, surgery may be required to relieve pressure on the brain. Orthodontic treatment is sometimes necessary to correct **malocclusion**, a condition that shifts the position of the teeth and makes closing the mouth impossible.

Physical and occupational therapy can help children reach their full potential and adults to retain function and independence. Speech therapy is often needed in young children, because the heavy skeleton can cause language delays even in children of normal intelligence. Professional counseling can help children and their families cope with the emotional aspects of deformed features.

Prognosis

The severity of anemia seems to determine the course of an individual's osteopetrosis. About two-thirds of children who have severe malignant infantile osteopetrosis die before age ten unless they have a successful bone marrow transplant. Individuals who develop the adult form of the disease have normal life spans, although they experience more bone fractures and complications related to compression of cranial nerves. Nerve compression can result in facial paralysis, deafness, or blindness.

Prevention

Osteopetrosis is an inherited disease that cannot be prevented.

KEY TERMS

Cranial nerves—The set of twelve nerves found on each side of the head and neck that control the sensory and muscle functions of the eyes, nose, tongue, face, and throat.

Osteoblast—A bone-building cell.

Osteoclast—A large, multinuclear cell involved in the physiological destruction and absorption of bone.

Parental concerns

Parents with children who develop intermediate or adult forms of this disease as teens or young adults should be aware that their children are very susceptible to bone fractures and should avoid situations and **sports** where they are likely to be injured.

Otitis externa

Definition

Otitis externa refers to an infection of the ear canal (outer ear), the tube leading from the outside opening of the ear in towards the ear drum. The infection usually develops in children and adolescents whose ears are exposed to persistent, excessive moisture.

Description

The external ear canal is a tube approximately 1 in (2.5 cm) in length that runs from the outside opening of the ear to the start of the middle ear, which is behind the tympanic membrane (ear drum). The canal is partly cartilage and partly bone. The lining of the ear canal is skin, which is attached directly to the covering of the bone. Glands within the skin of the canal produce a waxy substance called cerumen (popularly called earwax). Cerumen is designed to protect the ear canal, repel water, and keep the ear canal too acidic to allow bacteria to grow.

Continually exposing the ear canal to moisture may cause significant loss of cerumen. The delicate skin of the ear canal, unprotected by cerumen, retains moisture and becomes irritated. Without cerumen, the ear canal stops being appropriately acidic, which allows for the growth of microorganisms. Thus, the warm, moist, dark environment of the ear canal becomes a hospitable environment for development of an infection.

Otitis externa is commonly referred to as swimmer's ear.

Demographics

Although all age groups are affected by otitis externa, children, adolescents, and young adults whose ears are exposed to persistent, excessive moisture develop the infection most often. Otitis externa occurs most often in warm climates and during the summer months, when more people are participating in water activities. The ratio of occurrence in males is equal to that of females. People in some racial groups have a smaller size of the ear canal, which may predispose them to infection.

Causes and symptoms

Chidren and adolescents with otitis externa often have been diving or swimming for long periods of time, especially in polluted lakes, rivers, or ponds. Routine showering can also lead to otitis externa. Water in the ear canal can carry infectious microorganisms into the ear canal.

Bacteria, fungi, and viruses have all been implicated in causing otitis externa. However, most commonly otitis externa is caused by bacteria, especially *Pseudomonas aeruginosa*. Other bacteria that can cause otitis externa

include *Enterobacter aerogenes*, *Proteus mirabilis*, *Klebsiella pneumoniae*, *Staphylococcus epidermidis*, and bacteria of the family called Streptococci. Occasionally, fungi may cause otitis externa. These include *Candida* and *Aspergillus*. Two types of viruses, called herpesvirus hominis and varicella-zoster virus, have also been identified as causing otitis externa.

Other conditions predisposing to otitis externa include the use of cotton swabs to clean the ear canals. This pushes cerumen and normal skin debris back into the ear canal, instead of allowing the ear canal's normal cleaning mechanism of the ear to work, which would ordinarily move accumulations of cerumen and debris out of the ear. Also, putting other items into the ear can scratch the canal, making it more susceptible to infection. For example, children may insert a foreign body in their ear canal and not mention it to their parents. Hair spray or hair coloring, which can irritate the ear canal, may also lead to otitis externa. A hearing aid can trap moisture in the ear canal and should be taken out as often as possible to allow the ear an opportunity to dry out.

The first symptom of otitis externa is often **itching** of the ear canal, followed by watery discharge from the ear. Eventually, the ear begins to feel extremely painful. Any touch, movement, or pressure on the outside structure of the ear may cause severe **pain**. If the canal is excessively swollen, hearing may become muffled. The canal may appear swollen and red, and there may be evidence of foul-smelling, greenish-yellow pus.

In severe cases, otitis externa may be accompanied by **fever**. Often, this indicates that the outside ear structure has become infected as well. It will become red and swollen, and there may be enlarged and tender lymph nodes in front of, or behind, the ear.

A serious and life-threatening type of otitis externa is called malignant otitis externa. This is an infection that most commonly affects persons who have diabetes or in persons with weakened immune systems. In malignant otitis externa, a patient has usually had minor symptoms of otitis externa for some months, with pain and drainage. The causative bacteria is usually *Pseudomonas aeruginosa*. This bacteria spreads from the external canal into all of the nearby tissues, including the bones of the skull. Swelling and destruction of these tissues may lead to damage of certain nerves, resulting in spasms of the jaw muscles or paralysis of the facial muscles. Other, more severe, complications of this destructive infection include **meningitis** (swelling and infection of the coverings of the spinal cord and brain), brain infection, or brain abscess (the development of a pocket of infection with pus).

When to call the doctor

The doctor should be called if any of the following symptoms are present:

- pain in an ear with or without fever
- persistent itching of the ear or in the ear canal
- loss of hearing or decreased hearing in one or both ears
- discharge from an ear, especially if it is thick, discolored, bloody, or foul-smelling

Diagnosis

Diagnosis of uncomplicated otitis externa is usually quite simple. The symptoms alone, of ear pain worsened by any touch to the outer ear, are characteristic of otitis externa. Examination of the ear canal will usually reveal redness and swelling. It may be impossible (due to pain and swelling) to see much of the ear canal, but this inability itself is diagnostic.

If there is a need to identify the types of organisms causing otitis externa, the canal can be gently swabbed to obtain a specimen. The organisms present in the specimen can then be cultured (allowed to multiply) in a laboratory, and then viewed under a microscope to allow identification of the causative organisms.

If the rare infection malignant otitis externa is suspected, **computed tomography** scan (CT scan) or **magnetic resonance imaging** (MRI) scans will be performed to determine how widely the infection has spread within bone and tissue. A swab of the external canal will not necessarily reveal the actual causative organism, so some other tissue sample (biopsy) will need to be obtained. The CT or MRI will help the doctor decide where the most severe focus of infection is located, in order to guide the choice of a biopsy site.

Treatment

Otitis externa us usually not a dangerous condition and often clears up by itself within a few days. To aid in the healing, the infected ear canal can be washed with an over-the-counter topical antiseptic. Pain can be relieved be placing a warm heating pad or compress on the infected ear as well as through the use of an over-the-counter pain reliever such as **acetaminophen** or aspirin. During the healing process, the infected ear canal must be kept dry, even while showering, through the use of ear plugs or a shower cap.

If the pain worsens or does not improve within 24 hours, or for the fastest way to relieve pain and to prevent

the spread of infection, the doctor should be seen. The doctor will clean the ear with a suction-tipped probe or other type of suction device to relieve irritation and pain. **Antibiotics** will applied directly to the skin of the ear canal (**topical antibiotics**) to fight the infection. These antibiotics are often combined in a preparation that includes a steroid medication that reduces the itching, inflammation and swelling within the ear canal. For full treatment, eardrops are usually applied several times a day for seven to 10 days.

If the opening to the ear is narrowed by swelling, a cotton wick may be inserted into the ear canal to help carry the eardrops into the ear more effectively. The medications are applied directly to the wick, enough times per day to allow the wick to remain continuously saturated. After the wick is removed, usually after about 48 hours, the medications are then put directly into the ear canal three to four times each day.

For severe infection, oral antiobiotics may be prescribed. If the otitis externa infection is caused by the presence of a foreign body in the ear, the infection will not improve until the foreign body is removed.

In malignant otitis externa, antibiotics will almost always need to be given intravenously (IV). If the CT or MRI scan reveals that the infection has spread extensively, these IV antibiotics will need to be continued for six to eight weeks. If the infection is in an earlier stage, two weeks of IV antibiotics can be followed by six weeks of antibiotics by mouth.

Alternative treatment

Mullein (*Verbascum thapsus*) oil has anti-inflammatory properties and may be apppied to the infected ear canal (one to three drops every three hours) to help soothe and heal the ear. Garlic (*Allium sativum*) is a natural antibiotic. Garlic juice can be combined with equal parts of glycerin and a carrier oil such as olive or sweet olive and applied (one to three drops) to the infected ear every three hours.

Prognosis

The prognosis is excellent for otitis externa, for it is usually easily treated. Basic treatment measures will cure 90 percent of cases without complication. However, it may recur in certain susceptible individuals. Left untreated, malignant otitis externa may spread sufficiently to cause death.

KEY TERMS

Cerumen—The medical term for earwax.

Eardrum—A paper-thin covering stretching across the ear canal that separates the middle and outer ears.

Infectious disease—A disease caused by a virus or a bacterium. Examples of viruses causing an infectious disease are: HIV-1 virus, herpes simplex, cytomegalovirus, Epstein-Barr virus, leukemia virus. Examples of bacterial infectious diseases are: syphilis and tuberculosis.

Outer ear—Outer visible portion of the ear that collects and directs sound waves toward the tympanic membrane by way of a canal which extends inward through the temporal bone.

Prevention

Swimming in polluted water and in pools or hot tubs without good chlorine and pH control should be avoided.

Keeping the ear dry is an important aspect of prevention of otitis externa. Before swimming, a protective coating consisting of several drops of mineral oil, baby oil, or lanolin can be applied to the ear canal. After swimming, several drops of a mixture of isopropyl alcohol and white vinegar can be put into the ear canal to ensure that it dries adequately. The head should be tilted so that the solution reaches the bottom of the ear canal; then the liquid should be drained out.

Care should be taken when cleaning ears. The outer ear should be cleaned wiped with a clean washcloth. The use of pointed objects to dig into the ear canal, especially those that can scratch the skin, should be avoided.

The most serious complications of malignant otitis externa can be avoided by careful attention to early symptoms of ear pain and drainage from the ear canal. Children with conditions that put them at higher risk for this infection (diabetes or conditions that weaken the immune system) should always report new symptoms immediately to the doctor.

Parental concerns

Parents should teach their children how to clean their ears without using sharp objects and to dry their ears thoroughly after swimming, showering, or bathing.

Otitis media

Definition

Otitis media is an infection of the middle ear, which is located behind the eardrum. There are two main types of otitis media. In the first, called acute otitis media (AOM), parts of the ear are infected and swollen, and fluid and mucus are trapped inside the ear. AOM can be quite painful. In the second type, called otitis media with effusion (fluid), or OME, fluid and mucus remain trapped within the ear after the infection is over, making it more difficult for the ear to fight off new infections. This fluid may adversely affect a child's hearing.

Description

One of the most common childhood infections, Otitis media is the leading cause of visits to the doctor by children. It is also the most frequent reason children receive antibiotic prescriptions or undergo surgery.

In order to fully understand otitis media, it is helpful to have a basic knowledge of ear anatomy. Deep within the outer ear canal is the eardrum, which is a thin, transparent membrane that vibrates in response to sound. Behind the eardrum is the space called the middle ear. When the eardrum vibrates, three tiny bones within the middle ear, called ossicles, transmit these sounds to the inner ear. Nerves are stimulated in the inner ear, which then relay the sound signals to the brain. The eustachian tube, which connects the middle ear to the nose, normally equalizes pressure in the middle ear, allowing the eardrum and ossicles to vibrate correctly, so that hearing is normal.

There are certain factors particular to children that make them more at risk for otitis media. In children, the eustachian tube is shorter and less slanted than in adults. Its size and position allow bacteria and viruses to travel to the middle ear more easily. Children also have clumps of infection fighting cells, commonly called adenoids, in the area of the eustachian tube. These adenoids may enlarge with repeated respiratory tract infections and ultimately block the eustachian tubes. When these tubes are blocked, the middle ear is more likely to fill with fluid, which in turn increases the risk for infection.

Demographics

Otitis media is common. Fifty percent of children have an episode before their first birthday, and 80 percent of children have an occurrence by their third birthday. It is estimated that $3 to $4 billion are spent per year on patients with a diagnosis of acute otitis media and related complications. Ear infections are found in all age groups, but they are considerably more common in children, especially those aged six months to three years. Boys are affected more commonly than girls. Other children at higher risk include those from poor families, Native Americans, children born with **cleft palate** or other defects of the facial structures, and children with **Down syndrome**. Exposure to cigarette smoke and early entrance into daycare also increase the risk. Otitis media occurs more frequently in winter and early spring. It is less common among children who are breastfeeding. Some studies show a genetic predisposition towards developing otitis media.

Causes and symptoms

The first precondition for the development of acute otitis media is exposure to an organism capable of causing the infection. Otitis media may be caused by either viruses or bacteria. Viral infections account for approximately 15 percent of cases. The majority of other cases are caused by a variety of bacteria. The three most common bacteria are *Streptococcus pneumoniae* (responsible for 25–50% of cases), *Haemophilus influenzae* (15–30%), and *Moraxella catarrhalis* (3–20%).

Acute otitis media often occurs as an aftereffect of upper respiratory infections, in which the eustachian tube and nasal membranes become swollen and congested. This condition can lead to an impaired clearance and pressure regulation in the middle ear, which, if sustained, may be followed by viruses and bacteria traveling from the nasopharynx to the middle ear.

Otitis media with effusion may develop within weeks of an acute episode of middle ear infection, but in many cases the cause is unknown. It is often associated with an abnormal or malfunctioning eustachian tube, which causes negative pressure in the middle ear and leaking of fluid from tiny blood vessels, or capillaries, into the middle ear.

Symptoms of acute otitis media (AOM)

The following are symptoms of acute otitis media:

- **fever**
- ear pulling
- complaints of ear **pain**, ear fullness, or hearing loss by older children
- fussiness, irritability, or difficulties in hearing, feeding, or sleeping in younger children
- bloody or greenish-yellow pus draining from the ear (This seepage is the sign of a perforated the eardrum. The pain leading up to such a perforation may be severe, but it is often relieved by the rupture.)

Otitis media with effusion (OME) is the presence of middle ear fluid for six weeks or longer after the initial episode of acute otitis media. The hallmark of OME is the lack of obvious symptoms in those who most commonly have the condition. Older children often complain of muffled hearing or a sense of fullness in the ear. Younger children may turn up the television volume. Most often OME is diagnosed when someone examines the ear for another reason, such as a well-child physical. For this reason, OME is often referred to as silent otitis media.

When to call the doctor

Unresolved episodes of otitis media may lead to a variety of complications, including hearing loss and **dizziness**. Any child who reports an earache or a sense of fullness in the ear, especially if combined with a prior upper respiratory tract infection, or fever, should be evaluated by a physician.

Diagnosis

The physician will visualize the ear canal and ear drum by using a special lighted instrument called an otoscope. Normally, the light from the otoscope reflects off the eardrum in a characteristic fashion called the "cone of light." In an infection, this reflection is often shifted or absent. If fluid or pus is draining from the ear, it can be collected and sent to a laboratory to determine if any specific infectious organisms are present. Additionally, a tympanometry test will be performed. Here, the doctor inserts a probe into the ear which emits a tone with a certain amount of sound energy. The probe measures how much sound energy bounces back off the eardrum, rather than being transmitted to the middle ear. The more energy that is returned to the probe, the more blocked the middle ear is.

A diagnosis of acute otitis media is based on the following:

- recent, usually abrupt, onset of signs and symptoms of middle ear inflammation and middle ear effusion
- the presence of middle ear effusion that is indicated by any of the following: bulging of the tympanic membrane; limited or absent movement of the tympanic membrane; or discharge from the external ear
- signs or symptoms of middle ear inflammation as indicated by either distinct redness of the eardrum or ear pain that results in an interference with **sleep** or other normal activities

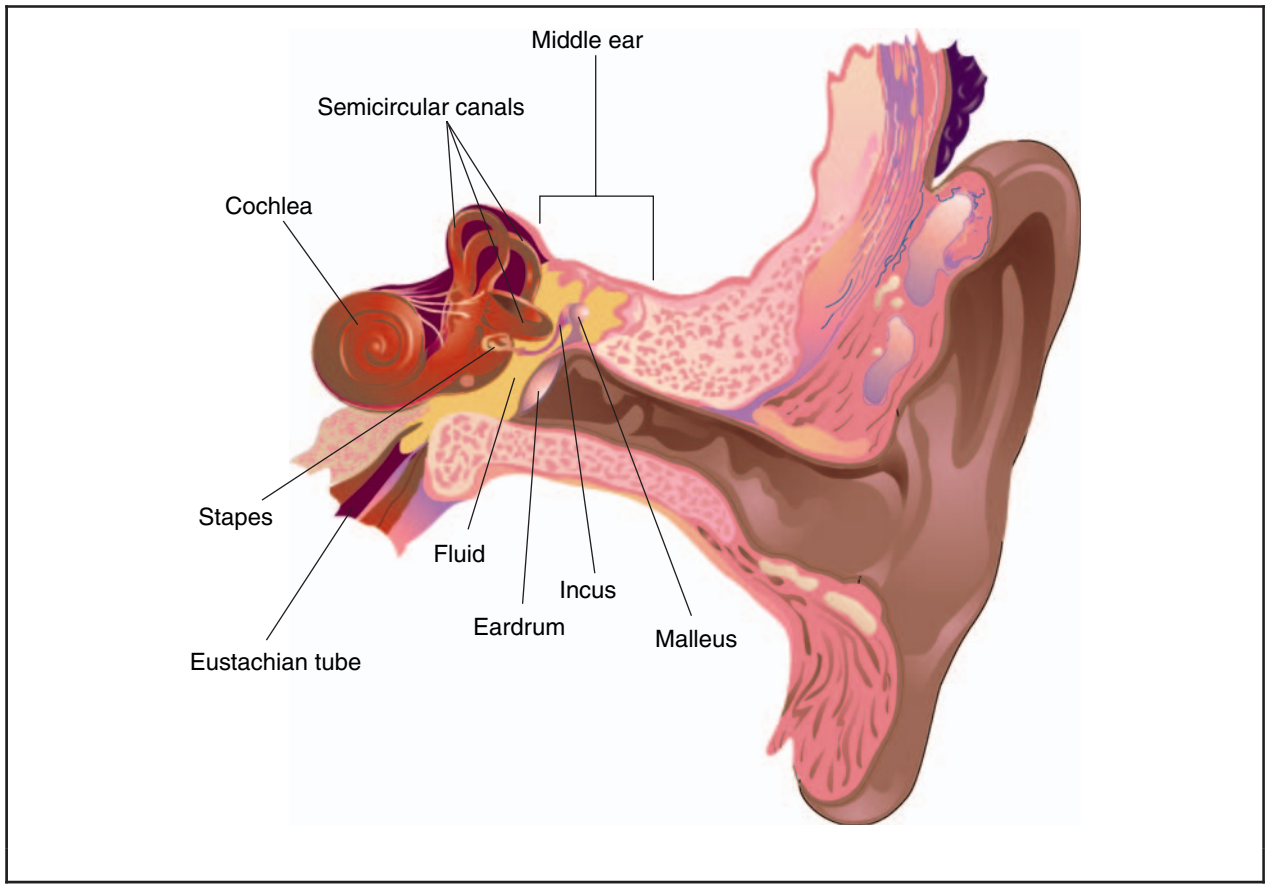
Otitis media with effusion can be more difficult to detect, since it is not painful and the child usually does not appear ill. The physician may rely on one or several tests to determine the diagnosis.

- A physical examination may reveal fluid behind the eardrum and poor movement of the eardrum. The eardrum may look clear and have no signs of redness, but may not move in response to air, as a normal eardrum would.
- A tympanometry test may reveal an impairment of eardrum mobility.
- A hearing test often shows some degree of hearing loss.

Treatment

Acute otitis media (AOM)

Treatment of AOM is focused on relieving any pain that may be present and addressing the infection itself. Usually, **acetaminophen** or ibuprofen prove adequate in



Otitis media is an ear infection in which fluid accumulates within the middle ear. A common condition occurring in childhood, it is estimated that 85 percent of all American children will develop otitis media at least once. *(Illustration by Electronic Illustrators Group.)*

relieving the pain. In cases of severe pain, narcotics may occasionally be prescribed.

Occasionally, an "observation option" will be used in a child who has uncomplicated acute otitis media. This refers to delaying antibacterial treatment of certain children for 48 to 72 hours and limiting management to symptomatic relief. The decision to observe or treat is based on the child's age, the certainty of the diagnosis, and the severity of the illness. To observe a child without initial antibacterial therapy, it is important that the parent or caregiver has a ready means of communicating with the doctor. There also must be a system in place that permits a prompt reevaluation of the child if symptoms persist or worsen. If the decision is made to use an antibiotic, the usual recommendation is for amoxicillin, preferably at a dose of 80 to 90mg/kg/day. If the initial treatment plan fails to work within 48 to 72 hours, the physician may reconsider the diagnosis of AOM. Further treatment may involve changing **antibiotics**.

Otitis media with effusion (OME)

For young children ages one to three years, most physicians prefer a conservative, or wait-and-see, approach, using antibiotics if the infection is persistent, the child is in pain, or there is evidence of hearing loss. Most cases of otitis media with effusion get better within three months without any treatment. If the child continues to have repeated episodes of OME, despite taking antibiotics, the physician may decide to try long-term, low-dose treatment with antibiotics, even after the condition has cleared. If OME persists for over three months, despite antibiotic treatment, the doctor may suggest a hearing test. If OME persists for more than four to six months, even if hearing tests are normal, the doctor may

suggest surgery to drain the eardrum and implant **ear tubes** for continuous drainage.

Surgery

In some cases, a surgical perforation to drain pus from the middle ear may be performed. This procedure is called a **myringotomy**. The hole created by the myringotomy generally heals itself in about a week. In 2002 a new minimally invasive procedure was introduced that uses a laser to perform the myringotomy. It can be performed in the doctor's office and heals more rapidly than the standard myringotomy. In some cases, the physician may decide that the placement of tubes during the myringotomy is recommended. These small tubes are placed to aid in draining the fluid from the middle ear. They fall out on their own after a few months. The decision to place these tubes is based on the following criteria:

- presence of fluid in the ears for more than three or four months following an ear infection
- fluid in the ears and more than three months of hearing loss
- changes in the structure of the eardrum as a result of ear infections
- a delay in speaking
- repeated infections that do not improve with antibiotics over several months

Another type of surgery, called an adenoidectomy, removes the adenoids. Removing the adenoids has been shown to help some children with otitis media between the ages of four to eight. It is a procedure generally reserved for those children who have recurrent otitis media after myringotomy tubes are extruded.

Alternative treatment

Treatment guidelines from the American Academy of Pediatrics and the American Academy of Family Physicians in the early 2000s state that there is insufficient evidence to either support or discourage the use of alternative medicines for acute otitis media. Increasing numbers of parents and caregivers are using various forms of nonconventional treatment for their children. Treatments that have been used for AOM include homeopathy, acupuncture, herbal remedies, chiropractic treatments, and nutritional supplements. Although most treatments are harmless, some are not. Some can have a direct and dangerous effect, whereas others may interfere with the effects of conventional treatments. Parent should inform their doctor if they are using any alternative or unconventional methods to treat their child's otitis media.

KEY TERMS

Adenoids—Common name for the pharyngeal tonsils, which are lymph masses in the wall of the air passageway (pharynx) just behind the nose.

Effusion—The escape of fluid from blood vessels or the lymphatic system and its collection in a cavity.

Eustachian tube—A thin tube between the middle ear and the pharnyx. Its purpose is to equalize pressure on either side of the ear drum.

Myringotomy—A surgical procedure in which an incision is made in the ear drum to allow fluid or pus to escape from the middle ear.

Nasopharynx—One of the three regions of the pharynx, the nasopharynx is the region behind the nasal cavity.

Ossicles—The three small bones of the middle ear: the malleus (hammer), the incus (anvil) and the stapes (stirrup). These bones help carry sound from the eardrum to the inner ear.

Prognosis

The prognosis of acute otitis media is excellent. The duration is variable. There may be improvement within 48 hours even without any treatment. Treatment with antibiotics for a week to 10 days is usually effective.

Prevention

Breastfeeding helps to pass along immunities to a child that may prevent otitis media. The position the child is in while breastfeeding is better than the usual bottle-feeding position for optimal eustachian tube function. If a child must be bottle-fed, it is best to hold the infant rather than allow him or her to lie down with the bottle. Because multiple upper respiratory infections may increase the risk for acute otitis media, reducing the exposure to large groups of children, particularly in day-care centers, may reduce the incidence. Children should also be kept away from environmental irritants such as secondhand tobacco smoke.

Parental concerns

A common concern among parents has been whether recurring episodes of otitis media will cause impairments in their child's development. Research indicates that

persistent otitis media in the first three years of life does not have an adverse effect on development.

Overhydration

Definition

Overhydration, also called water excess or water intoxication, is a condition in which the body contains too much water.

Description

Overhydration occurs when the body takes in more water than it excretes and its normal sodium level is diluted. This can result in digestive problems, behavioral changes, brain damage, seizures, or coma. An adult whose heart, kidneys, and pituitary gland are functioning properly would have to drink more than two gallons of water a day to develop water intoxication. This condition is most common in persons whose kidney function is impaired and may occur when doctors, nurses, or other healthcare professionals administer greater amounts of water-producing fluids and medications than the person's body can excrete.

Infants seem to be at greater risk for developing overhydration. The Centers for Disease Control and Prevention has declared that babies are especially susceptible to oral overhydration during the first month of life, when the kidneys' filtering mechanism is too immature to excrete fluid as rapidly as older infants do. Breast milk or formula provides all the fluids a healthy baby needs. Water should be given slowly, sparingly, and only during extremely hot weather. Overhydration, which has been cited as a hazard of infant swimming lessons, occurs whenever a baby drinks too much water, excretes too little fluid, or consumes and retains too much water.

Demographics

Overhydration is the most common electrolyte imbalance in hospitals, occurring in about 2 percent of all people.

Causes and symptoms

Drinking too much water rarely causes overhydration when the body's systems are working normally. People with heart, kidney, or liver disease are more likely to develop overhydration because their kidneys are unable to excrete water normally. It may be necessary for people with these disorders to restrict the amount of water they drink and/or adjust the amount of salt in their diets.

Since the brain is the organ most susceptible to overhydration, a change in behavior is usually the first symptom of water intoxication. The person may become confused, drowsy, or inattentive. Shouting and delirium are common. Symptoms of overhydration may include blurred vision, **muscle cramps** and twitching, paralysis on one side of the body, poor coordination, **nausea and vomiting**, rapid breathing, sudden weight gain, and weakness. The person's complexion is normal or flushed. Blood pressure is sometimes higher than normal, but elevations may not be noticed even when the degree of water intoxication is serious.

Overhydration can cause acidosis (a condition in which blood and body tissues have an abnormally high acid content), anemia, cyanosis (a condition that occurs when oxygen levels in the blood drop sharply), hemorrhage, and shock. The brain is the organ most vulnerable to the effects of overhydration. If excess fluid levels accumulate gradually, the brain may be able to adapt to them, and the person will have only a few symptoms. If the condition develops rapidly, confusion, seizures, and coma are likely to occur.

When to call the doctor

A doctor should be called when a person becomes confused, drowsy, or inattentive. Persons should also consider calling a doctor when a person experiences blurred vision, muscle cramps and twitching, paralysis on one side of the body, poor coordination, nausea and vomiting, rapid breathing, sudden weight gain, or weakness.

Diagnosis

Before treatment can begin, a doctor must determine whether an individual's symptoms are due to overhydration, in which excess water is found within and outside cells, or excess blood volume, in which high sodium levels prevent the body from storing excess water inside the cells. Overhydration is characterized by excess water both within and around the body's cells, while excess blood volume occurs when the body has too much sodium and cannot move water to reservoirs within the cells. In cases of overhydration, symptoms of fluid accumulation do not usually occur. On the other hand, in cases of excess blood volume, fluid tends to accumulate around cells in the lower legs, abdomen, and chest. Overhydration can occur alone or in conjunction with excess blood volume, and differentiating between these two conditions may be difficult.

KEY TERMS

Cyanosis—A bluish tinge to the skin that can occur when the blood oxygen level drops too low.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Shock—A medical emergency in which the organs and tissues of the body are not receiving an adequate flow of blood. This deprives the organs and tissues of oxygen and allows the build-up of waste products. Shock can be caused by certain diseases, serious injury, or blood loss.

Treatment

Mild overhydration can generally be corrected by following a doctor's instructions to limit fluid intake. In more serious cases, diuretics may be prescribed to increase urination, although these drugs tend to be most effective in the treatment of excess blood volume. Identifying and treating any underlying condition (such as impaired heart or kidney function) is a priority, and fluid restrictions are a critical component of every treatment plan.

In people with severe neurologic symptoms, fluid imbalances must be corrected without delay. A powerful diuretic and fluids to restore normal sodium concentrations are administered rapidly at first. When the person has absorbed 50 percent of the therapeutic substances, blood levels are measured. Therapy is continued at a more moderate pace in order to prevent brain damage as a result of sudden changes in blood chemistry.

Prognosis

Mild water intoxication is usually corrected by drinking less than a quart of water a day for several days. Untreated water intoxication can be fatal, but this outcome is quite rare.

Prevention

People should be careful not to drink excessive amounts of water. Persons with impaired kidney function must exert extra caution.

Parental concerns

Chronic illness, **malnutrition**, a tendency to retain water, and kidney diseases and disorders increase the likelihood of a person's becoming overhydrated. Infants and the elderly seem to be at increased risk for overhydration, as are people with certain mental disorders or **alcoholism**.

Pacifier use

Definition

A pacifier is an artificial nipple designed for babies to suck on for comfort.

Purpose

Infants have an intense need to suck that is separate from their need to eat. Fetuses may suck their thumbs before they are born, and some newborns begin to suck immediately. Infants suck when they are tired, bored, or in need of comfort. Some babies have a stronger need to suck than others and—next to eating and being held—sucking may provide the most comfort to an infant. Babies who do not suck their thumbs or fingers often rely on pacifiers.

In Western societies 75 to 85 percent of children use pacifiers. Hospital nurseries commonly give them to newborns. Premature infants seem to grow better when they suck on pacifiers. Professionals refer to a pacifier as a transitional object that helps children adjust to new situations and relieves stress.

Most infants cry because they do not yet have methods for soothing themselves. Some newborns do not have the coordination to suck their fingers or thumb. Although breastfeeding is the most effective way to calm infants, and their hands or thumbs can be placed in their mouths, pacifiers can be very helpful for discontented babies who cannot or will not suck their thumbs or fingers.

Arguments for pacifier use

Pacifier use is controversial. Some physicians are completely opposed to pacifier use, whereas others view pacifiers as helpful if used in moderation. Pacifiers can be particularly useful for unhappy babies who are difficult to comfort. The child's energy goes into sucking on a pacifier rather than crying. Although pacifiers can give children a sense of calm and security well into their toddler years, pacifier use may be most effective during the first few months of life when fussiness, **colic**, and the need to suck are at their peaks.

Pacifiers should only be used to satisfy the need to suck. They should never be used to delay or replace nurturing or feeding. As a child grows, a pacifier can be taken away, whereas it may be harder to discourage **thumb sucking**. For babies, pacifiers can be used for the following reasons:

- to sooth a baby to **sleep**
- to help a baby to stay asleep when disturbed
- to calm a frightened baby
- to keep the baby quiet

Arguments against pacifier use

The World Health Organization recommends against pacifier use. Disadvantages of pacifier use may include:

- They may get dirty and thus contribute to poor hygiene.
- If lost during sleep, the pacifier's absence may cause the baby to wake and cry.
- The pacifier may prevent babies from using their mouths to learn about **toys** and other objects.
- The pacifier may signal to a baby that crying is unacceptable even though crying is one of a baby's few means of communication.
- The pacifier is an easy fix that may cause parents not to seek to understand what is bothering the baby.
- Pacifiers may prevent children from learning how to comfort themselves.
- Older siblings may give the baby a pacifier to quiet a baby in situations where the parents would not use it.
- Many adults dislike the sight of babies with pacifiers.

The advantage of thumb sucking is that babies can adjust sucking to the feel of their skin. Some people believe that thumb sucking is an easier habit to break than pacifier use. Thumb sucking may be preferable to pacifier use because thumbs have the following benefits:

- Unlike pacifiers, the baby can find his thumb at night.
- Thumbs are more hygienic.
- Thumbs taste better.

Description

Types of pacifiers

Pacifiers consists of a latex or silicone nipple with a firm plastic shield and handle. Latex pacifiers are softer or more flexible but wear out faster than silicone. Silicone pacifiers are firmer, hold their shapes longer, and are easier to clean. The nipple should be knotted around the back of the handle and the shield and handle should be one piece. This prevents the nipple from falling off or the plastic from breaking in two and posing a **choking** hazard. The shield should be at least 1.5 inches (6 cm) across so that it will not fit in the baby's mouth. The shield should have air holes or vents to prevent saliva from collecting behind it and causing an irritation or rash. Large circular shields can obstruct an intensely sucking baby's nasal passages. Pacifiers should have easy-to-hold handles, be dishwasher-safe, and easy to clean.

Pacifiers come in several sizes designed for premature infants, newborns, babies younger than six months, and children older than six months. Pacifier nipples come in various shapes—long, short, flattened, or with a ball-shaped end. Some are shaped like bottle nipples and others resemble a breast nipple that is being sucked on. The latter may not always fit a baby's mouth. There is no evidence that one shape is preferable to another, although the baby may prefer a certain type. Some babies gag at the texture, taste, or smell of some pacifiers. A baby bottle nipple should never be used as a pacifier since the nipple could pop out of the ring and choke the baby.

Pacifier care

Infant pacifiers should be cleaned daily by boiling or washing in a dishwasher. Once a child is six months old, the pacifier can be washed daily with warm soapy water and rinsed with clean water. Children may be taught to wash their own pacifiers. Pacifiers should never be shared with playmates. They should never be stored in plastic bags where dampness can encourage fungal growth.

Pacifier nipples should be examined regularly for deterioration, including tears, frayed edges, holes, or a change in color. Emerging teeth can tear pacifiers. A worn or damaged pacifier should be replaced immediately. Since pacifiers are lost frequently, several should be kept on hand.

Precautions

Pacifiers are sometimes attached to a baby's clothing with a clip and a short cord or ribbon to prevent them from becoming lost or dirty. However a child can become entangled in even a short cord and should never be put to bed with a pacifier attached to a cord. A pacifier that is hung on a cord around the baby's neck, tied to the baby's hand, or attached to a crib can cause strangulation. Pacifiers should never be sweetened because sweetened pacifiers constitute a leading cause of **tooth decay** in babies under age three.

Pacifiers never should be used to replace a feeding, and children should never be given a pacifier if they are hungry. A hungry baby may become upset when there is no milk in the nipple and could develop feeding problems. Thus pacifiers should only be used between or after feedings.

Terminating pacifier use

Babies need their mouths for **play** and exploration. By the time a child is **crawling** and learning to walk, pacifiers are both unhygienic and limiting. Although many experts still recommend weaning a child from pacifier use at about age two, others suggest that six to ten months is the best time to end pacifier use. Before the age of two, children have short memories and may easily forget about a pacifier that has been lost for a few days. Pacifier use should not be terminated too soon or too abruptly since a baby may substitute thumb sucking or some other behavior such as hair pulling. A two-year-old is much less likely to revert to thumb sucking.

Sometimes severe stress or emotional upset causes a child to use a pacifier for a very long time. Even children who stop because of **peer pressure** at school may continue to use a pacifier to calm down at home or to go to sleep.

Risks

Breastfeeding

Pacifiers should never be given to a breastfeeding infant unless an efficient nursing routine is well-established. Pacifiers may cause nipple confusion. Newborns must learn to breastfeed effectively, and babies suck on

breast nipples differently than on a pacifier. Pacifiers have a narrow base so that infants do not have to open their lips widely. Pacifier use may prevent infants from learning how to latch onto their mother's breast, resulting in poor feedings and sore nipples.

A number of studies have found that frequent pacifier use reduces the duration of breastfeeding and increases the likelihood that a baby will be weaned by six months. The earlier a pacifier is introduced the sooner breastfeeding ceases. The reasons for this include the following:

- Pacifier use causes babies to breastfeed less.
- Mothers may introduce a pacifier because they want to stop breastfeeding.
- Infants who are given a pacifier, with or without supplemental food, may lose interest in nursing.
- A reduction in breastfeeding decreases the mother's milk production.
- A reduction in nipple stimulation by a nursing infant decreases milk production.

Ear infections

Research has found that pacifier use increases a child's risk of ear infections—acute **otitis media**, the second most common childhood illness after colds. In one study pacifier use increased the frequency of ear infections by 50 percent. Another study found a 33 percent decrease in ear infections when pacifier use was limited to babies aged six to ten months and only used when they were falling asleep. It may be that pacifier use spreads infection or that intense sucking on pacifiers hinders proper functioning of the eustachian tube that normally keeps the middle ear open and clean. The studies suggest that pacifiers only be used with babies under ten months of age, when the need to suck is strongest and the incidence of ear infection is relatively low.

Dental development

Both dental cavities and misaligned teeth have long been associated with pacifier use. Neither pacifier use nor thumb sucking is likely to interfere with early **dental development**. However, if continued past about age three, either one can contribute to protruding front teeth and an overbite. Orthodontic pacifiers do not prevent dental abnormalities. Many dentists believe that neither pacifier use nor thumb sucking should continue once all of the baby teeth have erupted. A dentist may recommend devices that are designed to discourage pacifier use.

Other risks

Pacifiers can exacerbate any problems with developing speech and language. They have been shown to interfere with normal babbling and speech development in babies older than 12 months. A child learning to speak with a pacifier may have distorted speech. The child may replace "t" and "d" sounds—that require the front of the tongue to brush against the teeth—with "k" and "g" sounds that come from the back of the throat. Pacifiers also can interfere with children's willingness to talk and the development of their social skills.

Some research has suggested that babies exhibit fewer visually exploratory behaviors when using a pacifier; they look around less and can seem less alert. Some of these children receive less of the following:

- mental stimulation
- encouragement to explore and learn
- parental attention

Additional risks of pacifier use include the following:

- the transmission of thrush, a yeast infection, that can be difficult to eradicate in children with pacifiers
- product recall of pacifiers due to **safety** concerns
- children who are unable to give them up, even after years of use

Normal results

Many babies lose interest in their pacifiers at about four months of age, as the need to suck begins to subside. They suck on it less or spit it out. Failing to replace the pacifier after the baby cries or spits it out can be a good method for breaking the pacifier habit. It is easier to end pacifier use in a younger child. By the age of three most children have learned to communicate effectively and have other means of coping with stress. **Preschool** children may experience pressure from their peers to give up pacifiers. However, most children give up both pacifiers and thumb sucking long before they become social or dental concerns.

Parental concerns

There are numerous ways to console a crying baby other than using a pacifier. During at least the first six months of life, crying should always be responded to promptly. If infants have been well-fed within the past hour and do not need a diaper change, parents can comfort them by the following:

Toddler using a pacifier to comfort himself. *(© Lawrence Migdale/Photo Researchers, Inc.)*

- placing their face directly in front of the baby's face and talking to the child
- picking the baby up
- rocking the baby
- placing a gentle hand on the baby's stomach
- swaddling a baby in soft blankets

Parents who choose to give their baby a pacifier should take the following steps:

- not use it every time the baby's mouth is open
- try alternative methods of calming a crying baby
- encourage the child to sleep without it
- remove it as soon as the need for extra sucking is gone—usually between 12 and 15 months of age

It may take several weeks for children to give up their pacifiers. Parents can encourage their children to give them up gradually by trying the following:

- ignoring the behavior
- reassuring them with affection

KEY TERMS

Otitis media—Inflammation or infection of the middle ear space behind the eardrum. It commonly occurs in early childhood and is characterized by ear pain, fever, and hearing problems.

Overbite—Protrusion of the upper teeth over the lower teeth.

Thrush—An infection of the mouth, caused by the yeast *Candida albicans* and characterized by a whitish growth and ulcers.

Tooth eruption—The emergence of a tooth through the gum.

- limiting pacifier use to bedtime or stressful situations
- finding them a comforting alternative
- providing activities in situations where they are likely to be bored
- helping them to express their emotions in words
- gently reminding them to not to use their pacifiers
- praising them for not using a pacifier
- failing to take the pacifier to daycare or other activities
- using a calendar to mark down pacifier-free days
- rewarding pacifier-free days
- dipping the pacifier in pickle juice to make it is less appealing
- offering to trade in the pacifier for a "big kid's" toy
- not pressuring the child to give up their pacifiers
- not punishing or humiliating the child for pacifier use

Pain

Definition

Pain is an unpleasant feeling that is conveyed to the brain by nerves in the body.

Description

Pain arises from any number of situations. Injury is a major cause, but pain may also arise from an illness. It may accompany a psychological condition, such as depression, or may even occur in the absence of a recognizable trigger. The discomfort signals actual or potential injury to the body. However, pain is more than a sensation or the physical awareness of pain; it also includes perception, the subjective interpretation of the discomfort. Perception gives information on the pain's location, intensity, and something about its nature. The various conscious and unconscious responses to both sensation and perception, including the emotional response, add further definition to the overall concept of pain.

Acute pain

Acute pain often results from tissue damage, such as a skin burn or broken bone. Acute pain can also be associated with headaches or **muscle cramps**. This type of pain usually goes away as the injury heals or the cause of the pain (stimulus) is removed. To understand acute pain, it is necessary to understand the nerves that support it. Nerve cells, or neurons, perform many functions in the body. Although their general purpose, providing an interface between the brain and the body, remains constant, their capabilities vary widely. Certain types of neurons are capable of transmitting a pain signal to the brain. As a group, these pain-sensing neurons are called nociceptors, and virtually every surface and organ of the body is wired with them. The central part of these cells is located in the spine, and they send threadlike projections to every part of the body. Nociceptors are classified according to the stimulus that prompts them to transmit a pain signal. Thermoreceptive nociceptors are stimulated by temperatures that are potentially tissue damaging. Mechanoreceptive nociceptors respond to a pressure stimulus that may cause injury. Polymodal nociceptors are the most sensitive and can respond to temperature and pressure. Polymodal nociceptors also respond to chemicals released by the cells in the area from which the pain originates.

Nerve cell endings, or receptors, are responsible for pain sensation. A stimulus at this part of the nociceptor unleashes a cascade of neurotransmitters (chemicals that transmit information within the nervous system) in the spine. Each neurotransmitter has a purpose. For example, substance P relays the pain message to nerves leading to the spinal cord and brain. These neurotransmitters may also stimulate nerves leading back to the site of the injury. This response prompts cells in the injured area to release chemicals that not only trigger an immune response but also influence the intensity and duration of the pain.

Chronic and abnormal pain

Chronic pain refers to pain that persists after an injury heals, **cancer** pain, pain related to a persistent or degenerative disease, and long-term pain from an unidentifiable cause. It is estimated that one in three people

in the United States experiences chronic pain at some point in their lives. Of these people, approximately 50 million are either partially or completely disabled. Chronic pain may be caused by the body's response to acute pain. In the presence of continued stimulation of nociceptors, changes occur within the nervous system. Changes at the molecular level are dramatic and may include alterations in genetic transcription of neurotransmitters and receptors. These changes may also occur in the absence of an identifiable cause; one of the frustrating aspects of chronic pain is that the stimulus may be unknown. For example, the stimulus cannot be medically identified in as many as 85 percent of individuals suffering from lower back pain.

Other types of abnormal pain include allodynia, hyperalgesia, and phantom limb pain. These types of pain often arise from some damage to the nervous system (neuropathic). Allodynia refers to a feeling of pain in response to a normally harmless stimulus. For example, some individuals who have suffered nerve damage as a result of viral infection experience unbearable pain from just the light weight of their clothing. Hyperalgesia is somewhat related to allodynia in that the response to a painful stimulus is extreme. In this case, a mild pain stimulus, such as a pinprick, causes a maximum pain response. Phantom limb pain occurs after a limb is amputated; although an individual may be missing the limb, the nervous system continues to perceive pain originating from the area.

Demographics

Pain is experienced by all age groups, both sexes, and all races and ethnic groups.

Causes and symptoms

Pain is the most common symptom of injury and disease, and descriptions can range in intensity from a mere ache to unbearable agony. Nociceptors have the ability to convey information to the brain that indicates the location, nature, and intensity of the pain. For example, stepping on a nail sends an information-packed message to the brain: the foot has experienced a puncture wound that hurts a lot. Pain perception also varies depending on the location of the pain. The kinds of stimuli that cause a pain response on the skin include pricking, cutting, crushing, burning, and freezing. These same stimuli would not generate much of a response in the intestine. Intestinal pain arises from stimuli such as swelling, inflammation, and distension.

When to call the doctor

Parents should notify their physician or pediatrician if any of the following occurs:

- The child is in severe pain.
- The child has pain that lasts for more than three days.
- Parents have questions or concerns about their child's treatment or condition.
- The child is in the hospital and the parent thinks he or she is in pain. The sooner the pain is treated, the easier it is to control.

Diagnosis

Pain is considered in view of other symptoms and individual experiences. An observable injury, such as a broken bone, may be a clear indicator of the type of pain a person is suffering. Determining the specific cause of internal pain is more difficult. Other symptoms, such as **fever** or **nausea**, help narrow the possibilities. In some cases, such as lower back pain, a specific physiological cause may not be identified. Diagnosis of the disease causing a specific pain is further complicated by the fact that pain can be referred to (felt at) a skin site that does not seem to be connected to the site of the pain's origin. For example, pain arising from fluid accumulating at the base of the lung may be referred to the shoulder.

Since pain is a subjective experience, it may be very difficult to communicate its exact quality and intensity to other people. There are no diagnostic tests that can determine the quality or intensity of an individual's pain. Therefore, a medical examination includes a lot of questions about where the pain is located, its intensity, and its nature. Questions are also directed at what kinds of things increase or relieve the pain, how long it has lasted, and whether there are any variations in it. An individual may be asked to use a pain scale to describe the pain. One such scale assigns a number to the pain intensity; for example, 0 may indicate no pain, and 10 may indicate the worst pain the person has ever experienced. Scales are modified for infants and children to accommodate their level of comprehension.

A subsequent method of evaluating pain in children up to age four years was as of 2004 set to be implemented in 60 hospitals in the Netherlands. The Pain Observation Scale for Young Children, called POCIS, measures pain levels according to children's behavior in seven categories: facial expressions, crying, breathing, torso movements, movements in the arms and fingers and in the legs and toes, and restlessness. Physicians and nurses observe the intensity of these behaviors and calculate a pain severity score ranging from 0 to 7. Researchers

from the University of Amsterdam who developed the scale said that existing behavioral pain measures were created for premature neonates or infants and may not be appropriate for older children. Some of those measures are upsetting for children because they require restraint or physical contact by a healthcare professional.

Alternative treatment

Both physical and psychological aspects of pain can be dealt with through alternative treatment. Some of the most popular treatment options include acupressure and acupuncture, massage, chiropractic, and relaxation techniques, such as **yoga**, hypnosis, and meditation. Herbal therapies are increasingly recognized as viable options; for example, capsaicin, the component that makes cayenne peppers spicy, is used in ointments to relieve the joint pain associated with arthritis. Contrast hydrotherapy can also be very beneficial for pain relief. Lifestyles can be changed to incorporate a healthier diet and regular **exercise**. Regular exercise, aside from relieving stress, has been shown to increase endorphins, painkillers naturally produced in the body.

Prognosis

Successful pain treatment is highly dependent on successful resolution of the pain's cause. Acute pain will stop when an injury heals or when an underlying problem is treated successfully. Chronic pain and abnormal pain are more difficult to treat, and it may take longer to find a successful resolution. Some pain is intractable and requires extreme measures for relief.

Prevention

Pain is generally preventable only to the degree that the cause of the pain is preventable; diseases and injuries are often unavoidable. However, increased pain, pain from surgery and other medical procedures, and continuing pain are preventable through drug treatments and alternative therapies.

Parental concerns

If a child has a lot of pain, it is likely that more can be done to help. The first step is for parents to tell the child's doctor or nurse what their concerns are. They can ask what more can be done for the child to control pain. If parents are still concerned about their child's pain control, they can request a meeting with the doctor. Parents should list their concerns as clearly as possible. They should take a constructive approach and seek to form a partnership with the healthcare team in managing the child's pain. For parents who are still not satisfied with what is being done, some type of formal complaint to the hospital may be unavoidable. **Pain management** is the right of every child. Parents working with health providers are the best advocates for this right. The U.S. Department of Health and Human Services Agency for Health Care Policy and Research has developed guidelines for pain management. These guidelines establish a standard of care that should be followed. Parents can get a copy from the hospital library or directly from the government.

KEY TERMS

Acute pain—Pain in response to injury or another stimulus that resolves when the injury heals or the stimulus is removed.

Chronic pain—Pain that lasts over a prolonged period and threatens to disrupt daily life.

Neuron—The fundamental nerve cell of the nervous system.

Neurotransmitters—Chemicals in the brain that transmit nerve impulses.

Nociceptor—A nerve cell that is capable of sensing pain and transmitting a pain signal.

Referred pain—Pain that is experienced in one part of the body but originates in another organ or area. The pain is referred because the nerves that supply the damaged organ enter the spine in the same segment as the nerves that supply the area where the pain is felt.

Stimulus—Anything capable of eliciting a response in an organism or a part of that organism.

Pain management

Definition

Pain management covers a number of methods to prevent, reduce, or stop pain sensations. These include the use of medications; physical methods such as ice and physical therapy; and psychological methods.

Purpose

Pain serves as an alert to potential or actual damage to the body. The definition for damage is quite broad; pain can arise from injury as well as disease. Pain that acts as a warning is called productive pain. After the message is received and interpreted, further pain offers no real benefit. Pain can have a negative impact on a person's quality of life and impede recovery from illness or injury. Unrelieved pain can become a syndrome in its own right and cause a downward spiral in a person's health and outlook. Managing pain properly facilitates recovery, prevents additional health complications, and improves a person's quality of life.

For many years it was believed that infants do not feel pain the way older children and adults do. As of the early 2000s, however, there has been a better understanding of the problems of pain, even in infancy.

Description

Before considering pain management, a review of pain definitions and mechanisms may be useful.

What is pain?

Pain is the means by which the peripheral nervous system (PNS) warns the central nervous system (CNS) of injury or potential injury to the body. The CNS comprises the brain and spinal cord, and the PNS is composed of the nerves that stem from and lead into the CNS. PNS includes all nerves throughout the body except the brain and spinal cord.

Once the brain has received and processed the pain message and coordinated an appropriate response, pain has served its purpose. The body uses natural pain killers, called endorphins, that are meant to derail further pain messages from the same source. However, these natural pain killers may not adequately dampen a continuing pain message. Pain is generally divided into two categories: acute and chronic.

Acute and chronic pain

Nociceptive pain, or the pain that is transmitted by nociceptors, is typically called acute pain. This kind of pain is associated with injury, headaches, disease, and many other conditions. It usually resolves once the condition that caused it is resolved. However, following some disorders, pain does not resolve. Even after healing or a cure has been achieved, the brain continues to perceive pain. In this situation, the pain may be considered chronic. The time limit used to define chronic pain typically ranges from three to six months, although some

healthcare professionals prefer a more flexible definition and consider pain chronic when it endures beyond a normal healing time. The pain associated with **cancer**, persistent and degenerative conditions, and neuropathy, or nerve damage, is included in the chronic category. Also, constant pain that lacks an identifiable physical cause, such as the majority of cases of low back pain, may be considered chronic.

It has been hypothesized that uninterrupted and unrelenting pain can induce changes in the spinal cord. As of 2004 evidence was accumulating that unrelenting pain or the complete lack of nerve signals increases the number of pain receptors in the spinal cord. Nerve cells in the spinal cord may also begin secreting pain-amplifying neurotransmitters independent of actual pain signals from the body. Other studies indicate that even newborn and premature infants who have constant pain will reach adulthood with greater sensitivity to pain and lower tolerance of stress.

Managing pain

Considering the different causes and types of pain, as well as its nature and intensity, management can require an interdisciplinary approach. The elements of this approach include treating the underlying cause of pain, pharmacological and nonpharmacological therapies, and some invasive (surgical) procedures.

Treating the cause of pain underpins the idea of managing it. Injuries are repaired, diseases are diagnosed, and certain encounters with pain can be anticipated and prevented. However, there are no guarantees of immediate relief from pain. Recovery can be impeded by pain, and quality of life can be damaged.

Pharmacological options

Pain-relieving drugs, otherwise called **analgesics**, include **nonsteroidal anti-inflammatory drugs** (NSAIDs), **acetaminophen**, narcotics, **antidepressants**, anticonvulsants, and others. NSAIDs and acetaminophen are available as over-the-counter and prescription medications and are frequently the initial pharmacological treatment for pain. These drugs can also be used as adjuncts to other drug therapies, which might require a doctor's prescription.

NSAIDs include aspirin, ibuprofen (Motrin, Advil, Nuprin), naproxen sodium (Aleve), and ketoprofen (Orudis KT). These drugs are used to treat pain from inflammation and work by blocking production of pain-enhancing neurotransmitters, such as prostaglandins. Acetaminophen is also effective against pain, but it is not an anti-inflammatory drug.

NSAIDs and acetaminophen are effective for most forms of mild pain, but moderate and severe pain may require stronger medication. Narcotics handle intense pain effectively and are used for cancer pain and acute pain that does not respond to NSAIDs and acetaminophen.

Narcotics may be ineffective against some forms of chronic pain, especially since changes in the spinal cord may alter the usual pain signaling pathways. Furthermore, narcotics are usually not recommended for long-term use because the body develops a tolerance to narcotics, reducing their effectiveness over time. In such situations, pain can be managed with antidepressants and anticonvulsants, which are also only available with a doctor's prescription.

Although antidepressant drugs were developed to treat depression, it has been discovered that they are also effective in combating chronic headaches, cancer pain, and pain associated with nerve damage. Antidepressants that have been shown to have analgesic (pain reducing) properties include amitriptyline (Elavil), trazodone (Desyrel), and imipramine (Tofranil). Anticonvulsant drugs share a similar background with antidepressants. Developed to treat epilepsy, anticonvulsants were found to relieve pain as well. Drugs such as phenytoin (Dilantin) and carbamazepine (Tegretol) are prescribed to treat the pain associated with nerve damage.

Other prescription drugs are used to treat specific types of pain or specific pain syndromes. For example, corticosteroids are very effective against pain caused by inflammation and swelling, and sumatriptan (Imitrex) was developed to treat migraine headaches.

Drug administration depends on the drug type and the required dose. Some drugs are not absorbed very well from the stomach and must be injected or administered intravenously. Injections and intravenous administration may also be used when high doses are needed or if an individual is nauseous. Following surgery and other medical procedures, patients may have the option of controlling the pain medication themselves. By pressing a button, they can release a set dose of medication into an intravenous solution. This procedure has also been employed in other situations requiring pain management. Another mode of administration involves implanted catheters that deliver pain medication directly to the spinal cord. Delivering drugs in this way can reduce side effects and increase the effectiveness of the drug.

Nonpharmacological options

Pain treatment options that do not use drugs are often used as adjuncts to, rather than replacements for,

drug therapy. One of the benefits of non-drug therapies is that an individual can take a more active stance against pain. Relaxation techniques, such as **yoga** and meditation, are used to decrease muscle tension and reduce stress. Tension and stress can also be reduced through biofeedback, in which an individual consciously attempts to modify skin temperature, muscle tension, blood pressure, and heart rate.

Participating in normal activities and exercising can also help control pain levels. Through physical therapy, an individual learns beneficial exercises for reducing stress, strengthening muscles, and staying fit. Regular **exercise** has been linked to production of endorphins, the body's natural pain killers.

Acupuncture involves the insertion of small needles into the skin at key points. Acupressure uses these same key points but involves applying pressure rather than inserting needles. Both of these methods may work by prompting the body to release endorphins. Applying heat or being massaged are very relaxing and help reduce stress. Transcutaneous electrical nerve stimulation (TENS) applies a small electric current to certain parts of nerves, potentially interrupt pain signals and induce the release of endorphins. To be effective, use of TENS should be medically supervised.

Invasive procedures

Three types of invasive procedures may be used to manage or treat pain: anatomic, augmentative, and ablative. These procedures involve surgery, and certain guidelines should be followed before carrying out a procedure with permanent effects. First, the cause of the pain must be clearly identified. Next, surgery should be done only if noninvasive procedures are ineffective. Third, any psychological issues should be addressed. Finally, there should be a reasonable expectation of success.

Anatomic procedures involve correcting the injury or removing the cause of pain. Relatively common anatomic procedures are decompression surgeries, such as repairing a herniated disk in the lower back or relieving the nerve compression related to carpal tunnel syndrome. Another anatomic procedure is neurolysis, also called a nerve block, which involves destroying a portion of a peripheral nerve.

Augmentative procedures include electrical stimulation or direct application of drugs to the nerves that are transmitting the pain signals. Electrical stimulation works on the same principle as TENS. In this procedure, instead of applying the current across the skin, electrodes are implanted to stimulate peripheral nerves or nerves in the spinal cord.

Ablative procedures are characterized by severing a nerve and disconnecting it from the spinal cord.

Preparation

Prior to beginning management, pain is thoroughly evaluated. Pain scales or questionnaires are used to attach an objective measure to a subjective experience. Objective measurements allow healthcare workers a better understanding of the pain being experienced by the patient. Evaluation also includes physical examinations and diagnostic tests to determine underlying causes. Some evaluations require assessments from several viewpoints, including neurology, psychiatry, psychology, and physical therapy. If pain is due to a medical procedure, management consists of anticipating the type and intensity of associated pain and managing it preemptively.

Risks

Owing to toxicity over the long term, some drugs can only be used for acute pain or as adjuncts in chronic pain management. NSAIDs have the well-known side effect of causing gastrointestinal bleeding, and long-term use of acetaminophen has been linked to kidney and liver damage. Other drugs, especially narcotics, have serious side effects, such as **constipation**, drowsiness, and **nausea**. Serious side effects can also accompany pharmacological therapies; mood swings, confusion, bone thinning, cataract formation, increased blood pressure, and other problems may discourage or prevent use of some analgesics.

Nonpharmacological therapies carry little or no risk. However, it is advised that individuals recovering from serious illness or injury consult with their healthcare providers or physical therapists before making use of adjunct therapies. Invasive procedures carry risks similar to other surgical procedures, such as infection, reaction to anesthesia, iatrogenic (injury as a result of treatment) injury, and failure.

A traditional concern about narcotics use has been the risk of promoting **addiction**. As narcotic use continues over time, the body becomes accustomed to the drug and adjusts normal functions to accommodate to its presence. Therefore, to elicit the same level of action, it is necessary to increase dosage over time. As dosage increases, an individual may become physically dependent on **narcotic drugs**.

KEY TERMS

Acute—Refers to a disease or symptom that has a sudden onset and lasts a relatively short period of time.

Central nervous system—Part of the nervous system consisting of the brain, cranial nerves, and spinal cord. The brain is the center of higher processes, such as thought and emotion and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system, that is the nerves present in the rest of body.

Chronic—Refers to a disease or condition that progresses slowly but persists or recurs over time.

Iatrogenic—A condition that is caused by the diagnostic procedures or treatments administered by medical professionals. Iatrogenic conditions may be caused by any number of things including contaminated medical instruments or devices, contaminated blood or implants, or contaminated air within the medical facility.

Neuropathy—A disease or abnormality of the peripheral nerves (the nerves outside the brain and spinal cord). Major symptoms include weakness, numbness, paralysis, or pain in the affected area.

Neurotransmitter—A chemical messenger that transmits an impulse from one nerve cell to the next.

Nociceptor—A nerve cell that is capable of sensing pain and transmitting a pain signal.

Nonpharmacological—Referring to therapy that does not involve drugs.

Peripheral nervous system (PNS)—The part of the nervous system that is outside the brain and spinal cord. Sensory, motor, and autonomic nerves are included. PNS nerves link the central nervous system with sensory organs, muscles, blood vessels, and glands.

Pharmacological—Referring to therapy that relies on drugs.

Stimulus—Anything capable of eliciting a response in an organism or a part of that organism.

However, physical dependence is different from psychological addiction. Physical dependence is characterized by discomfort if drug administration suddenly stops, while psychological addiction is characterized by an overpowering craving for the drug for reasons other than pain relief. Psychological addiction is a very real and necessary concern in some instances, but it should not interfere with a genuine need for narcotic pain relief. However, caution must be taken with people with a history of addictive behavior.

Parental concerns

Infants feel pain, but do not express it in the same manner as older children or young adults. Studies indicate that the majority of parents do not know how to recognize the signs of infant pain, and pediatricians fail to teach parents what to look for. Training of parents is essential in recognizing and dealing with pain in infants and young children.

In some cases, narcotic analgesics are essential for control of childhood pain. These drugs are safe when used properly and should not be withheld for fear of addiction.

Because exposure to chronic pain by children can lead to life-long changes in their pain response, parents must learn to recognize and treat pain promptly.

Over-the-counter pain relievers may be toxic. Parents must read the labeled directions carefully and follow them exactly. For liquids, it is essential to use the proper measuring devices, such as a measuring dropper or medicinal teaspoon. Household measures are not reliable.

Parent-child relationships

Definition

The parent-child relationship consists of a combination of behaviors, feelings, and expectations that are unique to a particular parent and a particular child. The relationship involves the full extent of a child's development.

Description

Of the many different relationships people form over the course of the life span, the relationship between parent and child is among the most important. The quality of the parent-child relationship is affected by the parent's age, experience, and self-confidence; the stability of the parents' marriage; and the unique characteristics of the child compared with those of the parent.

Characteristics of the parent

Parental self-confidence is an important indicator of parental competence. Mothers who believe that they are effective parents are more competent than mothers who feel incompetent. Also, mothers who see themselves as effective also tend to believe their infants as less difficult to handle. Parental age and previous experience are also important. Older mothers tend to be more responsive to their infants than younger mothers. In addition, parents who have had previous experience with children, whether through younger siblings, career paths, or previous children, are often times better able to cope with parenthood.

Characteristics of the child

Characteristics that may affect the parent-child relationship in a **family** include the child's physical appearance, sex, and **temperament**. At birth, the infant's physical appearance may not meet the parent's expectations, or the infant may resemble a disliked relative. As a result, the parent may subconsciously reject the child. If the parents wanted a baby of a particular sex, they may be disappointed if the baby is the opposite sex. If parents do not have the opportunity to talk about this disappointment, they may reject the infant.

Children who are loved thrive better than those who are not. Either parent or a nonparent caregiver may serve as the primary caregiver or form the primary parent-child love relationship. Loss of love from a primary caregiver can occur with the death of a parent or interruption of parental contact through prolonged hospitalizations. **Divorce** can interfere with the child's need to eat, improve, and advance. Cultural norms within the family also affect a child's likelihood to achieve particular developmental milestones.

Cultural impact

In some countries, childrearing is considered protective nurturing. Children are not rushed into new experiences like **toilet training** or being in school. In other countries, children are commonly treated in a harsh, strict manner, using shame or corporal punishment for **discipline**. In Central American nations, toilet training may begin as early as when the child can sit upright.

Childhood in the United States stretches across many years. In other countries, children are expected to enter the adult world of work when they are still quite young: girls assume domestic responsibilities, and boys do outside farm work. In addition, in Asian cultures, parents understand an infant's personality in part in terms of the child's year and time of birth.

Impact of birth order

The position of a child in the family, whether a firstborn, a middle child, the youngest, an only child, or one within a large family, has some bearing on the child's growth and development. An only child or the oldest child in a family excels in **language development** because conversations are mainly with adults. Children learn by watching other children; however, a firstborn or an only child, who has no example to watch, may not excel in other skills, such as toilet training, at an early age.

Infancy

As babies are cared for by their parents, both parties develop understandings of the other. Gradually, babies begin to expect that their parent will care for them when they cry. Gradually, parents respond to and even antici-

pate their baby's needs. This exchange and familiarity create the basis for a developing relationship.

PARENT-INFANT ATTACHMENT One of the most important aspects of infant psychosocial development is the infant's attachment to parents. Attachment is a sense of belonging to or connection with a particular other. This significant bond between infant and parent is critical to the infant's survival and development. Started immediately after birth, attachment is strengthened by mutually satisfying interaction between the parents and the infant throughout the first months of life, called bonding. By the end of the first year, most infants have formed an attachment relationship, usually with the primary caretaker.

If parents can adapt to their babies, meet their needs, and provide nurturance, the attachment is secure. Psychosocial development can continue based on a strong foundation of attachment. On the other hand, if a parent's personality and ability to cope with the infant's needs for care are minimal, the relationship is at risk and so is the infant's development.

By six to seven months, strong feelings of attachment enable the infant to distinguish between caregivers and strangers. The infant displays an obvious preference for parents over other caregivers and other unfamiliar people. **Anxiety**, demonstrated by crying, clinging, and turning away from the stranger, is revealed when separation occurs. This behavior peaks between seven and nine months and again during toddlerhood, when separation may be difficult. Although possibly stressful for the parents, **stranger anxiety** is a normal sign of healthy child attachment and occurs because of **cognitive development**. Most children develop a secure attachment when reunited with their caregiver after a temporary absence. In contrast, some children with an insecure attachment want to be held, but they are not comfortable; they kick or push away. Others seem indifferent to the parent's return and ignore them when they return.

The quality of the infant's attachment predicts later development. Youngsters who emerge from infancy with a secure attachment stand a better chance of developing happy and healthy relationships with others. The attachment relationship not only forms the emotional basis for the continued development of the parent-child relationship, but can serve as a foundation for future social connections. Secure infants have parents who sensitively read their infant's cues and respond properly to their needs.

Toddlerhood

When children move from infancy into toddlerhood, the parent-child relationship begins to change. During infancy, the primary role of the parent-child relationship is nurturing and predictability, and much of the relationship revolves around the day-to-day demands of caregiving: feeding, toileting, bathing, and going to bed.

As youngsters begin to talk and become more mobile during the second and third years of life, however, parents usually try to shape their child's social behavior. In essence, parents become teachers as well as nurturers, providers of guidance as well as affection. Socialization (preparing the youngster to live as a member of a social group) implicit during most of the first two years of life, becomes clear as the child moves toward his or her third birthday.

Socialization is an important part of the parent-child relationship. It includes various child-rearing practices, for example weaning, toilet training, and discipline.

Dimensions of the parent-child relationship are linked to the child's psychological development, specifically how responsive the parents are, and how demanding they are. Responsive parents are warm and accepting toward their children, enjoying them and trying to see things from their perspective. In contrast, nonresponsive parents are aloof, rejecting, or critical. They show little pleasure in their children and are often insensitive to their emotional needs. Some parents are demanding, while others are too tolerant. Children's healthy psychological development is facilitated when the parents are both responsive and moderately demanding.

During toddlerhood, children often begin to assert their need for autonomy by challenging their parents. Sometimes, the child's newfound assertiveness during the so-called terrible twos can put a strain on the parent-child relationship. It is important that parents recognize that this behavior is normal for the toddler, and the healthy development of independence is promoted by a parent-child relationship that provides support for the child's developing sense of autonomy. In many regards, the security of the first attachment between infant and parent provides the child with the emotional base to begin exploring the world outside the parent-child relationship.

Preschool

Various parenting styles evolve during the **preschool** years. Preschoolers with authoritative parents are curious about new experiences, focused and skilled at **play**, self-reliant, self-controlled, and cheerful.

School age

During the elementary school years, the child becomes increasingly interested in peers, but this is not be a sign of disinterest in the parent-child relationship. Rather, with the natural broadening of psychosocial and cognitive abilities, the child's social world expands to include more people and settings beyond the home environment. The parent-child relationship remains the most important influence on the child's development. Children whose parents are both responsive and demanding continue to thrive psychologically and socially during the middle childhood years.

During the school years, the parent-child relationship continues to be influenced by the child and the parents. In most families, patterns of interaction between parent and child are well established in the elementary school years.

Adolescence

As the child enters **adolescence**, biological, cognitive, and emotional changes transform the parent-child relationship. The child's urges for independence may challenge parents' authority. Many parents find early adolescence a difficult period. Adolescents fare best and their parents are happiest when parents can be both encouraging and accepting of the child's needs for more psychological independence.

Although the value of peer relations grows during adolescence, the parent-child relationship remains crucial for the child's psychological development. Authoritative parenting that combines warmth and firmness has the most positive impact on the youngster's development. Adolescents who have been reared authoritatively continue to show more success in school, better psychological development, and fewer behavior problems.

Adolescence may be a time of heightened bickering and diminished closeness in the parent-child relationship, but most disagreements between parents and young teenagers are over less important matters, and most teenagers and parents agree on the essentials. By late adolescence most children report feeling as close to their parents as they did during elementary school.

Parenting styles

Parenting has four main styles: authoritarian, authoritative, permissive (indulgent), and detached. Although no parent is consistent in all situations, parents do follow some general tendencies in their approach to childrearing, and it is possible to describe a parent-child relationship by the prevailing style of parenting. These descriptions provide guidelines for both professionals and parents interested in understanding how variations in the parent-child relationship affect the child's development.

Parenting style is shaped by the parent's developmental history, education, and personality; the child's behavior; and the immediate and broader context of the parent's life. Also, the parent's behavior is influenced by the parent's work, the parents' marriage, family finances, and other conditions likely to affect the parent's behavior and psychological well-being. In addition, parents in different cultures, from different social classes, and from different ethnic groups rear their children differently. In any event, children's behavior and psychological development are linked to the parenting style with which they are raised.

Authoritarian parents

Authoritarian parents are rigid in their rules; they expect absolute obedience from the child without any questioning. They also expect the child to accept the family beliefs and principles without questions. Authoritarian parents are strict disciplinarians, often relying on physical punishment and the withdrawal of affection to shape their child's behavior.

Children raised with this parenting style are often moody, unhappy, fearful, and irritable. They tend to be shy, withdrawn, and lack self-confidence. If affection is withheld, the child commonly is rebellious and antisocial.

Authoritative parents

Authoritative parents show respect for the opinions of each of their children by allowing them to be different. Although there are rules in the household, the parents allow discussion if the children do not understand or agree with the rules. These parents make it clear to the children that although they (the parents) have final authority, some negotiation and compromise may take place. Authoritative parents are both responsive and demanding; they are firm, but they discipline with love and affection, rather than power, and they are likely to explain rules and expectations to their children instead of simply asserting them. This style of parenting often results in children who have high **self-esteem** and are independent, inquisitive, happy, assertive, and interactive.

Permissive parents

Permissive (indulgent) parents have little or no control over the behavior of their children. If any rules exist in the home, they are followed inconsistently. Underlying reasons for rules are given, but the children decide

whether they will follow the rule and to what extent. They learn that they can get away with any behavior. Indulgent parents are responsive but not especially demanding. They have few expectations of their children and impose little or inconsistent discipline. There are empty threats of punishment without setting limits. Role reversal occurs; the children act more like the parents, and the parents behave like the children.

Children of permissive parents may be disrespectful, disobedient, aggressive, irresponsible, and defiant. They are insecure because they lack guidelines to direct their behavior. However, these children are frequently creative and spontaneous. Although low in both social responsibility and independence, they are usually more cheerful than the conflicted and irritable children of authoritarian parents.

Disengaged parents

Finally, disengaged (detached) parents are neither responsive nor demanding. They may be careless or unaware of the child's needs for affection and discipline. Children whose parents are detached have higher numbers of psychological difficulties and behavior problems than other youngsters.

Parental concerns

Child's development is affected by family conditions such as divorce, remarriage, and parental employment. The parent-child relationship has a more important influence on the child's psychological development than changes in the composition of the household. Parenting that is responsive and demanding is related to healthier child development regardless of the parent's marital or employment status. If changes in the parent's marital status or work life disrupt the parent-child relationship, short-term effects on the child's behavior may be noticeable. One goal of professionals who work with families under stress is to help them reestablish healthy patterns of parent-child interaction.

Discipline is also a concern of parents. Children's behavior offers challenges to even the most experienced and effective parents. The manner in which parents respond to a child's behavior has an effect on the child's self-esteem and future interactions with others. Children learn to view themselves in the same way the parent views them. Thus, if the parent views the child as wild, the child begins to view himself that way and soon his actions consistently reinforce his self image. This way, the child does not disappoint the parent. This pattern is a self-fulfilling prophecy. While discipline in necessary to teach a child how to live comfortably in society, it should not be confused with punishment.

KEY TERMS

Adolescence—A period of life in which the biological and psychosocial transition from childhood to adulthood occurs.

Coping—In psychology, a term that refers to a person's patterns of response to stress.

Culture—A test in which a sample of body fluid is placed on materials specially formulated to grow microorganisms. A culture is used to learn what type of bacterium is causing infection.

Discipline—In health care, a specific area of preparation or training, i.e., social work, nursing, or nutrition.

Family—Two or more emotionally involved people living in close proximity and having reciprocal obligations with a sense of commonness, caring, and commitment.

Patau syndrome

Definition

Patau syndrome, also called trisomy 13, is a congenital (present at birth) disorder associated with the presence of an extra copy of chromosome 13. The extra chromosome 13 causes numerous physical and mental abnormalities, especially heart defects. Patau syndrome

is named for Klaus Patau, who reported the syndrome and its association with trisomy in 1960.

Description

Children normally inherit 23 chromosomes from each parent, for a total of 46 chromosomes. A typical human being has 46 chromosomes: 22 pairs of non-sex linked chromosomes and one pair of sex-linked chromosomes that determine that person's sex. Sometimes a child may end up with more than 46 chromosomes because of problems with the father's sperm or the mother's egg or because of mutations that occurred after the sperm and the egg fused to form the embryo (conception).

Normally, there are two copies of each of the 23 chromosomes: one from each parent. A condition called trisomy occurs when three, instead of two, copies of a chromosome are present in a developing human embryo. An extra copy of a particular chromosome can come either from the egg or sperm or from mutations that occur after conception.

The most well-known trisomy-related disorder is **Down syndrome** (trisomy 21), in which the developing embryo has an extra copy of chromosome 21. Patau syndrome is trisomy 13, in which the developing embryo has three copies of chromosome 13.

An extra copy of chromosome 13 is not the only cause of Patau syndrome. Other changes in chromosome 13, such as mispositioning (translocation), can also result in the characteristics classified as Patau syndrome. In these cases, an error occurs that causes a portion of chromosome 13 to be exchanged for a portion of another chromosome. There is no production of extra chromosomes, but a portion of each affected chromosome is "misplaced" (translocated) to another chromosome.

Patau syndrome causes serious physical and mental abnormalities, including heart defects; incomplete brain development; unusual facial features such as a sloping forehead, a smaller than average head (microcephaly), small or missing eyes, low set ears, and **cleft palate** or hare lip; extra fingers and toes (**polydactyly**); abnormal genitalia; spinal defects; seizures; gastrointestinal hernias, particularly at the navel (omphalocele); and **mental retardation**. Due to the severity of these conditions, fewer than 20 percent of those affected with Patau syndrome survive beyond infancy.

Demographics

Patau syndrome occurs in approximately one in 10,000 live births. In many cases, spontaneous abortion (miscarriage) occurs, which means the fetus does not survive to term. In other cases, the affected individual is stillborn. As appears to be the case in all trisomies, the risks of Patau syndrome seem to increase with the mother's age, particularly if she is over 30 when pregnant. Male and female children are equally affected, and the syndrome occurs in all races.

Causes and symptoms

The severity and symptoms of Patau syndrome vary with the type of chromosomal anomaly, from extremely serious conditions to nearly normal appearance and functioning. Full trisomy 13, which is present in the majority of the cases, results in the most severe and numerous internal and external abnormalities. Commonly, the forebrain fails to divide into lobes or hemispheres (holoprosencephaly), and the entire head is unusually small (microcephaly). The spinal cord may protrude through a defect in the vertebrae of the spinal column (myelomeningocele). Children who survive infancy have profound mental retardation and may experience seizures.

Incomplete development of the optic (sight) and olfactory (smell) nerves often accompany the brain defects described above. The eyes may be unusually small (microphthalmia) or one eye may be absent (anophthalmia). The eyes are sometimes set close together (hypotelorism) or even fused into a single structure. Incomplete development of any structures in the eye (coloboma) or failure of the retina to develop properly (retinal dysplasia) produces vision problems. Patau syndrome affected individuals may be born either partially or totally deaf, and many are subject to recurring ear infections.

The facial features of many Patau syndrome affected individuals appear flattened. The ears are generally malformed and lowset. Frequently, a child with trisomy 13 has a **cleft lip**, a cleft palate, or both. Other physical characteristics include loose folds of skin at the back of the neck, extra fingers or toes (polydactyly), permanently flexed (closed) fingers (camptodactyly), noticeably prominent heels, "rocker-bottom foot," and missing ribs. Genital malformations are common in individuals affected with Patau syndrome and include undescended testicles (cryptorchidism), an abnormally developed scrotum, and ambiguous genitalia in males, or an abnormally formed uterus (bicornuate uterus) in females.

In nearly all cases, Patau syndrome affected infants have respiratory difficulties and heart defects, including atrial and ventricular septal defects (holes between chambers of the heart); malformed ducts that cause

abnormal direction of blood flow (**patent ductus arteriosus**); holes in the valves of the lungs and the heart (pulmonary and aortic valves); and misplacement of the heart in the right, rather than the left, side of the chest (dextrocardia). The kidneys and gastrointestinal system may also be affected with cysts similar to those seen in polycystic kidney disease. These defects are frequently severe and life-threatening.

Partial trisomy of the distal segment of chromosome 13 results in generally less severe, but still serious, symptoms and a distinctive facial appearance including a short upturned nose, a longer than usual area between the nose and upper lip (philtrum), bushy eyebrows, and tumors made up of blood capillaries on the forehead (frontal capillary hemangiomata). Partial trisomy of the proximal segment of chromosome 13 is much less likely to be fatal and has been associated with a variety of facial features including a large nose, a short upper lip, and a receding jaw. Both forms of partial trisomy also result in severe mental retardation.

Beyond one month of age, other symptoms that are seen in individuals with Patau syndrome are: feeding difficulties and **constipation**, reflux disease, slow growth rates, curvature of the spine (**scoliosis**), irritability, sensitivity to sunlight, low muscle tone, high blood pressure, sinus infections, urinary tract infections, and ear and eye infections.

Diagnosis

Patau syndrome is detectable during pregnancy through the use of ultrasound imaging, **amniocentesis**, and chorionic villus sampling (CVS). At birth, the newborn's numerous malformations indicate a possible chromosomal abnormality. Trisomy 13 is confirmed by examining the infant's chromosomal pattern through karyotyping or another procedure. Karyotyping involves the separation and isolation of the chromosomes present in cells taken from an individual. These cells are generally extracted from cells found in a blood sample. The 22 non-sex linked chromosomes are identified by size, from largest to smallest, as chromosomes 1 through 22. The sex determining chromosomes are also identified. Patau syndrome is confirmed by the presence of three, rather than the normal two, copies of the thirteenth largest chromosome.

Treatment

Some infants born with Patau syndrome have severe and incurable birth defects. However, children with better prognoses require medical treatment to correct structural abnormalities and associated complications. For feeding problems, special formulas, positions, and techniques may be used. Tube feeding or the placement of a gastric tube (gastrostomy may be required. Structural abnormalities such as cleft lip and cleft palate can be corrected through surgery. Special diets, hearing aids, and vision aids can be used to mitigate some symptoms of Patau syndrome. Physical therapy, speech therapy, and other types of developmental therapy help the child reach his or her potential.

Since the translocation form of Patau syndrome is genetically transmitted, genetic counseling for the parents should be part of the management of the disease.

Stillborn term infant with Patau's syndrome. The baby has no eyes, no nose opening, and anelongated bulb hanging from forehead. *(© Ralph C. Eagle, M.D./Photo Researchers, Inc.)*

Prognosis

Approximately 45 percent of trisomy 13 babies die within their first month of life; up to 70 percent in the first six months; and over 70 percent by one year of age. Survival to adulthood is very rare. Only one adult is known to have survived to age 33.

KEY TERMS

Amniocentesis—A procedure performed at 16-18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby for analysis. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of the chorionic membrane. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the human body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Chromosomes contain the genetic information necessary to direct the development and functioning of all cells and systems in the body. They pass on hereditary traits from parents to child (like eye color) and determine whether the child will be male or female.

Karyotyping—A laboratory test used to study an individual's chromosome make-up. Chromosomes are separated from cells, stained, and arranged in order from largest to smallest so that their number and structure can be studied under a microscope.

Mosaicism—A genetic condition resulting from a mutation, crossing over, or nondisjunction of chromosomes during cell division, causing a variation in the number of chromosomes in the cells.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trisomy—An abnormal condition where three copies of one chromosome are present in the cells of an individual's body instead of two, the normal number.

Ultrasonography—A medical test in which sound waves are directed against internal structures in the body. As sound waves bounce off the internal structure, they create an image on a video screen. Ultrasonography is often used to diagnose fetal abnormalities, gallstones, heart defects, and tumors. Also called ultrasound imaging.

Most survivors have profound mental and physical disabilities; however, the capacity for learning in children with Patau syndrome varies from case to case. Older children may be able to walk with or without a walker. They may also be able to understand words and phrases, follow simple commands, use a few words or signs, and recognize and interact with others.

Prevention

There is no known way to prevent Patau syndrome though it can be diagnosed prenatally via amniocentesis.

Parental concerns

Parents of children born with Patau syndrome should prepare themselves for the possiblity of their child dying within days or weeks of birth, in addition to the poor survival rates past early childhood. Also, parents who have already had a child with the disease and want to have another child should discuss potential problems with their physician.

Patent ductus arteriosus

Definition

Patent ductus arteriosus (PDA) is a heart defect that occurs in infants when the ductus arteriosus (the temporary fetal blood vessel that connects the aorta and the pulmonary artery) does not close at birth.

Description

The ductus arteriosus is a temporary fetal blood vessel that connects the aorta and the pulmonary artery before birth. The ductus arteriosus should be present and open before birth while the fetus is developing in the uterus. Since oxygen and nutrients are received from the placenta and the umbilical cord instead of the lungs, the ductus arteriosus acts as a "short cut" that allows blood to bypass the deflated lungs and go straight out to the body. After birth, when the lungs are needed to add oxygen to the blood, the ductus arteriosus normally closes. The closure of the ductus arteriosus ensures that blood goes to the lungs to pick up oxygen before going out to the body. Closure of the ductus arteriosus usually occurs at birth as levels of certain chemicals, called prostagladins, change, and the lungs fill with air. If the ductus arteriosus closes correctly, the blood pumped from the heart goes to the lungs, back into the heart, and then out to the body through the aorta. The blood returning from the lungs and moving out of the aorta carries oxygen to the cells of the body. In some infants, the ductus arteriosus remains open (or patent), and the resulting heart defect is known as patent ductus arteriosus. In most cases, a small PDA does not result in physical symptoms. If the PDA is larger, health complications may occur.

In an average individual's body, the power of blood being pumped by the heart and other forces leads to a certain level of pressure between the heart and lungs. The pressure between the heart and lungs of an individual affected by PDA causes some of the oxygenated blood that should go out to the body (through the aorta) to return back through the PDA into the pulmonary artery. The pulmonary artery takes the blood immediately back to the lungs. The recycling of the already oxygenated blood forces the heart to work harder as it tries to supply enough oxygenated blood to the body. In this case, usually the left side of the heart grows larger as it works harder and must contain all of the extra blood moving back into the heart. This is known as a left-to-right or aortic-pulmonary shunt.

As noted, the size of the PDA determines how much harder the heart has to work and how much bigger the heart becomes. If the PDA is large, the bottom left side of the heart is forced to pump twice as much blood because it must supply enough blood to recycle back to the lungs and move out to the body. As the heart responds to the increased demands for more oxygenated blood by pumping harder, the pulmonary artery has to change in size and shape in order to adapt to the increased amount and force of the blood. In some cases, the increase in size and shape changes the pressure in the pulmonary artery and lungs. If the pressure in the lungs is higher than that of the heart and body, blood returning to the heart will take the short cut back into the aorta from the pulmonary artery through the PDA instead of going to the lungs. This backward flowing of blood does not carry much oxygen. If blood without much oxygen is being delivered to the body, the legs and toes will turn blue or cyanotic. This condition is called a shunt reversal.

When a PDA results in a large amount of blood being cycled in the wrong order, either through a left-to-right shunt or shunt reversal, the overworked, enlarged heart may stop working (congestive heart failure) and the lungs can become filled with too much fluid (pulmonary edema). At this time, there is also an increased risk for bacterial infection that can inflame the lining of the heart (endocarditis). These three complications are very serious.

Demographics

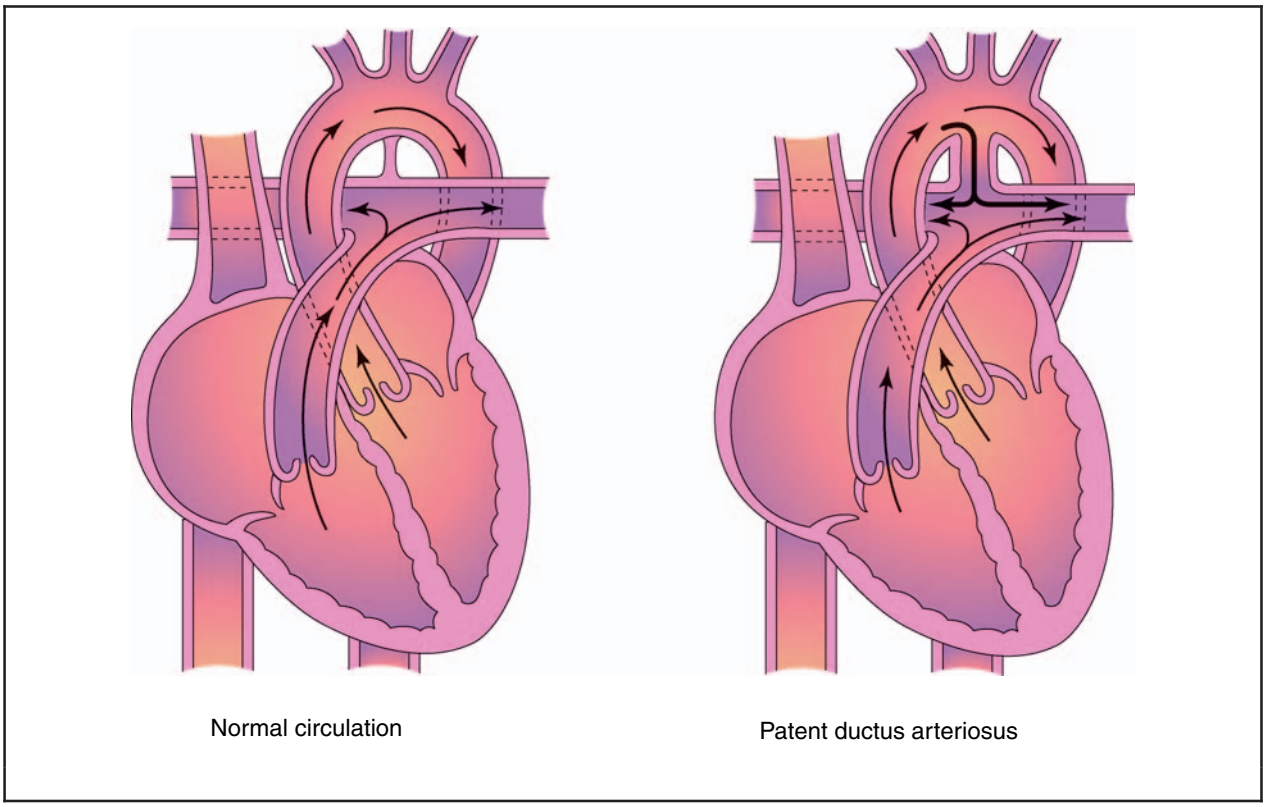
PDA is a very common heart defect, accounting for 5 to 10 percent of all types of **congenital heart disease**. Though an exact incidence of PDA is difficult to determine, researchers estimate that eight or nine in every 1,000 children are affected. PDA can occur in full-term infants, but it is seen most often in preterm infants, infants born at a high altitude, and babies whose mothers had a **rubella** infection during pregnancy. PDA occurs in individuals of every ethnic origin and does not occur more often in any one country or ethnic population; however, it is two to three times more common in females than males.

Causes and symptoms

PDA can be caused by environmental exposure before birth or the inheritance of a specific changed or mutated gene or genes. It can be a symptom of a genetic syndrome or may be caused by a combination of genetic and environmental factors (multifactorial).

Environmental exposures that can increase the chance for a baby to be affected by PDA include fetal exposure to rubella before birth, preterm delivery, and birth at a high altitude location.

PDA can be an inherited condition in families with isolated PDA or part of a genetic syndrome. In either case, there are specific gene changes or mutations which



Patent ductus arteriosus (PDA) is the failure of the ductus arteriosus to close after birth, allowing blood to inappropriately flow from the aorta into the pulmonary artery. *(Illustration by Electronic Illustrators Group.)*

lead to a defect in the elastic tissue forming the walls of the ductus arteriosus. As of 2004 the genes causing isolated PDA have not been identified, but it is known that PDA can be inherited through a **family** in an autosomal dominant pattern or an autosomal recessive pattern. Every person has approximately 30,000 genes, which tell the body how to grow and develop correctly. Each gene is present in pairs since one is inherited from the mother and one is inherited from the father. In an autosomal dominant condition, only one specific changed or mutated copy of the gene for PDA is necessary for a person to have PDA. If a parent has an autosomal dominant form of PDA, there is a 50 percent chance for each child to have the same or similar condition.

PDA can also be inherited in an autosomal recessive manner. A recessive condition occurs when a child receives two changed or mutated copies of the gene for a particular condition, such as PDA (one copy from each parent). Individuals with a single changed or mutated copy of a gene for a recessive condition are known as carriers and have no health problems related to the condition. However, when two people who each carry a changed or mutated copy of the same gene for a recessive condition have children, there is a chance with each pregnancy for the child to inherit the two changed or mutated copies from each parent. In this case, the child would have PDA. For two known carriers, there is a 25 percent risk with each child to have a child with PDA, a 50 percent chance to have a child who is a carrier, and a 25 percent chance to have a child who is neither affected nor a carrier.

Most cases of PDA occur as the result of multifactorial inheritance which is caused by the combination of genetic factors and environmental factors. The combined factors lead to isolated defects in the elastic tissue forming the walls of the ductus arteriosus.

The main sign of PDA is a constant heart murmur that sounds like the hum of a refrigerator or other machinery. This murmur is usually heard by the doctor using a stethoscope.

Other signs and symptoms of PDA include:

- shortness of breath after exertion such as crying, eating, or activity
- labored or fast breathing at rest

- cyanosis, or blue lips or fingernails especially after eating, crying, or activity
- problems with feeding and poor weight gain
- frequent colds and problems with the lungs

Diagnosis

Diagnosis is most often made by detecting the characteristic "machinery" heart murmur heard by a doctor through a stethoscope. Tests such as a chest x ray, echocardiograph, and ECG are used to support the initial diagnosis and to determine the severity of the PDA.

Treatment

The treatment and management of PDA depends upon the size of the PDA, the presence of other heart defects, and the symptoms experienced by the affected individual. In some cases, the PDA will close spontaneously and no further treatment will be required. In individuals for whom the PDA remains open, there are three treatment options: medical management, device closure, and surgical repair.

Medical management with medications such as indomethocin is often the first course of treatment in premature infants with PDA. Indomethocin causes the muscles within the heart to tighten, closing the PDA. In infants for whom indomethocin does not close the PDA, full-term infants, and older children, device closure or surgery may be necessary.

Device closure of PDA is a medical procedure in which a device such as a coil, very small rings of wire, or an occluder, a tiny wire mesh patch, is placed over the PDA causing the blood to clot and thus closing the open ductus. The device is inserted into the heart in a process called cardiac catheterization. A small thin flexible tube is inserted into a blood vessel, usually in the groin area, and guided into the heart. The device is then passed through the catheter to the PDA. For most patients, this procedure is highly effective, and no further treatment is required. In children for whom this procedure is unsuccessful, children with very large PDA, or those with multiple heart defects, surgery may be necessary.

In surgical closure of PDA, called a ligation, the chest cavity is opened, the blood vessels are separated, and the PDA is sewn closed.

Prognosis

Individuals can survive with a small opening remaining in the ductus arteriosus. Treatment, including surgery, of a larger PDA is usually successful and frequently occurs without complications. Proper treatment allows children to lead normal lives.

KEY TERMS

Aorta—The main artery located above the heart that pumps oxygenated blood out into the body. The aorta is the largest artery in the body.

Cyanosis—A bluish tinge to the skin that can occur when the blood oxygen level drops too low.

Ductus arteriosus—The temporary channel or blood vessel between the aorta and pulmonary artery in the fetus.

Echocardiogram—A record of the internal structures of the heart obtained from beams of ultrasonic waves directed through the wall of the chest.

Electrocardiagram (ECG, EKG)—A record of the electrical activity of the heart, with each wave being labeled as P, Q, R, S, and T waves. It is often used in the diagnosis of cases of abnormal cardiac rhythm and myocardial damage.

Endocarditis—Inflammation of the inner membrane lining heart and/or of the heart valves caused by infection.

Oxygenated blood—Blood carrying oxygen through the body.

Pulmonary artery—An artery that carries blood from the heart to the lungs.

Pulmonary edema—An accumulation of fluid in the tissue of the lungs.

Prevention

While there is no known prevention for PDA, appropriate prenatal care for expectant women is important and may prevent premature delivery, a major risk factor for PDA.

Parental concerns

Slow weight gain is common in children with congenital heart defects and may be alarming for parents. The pediatrician closely monitors the child's growth rate. There are many ways to increase the caloric intake of infants and children with PDA. A pediatrician, nurse, or dietitian can assist parents in ways to insure the child is getting proper **nutrition**. Infants with PDA may not be able to tolerate a large volume of breast milk or formula and therefore may need to be fed more frequently.

In addition to slow growth, children with PDA may be more susceptible to infections such as colds,

pneumonia, and a rare but potentially life threatening infection of the heart called endocarditis. Children with PDA may need to receive preventative **antibiotics** prior to dental work. Annual flu vaccines are recommended, and parents should watch for signs of infection such as **fever**, **cough**, chills, and any difficulty breathing.

When to call the doctor

Parents of children with PDA should watch for the following symptoms and contact the doctor if any of these occurs:

- problems feeding or slow weight gain
- difficulty breathing
- shortness of breath after crying, eating, or activity
- blue color in the lips and fingernails with activity
- fever of 100.4°F (38°C) or higher
- chills, cough, or lethargy
- itchy rash or swollen skin

Peer acceptance

Definition

Peer acceptance is the degree to which a child or adolescent is socially accepted by peers. It includes the level of peer popularity and the ease with which a child or adolescent can initiate and maintain satisfactory peer relationships.

Description

Peer acceptance and relationships are important to children's social and emotional development. Peer acceptance and friendship provide a wide range of learning and development opportunities for children. These include companionship, recreation, building social skills, participating in group problem solving, and managing competition and conflict. They also allow for self-exploration, emotional growth, and moral and ethical development. Parents, teachers, and other adults are a good source of social support for children, but it is among other children that kids learn how to interact with each other.

When examining peer acceptance among children, researchers usually look at two areas that are related to a child's psychological and social development. The first area is the child's social standing in the peer group as a whole and is indicated by the child's level of social acceptance by other members in the group, usually classmates. The second area is the child's individual friendships, characterized by both the quantity and quality of these friendships.

Although genes may be a factor in a child's **social competence** and level of peer acceptance, environmental factors are also extremely important. Some of the factors contributing to peer acceptance include:

- the quality of attachment between mother or primary caregiver and child during infancy
- during childhood, the quantity and quality of opportunities for interaction with different types of peers in different environments, such as in the **family**, at school, church, camp, activity centers, in **sports**, or in the neighborhood
- parenting style (A highly nurturing but moderately controlling authoritative parenting style is associated with the highest levels of social competence. By contrast, a low nurturing, highly controlling authoritarian parenting style is associated with children's aggressiveness, while the high nurturing but low-controlling permissive style is associated with failure to take responsibility for behavior.)

Regarding having friends, the academic benefits show up very early in a child's school career. Research suggests that those who start kindergarten from **preschool** with a friend in their class make a better adjustment to school than those who do not start with a friend. Furthermore, children who maintain their friendships as the school year progresses like school better, and children who make new friends make greater gains in school performance.

Infancy and toddlerhood

The first step in childhood affiliations is the categorization of people into groups. Although some researchers believe that the ability to categorize is an achievement of toddlerhood, others suggest it is present in infancy. In children, the top three categories of peer affiliation are age, sex, and race. Children do not appear to make racial distinctions before they are of preschool age but age and sex discriminations are made earlier. There is evidence that infants make categorical distinctions between males and females and between adults and children before they are a year old. Signs of a preferential attraction to others like the self also appear at an early age. Year-old infants are interested in and attracted to other infants—including those they have never met before—at an age when they are wary of strange adults. By the age of two, they begin to show a preference for children of their own sex. There is also research that suggests the quality of attachment between mothers or primary caregivers during infancy can contribute to peer acceptance later in childhood.

Customs of child rearing and patterns of parent-infant interaction vary widely from culture to culture, but the children's playgroup is universal. If the number of children in a given locality is small, the playgroup will consist of children of both sexes and a range of ages; if the number is larger, the children generally divide up into age- and sex-segregated groups. Girls' groups tend to be split up into subgroups. It is the social category, or psychological group that is important here. Children can categorize themselves as members of a social category even if it does not assemble in one place.

Preschool

It is important to recognize the role of the peer group in maintaining a preschool-age child's level of social acceptance. Once a child has established a reputation among peers either as someone with whom it is fun to **play** or as someone with whom joint play is unpleasant or dissatisfying, this reputation may influence the way other children perceive the child's later behavior. If a negative reputation is developed, helping the child become accepted may require more than a change in the child's behavior; it may also be necessary to point out to the other children when the child's behavior changes and to guide them to respond to the child in positive ways.

Research on imaginary companions suggests that young children who create them do so to compensate for poor social relationships, according to a study published in the May 2004 issue of the *International Journal of Behavioral Development*. As a result, there is less peer acceptance of children with imaginary companions. Several other studies have shown that fantasy play is also related to peer acceptance in children in preschool. Using a scoring system that included the reality and unfamiliarity levels of fantasy play, researchers found players who scored high had higher self-ratings of peer acceptance than did average scoring fantasy players. However, the high scoring fantasy players had lower teacher ratings of peer acceptance than the average scoring fantasy players. Researchers suggest the difference may occur because the high scoring fantasy players were unable to distinguish imagined popularity from actual peer acceptance.

School age

In school-aged children, factors such as physical attractiveness, cultural traits, and disabilities greatly affect the level of peer acceptance, with a child's degree of social competence being the best predictor of peer acceptance. The peer groups of **adolescence**, especially teens, are often based on athletic, social, or academic interests and abilities; on distinctions of race, ethnicity, and social class; and on proclivities such as drug use and delinquency. Children who are peer-accepted or popular have fewer problems in middle and high school, and teens who are peer-accepted have fewer emotional and social adjustment problems as adults. Peer-accepted children may be shy or assertive, but they often have well-developed **communication skills**.

Peer-accepted children tend to be able to function in the following ways:

- Correctly interpret other children's body language and tone of voice. Well-liked children can distinguish subtleties in emotions. For example, they can distinguish between anger directed toward them and anger directed toward a parent.
- Directly respond to the statements and gestures of other children. Well-liked children will say other children's names, establish eye contact, and use touch to get attention.
- Give reasons for their own statements, gestures, and actions. For example, well-liked children will explain why they want to do something the other child does not want to do.
- Cooperate with, show tact towards, and compromise with other children, demonstrating the willingness to subordinate the self by modifying behavior and opinions in the interests of others. For example, when joining a new group where a conversation is already in progress, well-liked children will listen first, establishing a tentative presence in the group before speaking, even if it is to change the subject.

These skills are crucial in initiating and maintaining relationships and in resolving conflicts. By contrast, rejected children tend either towards aggressive, **antisocial behavior** or withdrawn, depressive behavior. They also do not listen well, tend not to offer reasons for their behavior, do not positively reinforce their peers, and have trouble cooperating. Antisocial children interrupt people, dominate other children, and either verbally or physically attack them. Depressive or withdrawn children may be excessively reserved, submissive, anxious, and inhibited. Competitiveness or dominance by itself is not necessarily indicative of low peer acceptance. In fact, popular children tend to have characteristics associated with both competitiveness and friendliness.

The need to be "one of the gang" is stronger as children approach the teen years than at any other age. Children of all ages need to feel that they fit in—that they belong.

Common problems

Children learn to relate to peers by engaging in peer relationships. Some children have problems making friends or "fitting in." Often a vicious circle develops where a rejected child is given fewer and fewer opportunities by his peers to relate and thereby learn new skills. Lack of opportunity to participate normally in peer interaction is especially a problem for children who differ in some obvious way, either culturally, racially, or through some mental or physical disability. Parents and teachers should address issues of peer acceptance as early as possible in order to prevent loss of self-confidence and **self-esteem**.

In addition to providing direct social skills training or counseling for the child with peer acceptance problems, parents and teachers can create opportunities for non-threatening social interaction to occur. Though children should never be forced to play together since this can create the rejection it is intended to remedy, popular and less-popular preschoolers can be encouraged to interact with one another. For example, a less sociable child may be encouraged to answer and ask questions of others. Older children should be provided opportunities to interact in smaller groups and in one-on-one situations, where it may be easier to try out new behaviors and make up for social mistakes. Shy or withdrawn children can be encouraged to develop outside interests that will place them in structured contact with others. In school, peer helping programs and collaborative learning provide opportunities for popular and less-popular children to work together. Ideally, collaboration should highlight the less-popular students' strengths, such as special interests and talents, rather than weaknesses. At any age, the small, positive changes in behavior should be reinforced with attention and praise.

KEY TERMS

Fantasy play—Play activities in which children act out their fantasies.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Primary caregiver—A person who is responsible for the primary care and upbringing of a child.

Parental concerns

Peer rejection in childhood often brings with it serious emotional difficulties. Rejected children are frequently discontent with themselves and with their relationships with other children. Many of these children experience strong feelings of loneliness and social dissatisfaction. Rejected children also report lower self-esteem and may be more depressed than other children. Peer rejection is also predictive of later life problems, such as dropping out of school, juvenile delinquency, and mental health problems. Dropping out of school seems to be a particularly frequent outcome. Results from research indicate that, on average, about 25 percent of low-accepted children drop out of school compared to 8 percent of other children, according to the National Network for Child Care at Iowa State University.

There are various reasons why children are disliked by their peers. When trying to find ways to help these children, it is easy to fall into the trap of thinking about what they do that bothers others. This focuses only on reducing these behavior problems but most rejected children also lack important social skills. They may not cooperate or be responsive to others, or they may not know how to respond in certain social situations. Teaching a child the missing skills is often more effective in improving peer relationships than working only on reducing negative behavior.

When to call the doctor

Parents may need to seek professional psychological help for children who suffer from peer rejection, especially when the child is depressed or shows overly **aggressive behavior**. Help may also be needed for adolescents whose acceptance by peers relates to common

negative behaviors, such as gang affiliation, bullying, **smoking**, and drug and alcohol abuse.

Peer pressure

Definition

Peer pressure is the influence of a social group on an individual.

Description

Children and teenagers feel social pressure to conform to the group of peers with whom they socialize. This peer pressure can influence how children dress, what kind of music they listen to, and what types of behavior they engage in, including risky behaviors such as using drugs, cigarettes, and alcohol, and engaging in sex. The intensity of peer pressure differs from situation to situation.

Peer groups are usually cliques of friends who are about the same age. Peer pressure can begin in early childhood with children trying to get other kids to **play** the games they want. It generally increases through childhood and reaches its intensity in the preteen and teen years. Virtually all adolescents in middle and high school deal with peer pressure, often on a daily basis. It is how children and teens learn to get along with others of their own age group and eventually learn how to become independent. Depending on the group trying to apply the influence, peer pressure can be negative or positive.

Starting in middle school, children begin to spend more time with their friends and less time with their parents and **family**. Although some children remain loners and not part of any group, most preteens tend to be part of a small group of friends called a clique. In children ages eleven to fourteen, it is most common for members of these cliques to be of the same sex. Children will spend a lot of time with friends in their clique, interacting by going to the movies or the mall, talking on the

telephone, or chatting online with instant messaging. They know which kids belong to particular cliques and who the loners are. Within the cliques, talk about the opposite sex is popular as is making arrangements for out of school activities.

Children also generally belong to a crowd, which is a larger group of kids from several cliques. While members of the cliques are close friends, members of the crowd outside a clique are casual acquaintances. Crowds are often large groups with common interests such as athletes (jocks), kids who like school (preppies), kids lacking good looks or social skills but who excel at particular intellectual interests (nerds), and drug users (druggies).

Some kids give in to peer pressure because they want to be liked, to fit in, or because they worry that other kids may make fun of them if they do not go along with the group. Others may go along because they are curious to try something new that others are doing. The idea that "everyone is doing it" may influence some kids to ignore their better judgment or their common sense. Peer pressure can be extremely strong and seductive. Experiments have shown how peer pressure can influence children to change their minds from what they know for sure is acceptable behavior to unacceptable behavior just because everyone else in their peer group is doing it. These studies have also shown that all it takes for individuals to stand their ground on what they know is right is for one other peer to join them. That principle holds true for youth of any age in peer pressure situations, according to the Online organization KidsHealth (<www.kidshealth.org>).

Children and adolescents cannot always avoid negative peer pressure. It may continue to be a fact of life through childhood, **adolescence**, and into adulthood. Quoted from an article in the September 2002 issue of *Current Health 2, A Weekly Reader Publication*, the following are strategies young people can use to deal with negative peer pressure effectively:

- Avoid putting yourself in situations that make you feel uncomfortable. For example, if you don't want to start **smoking**, stay away from areas where you know kids go to smoke.
- Choose your friends wisely. If you hang around with people who share your values, chances are you'll never be asked to do something you don't want to do.
- Think about the consequences whenever you are asked to do something you are not sure about. Stop for a moment and ask: Will this activity get me in trouble? Will it be harmful to my health?
- Be true to yourself. Think about the reasons why you are considering doing something you are uncomfortable with. Is it to gain popularity? Although there is nothing wrong with wanting to be popular, there are right ways and wrong ways to achieve it. If you change your behavior just to fit in with a particular group, you are not being true to yourself.
- Learn how to say no. This is perhaps the most difficult thing in the world for many people to do, but it is an essential skill if you are to successfully fend off negative peer pressure. There are many ways to say no, some of them subtle and some of them a little more "in your face." Several examples are: "You see it your way. I see it my way." "If you are really a friend, then back off." "You must think I'm pretty dumb to fall for that one."

Toddlerhood

Peer pressure can be found in groups as young as age two, when children will do things simply because other kids are doing it or tell them to. This can effect the child's behavior, social and emotional development, eating habits, play time, and sleeping patterns.

Preschool

Preschoolers will go out of their way to think and act like their friends, even though they know it may go against what they have been taught by their parents. At the ages of three and four, children start to see there are other values, opinions, and rules besides those set by their parents. They may demand to do things that their parents do not allow, such as watching television beyond a certain time or time limit, eating junk food, and playing with **toys** their parents do not deem appropriate, such as toy guns, simply because their friends do so.

At this age, it is normal for children to start challenging their parents, testing the limits and rules to see how far they can bend or break them. Many pediatricians suggest parents should remain firm, not overreact, and then move on. Peer pressure can have positive benefits for preschoolers, such as taking a nap or eating vegetables when they see their friends doing it.

School age

At ages five to eight, children make a concerted effort to please their friends, classmates, and playmates. Peer pressure can be a positive influence if friends encourage each other to strive to do better in school, **sports**, and creative activities. For example, a child may try harder at soccer if he or she has a friend who does well or may read more if that is what a friend does.

Peer pressure can also have a negative influence on children ages five to eight when a friend or friends encourage them to act in a way that is not natural for the child. Many pediatricians and child psychologists say it is best not to prohibit the child from hanging out with these friends but to make sure the child is aware of the consequences of unacceptable behavior. Focus on specific negative behaviors and explain why they are bad. Most children will not respond well if a parent or primary caregiver forbids them to associate with a friend or group of friends.

The effects of peer pressure usually begin to be seen heavily by middle school and through high school. As children turn into adolescents, involvement with their peers and the attraction of peer identification increases. Teens begin to experience rapid physical, emotional, and social changes, and they begin to question adult standards and the need for parental guidance. It is reassuring for teens to turn for advice to friends who understand and sympathize with them.

Adolescents expand their peer relationships to occupy a central role in their lives, often replacing their parents and family as their main source of advice, socializing, and entertainment activities. The peer group is a source of affection, sympathy, understanding, and experimentation. It is also a supportive setting for achieving the two primary developmental tasks of teens: finding answers to questions about their identity and discovering their autonomous self that is separate and independent from their parents.

At adolescence, peer relations expand to occupy a particularly central role in young people's lives. New types (opposite sex, romantic ties) and levels (crowds) of peer relationships emerge. Peers typically replace the family as the center of a young person's socializing and leisure activities. Teenagers have multiple peer relationships, and they confront multiple peer cultures that have remarkably different norms and value systems. The perception many adults have that peer pressure is one culture or a unified front of dangerous influence is inaccurate. More often than not, peers reinforce family values, but they have the potential to encourage problem behaviors as well. Although the negative peer influence is overemphasized, more can be done to help teenagers experience the family and the peer group as mutually constructive environments. The following are facts about parent, adolescent and peer relations.

- During adolescence, parents and adolescents become more physically and psychologically distant from each other. This normal distancing is seen in decreases in emotional closeness and warmth, increases in parent-adolescent conflict and disagreement, and an increase in time adolescents spend with peers. Unfortunately, this tendency sometimes is encouraged by parents who are emotionally unavailable to their teenaged children.
- Increases in family strains such as economic pressures or **divorce** may prompt teenagers to depend more on peers for emotional support. By the high school years, most teenagers report feeling closer to friends than parents. Stress caused by work, marital dissatisfaction, family break-up caused by divorce, entering a step-family relationship, lower family income or increasing expenses, all produce increased individual and family stress.
- In 10 to 20 percent of families, parents and adolescents are in distressed relationships characterized by emotional coldness and frequent outbursts of anger and conflict. Unresolved conflicts produce discouragement and withdrawal from family life. Adolescents in these families are at high risk for various psychological and behavioral problems.
- Youth **gangs**, commonly associated with inner-city neighborhoods, are a recognizable peer group among youth in smaller cities, suburbs, and even rural areas. Gangs are particularly visible in communities with a significant portion of economically disadvantaged families and when parents are conflicted, distant, or unavailable.
- Formal dating patterns of the 1980s have been replaced in the early 2000s with informal socializing patterns in mixed-sex groups. This may encourage casual sexual relationships that heighten the risk of exposure to human **immunodeficiency** virus (HIV) and other sexually transmitted diseases.
- There has been an increase in part-time employment among youth, but it has had little impact on peer relations. To find time for work, teenagers drop **extracurricular activities**, reduce time spent on homework, and withdraw from family interactions, but they protect time spent with friends.

Common problems

Negative peer pressure occurs when a child's or teen's friends or other people their age try to convince them to do something that is either harmful to their body or is against the law. Examples include drinking alcohol, taking drugs, smoking cigarettes, cutting classes, vandalizing, and **stealing**. Although teens usually know when something is bad for them, they often choose to do it because they want to be liked, to fit in, to be accepted, or because they're afraid they'll be looked down upon or made fun of.

KEY TERMS

Clique—A close group of friends having similar interests and goals and whom outsiders regard as excluding them.

Human immunodeficiency virus (HIV)—A transmissible retrovirus that causes AIDS in humans. Two forms of HIV are now recognized: HIV-1, which causes most cases of AIDS in Europe, North and South America, and most parts of Africa; and HIV-2, which is chiefly found in West African patients. HIV-2, discovered in 1986, appears to be less virulent than HIV-1 and may also have a longer latency period.

Primary caregiver—A person who is responsible for the primary care and upbringing of a child.

Bruce A. Epstein in "How to combat negative peer pressure," in the September 2002 issue of *Current Health 2, A Weekly Reader Publication*, is quoted as saying, The "desire to be accepted by their peers is perhaps the strongest motivating force during dolescence." Many studies reinforce his theory. One study showed, for example, that a student who knew the correct answer to a question gave the wrong answer just because everyone else in the class gave the wrong answer.

There are various reasons why children are disliked by their peers. When trying to find ways to help these children, it is easy to fall into the trap of thinking about what they do that bothers others. This focuses only on reducing these behavior problems but most rejected children also lack important social skills. They may not cooperate or be responsive to others, or they may not know how to respond in certain social situations. Teaching a child the missing skills is often more effective in improving peer relationships than working only on reducing negative behavior.

Parental concerns

Peer rejection in childhood often brings with it serious emotional difficulties. Rejected children are frequently discontent with themselves and with their relationships with other children. Many of these children experience strong feelings of loneliness and social dissatisfaction. Rejected children also report lower **self-esteem** and may be more depressed than other children. Peer rejection is also predictive of later life problems, such as dropping out of school, juvenile delinquency, and mental health problems. Dropping out of school seems to be a particularly frequent outcome. Results from research indicate that, on average, about 25 percent of low-accepted children drop out of school compared to 8 percent of other children, according to the National Network for Child Care at Iowa State University.

When to call the doctor

Parents may need to seek professional psychological help for children suffering from peer rejection, especially when the child is depressed or shows overly **aggressive behavior**. Help may also be needed for adolescents whose acceptance by peers relates to common negative behaviors, such as criminal activities, gang affiliation, bullying, smoking, and drug and alcohol abuse. Professional psychological help may also be needed if the child is depressed. If the child talks about or threatens **suicide**, professional help should be sought immediately.

Penicillins

Definition

Penicillins are a group of closely related **antibiotics** that kill bacteria.

Description

There are several types of penicillins, each used to treat different kinds of infections, such as skin infections, dental infections, ear infections, respiratory tract infections, urinary tract infections, gonorrhea, and other infections caused by bacteria. These drugs will not work for olds, flu, and other infections caused by viruses.

Examples of penicillins are penicillin V (Beepen-VK, Pen-Vee K, V-cillin K, Veetids) and amoxicillin (Amoxil, Polymox, Trimox, Wymox). Penicillins are sometimes combined with other ingredients called beta-lactamase inhibitors, which protect the penicillin from bacterial enzymes that may destroy it before it can do its work. The drug Augmentin, for example, contains a combination of amoxicillin and a beta-lactamase inhibitor, clavulanic acid. Penicillins are available only with a prescription.

The original form of penicillin is called penicillin G. It is a narrow-spectrum antibiotic, which can be destroyed by stomach acid, but it is still useful against anaerobic bacteria (bacteria that can live in the absence of air). Newer penicillins are resistant to stomach acid, such as penicillin V, or have a broader spectrum, such as ampicillin and amoxicillin.

General use

Penicillins are useful against infections in many parts of the body, including the mouth and throat, skin and soft tissue, tonsils, heart, lungs, and ears. However, since many bacteria are resistant to penicillin, it is often wise to do a culture and sensitivity test before using penicillins. In some cases, there are only a few types of bacteria that are likely to be a problem, and so it is appropriate to use a penicillin without testing. For example, dentists often prescribe penicillin to prevent infections after dental surgery.

Precautions

Penicillins are usually very safe. The greatest risk is an allergic reaction, which can be severe. People who have been allergic to cephalosporins are likely to be allergic to penicillins. Moreover, people with certain medical conditions or who are taking certain other medicines can have problems if they take penicillins. Before taking these drugs, patients should be sure to let the physician know about any of the following conditions.

Low-sodium diet

Some penicillin medicines contain large enough amounts of sodium to cause problems for people on low-sodium diets. Parents of children on on such a diet should make sure that the physician treating the infection knows about the special diet.

Diabetes

Penicillins may cause false positive results on urine sugar tests for diabetes. People with diabetes should check with their physicians to see if they need to change their diet or the doses of their diabetes medicine.

Phenylketonuria

Some formulations of Augmentin contain phenylalanine. People with **phenylketonuria** (PKU) should consult a physician before taking this medicine.

Side effects

The most common side effect of penicillin is **diarrhea**. **Nausea**, **vomiting**, and upset stomach are also

common. With some penicillins, particularly the broad spectrum products, there is a risk of increased growth of organisms that are not affected by penicillin. This situation can lead to candidal infections of the mouth and vagina.

Most side effects of penicillin cannot be prevented. Amoxicillin has a lower incidence of diarrhea than ampicillin and is the preferred drug in most cases.

Interactions

Birth control pills may not work properly when taken at the same time as penicillin. Penicillins may also interact with many other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. People who take penicillin should let their physician know all other medicines they are taking. Among the drugs that may interact with penicillins are the following:

- acetaminophen (Tylenol) and other medicines that relieve **pain** and inflammation
- medicine for overactive thyroid
- other antibiotics
- blood thinners
- antiseizure medicines such as Depakote and Depakene
- blood pressure drugs such as Capoten, Monopril, and Lotensin

The list above does not include every drug that may interact with penicillins. A physician or pharmacist should be consulted before a patient combines penicillins with any other prescription or nonprescription (over-the-counter) medicine.

Parental concerns

Parents should verify that their children have an infection requiring antibiotic therapy. Unnecessary use of antibiotics leads to development of bacterial resistance, while it subjects the child to some needless risk of adverse effects and wastes money.

Liquid forms of penicillin should be refrigerated after reconstitution. These preparations must be shaken well before use and measured with a medicinal teaspoon, not a household teaspoon.

Any adverse effects should be discussed with the prescriber. Penicillin should not be used in patients allergic to the drug; however, an incorrect report of an allergy to penicillin may cause prescribers to select a different drug which may cause even more severe side effects.

KEY TERMS

Anaerobic—An organism that grows and thrives in an oxygen-free environment.

Beta-lactamase—An enzyme produced by some bacteria that destroys penicillins.

Broad spectrum—A term applied to antibiotics to indicate that they are effective against many different types of bacteria.

Enzyme—A protein that catalyzes a biochemical reaction without changing its own structure or function.

Microorganism—An organism that is too small to be seen with the naked eye, such as a bacterium, virus, or fungus.

Mononucleosis—An infection, caused by the Epstein-Barr virus, that causes swelling of lymph nodes, spleen, and liver, usually accompanied by extremely sore throat, fever, headache, and intense long-lasting fatigue. Also called infectious mononucleosis.

Penicillins should be administered exactly as directed. Users should never give larger, smaller, more frequent, or less frequent doses. To make sure the infection clears up completely, patients should take the medicine for as long as it has been prescribed. They should not stop taking the drug just because symptoms begin to improve. This point is important with all types of infections, but it is especially important with strep infections, which can lead to serious heart problems if they are not cleared up completely.

This medicine should be used only for the infection for which it was prescribed. Different kinds of penicillins cannot be substituted for one another. Do not save some of the medicine to use on future infections. It may not be the right treatment for other kinds of infections, even if the symptoms are the same.

Perforated eardrum

Definition

A perforated eardrum (tympanum perforation) is an opening or rupture in the eardrum (tympanic membrane), the thin membrane that separates the outer ear canal from the middle ear. A perforated eardrum may be caused by infection, trauma, or negative pressure from underwater diving or an airplane flight. The hole or rupture can cause temporary hearing loss, **pain**, and occasional discharge.

Description

The eardrum (tympanic membrane) is a thin, semi-transparent membranous wall that stretches across the ear canal and separates the outer ear from the middle ear. The side that faces outward into the ear canal is covered with skin and the inside is covered with mucous membrane. The eardrum vibrates when sound waves travel into the ear canal and strike it. One of the bones of the middle ear (the malleus) attaches to the center of the membrane and receives vibrations, transmitting them to other bones (the incus and stapes) and the inner ear fluid, and finally to nerves in the brain where sound is perceived. The middle ear is connected to the nose by the eustachian tube, a narrow channel that runs from the ear drum to the back of the throat.

In addition to conducting sound, the eardrum also protects the middle ear from bacteria and possible infection. When perforation occurs, bacteria can pass more easily into the middle ear, potentially causing ear infections.

Perforation is most commonly caused by either chronic or acute infection of the middle ear, usually related to infection of the nose and throat (nasopharynx). It may also be the result of trauma from direct injury, pressure, or loud noise. In general, the larger the opening in the eardrum, the greater the potential for temporary hearing loss. The location of the perforation also affects the degree of hearing loss. Severe hearing loss may follow a skull fracture that disrupts the bones in the middle ear. Eardrum perforation caused by a loud noise may result in disturbing ear noise (tinnitus) as well as a temporary hearing loss. Tinnitus usually fades in a few days and, over time, hearing loss improves.

Demographics

Perforated eardrum occurs commonly in people of all ages; it is especially common in early childhood when children are exposed regularly to colds and upper respiratory infections in their contact with other children. Middle ear infection, the most frequent cause of perforated eardrum, is the most prevalent reported illness in children between six months and 20 months of age.

Causes and symptoms

Middle ear infection (**otitis media**) is the most common cause of perforation of the eardrum. Infection usually stems from an upper respiratory infection in which swelling (edema) in the eustachian tube causes fluid and mucous to gather behind the eardrum. Bacteria that find their way from the nasopharynx into the built up fluid may cause a middle ear infection. The resulting congestion builds up pressure behind the eardrum, causing severe pain and spontaneous rupture, which reduces the pain immediately. Infected or bloody mucus may then drain from the ear. In some cases, the doctor may decide to rupture the membrane on purpose, making an incision (**myringotomy**) that relives pressure, reduces pain, and allows the infection to drain. Chronic middle ear infections can also erode a hole in the eardrum, which can eventually destroy the tiny bones of the middle ear and increase the likelihood of infected material passing from the nasopharynx into the middle ear, causing more infections.

The eardrum can also become damaged by direct injury from a foreign object or sudden noise. It is possible to perforate the eardrum by injury from the following:

- cotton-tipped swabs
- trauma, such as a hard bang or hitting the ear with an open hand
- fracture of the skull
- a nearby explosion or other extremely loud noise

Other causes of tympanum perforation include pressure trauma (barotrauma) injury such as the following:

- sudden change of air pressure during diving into water
- sudden change of air pressure during air travel
- middle ear tumor, which puts pressure against the inner ear drum

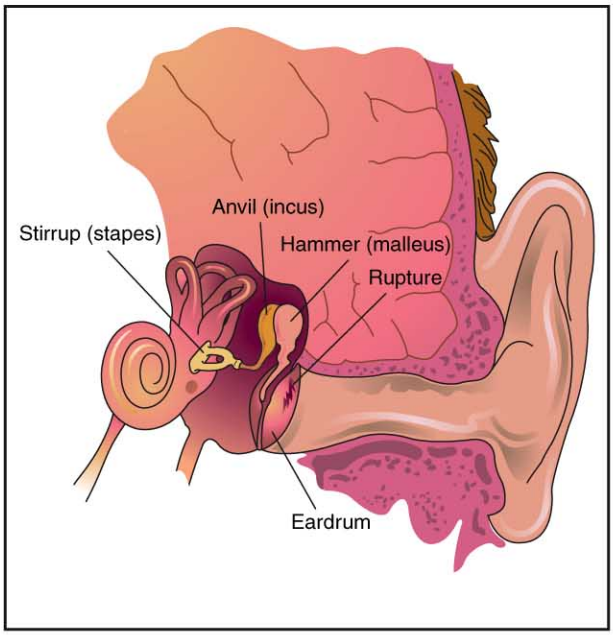
Symptoms may include an earache or severe pain in the ear or a sudden decrease in ear pain followed by drainage of clear, bloody, or pus-filled fluid. Hearing loss may be the first symptom experienced, either immediate or delayed, but will usually be restored. Tinnitus may occur as buzzing, swishing, or ringing, which will typically subside after a few days. Rarely, a small hole may remain in the eardrum after a pressure-equalizing tube (tympanostomy tube) falls out or is removed by a doctor. Tympanostomy tube insertion can also cause perforation.

When to call the doctor

If a child with a cold or upper respiratory infection cries constantly or complains of pain in the ear, it is wise to have the ears checked by a physician. Likewise, if the child seems to have pain or difficulty hearing after any type of trauma to the ear (injury with a foreign object, a bang or slap to the head, exposure to extremely loud noise, or after recent air travel), the doctor should be consulted. Early treatment of ear infection may help avoid perforation or hearing loss.

Diagnosis

The doctor may examine the ear with an otoscope, a microscope-type device with a light source for direct inspection of the ear. This examination makes possible the diagnosis of eardrum perforation by allowing the doctor to see an opening in the eardrum or damage to bones in the middle ear. Hearing tests with an audiogram may be done to measure the extent of any hearing loss. If drainage from infection is present, the doctor may have the material cultured in the laboratory to identify the organism causing infection. The nose and throat may also be cultured to see if the same organism is responsible for an upper respiratory infection. MRI or CT imaging studies may be done to rule out skull fracture, middle ear tumor, or acoustic neuroma, which may cause pain and hearing loss and be confused with a possible perforated eardrum.



A perforated eardrum is a hole or rupture in the eardrum, the thin membrane that separates the outer ear canal from the middle ear. It may result in temporary hearing loss and occasional discharge. *(Illustration by Electronic Illustrators Group.)*

Treatment

Treatment of a perforated eardrum is aimed at relieving pain or pressure behind the eardrum, treating any infection of the ear itself or of the upper respiratory tract, and restoring hearing. **Antibiotics** are usually the treatment of choice for existing ear infection or to prevent infection and reduce the likelihood of recurrence. Painkillers can relieve associated ear pain. Sometimes the doctor may lance a bulging eardrum and place a tympanostomy tube in it to relieve pain and pressure and allow the ear infection to drain before spontaneous rupture occurs.

A perforated eardrum usually heals by itself within two months. Sometimes, a paper patch is placed over the eardrum until the membrane heals. Three or four patches may be needed before the perforation closes completely. If the eardrum does not heal on its own, surgical repair (tympanoplasty) may be necessary to resolve the infection and restore hearing.

KEY TERMS

Edema—The presence of abnormally large amounts of fluid in the intercellular tissue spaces of the body.

Eustachian tube—A thin tube between the middle ear and the pharnyx. Its purpose is to equalize pressure on either side of the ear drum.

Otitis media—Inflammation or infection of the middle ear space behind the eardrum. It commonly occurs in early childhood and is characterized by ear pain, fever, and hearing problems.

Otoscope—A hand-held instrument with a tiny light and a funnel-shaped attachment called an ear speculum, which is used to examine the ear canal and eardrum.

Tinnitus—A noise, ranging from faint ringing or thumping to roaring, that originates in the ear not in the environment.

The ear should be kept clean and dry while the eardrum heals; it may help to insert ear plugs into the ears when showering or shampooing to block any water from getting in. (Cotton balls are not advised because they actually help moisture get into the ear through a wicking effect.) Pain in the ear may be eased by applying warm compresses.

Prognosis

While a perforated eardrum may be uncomfortable, it usually heals on its own within two months. Any hearing loss or ear noise that accompanies the perforation is usually temporary.

Prevention

A perforated eardrum can be prevented by avoiding insertion of any object into the ear to clean it or to remove ear wax (cerumen). Excess cerumen should only be removed by a doctor. If a foreign object becomes lodged in the ear, only a doctor should try to remove it.

Preventing ear infection is the primary way to prevent a perforated eardrum. Because infection-causing bacteria are found in the ears, nose, and throat in most cases (65-75%) of middle ear infection, avoiding contact as much as possible with children or adults who have colds or upper respiratory infections is one way to reduce the occurrence of infections in children that may lead to middle ear infection. School-age children are especially susceptible to repeat infections. Promptly treating all nose and throat infections will help avoid ear infections. Early treatment of ear infection is another way to guard against a ruptured eardrum and associated hearing loss.

Parental concerns

Parents will likely be concerned about the possibility of ear infection, especially in children who have already had ear infections. It may help to be especially watchful for symptoms of colds, sinus infections, and upper respiratory symptoms that may lead to ear infection. Physicians may recommend immune system boosters to help prevent infection. Parents can also make sure the child is getting proper rest and **nutrition** to increase resistance to the **common cold** and infections present in other children with whom their child plays or attends school.

Perinatal infection

Definition

An infection caused by a bacteria or virus that can be passed from a mother to her baby during pregnancy or delivery is called a perinatal infection.

Description

Perinatal infections include bacterial or viral illnesses that can be passed from a mother to her baby either while the baby is still in the uterus or during the delivery process. Maternal infection can, in some cases, cause complications at birth. The mother may or may not experience active symptoms of the infection during the pregnancy. Some perinatal infections are sexually transmitted.

Transmission

Transmission of many perinatal infections occurs during **childbirth**, particularly in cases when invasive techniques such as episiotomy or artificial rupture of membranes are employed. In other cases, transmission may occur during pregnancy, if the infectious agent can cross the placental barrier, and it may occur during breastfeeding, if the infectious agent can be found in breast milk.

Demographics

The incidence of perinatal infection depends on the causative agent of infection. For example, perinatal transmission of cytomegalovirus occurs in two to 24 out of every 1,000 live births. The rate of transmission of genital herpes during pregnancy is one to two out of every 2,000 pregnancies; the rate of transmission during childbirth changes to one out of every 2,000 to 5,000 live births. Perinatal transmission of group beta streptococcus causes neonatal infection in one to five out of every 1,000 live births, and **rubella** (German **measles**), 0.02 out of every 1,000 live births. HIV is transmitted from untreated mother to child in 25 to 40 percent of cases, but in only 1 percent of cases if mother receives treatment and the infant receives prophylaxis.

Causes and symptoms

The following represent some of the more common infections that can be transmitted perinatally.

Chlamydia

The bacterium *Chlamydia trachomatis* is the cause of the most common bacterial sexually transmitted disease in the United States, causing more than 4 million infections each year. The majority of women with chlamydial infection experience no obvious symptoms. The infection affects the reproductive tract and causes pelvic inflammatory disease, infertility, and ectopic pregnancy (when the fertilized egg implants somewhere other than in the uterus). This infection can cause premature rupture of the membranes and early labor. It can be passed to the infant during delivery and can cause ophthalmia neonatorum (an eye infection) within the first month of life and **pneumonia** within one to three months of age. Symptoms of chlamydial pneumonia are a repetitive **cough** and rapid breathing. Wheezing is rare and the infant is usually without a **fever**.

Cytomegalovirus

Cytomegalovirus (CMV) is a common virus in the herpes virus family. It is found in saliva, urine, and other body fluids and can be spread through sexual contact or other more casual forms of physical contact such as kissing. In adults, CMV may cause mild symptoms of swollen lymph glands, fever, and fatigue. Many people who carry the virus experience no symptoms at all. Infants can become infected with CMV while still in the uterus if the mother becomes infected or develops a recurrence of the infection during pregnancy. Although most infants exposed to CMV before birth develop normally and do not show any symptoms, as many as 6,000 infants who were exposed to CMV before birth are born with serious complications each year. CMV interferes with normal fetal development and can cause **mental retardation**, blindness, deafness, or epilepsy in these infants.

Genital herpes

Genital herpes, which is usually caused by **herpes simplex** virus type 2 (HSV-2), is a sexually transmitted disease that causes painful sores on the genitals. Women who have their first outbreak of genital herpes during pregnancy are at high risk of miscarriage or delivering a low birth weight baby. The infection can be passed to the infant at the time of delivery if the mother has an active sore. The most serious risk to the infant is the possibility of developing HSV-2 **encephalitis**, an inflammation of the brain, with symptoms of irritability and poor feeding.

Hepatitis B

Hepatitis B is a contagious virus that causes liver damage and is a leading cause of chronic liver disease and cirrhosis. Approximately 20,000 infants are born

each year to mothers who test positive for the hepatitis B virus. These infants are at high risk for developing hepatitis B infection through exposure to their mothers blood during delivery.

Human immunodeficiency virus (HIV)

Human **immunodeficiency** virus (HIV) is a serious, contagious virus that causes acquired immunodeficiency syndrome (**AIDS**). About 25 to 40 percent of untreated pregnant women pass the infection on to their newborn infants, while only 1 percent of treated pregnant women transmit the virus. There are often no symptoms of HIV in infants, but within a few months most infants who are infected show signs of opportunistic infections such as **failure to thrive**, chronic thrush, and persistent **diarrhea**.

Human papillomavirus

Human papillomavirus (HPV) is a sexually transmitted disease that causes genital **warts** and can increase the risk of developing some cancers. HPV appears to be transferred from the mother to the infant during the birth process and can cause tracheal narrowing due to lesions (warts) from the virus.

Rubella (German measles)

Rubella is a virus that causes German measles, an illness that includes rash, fever, and symptoms of an upper respiratory tract infection. Most people are exposed to rubella during childhood and develop antibodies to the virus so they never get it again. Rubella infection during early pregnancy can pass through the placenta to the developing infant and cause serious birth defects, including heart abnormalities, mental retardation, blindness, and deafness.

Group beta streptococcus

Group beta streptococcus (GBS) infection is the most common bacterial cause of infection and death in newborn infants. Although rates have declined in the United States since the introduction of **antibiotics** to at-risk women during labor in the 1980s, about 1,600 cases and 80 newborn deaths still occur each year. In women, GBS can cause vaginitis and urinary tract infections. Both infections can cause premature birth, and the bacteria can be transferred to the infant in the uterus or during delivery. GBS causes pneumonia, **meningitis**, and other serious infections in infants.

Syphilis

Syphilis is a sexually transmitted bacterial infection that can be transferred from a mother to an infant through the placenta before birth. Up to 50 percent of infants born to mothers with syphilis are premature or stillborn or die shortly after birth. Infected infants may have severe birth defects. Those infants who survive infancy may develop symptoms of syphilis up to two years later.

When to call the doctor

Pregnant women who exhibit symptoms of infection should contact their healthcare provider to determine if the infection can be passed vertically to the child during pregnancy, childbirth, and/or breastfeeding. In some cases, early detection and treatment of infection can minimize the risk of perinatal transmission.

Diagnosis

How a bacterial or viral infection is diagnosed depends on the causative agent. Examples include the following:

- Chlamydia can be diagnosed by taking a cotton swab sample of the cervix and vagina during the third trimester of the pregnancy. Chlamydial cell cultures take three to seven days to grow. DNA probes are available for more rapid diagnosis.
- Past or recent infection with cytomegalovirus (CMV) can be identified by antibody tests and CMV can be grown from body fluids.
- Genital herpes is suspected with the outbreak of a particular kind of genital sore. The sore can be cultured and tested to confirm that HSV-2 is present.
- Hepatitis B can be identified through a blood test for the hepatitis B surface antigen (HBsAg) in pregnant women. The test is part of prenatal health programs.
- Human immunodeficiency virus (HIV) can be detected using a blood test and is part of most prenatal screening programs.
- Human papillomavirus (HPV) causes the growth of warts in the genital area. The wart tissue can be removed with a scalpel and tested to determine what type of HPV virus caused the infection.
- Pregnant women are usually tested for antibodies to rubella, which would indicate that they have been previously exposed to the virus and, therefore, would not develop infection during pregnancy if exposed.
- Group beta streptococcus (GBS) can be detected by a vaginal or rectal swab culture and sometimes from a

urine culture. Blood tests can be used to confirm GBS infection in infants who exhibit symptoms.

- Pregnant women are usually tested for syphilis as part of the prenatal screening, generally with a blood test.

Treatment

Methods of treating some of the more common causes of perinatal infection include:

- Chlamydia: Pregnant women can be treated during the third trimester with oral erythromycin, for seven to 14 days depending on the dose used. Newborn infants can be treated with erythromycin liquid for ten to 14 days at a dosage determined by their body weight.
- Cytomegalovirus (CMV): No drugs or vaccines were as of 2004 available for prevention or treatment of CMV except in immunocompromised persons.
- Genital herpes: The **antiviral drugs** acyclovir or famciclovir can be administered to the mother during pregnancy. Little is known about the risks of these drugs to the fetus; however, the risk of birth defects does not seem to be any higher than for women who do not take these medications. Infants with suspected HSV-2 can be treated with acyclovir. Delivery of the infant by **cesarean section** is recommended if the mother has an active case of genital herpes.
- Hepatitis B: Infants born to mothers who test positive to the HBsAg test should be treated with hepatitis B immune globulin at birth to give them immediate protection against developing hepatitis B. All infants should also receive a series of three **hepatitis B vaccine** injections as part of their routine immunizations.
- Human immunodeficiency virus (HIV): Recent studies have shown that prenatal care and HIV testing before delivery are major opportunities for preventing perinatal **HIV infection**. Pregnant women with HIV should be treated as early in the pregnancy as possible with zidovudine (AZT). Other newer drugs designed to treat HIV/AIDS also may be used during pregnancy with the knowledge that these drugs may have unknown effects on the infant. Infants born with HIV should receive aggressive drug treatment to prevent development of AIDS. Most of the drugs designed to treat HIV are routinely used during pregnancy because of the mother's health needs and because transmission rate is directly related to the mother's viral load. Teratogenicity is not fully established for some of the subsequent HIV medications.
- Human papillomavirus: Genital warts are very difficult to treat and frequently recur even after treatment. They can be removed by cryotherapy (freezing), laser or electrocauterization (burning), or surgical excision (cutting). Some medications (imiquimod 5% cream, podophyllin, trichloroacetic acid, or topical 5-fluorouracil) can be applied to help dissolve genital warts. Cesarean delivery rather than vaginal delivery reduces the risk of transmission of HPV from mothers to infants.
- Rubella (German measles): No treatment is available. Some healthcare providers may recommend giving the mother an injection of immune globulin (to boost the immune system to fight off the virus) if she is exposed to rubella early in the pregnancy. However, no evidence to support the use of these injections existed as of 2004. Exposure to rubella early in pregnancy poses a high risk that the infant will have serious birth defects. Termination of the pregnancy may be considered. Women who have not been previously exposed to rubella are usually vaccinated immediately after the first pregnancy to protect infants of future pregnancies.
- Group beta streptococcus (GBS): Pregnant women diagnosed with GBS late in the pregnancy should be treated with antibiotics injected intravenously to prevent premature labor. In 2003, the Centers for Disease Control and Prevention (CDC) issued revised guidelines for preventing perinatal GBS disease. They began recommending that women not only be tested as soon as they learn of their pregnancy, but again at 35 to 37 weeks of gestation. The CDC also recommended updated prophylaxis regimens for women with penicillin **allergies**, as well as other guidelines for patients with threatened preterm deliveries and other recommendations. If transmission of GBS to the newborn infant already is suspected or if the baby develops symptoms of infection, infants often are treated with antibiotics.
- Syphilis: Antibiotic therapy, usually penicillin, given early in the pregnancy can be used to treat the infection and may prevent transmission to the infant.

Prognosis

The prognosis of a neonate who has contracted an infection perinatally depends on the specific infection. Examples include the following:

- Chlamydia: Without treatment, the most serious consequences of chlamydial infection are related to complications of premature delivery. Treatment of the mother with antibiotics during the third trimester can prevent premature delivery and the transfer of the infection to the baby. Infants treated with antibiotics for eye infection or pneumonia generally recover.
- Cytomegalovirus: The chance for recovery after exposure to CMV is very good for both the mother and the

infant. Exposure to CMV can be serious and even life threatening for mothers and infants whose immune systems are compromised, for example, those receiving **chemotherapy** or who have HIV/AIDS. Those infants who develop birth defects after CMV exposure may have serious, lifelong complications.

- Genital herpes: Once a woman or infant is infected, outbreaks of genital herpes sores can recur at any point during their lifetimes.
- Hepatitis B: Infants treated at birth with immune globulin and the series of vaccinations are protected from development of hepatitis B infection. Infants infected with hepatitis B develop a chronic, mild form of hepatitis and are at increased risk for developing liver disease.
- Human immunodeficiency virus (HIV): A combination of treatment with highly active antiretroviral therapy during pregnancy, zidovudine (AZT) during delivery, and AZT to the baby for six weeks after birth significantly reduces the chance that the infant will be infected with HIV from the mother.
- Human papillomavirus: Once infected with HPV, there is a lifelong risk of developing warts and an increased risk of some cancers.
- Rubella (German measles): Infants exposed to rubella virus in the uterus are at high risk for severe birth defects, including heart defects, blindness, and deafness.
- Streptococcus: Infection of the urinary tract or genital tract of pregnant women can cause premature birth. Infants infected with GBS can develop serious, life-threatening infections.
- Syphilis: Premature birth, birth defects, or the development of serious syphilis symptoms is likely to occur in untreated pregnant women.

Prevention

Use of a barrier method of contraceptive (e.g. **condom**) can prevent transmission of some sexually transmitted infections during intercourse. Intravenous drug use and sexual intercourse with infected partners increase the risks of exposure to most of these infections. Pregnant women can be tested for many of the bacterial or viral infections described; however, effective treatment may not be available to protect the infant.

In some cases, the method of childbirth may impact the chance of passing an infection from mother to child. For instance, research has shown that delivering a baby by caesarian section over vaginal delivery reduces the risk of transmitting HIV from mother to child.

KEY TERMS

Cesarean section—Delivery of a baby through an incision in the mother's abdomen instead of through the vagina; also called a c-section, cesarean birth, or cesarean delivery.

Ectopic pregnancy—A pregnancy that develops outside of the mother's uterus, such as in the fallopian tube. Ectopic pregnancies often cause severe pain in the lower abdomen and are potentially life-threatening because of the massive blood loss that may occur as the developing embryo/fetus ruptures and damages the tissues in which it has implanted.

Encephalitis—Inflammation of the brain, usually caused by a virus. The inflammation may interfere with normal brain function and may cause seizures, sleepiness, confusion, personality changes, weakness in one or more parts of the body, and even coma.

Episiotomy—An incision made in the perineum (the area between the vulva and the anus) during labor to assist in delivery and to avoid abnormal tearing of the perineum.

Perinatal—Referring to the period of time surrounding an infant's birth, from the last two months of pregnancy through the first 28 days of life.

Pneumonia—An infection in which the lungs become inflamed. It can be caused by nearly any class of organism known to cause human infections, including bacteria, viruses, fungi, and parasites.

Nutritional concerns

A woman's nutritional status may contribute to her ability to fight off infections, particularly in cases of **malnutrition**. A well-balanced diet rich in nutrients such as **folic acid**, calcium, iron, zinc, vitamin D, and the B **vitamins** is recommended for pregnant women. Mothers are recommended to eat approximately 300 additional calories day (above and beyond a normal non-pregnancy diet) to support the fetus's growth and development.

Parental concerns

Minimizing the risk of transmitting a maternal infection to a fetus is often a major concern for parents. The first step is identifying possible maternal infections. Proper prenatal care in many cases allows for early

diagnosis and thus early treatment of certain infections, thus improving the newborn's prognosis.

Periodontal disease

Definition

Periodontal diseases are a group of diseases that affect the tissues that support and anchor the teeth. Left untreated, periodontal disease results in the destruction of the gums, alveolar bone (the part of the jaws where the teeth arise), and the outer layer of the tooth root.

Description

Periodontal (meaning "around the tooth") disease is usually seen as a chronic (long-term) inflammatory disease. An acute (sudden) infection of the tissue surrounding the teeth (periodontal tissue) may occur, but acute inflammation usually resolves on its own and is not treated by a dentist.

Periodontal diseases affect the gums, which consist of the gingiva, periodontal ligament, cementum, and alveolar bone. The gingiva is a pink-colored mucous membrane that covers part of the teeth and the alveolar bone. The periodontal ligament, also called the periodontal membrane, is the tough, fibrous tissue that holds the teeth in the gums. The cementum is a bony layer that covers the lower parts of the teeth. The alveolar bone is a set of ridges along the jaw bones (maxillary and mandible) from which the teeth arise.

Periodontal disease most often develops when a pocket or space is formed between the teeth and the gums. This pocket is called the gingival sulcus. A number of distinct forms of periodontal disease are known, including gingivitis, acute necrotizing ulcerative gingivitis, adult periodontitis, and localized juvenile periodontitis. Although many people have some form of periodontal disease, serious cases are not common.

Gingivitis is an inflammation of the outermost soft tissue of the gums. The gums become red and inflamed, lose their normal shape, and bleed easily. Gingivitis may remain a chronic disease for years without affecting other periodontal tissues. Chronic gingivitis may lead to a deepening of the pockets between the gum and tooth. In some children, gingivitis and bleeding gums are among the early signs of leukemia.

Acute necrotizing ulcerative gingivitis is seen mainly in young adults. This form of gingivitis is characterized by painful, bleeding gums, and death (necrosis) and erosion of gums between the teeth.

Localized juvenile periodontitis is a less common form of periodontal disease and is seen mainly in young people. Localized juvenile periodontitis usually affects

the molars (back grinding teeth) and incisors. Among the distinctions that separate this form of periodontitis are the low incidence of bacteria in the periodontal pocket, minimal plaque formation, and mild inflammation.

Pericoronitis is a condition found in children whose molars are in the process of erupting through the gum. The disease is seen more frequently in the lower molar teeth. As the molar emerges, a flap of gum still covers the tooth. The flap of gum traps bacteria and food, leading to mild irritation. If the upper molar fully emerges before the lower one, it may bite down on the flap during chewing and increase the irritation of the flap, leading to infection. In severe cases, the infection can spread to the neck and cheeks.

Periodontitis, also called pyorrhea, is a condition in which gingivitis has extended down around the tooth and into the supporting bone structure. Plaque and tarter build-up lead to the formation of large pockets between the gums and teeth. When this happens, anaerobic bacteria (bacteria that do not need oxygen) grow in the pockets. The pockets eventually extend down around the roots of the teeth where the bacteria cause damage to the bone structure supporting the teeth.

Herpetic gingivostomatitis, which is relatively common in children, is an inflammation of the gums and mouth caused by the **herpes simplex** virus. This disease is contagious, but tends to heal without medical intervention in about two weeks.

Desquamative gingivitis occurs mainly in postmenopausal women and is not well understood.

Trench mouth, also called Vincent's disease, is a suddenly developing (acute) complication of gingivitis. It causes tissue death and open sores on the gums and is often accompanied by **fever**, fatigue, and painful bleeding gums. Trench mouth usually develops because of poor **oral hygiene**, stress, fatigue, and **smoking**. It requires immediate treatment by a dentist, since **pain** can increase to the point where eating and swallowing become difficult, and the inflammation can spread to nearby tissues of the face and neck.

Demographics

Periodontal disease is common. It is estimated that 9–17 percent of children between the ages of three and 11 years have gingivitis. The number increases sharply at **puberty**, with 70–90 percent of teens developing the disease. More boys than girls have gingivitis, probably because girls have better oral hygiene habits than boys, rather than because of any physiological differences.

Some medical conditions are associated with an increased likelihood of developing periodontitis. These diseases include diabetes, **Down syndrome**, **AIDS**, and any disease or condition that compromises the immune system and reduces the number of white blood cells in the body for extended periods.

Causes and symptoms

Bacteria present on the gingival tissues cause periodontal diseases. The mechanisms by which bacteria in the periodontal pocket cause tissue destruction in the surrounding region are not fully understood. However, removal of bacteria through good oral hygiene practices and regular dental care helps reduce or eliminate these diseases. There are indications that a tendency toward developing periodontal disease is genetic, with up to 30 percent of the population being highly susceptible despite aggressive oral hygiene habits.

Other factors that put individuals at higher risk for developing periodontal diseases include smoking, stress, poor diet, and taking certain medications such as antidepressants, some heart medicines, and **oral contraceptives**. Gingivitis can be aggravated by hormones and may temporarily worsen during puberty and pregnancy. Individuals with diabetes and diseases that depress the immune system are more likely to develop periodontal disease.

The main symptoms of periodontal disease include:

- bleeding gums
- red, sore, or swollen gums
- gums that have receded from the base of the teeth
- chronic bad breath
- loose permanent teeth
- open sores on the gums

When to call the dentist

Beginning as toddlers, all children need regular checks-up by a dentist. Children who have chronically bleeding gums, open sores on the gums, or who complain of gum or tooth pain, should see a dentist promptly. Those with bleeding gums should see their pediatrician urgently, as this is also a symptom of leukemia in some children.

Diagnosis

Diagnosis of periodontal disease is made by observation of infected gums. Usually a dentist diagnoses and characterizes the various types of periodontal disease.

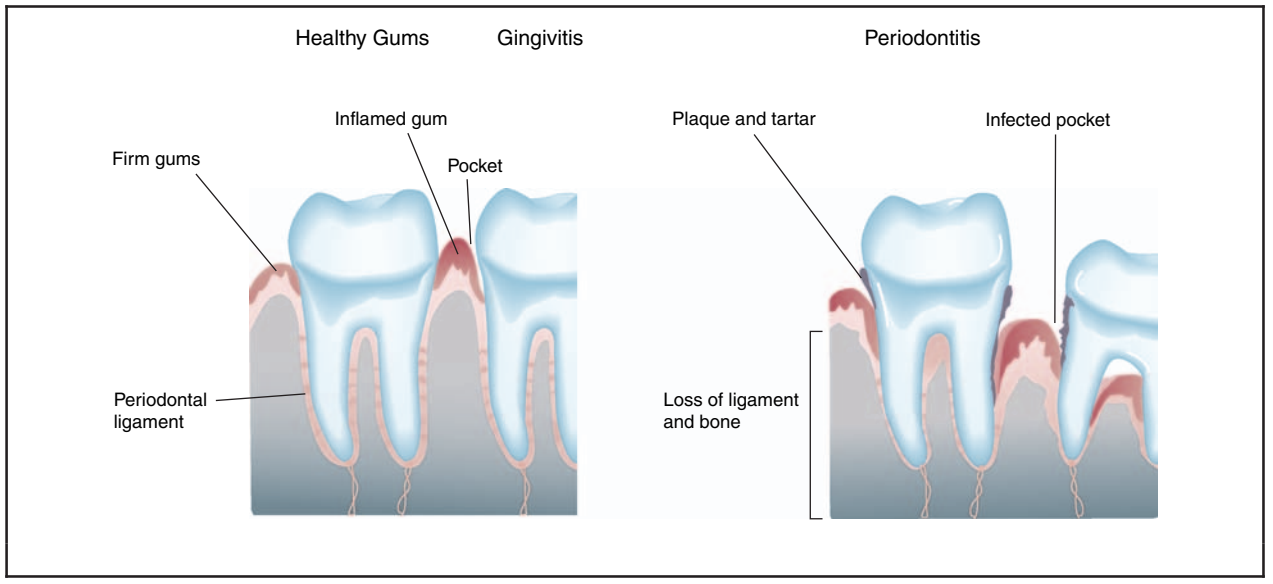

Diagram showing healthy gums (far left) with no pockets or redness; gingivitis (left) with inflamed gum and pocket; and periodontitis (right) with infected pockets, plaque, and tartar. *(Illustration by Argosy, Inc.)*

Many periodontal diseases are distinguished based on the severity of the infection and the number and type of tissues involved.

Diagnosis of periodontitis includes measuring the size of the pockets formed between the gums and teeth. Normal gingival pockets are shallow. If periodontal disease is severe, jawbone loss will be detected in **x rays** of the teeth. If too much bone is lost, the teeth become loose and can change position. This will also be seen in x-ray images.

Treatment

Tartar can be removed only by professional dental treatment. Following treatment, periodontal tissues usually heal quickly. Administering the needed **vitamins** and improving diet treats gingivitis caused by poor **nutrition** or vitamin deficiencies. Removing debris under the flap of gum covering the molar treats pericoronitis.

Treatment of periodontitis requires professional dental care. The pockets around the teeth are cleaned, and all tartar and plaque removed. In periodontitis, tartar and plaque can extend far down the tooth root. Normal dental hygiene, brushing and flossing, cannot reach deep enough to effectively treat periodontitis. In cases where pockets are very deep (more than 0.25 in, or 0.64 cm, deep), surgery is required to clean the pocket. This is performed in a dental office. Sections of gum that are not likely to reattach to the teeth may be removed to promote healing by healthy sections of gum. Abscesses are treated with a combination of **antibiotics** and surgery. If antibiotics are needed for gum disease, they are usually given orally. The antibiotics may be delivered directly to the infected gum and bone tissues to ensure that high concentrations reach the infected area. Abscess infections, especially of bone, are difficult to treat and require long term antibiotic therapy to prevent a reoccurrence of infection.

There are no useful drugs to treat herpetic gingivostomatitis, but acyclovir is used in high-risk patients or those with a compromised immune system. Herpes lesions heal by themselves without treatment. After the herpetic lesions have disappeared, the gums usually return to normal if good oral hygiene is resumed.

Prognosis

Most cases of periodontal disease are mild and can be cleared up with improved oral hygiene, as well as tooth and gum cleaning by a trained professional. Serious cases of periodontal disease may be persistent, but they can usually be controlled. Untreated periodontal disease may cause teeth to loosen and fall out, and infection may spread to surrounding tissues.

Prevention

Good oral hygiene, a well-balanced nutritious diet, and regular dental visits for tooth cleaning all help prevent periodontal disease. Prompt attention to gingivitis can prevent it from progressing to more serious periodontal diseases.

KEY TERMS

Alveolar bone—A set of ridges from the jawbones.

Cementum—A bony substance that covers the root of the tooth.

Gingiva—The gum tissue surrounding the teeth.

Gingival sulcus—The space between the tooth and the gum that often traps food and bacteria, leading to periodontal disease.

Periodontal ligament—Also called the periodontal membrane, this tough fibrous tissue holds the teeth in place in the gums.

Plaque—A deposit, usually of fatty material, on the inside wall of a blood vessel. Also refers to a small, round demyelinated area that develops in the brain and spinal cord of an individual with multiple sclerosis.

Tartar—A hardened yellow or brown mineral deposit from unremoved plaque. Also called calculus.

Parental concerns

Sometimes parents are less concerned about their child's first (baby) teeth than their permanent teeth. However, poor oral hygiene and lack of care of the first set of teeth are apt to be reflected in problems with the gums and the permanent teeth.

Peroxisomal disorders

Definition

Peroxisomal disorders are a group of congenital diseases characterized by the absence of normal peroxisomes in the cells of the body.

Description

Peroxisomes are organelles within a cell that contain enzymes responsible for critical cellular processes. A cell can contain several hundred peroxisomes, round or oval bodies with diameters of about 0.5 micron that contain proteins that function as enzymes in metabolic processes. By definition, a peroxisome must contain catalase, which is an enzyme that breaks down hydrogen peroxide.

Peroxisomal disorders are subdivided into two major categories: those disorders resulting from a failure to form intact, normal peroxisomes, resulting in multiple metabolical abnormalities, which are referred to as peroxisome biogenesis disorders (PBD) or generalized peroxisomal disorders; and those disorders resulting from the deficiency of a single peroxisomal enzyme. There are about 25 known peroxisomal disorders, although the number of diseases that are considered to be separate, distinct peroxisomal disorders varies among researchers and healthcare practitioners.

Approximately 50 different biochemical reactions occur entirely or partially within a peroxisome. Some of the processes are anabolic (constructive), resulting in the synthesis of essential biochemical compounds, including bile acids, cholesterol, plasmalogens, and docosahexanoic acid (DHA), which is a long chain fatty acid that is a component of complex lipids, including the membranes of the central nervous system. Other reactions are catabolic (destructive) and lead to the

destruction of some fatty acids, including very long chain fatty acids (VLCFAs, fatty acids with more than 22 carbon atoms in their chains), phytanic acid, pipecolic acid, and the prostoglandins. The peroxisome is involved in breaking down VLCFAs to lengths that the body can use or get rid of.

When VLCFAs accumulate due to abnormal functioning of the peroxisomes, they are disruptive to the structure and stability of certain cells, especially those associated with the central nervous system and the myelin sheath, which is the fatty covering of nerve fibers. The peroxisomal disorders that include effects on the growth of the myelin sheath are considered to be part of a group of genetic disorders referred to as leukodystrophies.

Peroxisomal disorders form a heterogeneous disease group, with different degrees of severity. The differences among these disorders are continuous, with overlap between abnormalities. Examples of peroxisomal disorders are:

- X-linked adrenoleukodystrophy (X-ALD), a sex-linked disorder characterized by progressive symptoms that begin as behavioral changes, muscle weakness, and speech difficulties.
- Zellweger syndrome (ZS), which is usually fatal within the first year of life.
- Neonatal adrenoleukodystrophy (NALD), which is usually fatal within the first ten years.
- Infantile Refsum disease (IRD), which is not as devastating as ZS and NALD, as the children with this disorder with time and patience can develop some degree of motor, cognitive, and **communication skills**, although death generally occurs during the second decade of life.
- Rhizomelic chondrodysplasia punctata (RCDP), which in its most severe form is fatal within the first year or two of life; however, survival into the teens has been known to occur. It is characterized by shortening of the proximal limbs (i.e., the legs from knee to foot and the arms from elbow to hand).
- Zellweger-like syndrome, which is fatal in infancy and known to be a defect of three particular enzymes.

Transmission

Most peroxisomal disorders are inherited autosomal recessive diseases. This means that both parents need to be carriers of the defective gene in order for a child to develop the disease. If both parents are carriers but do not show signs of disease, each child has a 25 percent chance of having the disease. If one parent has the disease and the other is a carrier, each child has a 50 percent chance of having the disease. As a sex-linked genetic disorder, the daughters of males affected with X-ALD become carriers and the sons are not affected. The children of female carriers have a 50 percent chance of having the genetic mutation, which means that sons who inherit the mutation have the disease, and daughters who inherit the mutation are carriers.

Demographics

Peroxisomal disorders occur in all countries, among all races and ethnic groups. They are extremely rare, with frequencies reported at one in 30,000 to one in 150,000, although these numbers are only estimates. X-ALD is the most common of the peroxisomal disorders, affecting about one in 20,000 males. It is estimated that there are about 1,400 people in the United States with the disorder. ZS is estimated to affect one in 50,000 to 100,000 live births.

Causes and symptoms

The range of disease abnormalities may be a result of a corresponding range of peroxisome failure. For example, in severe cases of ZS, the failure is nearly complete, while in IRD, there is some degree of peroxisome activity. In peroxisomal single-enzyme disorders, the peroxisome is intact and functioning, but there is a defect in only one enzymatic process, with only one corresponding biochemical abnormality. These disorders, however, can be as severe as those in which peroxisomal activity is nearly or completely absent.

In general, **developmental delay**, **mental retardation**, and vision and **hearing impairment** are common in those who have these disorders. Acquisition of speech appears to be especially difficult, and because of the reduced communication abilities, **autism** is common in those who live longer. Peroxisomal disorder patients have decreased muscle tone (**hypotonia**), which in the most severe cases is generalized, while in less severe cases, is usually restricted to the neck and trunk muscles. Sometimes this lack of control is only noticeable by a curved back in the sitting position. Head control and independent sitting is delayed, with most patients unable to walk independently.

Failure to thrive is a common characteristic of patients with peroxisomal disorder, along with an enlarged liver, abnormalities in liver enzyme function, and loss of fats in stools (steatorrhea). Peroxisomal disorders are also associated with facial abnormalities, including high forehead, frontal bossing (swelling), small face, low set ears, and slanted eyes. These characteristics may

not be prominent in some children and are especially difficult to identify in an infant.

In X-ALD there is a deficiency in the enzyme that breaks down VLCFAs, which then accumulate in myelin and the adrenal glands. Onset of X-ALD-related neurological symptoms occurs at about five to 12 years of age, with death occurring within one to ten years after onset of symptoms. In addition to physical abnormalities seen in other types of peroxisomal disorders, common symptoms of X-ALD also include behavioral changes such as abnormal withdrawal or aggression, poor memory, dementia, and poor academic performance. Other symptoms are muscle weakness and difficulties with hearing, speech, and vision. As the disease progresses, muscle tone deteriorates, swallowing becomes difficult, and the patient becomes comatose. Unless treated with a diet that includes a mixture of oils called Lorenzo's oil, the disease will result in paralysis, hearing loss, blindness, vegetative state, and death. There are also milder forms of X-ALD, an adult onset ALD that typically begins between the ages of 21 and 35, and a form that is occasionally seen in women who are carriers of the disorder. In addition to X-ALD, there are at least ten other single-enzyme peroxisomal disorders, each with its own specific abnormalities.

When to call the doctor

A healthcare provider should be contacted if a child develops symptoms suggestive of peroxisomal disorder or if a child already diagnosed with a peroxisomal disorder shows signs of worsening disease.

Diagnosis

Since hearing and vision deficiencies may be difficult to identify in infants, peroxisomal disorders are usually detected by observations of failure to thrive, hypotonia, mental retardation, widely open fontanel, abnormalities in liver enzymes, and an enlarged liver. If peroxisomal disorders are suspected, blood plasma assays for VLCFAs, phytanic acid, and pipecolic acid are conducted. Additional tests include plasmalogen biosynthesis potential.

It is possible to diagnose peroxisomal disorders in utero. For example, for X-ALD, diagnosis can be made from cultured skin fibroblasts or amniotic fluid cells. This allows prenatal diagnosis and carrier identification in 90 percent of those affected. As of the early 2000s it has been shown that biochemical diagnosis can be performed through chorionic villus testing, a procedure performed very early in the first trimester of pregnancy.

Treatment

For many of the peroxisomal disorders, there is no standard course of treatment, with supportive treatment strategies focusing on alleviation of complications and symptoms. Bone marrow transplants may be effective for children with X-ALD if administered early in the course of the childhood form of the disease. Physical and psychological therapies are important for all types of peroxisomal disorders.

Alternative treatment

Patients with peroxisomal disorders, and particularly X-ALD, have been treated with a mixture of glycerol trioleate-glycerol trieucate (4:1 by volume), prepared from olive and rapeseed oils, and referred to as Lorenzo's oil (developed by the parents of a son, Lorenzo, who had X-ALD, whose story was documented in the 1992 movie, *Lorenzo's Oil*), to decrease the levels of VLCFA. Other diets that have been tried with varying success include dietary supplementation with plasmalogen precursors to increase plasmalogen levels and with cholic acid to normalize bile acids.

Nutritional concerns

In general, most treatments that are attempted for peroxisomal disorders are dietary, whereby attempts are made to artificially correct biochemical abnormalities associated with the disorders. Therapies include supplementation of the diet with antioxidant **vitamins** or limitation of intake of fatty acids, especially VLCFAs.

Another area of dietary therapy that is being investigated is the supplementation of the diet with pure DHA, given as early in life as possible, in conjunction with a normal well-balanced diet. Some results have indicated that if given soon enough during development, DHA therapy may prevent some of the devastating consequences of peroxisomal disorders, including the loss of vision and brain damage.

Other treatment strategies include addition of important missing chemicals. For example, in disorders where there is faulty adrenal function, replacement adrenal hormone therapy is used.

Any dietary changes should be monitored biochemically to determine if the supplements are having their desired effects and are not causing additional adverse effects.

Prognosis

Peroxisomal disorders range from life-threatening to cases in which people may function with some degree of

KEY TERMS

Adrenal glands—A pair of endocrine glands (glands that secrete hormones directly into the bloodstream) that are located on top of the kidneys. The outer tissue of the glands (cortex) produces several steroid hormones, while the inner tissue (medulla) produces the hormones epinephrine (adrenaline) and norepinephrine.

Autosomal recessive mutation—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Autosome—A chromosome not involved in sex determination.

Enzyme—A protein that catalyzes a biochemical reaction without changing its own structure or function.

Fontanelle—One of several "soft spots" on the skull where the developing bones of the skull have yet to fuse.

Organelle—A specialized structure within a cell, which is separated from the rest of the cell by a membrane composed of lipids and proteins, where chemical and metabolic functions take place.

mental and motor delays. As of 2004, there was not yet a cure for peroxisomal disorders. Enzyme replacement therapies, including enzyme infusion, transplantation, and gene therapy, may hold promise for future advances in the treatment of these disorders. As of the early 2000s research is conducted in order to increase scientific understanding of these disorders and find ways to prevent, treat, and cure them.

Prevention

It is not possible to prevent the transmission of an abnormal peroxisomal gene from parent to child or spontaneous mutations that may arise.

Parental concerns

Numerous professional and parent-led organizations exist to support parents as they first learn of a peroxisomal disorder diagnosis and as they provide care for their child. Genetic counseling is recommended for known or suspected carriers. As genes are identified that result in the disorders, genetic testing is being developed to identify carriers, who then can manage their reproduction to avoid the possibility of children being born with these deficiencies.

Personality development

Definition

Personality development is the development of the organized pattern of behaviors and attitudes that makes a person distinctive. Personality development occurs by the ongoing interaction of **temperament**, character, and environment.

Description

Personality is what makes a person a unique person, and it is recognizable soon after birth. A child's personality has several components: temperament, environment, and character. Temperament is the set of genetically determined traits that determine the child's approach to the world and how the child learns about the world. There are no genes that specify personality traits, but some genes do control the development of the nervous system, which in turn controls behavior.

A second component of personality comes from adaptive patterns related to a child's specific environment. Most psychologists agree that these two factors—temperament and environment—influence the development of a person's personality the most. Temperament, with its dependence on genetic factors, is sometimes referred to as "nature," while the environmental factors are called "nurture."

While there is still controversy as to which factor ranks higher in affecting personality development, all experts agree that high-quality parenting plays a critical role in the development of a child's personality. When parents understand how their child responds to certain situations, they can anticipate issues that might be problematic for their child. They can prepare the child for the situation or in some cases they may avoid a potentially difficult situation altogether. Parents who know how to adapt their parenting approach to the particular temperament of their child can best provide guidance and ensure the successful development of their child's personality.

Finally, the third component of personality is character—the set of emotional, cognitive, and behavioral patterns learned from experience that determines how a person thinks, feels, and behaves. A person's character continues to evolve throughout life, although much depends on inborn traits and early experiences. Character is also dependent on a person's **moral development**.

In 1956, psychiatrist Erik Erikson provided an insightful description as to how personality develops based on his extensive experience in psychotherapy with children and adolescents from low, upper, and middle-class backgrounds. According to Erikson, the socialization process of an individual consists of eight phases, each one accompanied by a "psychosocial crisis" that must be solved if the person is to manage the next and subsequent phases satisfactorily. The stages significantly influence personality development, with five of them occurring during infancy, childhood, and **adolescence**.

Infancy

During the first two years of life, an infant goes through the first stage: *Learning Basic Trust or Mistrust (Hope)*. Well-nurtured and loved, the infant develops trust and security and a basic optimism. Badly handled, the infant becomes insecure and learns "basic mistrust."

Toddlerhood

The second stage occurs during early childhood, between about 18 months to two years and three to four years of age. It deals with *Learning Autonomy or Shame (Will)*. Well-parented, the child emerges from this stage with self-confidence, elated with his or her newly found control. The early part of this stage can also include stormy **tantrums**, stubbornness, and negativism, depending on the child's temperament.

Preschool

The third stage occurs during the "play age," or the later **preschool** years from about three to entry into formal school. The developing child goes through *Learning Initiative or Guilt (Purpose)*. The child learns to use imagination; to broaden skills through active **play** and fantasy; to cooperate with others; and to lead as well as to follow. If unsuccessful, the child becomes fearful, is unable to join groups, and harbors guilty feelings. The child depends excessively on adults and is restricted both in the development of play skills and in imagination.

School age

The fourth stage, *Learning Industry or Inferiority (Competence)*, occurs during school age, up to and possibly including junior high school. The child learns to master more formal skills:

- relating with peers according to rules
- progressing from free play to play that is structured by rules and requires teamwork (team sports)
- learning basic intellectual skills (reading, arithmetic)

At this stage, the need for self-discipline increases every year. The child who, because of his or her successful passage through earlier stages, is trusting, autonomous, and full of initiative, will quickly learn to be industrious. However, the mistrusting child will doubt the future and will feel inferior.

Adolescence

The fifth stage, *Learning Identity or Identity Diffusion (Fidelity)*, occurs during adolescence from age 13 or 14. Maturity starts developing during this time; the

young person acquires self-certainty as opposed to self-doubt and experiments with different constructive roles rather than adopting a negative identity, such as delinquency. The well-adjusted adolescent actually looks forward to achievement, and, in later adolescence, clear sexual identity is established. The adolescent seeks leadership (someone to inspire him or her), and gradually develops a set of ideals to live by.

The Child Development Institute (CDI) rightfully points out that very little knowledge is available on the type of specific environment that will result, for example, in traits of trust being more developed in a person's personality. Helping the child through the various stages of emotional and personality development is a complex and difficult task. Searching for the best ways of accomplishing this task accounts for most of the research carried out in the field of child development today.

Renowned psychologist Carl Rogers emphasized how childhood experiences affect personality development. Many psychologists believe that there are certain critical periods in personality development—periods when the child will be more sensitive to certain environmental factors. Most experts believe that a child's experiences in the **family** are important for his or her personality development, although not exactly as described by Erikson's stages, but in good agreement with the importance of how a child's needs should to be met in the family environment. For example, children who are toilet trained too early or have their **toilet training** carried out too strictly may become rebellious. Another example is shown by children who learn appropriate behavior to their sex lives when there is a good relationship with their same-sex parent.

Another environmental factor of importance is culture. Researchers comparing cultural groups for specific personality types have found some important differences. For example, Northern European countries and the United States have individualistic cultures that put more emphasis on individual needs and accomplishments. In contrast, Asian, African, Central American, and South American countries are characterized more by community-centered cultures that focus on belonging to a larger group, such as a family, or nation. In these cultures, cooperation is considered a more important value than competitiveness, which will necessarily affect personality development.

Common problems

Infants who are just a few weeks old display differences between each other in how active they are, how responsive they are to change, and how irritable they are. Some infants cry constantly while others seem happy and stay fairly quiet. Child development research conducted by the CDI has identified nine temperamental traits that may contribute to a child's personality development being challenging or difficult:

- activity level (how active the child is generally)
- distractibility (degree of concentration and paying attention when the child is not particularly interested)
- intensity (how loud the child is)
- regularity (the predictability of biological functions like appetite and sleep)
- sensory threshold (how sensitive the child is to physical stimuli: touch, taste, smell, sound, light)
- approach/withdrawal (characteristic responses of a child to a new situation or to strangers)
- adaptability (how easily the child adapts to transitions and changes such as switching to a new activity)
- persistence (stubbornness, inability to give up)
- mood (tendency to react to the world primarily in a positive or negative way)

Temperamental traits are enduring personality characteristics that are neither "good" nor "bad." Early on, parents can work with the child's temperamental traits rather than oppose them. Later, as the child grows up, parents can help the child to adapt to his or her own world in spite of inborn temperament.

Parental concerns

Most children experience healthy personality development. However, some parents worry as to whether their infant, child, or teenager has a personality disorder. Parents are usually the first to recognize that their child has a problem with emotions or behaviors that may point to a personality disorder.

Children with **personality disorders** have great difficulty dealing with other people. They tend to be inflexible, rigid, and unable to respond to the changes and normal stresses of life and find it very difficult to participate in social activities. When these characteristics are present in a child to an extreme, when they are persistent and when they interfere with healthy development, a diagnostic evaluation with a licensed physician or mental health professional is recommended.

When to call the doctor

Parents who suspect that their child has a personality disorder should seek professional help. It is a very

KEY TERMS

Behavior—A stereotyped motor response to an internal or external stimulus.

Character—An individual's set of emotional, cognitive, and behavioral patterns learned and accumulated over time.

Cognition—The act or process of knowing or perceiving.

Cognitive—The ability (or lack of) to think, learn, and memorize.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Identity—The condition of being the same with, or possessing, a character that is well described, asserted, or defined.

Maturity—A state of full development or completed growth.

Personality—The organized pattern of behaviors and attitudes that makes a human being distinctive. Personality is formed by the ongoing interaction of temperament, character, and environment.

Socialization—The process by which new members of a social group are integrated in the group.

Temperament—A person's natural disposition or inborn combination of mental and emotional traits.

important first step in knowing for sure whether there is a disorder, and if so, what treatment can best help the child. Child and adolescent psychiatrists are trained to help parents sort out whether their child's personality development is normal.

Personality disorders

Definition

Personality disorders (PD) are a group of psychiatric conditions characterized by experience and behavior patterns that cause serious problems with respect to any two of the following: thinking, mood, personal relations, and the control of impulses.

Description

Most personality disorders are associated with problems in personal development and character which peak during **adolescence** and are then defined as personality disorders. Children and adolescents with a personality disorder have great difficulty dealing with others. They tend to be inflexible, rigid, with inadequate response to the changes and demands of life. They have a narrow view of the world and find it hard to participate in social activities. There are many formally identified personality disorders, each with its own types of associated behaviors. Most PDs, however, fall into three distinct categories or clusters, namely: cluster A, which includes disorders characterized by odd or eccentric behavior; cluster B, which includes disorders marked by dramatic, emotional or erratic behavior; and cluster C, which includes disorders accompanied by anxious and fearful behavior. The most common disorders in each cluster are given below.

Cluster A disorders

These disorders include the following:

- Schizoid personality disorder. Schizoid personalities are introverted, withdrawn, solitary, emotionally cold, and distant. Often absorbed with their own thoughts and feelings, they **fear** closeness and intimacy with others. People suffering from schizoid personality tend to be more daydreamers than practical action takers, often living "in a world of their own."
- Paranoid personality disorder. Paranoid personalities interpret the actions of others as deliberately threatening or demeaning. People with paranoid personality disorder are untrusting, unforgiving, and often resort to angry or aggressive outbursts without justification because they see others as unfaithful, disloyal, or dishonest. Paranoid personalities are often jealous, guarded, secretive, and scheming, and may appear to be emotionally "cold" or excessively serious.
- Schizotypal personality disorder. Schizotypal personalities tend to have odd or eccentric manners of speaking or dressing. They often have strange, outlandish, or paranoid beliefs and thoughts. People with schizotypal personality disorder have difficulties **bonding** with others and experience extreme **anxiety** in social situations. They tend to react inappropriately or not react at all during a conversation, or they may talk to themselves. They also have delusions characterized by "magical thinking," for example, by saying that they can foretell the future or read other people's minds.

Cluster B disorders

Cluster B disorders include the following:

- **Antisocial personality disorder**. Antisocial personalities typically ignore the normal rules of social behavior. These individuals are impulsive, irresponsible, and callous. They often have a history of violent and irresponsible behavior, aggressive and even violent relationships. They have no respect for other people and feel no remorse about the effects of their behavior on others. Antisocial personalities are at high risk for substance abuse, since it helps them to relieve tension, irritability, and boredom.
- Borderline personality disorder. Borderline personalities are unstable in interpersonal relationships, beha-

vior, mood, and self-image. They are prone to sudden and extreme mood changes, stormy relationships, unpredictable and often self-destructive behavior. These personalities have great difficulty with their own sense of identity and often experience the world in extremes, viewing experiences and others as either "black" or "white." They often form intense personal attachments only to quickly dissolve them over a perceived offense. Fears of **abandonment** and rejection often lead to an excessive dependency on others. **Self-mutilation** or suicidal threats may be used to get attention or manipulate others. Impulsive actions, persistent feelings of boredom or emptiness, and intense anger outbursts are other traits of this disorder.

- Narcissistic personality disorder. Narcissistic personalities tend to have an exaggerated sense of self-importance, and are absorbed by fantasies of unlimited success. They also seek constant attention, and are oversensitive to failure, often complaining about multiple physical disorders. They also tend to be prone to extreme mood swings between self-admiration and insecurity, and tend to exploit interpersonal relationships.

Cluster C disorders

Cluster C disorders include the following:

- Avoidant personality disorder. Avoidant personalities are often fearful of rejection and unwilling to become involved with others. They are characterized by excessive social discomfort, **shyness**, fear of criticism, and avoidance of social activities that involve interpersonal contact. They are afraid of saying something considered foolish by others and are deeply hurt by any disapproval from others. They tend to have no close relationships outside the **family** circle and are upset at their inability to form meaningful relationships.
- **Dependent personality disorder**. As the name implies, dependent personalities exhibit a pattern of dependent and submissive behavior, relying on others to make decisions for them. They fear rejection, need constant reassurance and advice, and are oversensitive to criticism or disapproval. They feel uncomfortable and helpless if they are alone and can be devastated when a close relationship ends. Typically lacking in self-confidence, the dependent personality rarely initiates projects or does things independently.
- Compulsive personality disorder. Compulsive personalities are conscientious, reliable, dependable, orderly, and methodical, but with an inflexibility that often makes them incapable of adapting to changing circumstances. They have such high standards of achievement that they constantly strive for perfection. Never satisfied with their performance or with that of others, they take on more and more responsibilities. They also pay excessive attention to detail, which makes it very hard for them to make decisions and complete tasks. When their feelings are not under strict control, when events are unpredictable, or when they must rely on others, compulsive personalities often feel a sense of isolation and helplessness.

Demographics

In 2001 to 2002, fully 16.4 million Americans (7.9% of all adults) had obsessive-compulsive personality disorder; 9.2 million (4.4%) had paranoid personality disorder; 7.6 million (3.6%) had antisocial personality disorder; 6.5 million (3.1%) had schizoid personality disorder; 4.9 million (2.4%) had avoidant personality disorder; and 1.0 million (0.5%) had dependent personality disorder. According to the National Institutes of Health, nearly 31 million Americans meet criteria for at least one personality disorder. A 2004 survey showed that nearly 14.8 percent of adult Americans met diagnostic criteria for personality disorders as defined by the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders. The risk of having avoidant, dependent, and paranoid personality disorders is greater for females than males, whereas risk of having antisocial personality disorder is greater for males than females. There are no gender differences in the risk of having compulsive or schizoid personality disorders. In general, other risk factors contributing to the emergence of personality disorders include being Native American or African American; being a young adult; having a low socioeconomic status; and having any other status than married.

Causes and symptoms

The exact cause of personality disorders is unknown. However, evidence points to genetic and environmental factors such as a history of personality disorders in the family. Some experts believe that traumatic events occurring in early childhood exert a crucial influence upon behavior later in life. Others propose that people are genetically predisposed to personality disorders or that they have an underlying biological disturbance (anatomical, electrical, or neurochemical).

Symptoms vary widely depending on the specific type of PD, but according to the American Psychiatric Association, individuals with personality disorders have most of the following symptoms in common:

- self-centeredness that manifests itself through a "me-first," self-preoccupied attitude

- lack of individual accountability that results in a "victim mentality" and blaming others for their problems
- lack of empathy and caring
- manipulative and exploitative behavior
- unhappiness, suffering from depression, and other mood and anxiety disorders
- vulnerability to other mental disorders
- distorted or superficial understanding of self and others' perceptions that results in being unable to see how objectionable, unacceptable, and disagreeable their behavior is
- self-destructive behavior
- socially maladaptive, changing the "rules of the game," or otherwise influencing the external world to conform to their own needs

When to call the doctor

An appointment should be made with a healthcare provider or a mental health professional if a child has persistent symptoms of a personality disorder. Parents are often concerned about their child's emotional health or behavior, but they do not know where to start to get help. The mental health system can also be complicated and difficult for parents to understand. When worried about their child's behavior, parents can start by talking to the child's pediatrician or family physician about their concerns. Personality disorders require treatment and parents should try to find a mental health professional with advanced training and experience with children, adolescents, and families. Parents should always ask about the professional's training and experience. It is also very important to find a good match between child, family, and the mental health professional.

Diagnosis

The character of a person is shown through his or her personality, by the way the person thinks, feels, and behaves. When the behavior is inflexible, maladaptive, and antisocial, then that individual is diagnosed with a personality disorder. Personality disorders are diagnosed following a psychological evaluation that records the history and severity of the symptoms. A personality disorder must fulfill several criteria. A deeply ingrained, inflexible pattern of relating, perceiving, and thinking that is serious enough to cause distress or impaired functioning defines a personality disorder. Personality disorders are usually recognizable by adolescence or earlier, continue throughout adulthood, and become less obvious in middle age.

Treatment

There are many types of help available for the different personality disorders. Treatment may include individual, group, or family psychotherapy. Medications, prescribed by a patient's physician, may also be helpful in relieving some of the symptoms of personality disorders, such as problems with anxiety and delusions. Psychotherapy is a form of treatment designed to help children and families understand and resolve the problems due to PD and modify the inappropriate behavior. In some cases a combination of medication with psychotherapy may be more effective. PD psychotherapy focuses on helping patients see the unconscious conflicts that are causing their disorder. It also helps them become more flexible and is aimed at reducing the behavior patterns that interfere with everyday living. In psychotherapy, patients have the opportunity to learn to recognize the effects of their behavior on others. The different types of psychotherapies available to children and adolescents include the following:

- Cognitive behavior therapy (CBT). CBT is focused on improving a child's moods and behavior by examining confused or distorted patterns of thinking. With CBT, the child learns that thoughts cause feelings and moods that can influence behavior. For example, if a child has problematic behavior patterns, the therapist seeks to identify the underlying thinking that is causing them. The therapist then helps the child replace this thinking with thoughts that result in more appropriate feelings and behaviors.
- Dialectical behavior therapy (DBT). DBT is used to treat older adolescents with suicidal thoughts or who intentionally engage in self-destructive behavior or who have borderline personality disorder. DBT teaches how to take responsibility for one's problems and how to deal with conflict and negative feelings. DBT often involves a combination of group and individual sessions.
- **Family therapy**. This therapy approach is designed to help the family unit function in more positive and constructive ways by exploring patterns of communication and providing support and education. Family therapy sessions can include the child or adolescent along with parents and siblings.
- Group therapy (GT). GT uses group dynamics and peer interactions to increase understanding, communication, and improve social skills.
- **Play** therapy. This type of therapy is directed at helping younger children. It involves the use of **toys**, blocks, dolls, puppets, **drawings**, and games to help the child recognize, identify, and verbalize feelings. The psychotherapist observes how the child uses play

materials and identifies themes or patterns to understand the child's problems. Through a combination of talk and play the child has an opportunity to better understand conflicts, feelings, and behavior.

Alternative treatment

Alternative treatments are available for personality disorders and most are complementary to conventional psychotherapy. They include the following:

- Coloring therapy. CT uses the activity of coloring as a self-help medium. While a person colors (with felt tipped markers, colored pens, pencils, etc.) a state of consciousness similar to meditation occurs. The approach is based on how people speak to themselves on the "inside." During a coloring session, people are asked to listen to the thoughts going on in their minds so as to become aware of where their thoughts, feelings, and opinions come from.
- Creative arts therapies. These therapies include art therapy, dance/movement therapy, drama therapy, music therapy, poetry therapy, and psychodrama. They use arts and creative processes to promote health, communication, and expression; they encourage the integration of physical, emotional, cognitive, and social functioning while enhancing self-awareness and facilitating change.
- Neurolinguistic programming. NLP is a method of examining the way a person thinks and acts through language and using this knowledge to effect change.

Nutritional concerns

The notion that foods and nutrients influence brain function and behavior generated in the early 2000s widespread interest in the general public and in the scientific community. However, the evaluation data are still ambiguous when it comes to establishing a direct link between personality disorders and diet, aside from recommending the avoidance of alcoholic and stimulant beverages.

Prognosis

The PD outlook varies. Some personality disorders diminish during middle age without any treatment, while others persist throughout life despite treatment.

Prevention

The prevention of personality disorders is an area surrounded with pessimism and controversy. Many mental health specialists believe that these disorders are untreatable, that individuals with personality disorder have little capacity for change; therefore not surprisingly, they remain skeptical about prevention prospects. However, even though the innate **temperament** of a person cannot be modified, understanding the factors that influence the development of personality disorders (such as genetic risks and environmental factors) may help prevention. Accordingly, some mental health professionals advocate primary prevention steps, which should include education of parents and primary healthcare workers, as well as early psychotherapy and protection of traumatized children, which can be carried out by child developing services. Some evidence suggests that traditional doctor-patient relationships are of much less value than programs which enable parents to see their own role as crucial and their own actions as able to bring changes for the better in their child's behavior. High quality parenting plays a critical role in child development and, thus, in the prevention of personality disorders.

Parental concerns

Understanding personality disorders can be challenging for parents as well as for children. During the last third of the twentieth century, great advances were made in the areas of diagnosis and treatment of personality disorders. Parents can help children understand that these are real illnesses that can be treated. In order for parents to talk with a child about a personality disorder, they must be knowledgeable of the subject. Parents may have to do some homework to become better informed. They should have a basic understanding and answers to questions such as what are personality disorders, who gets them, what causes them, how are diagnoses made, and what treatments are available. When explaining to a child about how personality disorders affect a person, it may be helpful to explain that feelings of anxiety, worry, and irritability are common for most people. However, when these feelings get very intense, last for a long period of time, and begin to interfere with school and relationships, it may be a sign of a personality disorder that can, however, be treated.

A child's personality disorder often causes disruption to both the parents' and the child's world. Parents may have difficulty being objective. They may blame themselves or worry that others such as teachers or family members will blame them. Recognizing these feelings and seeking the help of professional care providers and support groups is the best way to cope with this issue.

Medication can also be an effective part of the treatment for several personality disorders in childhood and adolescence. A doctor's recommendation to use

KEY TERMS

Anxiety—Worry or tension in response to real or imagined stress, danger, or dreaded situations. Physical reactions, such as fast pulse, sweating, trembling, fatigue, and weakness, may accompany anxiety.

Caring—The demonstration of an awareness of and a concern for the good of others.

Character—An individual's set of emotional, cognitive, and behavioral patterns learned and accumulated over time.

Delusion—A belief that is resistant to reason or contrary to actual fact. Common delusions include delusions of persecution, delusions about one's importance (sometimes called delusions of grandeur), or delusions of being controlled by others.

Eccentric—Deviating from the center; conduct and behavior departing from accepted norms and conventions.

Empathy—A quality of the client-centered therapist, characterized by the therapist s conveying appreciation and understanding of the client's point of view.

Erratic—Having no fixed course; behavior that deviates from common and accepted opinions.

Introversion—A personal preference for solitary, non-social activities and settings.

Maladaptive—Unsuitable or counterproductive; for example, maladaptive behavior is behavior that is inappropriate to a given situation.

Personality—The organized pattern of behaviors and attitudes that makes a human being distinctive. Personality is formed by the ongoing interaction of temperament, character, and environment.

Substance abuse—Maladaptive pattern of drug or alcohol use that may lead to social, occupational, psychological, or physical problems.

Temperament— A person's natural disposition or inborn combination of mental and emotional traits.

medication often raises many concerns and questions in both the parents and the child. The physician who recommends medication should be experienced in treating psychiatric illnesses in children and adolescents. He or she should fully explain the reasons for medication use, what benefits the medication should provide, as well as the possible negative side-effects or dangers and other treatment alternatives.

Pervasive developmental disorders

Definition

Pervasive developmental disorders are a group of neurological disorders that include autistic disorder (**autism**), Asperger's syndrome, childhood disintegrative disorder, Rett's syndrome, and pervasive developmental disorder not otherwise specified (PDDNOS). These disorders are characterized by delayed development in functional, socialization, and **communication skills**.

Description

The term pervasive developmental disorders was first used in the 1980s to describe a class of neurological disorders that involved impaired social and communication skills and repetitive behaviors.

Due to difficulties in accurately describing these disorders using the term pervasive developmental disorders, some neurological and psychiatric specialists have proposed new terminology to describe this class of disorders, including autistic spectrum disorders and multi-system neurological disorders.

Asperger's syndrome

Asperger's syndrome is characterized by difficulties with social relationships and skills and with poor coordination and restricted range of interests. Children with Asperger's syndrome generally have a normal to above average **intelligence** level and adequate knowledge of vocabulary and grammar but poor concentration and ability to understand language subtleties, such as humor. Asperger's syndrome is often incorrectly referred to as "high-functioning autism."

Autistic disorder

Autistic disorder, also referred to as autism, is characterized by moderate to severe communication, socialization, and behavioral problems, and in some children, **mental retardation**.

Childhood disintegrative disorder

Childhood disintegrative disorder is extremely rare, relative to the other pervasive developmental disorders. Children with this disorder develop normally until at least two years of age, after which an obvious regression in multiple functional skills occurs, including bladder and bowel control, ability to move, and language skills.

Pervasive developmental disorder not otherwise specified (PDDNOS)

Children are diagnosed with PDDNOS if their symptoms do not fit any of the other four types and/or they do not have the degree of impairment of the other four types. PDDNOS involves developmental impairments, such as communication and social skills, and repetitive behaviors that cannot be attributed to a specific developmental disorder or personality disorder. Usually, children with PDDNOS do not exhibit symptoms until age three or four.

Rett's syndrome

Rett's syndrome occurs primarily in female children and is characterized by normal development for the first six to 18 months, followed by a noticeable change in behavior and loss of some abilities, especially motor skills. As the child ages, significant loss of speech, hand movement, and reasoning develops. Children with Rett's syndrome usually repeat certain movements and gestures, in particular, hand wringing or hand washing. Rett's syndrome is the rarest of the pervasive developmental disorders.

Demographics

About one in 1,000 children born in the United States is diagnosed with autistic disorder, and it is four to five times more common in boys. Rett's syndrome has been diagnosed primarily in girls. Although autism is the most well-known of these disorders, PDDNOS is at least twice as common in children.

Causes and symptoms

As of 2004, the causes of these disorders were unknown. While genetics is believed to play a primary role, some children in families with a history of pervasive developmental disorders do not have a disorder. Medical researchers believe that genetic susceptibility plus additional factors contribute to the development of one of these disorders. Factors under investigation as a cause of these disorders include immune system problems, **allergies**, drugs, environmental pollution, and infections. Autopsy studies of individuals with pervasive developmental disorders have shown that brain cell structure is different, particularly in the brain stem area. In addition, because many individuals with pervasive developmental disorders are also affected by seizures, "electrical miswiring" of the brain may also contribute to these disorders. Researchers have used **magnetic resonance imaging** (MRI) and positron emission tomography (PET) to find

subtle differences in the brain structure and function of children with these disorders.

Symptoms of pervasive developmental disorders may be visible as early as infancy; however, the typical age of onset is age three. Although each of the five types has some distinctive symptoms, in general, early symptoms of a pervasive developmental disorder include the following:

- impaired language skills
- difficulties relating to people, objects, or activities
- unusual play
- repetitive body movements or behavior patterns
- difficulties handling changes in routine or surroundings
- unusual responses to sensory stimuli, like loud noises and lights

When to call the doctor

Parents should see a physician as soon as they notice developmental problems or delays in their infant or child.

Diagnosis

Pervasive developmental disorders are diagnosed using the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), which provides criteria for physicians to diagnose the specific type. Diagnosis of a pervasive developmental disorder is difficult because there is no specific medical test, like a blood test or imaging test that can confirm the diagnosis. Some physicians may hesitate to diagnose very young children with a specific type of pervasive developmental disorder.
