INTRODUCTION

Invention of the light microscope by Janssens in 1590 was the first milestone in the microscopic world. Janssens' microscope magnified objects up to 20–30 times their original size. By the beginning of the twentieth century, objects could be magnified only up to 1000 times with a resolution of 0.2 μm . In the early 1930s, the limitations of light microscopes and the scientific desire to see intracellular structural details, such as mitochondria and nuclei led to the development of electron microscopes. The electron microscope took advantage of the much shorter wavelength of the electron compared to that of visible light. With the electron microscope, another 1000-fold increase in magnification was accomplished with a concomitant increase in resolution, allowing visualization of viruses, deoxyribonucleic acid (DNA), and smaller objects, such as molecules and atoms. The transmission electron microscope (TEM) was the first type of electron microscope, and was developed by Ruska and Knoll in Germany in 1931. Electron microscopy is based on a fundamental physics concept stated in the de Broglie theory (1924). This concept is that moving electrons have the properties of waves. The second major advancement in electron microscopy was made by Busch, who demonstrated in 1926 that electrostatic or magnetic fields could be used as a lens to focus an electron beam. In 1939, Siemens Corp. began commercial production of a microscope developed by Von Borries and Ruska in Germany. Hiller, Vance and others constructed the first TEM in North America in 1941. This instrument had a resolution of 2.5 nm.

About the same time that the first TEM was nearing completion in the 1930s, a prototype of the scanning electron microscope (SEM) was constructed by Knoll and Von Ardenne in Germany. However, the resolution of this microscope was no better than that of the light microscope. Following several improvements made by RCA in the United States, as well as Cambridge University in England, a commercial SEM became available in 1963. A later version of the SEM made by the Cambridge Instrument Co. had a resolving power of $\sim 20\text{--}50\text{ nm}$ and a useful magnification of $75,000\times$. Recent models of the SEM have a resolving power of 3.0 nm and magnifications up to $300,000\times$.

Although the design of TEM and SEM is similar in many ways, their applications are very different. The TEM is patterned after as light microscope, except that electrons instead of light pass through the object. The electrons are then focused by two or more electron lenses to form a greatly magnified image onto photographic film or a charge coupled device (CCD) camera. The image produced by TEM is two-dimensional (2D) and the brightness of a particular

region of the image is proportional to the number of electrons that are transmitted through the specimen at that position on the image. The SEM produces a three-dimensional (3D) image by scanning the surface of a specimen with a 2–3 nm spot of electrons to generate secondary electrons from the specimen that are then detected by a sensor. The resolution of an SEM is limited by two quite different sets of circumstances. One of these is concerned with the physics of electron optics, while the other depends on the penetration of electrons into the object being imaged.

A third type of electron microscope, the scanning transmission electron microscope (STEM) has features of both the transmission and scanning electron microscopes. This microscope is an analytical tool that determines the presence and distribution of the atomic elements in the specimen. Recently, two groups of researchers have accomplished a subangstrom resolution (0.06 nm) for STEM using an aberration corrector. They have reported that columns of atoms in a silicone crystal that are 0.078 nm apart can be distinguished at this resolution (1). The image of Si shown in Fig. 1 has been recorded in a high angle annular dark field (HAADF) mode, and the pairs of atomic columns are seen directly resolved. The HAADF detector collects electrons scattered by the sample to angles greater than the detector inner radius. Such high angle scattering is largely incoherent thermal diffuse scattering, which means that the resolution observed in the image is determined by the intensity distribution of the illuminating probe. With this advantage over conventional coherent high resolution transmission electron microscopy (HRTEM), HAADF-STEM has enabled imaging not only of individual atomic columns in crystals, but single dopant atoms on their surface and within their interior.

In 1982, another type of electron microscope, the scanning tunneling microscope (STM) was developed by two scientists, Rohrer and Binnig, for studying surface structure. This invention was quickly followed by the development of a family of related techniques classified as scanning probe microscopy (SPM). These techniques are based upon moving a probe (typically called a tip in STM, which is literally a sharp metallic object) just above a specimen's surface while monitoring some interaction

Figure 1. Image of a silicone crystal observed in the [112] orientation recorded with an aberration corrected STEM. (From Ref. 1). Reproduced by courtesy of American Association for the Advancement of Science.)

between the probe and the surface. Atomic force microscopy (AFM) is another important technique of this kind but is not categorized as electron microscopy. Binnig and Rohrer were awarded one-half of the 1986 Nobel Prize in physics for invention of the STM, while Ernst Ruska was awarded the other one-half of that same Nobel Prize for his 1931 invention of the electron microscope. In STM, electrons are speeded up in a vacuum until their wavelength is extremely short, only one hundred-thousandth that of white light. Beams of these fast-moving electrons are focused on a cell sample and are absorbed or scattered by the cell's parts so as to form an image on an electron-sensitive photographic plate. The STM is widely used in both industrial and academic research to obtain atomic scale images of metal surfaces. It provides a 3D profile of the surface, which is useful in characterizing surface roughness and determining the size and conformation of surface molecules. (2) Invention of electron microscopy had an enormous impact in the field of biology, specifically in cell and tissue analysis. Almost 15 years after the invention of the first electron microscope by Ruska, many efforts were made to apply this technique to biological problems. Using the electron microscope, cell organelles and cell inclusions were discovered or resolved in finer details. Electron microscopy, specifically TEM, is now among the most important tools in cell biology and diagnostic pathology.

The latest advancement in electron microscopy is 3D reconstruction of cellular components at a resolution that is on the order of magnitude of atomic structures defined by X-ray crystallography. The method for reconstruction of 3D images of single, transparent objects recorded by TEM is called electron tomography (ET). In order to generate 3D images of individual molecules, one needs to obtain as many tilt images as possible, covering the widest possible angular range. The representative images of particles obtained from different orientations is then analyzed and combined by a software program to reconstruct the molecule in 3D. With improvements in instrumentation, data collection methods and techniques for computation, ET may become a preferred method for imaging isolated organelles and small cells. So far, the electron tomography method covers the resolution range of 2.5–5.0 nm. Data obtained via electron tomography furnish a rich source of quantitative information about the structural composition and organization of cellular components. It offers the opportunity to obtain 3D information on structural cellular arrangements with a significantly higher resolution than that provided by any other method currently available (e.g., confocal laser microscopy) (3).

THEORY OF ELECTRON MICROSCOPY

According to electromagnetic theory, a light source initiates a vibrational motion that transmits energy in the direction of propagation. The wave motion of light is analogous to that produced by a stone thrown into a pool of water. When the waves generated from throwing a stone strike an object that has an opening or aperture, another series of waves is generated from the edge of the object. The result is a new source of waves that emerges with the

Figure 2. Diffraction of light waves.

original waves. This bending or spreading phenomenon is known as diffraction. Diffracted waves interfere with the initial waves, and the result is an image of the edge of the object. The edge appears to have a series of bands or fringes called Fresnel fringes running parallel to the edge (Fig. 2). Thus, if a strong beam of light illuminates a pinhole in a screen and thus a pinhole serves as a point source and the light passing through is focused by an apertured "perfect" lens on a second screen, the image obtained is not a pinpoint of light, but rather a bright central disk surrounded by a diffuse ring of light. Even if monochromatic light was used to illuminate the point source and was to pass through a perfect lens, the image will not be a sharp one, but rather a diffuse disk composed of concentric rings. This type of image is known as an Airy disk after Sir George Airy, who first described this pattern during the nineteenth century (Fig. 3) (4). To determine resolving power (RP), it is important to know the radius of the Airy disk. The radius of the Airy disk as measured to the first dark ring (r) is expressed by following equation:

$$r = \frac{0.612 \lambda}{n(\sin \alpha)} \quad (1)$$

In Eq. 1, λ = wavelength of illumination; n = refractive index of the medium between the point source and the lens, relative to free space; α = half the angle of the cone of light from the specimen plane accepted by the front lens of objective

Figure 3. Airy disks generated by viewing three pinholes in a light microscope. Magnification of micrograph is 1000 \times . (From Ref. 4. Reproduced by courtesy of Jones and Bartlett Publishers.)

The above equation can be shown in another form as:

$$d = \frac{0.612\lambda}{NA} \quad (2)$$

where NA (numerical aperture) = $n \sin \alpha$ and represents the light gathering power of the lens aperture.

From the above equation, RP is defined as the minimum distance that two objects can be placed apart and still be seen as separate entities. Consequently, the shorter the distance, the better (or higher) is the RP of the system. For example, consider a light microscope using ultraviolet (UV) light, which lies beyond the lower end of the visible spectrum (400 nm). Further specifications of this system include a glass slide with standard immersion oil (refractive index, $n = 1.5$), and $\sin \alpha = 0.87$ (sine of a 64° angle, representing one-half of the 128° acceptance angle of a glass lens). The theoretical resolution that can be attained by this system is $\sim 0.2 \mu\text{m}$. In other words, two points in the specimen that are not separated by at least this distance will not be seen as two distinct points, but will be observed as a single blurred image. Since the values of $\sin \alpha$ and n cannot be significantly increased beyond the stated values, the RP can most effectively be improved by reducing wavelength.

Electron Beams And Resolution

The concept that moving electrons might be used as an illumination source was suggested by a tenet of the de Broglie theory, that moving electrons have wave properties. The wavelength of this particle-associated radiation is given by following equation:

$$\lambda = \frac{h}{mv} \quad (3)$$

where m is the mass of the particle, v the velocity of particle, and h is Planck's constant ($6.626 \times 10^{-34} \text{J}\cdot\text{s}$). For an electron accelerated by a potential of 60,000 V (60 kV), the wavelength of the electron beam would be $\sim 0.005 \text{ nm}$, which is 100,000 times shorter than that for green light. By using Eq. 1, a TEM with perfect lenses would therefore in theory be able to provide a resolution of 0.0025 nm. In practice, the actual resolution of a modern high resolution transmission electron microscope is closer to 0.2 nm. The reason we are not able to achieve the nearly 100-fold better resolution of 0.002 nm is due to extremely narrow aperture angles (~ 1000 times smaller than that of the light microscope) needed by the electron microscope lenses to overcome a major resolution limiting phenomenon called spherical aberration. In addition, diffraction, chromatic aberration and astigmatism all contribute to decreased resolution in TEM, and need to be corrected to achieve higher resolution. (5)

Magnification

The maximum magnification of any microscope is simply the ratio of the microscope's resolution to the resolution of the unaided human eye. The resolution of the eye viewing an object at 25 cm is generally taken to be 0.25 mm. Since the resolution of a light microscope is $\sim 0.25 \mu\text{m}$, maximum useful light magnification is $\sim 1000\times$, obtainable from an

objective lens of $100\times$ followed by an eyepiece of $10\times$. The magnification of TEM would be $\sim 0.25 \text{ mm}/0.25 \text{ nm}$. This is a $10^6\times$ magnification, and corresponds to a 1000-fold increase in resolution compared to a light microscope. An objective lens of $100\times$ is followed by an "intermediate" lens of $25\times$, and the final image is projected by a projector lens of $100\times$. Further magnification for critical focusing is obtained by viewing the image on the fluorescent screen with a long working distance binocular microscope of $10\times$. The final image is photographed at $250,000\times$. The processed negative is then enlarged a further $4\times$ in a photographic enlarger. This result in a final prints (the electron micrograph) at the desired magnification of $10^6\times 6$.

Electromagnetic Lenses

An electromagnetic lens is generated by a coil of wire with a direct current (dc) that passes through the coil. This electromagnetic coil is called a solenoid. It forms an axially and radially symmetric magnetic field that converges to a point. A divergent cone of electrons enters from a point source, and thus forms a real image on the lens axis. An advantage of electromagnetic lenses is that the focal length can be made infinitely variable by varying the coil current. Therefore, both magnification and image focus can be adjusted by controlling the lens current (Fig. 4) (7).

Lens Aberrations

Electron lenses are affected by all the aberrations of optical lenses, such as spherical aberration, chromatic aberration, astigmatism, and distortion. Spherical aberration results from the geometry of both glass and electromagnetic lenses such that rays passing through the periphery of the lens are refracted more than rays passing along the axis. Spherical aberration may be reduced by using an aperture to eliminate some of the peripheral rays. Although this aperture is attractive for reducing spherical aberration, it decreases the aperture angle and thereby prevents the electron microscope from achieving the theoretical resolution predicted by Eq. 1.

Chromatic aberration results when electromagnetic radiations of different energies converge at different focal

Figure 4. Single electron passing through electromagnetic lens. The electron is focused by the magnetic field to follow a trajectory that will converge at a defined focal point after it emerges from the lens.

planes. Chromatic aberration results in the enlargement of a focal point with a consequential loss of resolution. It can be corrected by using a monochromatic source of electromagnetic radiation. This entails stabilizing the accelerating voltage to generate the electrons with same levels of energy, and having a good vacuum to minimize the energy loss of the electrons during their passage through the transmission specimen. This effect can also be reduced by decreasing the aperture of the objective lens. (6)

Astigmatism is caused by radial asymmetry in a lens, giving rise to a focal length in one plane that is different from that in another plane. The fabrication and maintenance of a lens that has a perfectly symmetric lens field is not feasible in practice. Thus, it is necessary to correct astigmatism by applying a radial symmetry compensator device called a stigmator. This consists of an adjustable electric or magnetic field that can be applied across the lens in any chosen direction, thus compensating for astigmatism. Image distortion, due to magnification changing across the field from the value at the center, may be positive (called barrel distortion) or negative (called pincushion distortion). These effects can be compensated by operating two lenses in series, arranging for barrel distortion in one to be compensated by pincushion distortion in the other. The lens system in modern electron microscopes is designed to automatically counterbalance the various types of distortions throughout a wide magnification range. (4)

DESIGN OF THE TRANSMISSION ELECTRELECTRON MICROSCOPE

Both the light and electron microscopes are similar so far as the arrangement and function of their components are concerned. Thus, both microscopes, when used for photographic purposes, can be conveniently divided into the following component systems.

Illuminating System

This system serves to produce the required radiation and to direct it onto the specimen. It consists of source and condenser lenses.

Source Lens. The source of electrons, or cathode, is a hairpin of fine tungsten wire about 2 mm long, maintained at ~ 2500 K by ~ 2 W of alternating current (ac) or dc power. Electrons boil off the white-hot tungsten surface, and are shaped into a conical beam by an electrode system called the gun. Two further electrodes, the shield and the anode, combine to form an electrostatic collimating lens and accelerator. A suitable accelerating voltage (20–100 kV) is chosen for the specimen under examination, and is applied to the cathode as a negative potential so that the anode may remain at earth potential. The cathode and shield are therefore carried on an insulator. The filament-shield voltage (cathode bias) is made variable to adjust the total current drawn from the filament, which in turn varies the brightness of the final image (4).

The energy of the electrons in the TEM determines the relative degree of penetration of electrons into a specific sample, or alternatively, influences the thickness of mate-

rial from which useful information may be obtained. Thus, a high energy TEM (400 kV) not only provides the highest resolution but also allows for the observation of relatively thick samples (e.g., $\sim 0.2 \mu\text{m}$) when compared with the more conventional 100 kV or 200 kV instruments. Because of the high spatial resolution obtained, TEMs are often employed to determine the detailed crystallography of fine-grained, or rare, materials (6,8).

Condenser Lens. The condenser lens regulates the convergence (and thus the intensity) of the illuminating beam on the specimen. The divergent electron beam emerging from the anode aperture can, in simple instruments, be used to illuminate the specimen directly. However, sufficient image brightness for high magnification is difficult to obtain. As in the light microscope, a condenser system is almost invariably interposed between the gun and specimen to concentrate the beam on the region of the specimen under examination. A single condenser lens suffices for electronoptical work up to $50,000\times$. However, for high resolution work a double condenser system is always used, which will concentrate the beam into an area as small as 1μ diameter.

Specimen Manipulation System

The pierced metal grid carrying the specimen proper is clamped at its periphery to a suitable holder designed to conduct heat rapidly away. The specimen temperature in a TEM may rise to 200°C . The holder, including its attached specimen grid is introduced into the evacuated specimen chamber through an airlock by means of an insertion tool. This tool is then generally withdrawn after the holder has been placed on the translation stage. The holder is then free to move with the stage, which is driven from outside the column through airlocks, by means of levers and micrometer screws. Two mutually perpendicular stage movements, each of about ± 1 mm, allow any part of the grid area to be brought to the microscope axis and viewed at the highest magnification. Most instruments provide a scan magnification so that the whole grid area may be viewed at $\sim 100\times$. Suitable specimen areas are then chosen, and centered for study at higher magnifications.

Imaging System

This part of the microscope includes the objective, intermediate, and projector lenses. It is involved in the generation of the image and the magnification and projection of the final image onto a viewing screen or camera system. Electrons transmitted by the specimen enter the objective lens. Those passing through the physical aperture are imaged at $\sim 100\times$ in the intermediate lens object plane, 10–20 cm below the specimen. The position of this primary image plane is controlled by the objective lens current (focus control). A second image, which may be magnified or diminished, is formed by the intermediate lens, the current through which controls overall magnification (magnification control). This secondary image, formed in the objective plane of the projector lens, is then further magnified, and the overall magnification is determined by the position of the fluorescent screen or film.

Image Recording System

The final image is projected onto a viewing screen coated with a phosphorescent zinc-activated cadmium sulfide powder. This powder is attached to the screen with a binder, such as cellulose nitrate. Most electron microscopes provide for an inclination of the viewing screen so that the image may be conveniently examined either with the unaided eye or through a stereomicroscope (the binoculars). Although the stereomicroscope image may appear to be rough due to the 100 μm sized phosphorescent particles that make up the screen, it is necessary to view a magnified image in order to focus accurately. Some microscopes may provide a second, smaller screen that is brought into position for focusing. In this case, the main screen remains horizontal, except during exposure of the film. All viewing screens will have areas marked to indicate where to position the image so that it will be properly situated on the film. Preevacuated films are placed into an air lock (*camera chamber*) under the viewing screen and the chamber evacuated to high vacuum. The chamber is then opened to the column to permit exposure of the film. In modern electron microscopes (Fig. 5), exposure is controlled by an electrically operated shutter placed below the projector lens. As one begins to raise the viewing screen, the shutter blocks the beam until the screen is in the appropriate position for exposure. The shutter is then opened for the proper interval, after which the beam is again blocked until the screen is repositioned.

DESIGN OF THE SCANNING ELECTRON MICROSCOPE

The SEM is made up of two basic systems, and the specimen is at their boundary. The first system is the electron optical column that provides the beam of illumination that is directed to the specimen. The second system consists of the electron collection, signal amplification, and image display units, which converts the electrons emitted from the specimen into a visible image of the specimen.

Electron Optical Column

The electron gun and electron lenses are present in the electron optical column of the SEM in an analogous fashion to their presence in the TEM.

1. **Electron Gun:** The electron source is most commonly the hairpin tungsten filament located in a triode electron gun. The electrons are emitted by the filament (also called the cathode), and accelerated by a field produced by the anode. The anode is usually at a positive potential on the order of 15 kV with respect to the cathode. A third electrode, the shield, lies between the anode and cathode and is negative with respect to the cathode. After leaving the bias shield and forming an initial focused spot of electrons of $\sim 50 \mu\text{m}$ in diameter, a series of two to three condenser lenses are used to successively demagnify this spot sometimes down to $\sim 2 \text{nm}$. These small spot sizes are essential for the resolutions required at high magnifications. A heated tungsten filament is the conventional electron source for most SEMs; other special sources are lanthanum hexaboride (LaB_6) and the field emission guns (FEG). Both of these latter sources produce bright beams of small diameter and have much longer lifetimes than heated tungsten filaments. Schottky emission has largely replaced earlier source technologies based on either tungsten and LaB_6 emission or cold-field emission in today's focused electron beam equipment including SEM, TEM, Auger systems, and semiconductor inspection tools. Schottky and cold-field emission are superior to thermionic sources in terms of source size, brightness and lifetime. Both are up to 1000 times smaller and up to 100 times brighter than thermionic emitters.
2. **Electron Lenses:** Most SEMs have three magnetic lenses in their column: the first, second, and final condenser lenses. The first condenser lens begins the demagnification of the $50 \mu\text{m}$ focused spot of electrons formed in the region of the electron gun. As the amount of current running through the first condenser lens is increased, the focal length of the lens becomes progressively shorter and the focused spot of electrons becomes smaller. In our earlier discussion of electron lenses, it was noted that focusing takes place by varying the focal length. This is accomplished by changing the intensity of the lens coil current, which in turn alters the intensity of the magnetic field that is generated by the lens. As the lens current increases, the lens strength increases

and the focal length decreases. A short focal length lens consequently causes such a wide divergence of the electrons leaving the lens that many electrons are not able to enter the next condenser lens. The overall effect of increasing the strength of first condenser lens is to decrease the spot size, but with a loss of electrons. An aperture is positioned in the lenses to decrease the spot size and reduce spherical aberration by excluding the more peripheral electrons. Each of the condenser lenses behaves in a similar manner and possesses apertures.

In designing the final condenser lens, several performance characteristics must be considered:

- (a) **Aberrations.** Since the intermediate images of the crossover produced by the condenser lenses have significantly larger diameters than the final spot size, the effect of aberrations on these lenses are relatively small. It is thus the effects of spherical and chromatic aberration as well as the astigmatism of the final condenser lens that are critical in the design and performance of the objective lens of SEM.
- (b) **Magnetic Field.** As a result of electron bombardment, secondary electrons in the SEM are emitted over a wide solid angle. These have energies of only few electron volts, yet they must be able to reach the detector to produce the necessary signal. As a result, the magnetic field at the specimen must be designed so that it will not restrict effective secondary electron collection.
- (c) **Focal Length.** The extent of lens aberrations is dependent upon the focal length. Thus, it is desirable to keep the latter as short as possible in order to help minimize the effects of aberrations.

The final lens usually has externally adjustable apertures. Normally, final apertures on the order of 50–70 μm are used to generate smaller, less electron dense spots for secondary electron generation and imaging. Larger apertures, for example, 200 μm , are used to generate larger spots with greater numbers of electrons. These large spots contain a great deal of energy and may damage fragile specimens. They are used primarily to generate X rays for elemental analysis rather than for imaging purposes.

Specimen Manipulation System

The specimen is normally secured to a metal stub and is grounded to prevent the build up of static high voltage charges when the beam electrons strike the specimen. In order to orient the specimen precisely, relative to the electron beam and electron detectors, all SEMs have controls for rotating and traversing the specimen in x , y , and z directions. It is also possible to tilt the specimen in order to enhance the collection of electrons by a particular detector. These movements have a large effect on magnification, contrast, resolution and depth of field. Some improvement can be made in imaging by reorientation of the specimen.

Interaction Of Electron Beam With Specimen

Three basic possibilities exist as to the nature of the beam-specimen interaction used to generate the image:

1. Some primary electrons, depending on the accelerating voltage, penetrate the solid to depths as much as 10 μm . The electrons scatter randomly throughout the specimen until their energy is dissipated by interaction with atoms of the specimen.
2. Some primary electrons collide with or pass close to the nucleus of an atom of the specimen such that there is a change in the electron's momentum. This results in electron scatter through a large angle and electron reflection from the specimen. Such elastically reflected primary electrons are known as backscattered electrons.
3. Some primary electrons interact with the host atoms so that as a result of collisions, a cascade of secondary electrons is formed along the penetration path. Secondary electrons have energy ranges of 0–50 eV and are the electrons most commonly used to generate the 3D image. The mean path length of secondary electrons in many materials is ~ 1 nm. Thus, although electrons are generated throughout the region excited by the incident beam, only those electrons that originate < 1 nm deep in the sample escape to be detected as secondary. The shallow depth of production of detected secondary electrons makes them very sensitive to topography.

In addition to producing backscattered and secondary electrons, specimen-beam interactions also produce photons, specimen currents, Auger electrons and X rays that are characteristic of the probed specimen. These emanations can be detected by X ray or electron spectroscopy for elemental analysis of the specimen surface. However, it is rarely used for biological specimens.

Signal Versus Noise

The signals generated as a result of the electron beam striking a specimen are used to convey different types of information about the specimen. In the usual SEM imaging mode, signals consist of the secondary electrons generated from the spot struck by the electron beam and noise consists of secondary electrons originating at locations away from where the beam struck the specimen. The image quality is eventually expressed by the signal-to-noise (S/N) ratio. In a poor quality image the signal to noise ratio is low. One may achieve a better image by either reducing the noise or raising the signal. Since it is more difficult to reduce the noise level, the signal is usually raised by increasing the electron emissions from the gun. Several methods to accomplish increased electron emissions include: altering the bias settings, decreasing the distance between the anode and the filament, decreasing the distance between the filament and the shield aperture, and using either a lanthanum hexaboride filament or a cold-field emissions gun. A second method to increase the signal is to use slower scan rates on the

specimen. Longer dwell times of the beam on the specimen will generate more secondary electrons from the spot where the beam strikes the specimen. This increase in current, however, carries with it an increased risk of damage to sensitive specimens (9).

Secondary Electron Detection

To collect the secondary electrons, a suitable electrode is held at a positive potential and serves to attract them and produce an emission current. The strength of this signal is proportional to the number of electrons striking the collector. This signal is used, after amplification; to modulate the intensity of the cathode-ray tube (CRT) beam as it moves across the tube face, synchronously with the path of the electron probe across the specimen surface.

Typically, the secondary electron collector is based on the original 1960 scintillator-photomultiplier design of Everhart and Thornley. In this system, the secondary electrons are accelerated towards the scintillator by a potential difference of a few hundred to a few thousands volts. Upon hitting the scintillator, each electron produces many photons that are guided by the light pipe to the photomultiplier. Each photoelectron triggers a release of two or more secondary electrons at the first electrode (dynode) and process cascades, yielding from 100,000 to 50 million additional electrons. Thus, the photomultiplier reconverts the light to an electron current and provides a high degree of amplification that can be controlled by variation of the voltage applied to the dynodes (8).

Image Recording System

The final magnified image in the SEM is formed on a CRT or monitor. Unlike TEM, in which the electrons interact directly with the photographic medium, SEM images are most often photographed directly from the monitor through the lens of either a 35 mm roll film camera or a larger 4 in. × 5 in. (10.6 cm × 12.7 cm) sheet film camera. The camera shutter remains open as the electron beam slowly scans across the specimen. A valuable addition to most SEMs is the automatic data display that permits the generation of informational data on the viewing and recording monitors. With this accessory, experiment numbers, dates, accelerating voltages and magnifications may be displayed.

DIAGNOSTIC ELECTRON MICROSCOPY

Electron microscopy excels as a diagnostic tool with respect to the detection and identification of both abnormal tissue anatomy and the pathogens responsible for the disease. The value of electron microscopy in difficult diagnostic situations has been demonstrated repeatedly, particularly when there is close coordination between the pathologist and the attending clinician. Ultrastructural study may be applied to a variety of substances including biological materials. By examination of specially prepared tissue sections, changes not perceived by light microscopy can be identified, leading to improved diagnostic interpretations. For example, in certain kidney diseases, such as nephrotic syndrome and Nil disease, the correct diagnosis can be made only by these means, and this in turn affects the

selection of therapy. Similarly, certain neoplasms can be identified definitively only through ultrastructural studies, with obvious implications for treatment and prognosis. Another area of growing importance is the identification of viral particles in biological material. In some instances, ultrastructural study is the only way to establish the presence of a viral infection, and in other instances a diagnosis may be made earlier than by serological methods. The costs of diagnostic electron microscopy are relatively small in light of the benefits to patient care. The following are examples highlighting the use of electron microscopy in the diagnosis of certain diseases.

Neoplasms

Many neoplasms appear undifferentiated by light microscopy, but most show differentiation along one cell line or another at the ultrastructural level. However, it is noteworthy that not all of the ultrastructural criteria for identifying the cell type may be present in every neoplasm. As expected, the more differentiated the neoplasm, the more likely will its cells contain a broad complement of diagnostic morphologic features. Usually, the ultrastructural findings do allow the pathologist to make a definitive diagnosis when interpreted in conjunction with the light microscopic picture, and in some cases with the histochemical and immunohistochemical results. The example that follows will highlight the use of diagnostic electron microscopy in the identification of carcinomas. Various types of carcinomas have a number of distinguishing features, but one common characteristic of all carcinomas is the presence of intracellular junctions, usually desmosomes and/or intermediate junctions. The presence of lumens, microvilli, tight junctions, junctional complexes, basal lamina, secretory granules, prominent Golgi apparatus, and moderately prominent rough endoplasmic reticulum are all suggestive of adenocarcinoma in the differential diagnosis of a neoplasm (10). Figure 6 shows a pancreatic carcinoma, which may arise from acinar cells, centroacinar cells, intercalated duct cells, interlobular duct cells, interlobular duct cells and main pancreatic duct cells. Adenocarcinomas arising from main and interlobular ducts (mucinous cystadenocarcinomas) have cells similar to those of bile ducts and intestinal epithelium; that is, the cytoplasm contains mucin granules, and the free surface has microvilli filled with thin filaments that anchor into the subjacent cytoplasm (11–13).

Infectious Diseases

Bacteria. Diagnostic criteria for bacterial rods and cocci are (1) the presence of an outer-cell wall, (2) the presence flagella or pili (fimbria) on the outer surface of the cell, (3) the presence of an inner-cell membrane, (4) a central nuclear region (nucleoid), without a limiting membrane, (5) dense cytoplasm composed mostly of ribosomes, and (6) a varying number of vesicles formed from the inner-cell membrane (mesosomes), storage vacuoles and endospores (14). Figure 7 shows the bacteria in Whipple disease. The rods are present both free and within macrophages.

Viruses. The distinct morphology of members of different viral families usually allows an agent to be assigned to

Figure 6. Ductal, mucinous cystadenocarcinoma (pancreas). In this field, the neoplastic cells form a cystic lumen (L) lined by innumerable microvilli. An intracytoplasmic lumen (IL), without junctional complexes, is present in one cell. Some of the cells lining the lumen have a rich collection of mucinous granules (M) in their apical cytoplasm. Lateral cell borders show a switch-backing pattern of interdigitation (arrows). (6800 \times) (From Ref. 10. Reproduced by courtesy of Springer-Verlag GmbH.)

a particular family. This morpho-diagnosis, combined with clinical information is often sufficient to permit a provisional diagnosis and to initiate treatment and containment protocols while waiting for other test results. Diagnostic criteria that apply to viruses in general are (1) the presence of intracellular and/or extracellular elliptical, stand-like, round or polygonal structures measuring 20–300 nm in diameter; and (2) the identification of viral morphology, consisting of a central, electron dense core (DNA-containing nucleoid) and an outer shell (capsid), which may have more than one layer (Fig. 8) (15).

Fungi. The electron microscopic diagnostic criteria for fungi include the identification of mononucleated oval yeast forms measuring 2–4 μm in diameter, with a thin cell wall and no true capsule. These can be located either extracellularly or intracellularly (16). A representative fungus, *Histoplasma capsulatum*, is shown in Fig. 9. The organisms have a clear halo between their visible cytoplasm and their thin cell wall.

Skeletal Muscle Diseases

The skeletal muscle responses to injury that are visible with the electron microscope can be categorized as follows: (1) alterations in the sarcolemma (e.g., discontinuities of

Figure 7. Whipple's disease. The lamina propria of the jejunal mucosa contained numerous Whipple's type macrophages [M= macrophage nucleus) and bacteria rods (B)]. Most of the intact bacilli are extracellular, whereas those in the macrophage are in various stages of degeneration, including the end-stage of serpiginous membrane (*). (16,500 \times) (From Ref. 10. Reproduced by courtesy of Springer-Verlag GmbH.)

the plasma membrane or the basement membrane); (2) alterations in myofilaments; (3) Z-band alterations (e.g., streaming and nemaline bodies); (4) nuclear changes (e.g., abnormal location of the nucleus within the muscle fiber and nuclear inclusions); (5) abnormalities of the sarcoplasmic reticulum and the T-system (e.g., tubular aggregates), (6) abnormal accumulations of metabolites (e.g., glycogen and lipids); (7) abnormal cytoplasmic structures (e.g., vacuoles, cytoplasmic bodies, concentric laminated bodies, fingerprint bodies, curvilinear bodies). In general, many of these ultrastructural abnormalities are not specific for a single disease. Electron microscopy can be a valuable adjunct to help the pathologist arrive at the proper interpretation of a muscle biopsy when taken together with all other available clinical, electrophysiologic, and histopathological data. In addition to the pathologic changes that might involve the muscle fibers themselves, many diseases of muscle also simultaneously affect adjoining connective tissue components, blood vessels and intramuscular nerves. It is therefore important to pay particular attention to these structures when examining muscle with the light and electron microscope (10). The light micrograph shown in Fig. 10 demonstrates centrally placed nuclei in the majority of the muscle fibers. The central nuclei often are surrounded by a clear area that is devoid of adenosine triphosphatase (ATPase) activity. Ultrastructural features of the paranuclear clear zone in Fig. 11 include (1) the

Figure 8. Herpes simplex encephalitis (cerebrum). Virions (V) have a central dense nucleoid and an outer three-layered capsid. (63,800×) (From Ref. 10. Reproduced by courtesy of Springer-Verlag GmbH.)

absence of myofilaments, (2) numerous mitochondria, (3) glycogen accumulation. In some patients, especially infants, the central clear zone may be more evident than the nuclei within that zone when examining the tissue in cross-section (10).

Peripheral Nerve Diseases

Wallerian Degeneration. Ultrastructural changes detected in peripheral nerve specimens include either the general pathologic responses of the peripheral nerve to either the injury or the specific disease entity that afflicts the patient. The general pathologic processes involving peripheral nerve can be divided into two broad categories: those that indicate a process primarily affecting the axon and those that indicate a process primarily affecting the myelin sheath. Examination of peripheral nerve biopsies by electron microscopy therefore must include evaluation of the axons, the interstitium, and the myelin and Schwann cells.

The sequence of structural changes following nerve injury that are collectively called Wallerian degeneration is shown in Fig. 12. Wallerian degeneration specifically refers to degeneration of the distal segments of a peripheral nerve after severance of the axons from their cell bodies (17). When the nerve injury is a contusion, the basement membrane of the Schwann cell is preserved, allowing regeneration within the endoneurial tube. In contrast, when the nerve injury is a transection, the endoneurial tube (composed of denervated Schwann cells and extracellular matrix) may not be appropriately aligned with the regenerating axons. Axonal regeneration is therefore less efficient after nerve degeneration that follows a transection injury compared to that following a crush injury (10,17).

PROSPECTS OF ELECTRON MICROSCOPY

In the 1980s, electron microscopy lost much of its former role in the life sciences due to the introduction of modern, highly effective molecular analytical techniques, such as immunohistochemistry, chip technology, and confocal laser scan microscopy. In recent years, however, substantial technical improvements were made in specimen preparation, instrumentation and software, allowing the

electron microscope to reemerge as a valuable tool for analyzing molecular complexes.

Electron microscopy as an imaging technique allows a direct view of biological objects, while some of the other available techniques are indirect and in some instances nonspecific. Using electron microscopy, all components of the object and their mutual relationships at the molecular level can be analyzed. This information provides insight toward an understanding of structure–function relations.

The possibility of 3D reconstruction of cellular components via electron microscopy, along with the ease and speed with which newer instruments can provide data, have given the way to what many in the field are referring as a revolution. Recent technological advancements

have made automated data acquisition possible, and have thus allowed a reduction of the total electron dose needed to image a specimen. Specimen preparation advances, such as embedding biological specimens in vitreous ice, have enabled studies of the macromolecular organization of cells. Whole prokaryotic and small eukaryotic cells can be directly grown and hydrated frozen on electron microscopy grids. Examination of the naturally preserved cells delivers images of the cellular structures in their functional environment. Such so-called tomograms contain all available information about the spatial relationships of macromolecular structures within the cell. However, due to their poor S/N and the generally highly crowded nature of the cytoplasm, the interpretation of

Figure 11. Muscle fiber with degenerated nucleus. Note absence of myofilaments and accumulation of glycogen in the paranuclear region to the right (15,000 \times). (From Ref. 10. Reproduced by courtesy of Springer-Verlag GmbH.)

these tomograms remains difficult. To get significant information about specific structures in the cell, the images have to be evaluated using advanced pattern recognition methods. Existing structural models of cellular constituents at lower resolutions can guide the systematic evaluation of the tomograms. The aim is to visualize the complete 3D organization of the cell at molecular resolution. Structural evaluation by single particle analysis, electron crystallography and electron tomography is slow compared to other structure determination technologies, in particular X-ray crystallography. Processing time for the electronic technique is typically in the range of several months per solved structure, depending on the resolution achieved. The same task can be accomplished in the range of hours or days for X-ray crystallography, once suitable crystals are available. Continued joint efforts between the research community and manufacturers to develop user-friendly, universal interfaces between electron crystallography, single-particle analysis and electron tomography would improve this situation, and further expand the usefulness of these electronic technologies.

INTRODUCTION

Fluorescence microscopy quantifies the distribution of fluorophores and their biochemical environment on the

micron length scale and allows *In vivo* measurement of biological structures and functions (1–3). Heimstädt developed one of the earliest fluorescence microscopes in 1911. Some of the first biochemical applications of this technique include the study of living cells by the protozoologist Provasnik in 1914.

Fluorescence microscopy is one of the most ubiquitous tools in biomedical laboratories. Fluorescence microscopy has three unique strengths. First, the fluorescence microscope has high biological specificity. Based on endogenous fluorophores or exogenous probes, fluorescence microscopy allows the association of a fluorescence signal with a specimen structural and biochemical state. While fluorescence microscopy has comparable resolution to white light microscopes, their range of applications in biomedicine is much broader.

Second fluorescence microscopy is highly sensitive in the imaging of cells and tissues. The high sensitivity of fluorescence microscopy originates from two factors. One factor is the significant separation between the fluorophores' excitation and emission spectra. This separation allows the fluorescence signal to be detected by efficiently rejecting the excitation radiation background using band-pass filters. The fluorescence microscope has the sensitivity to image even a single fluorophore. The other factor is the weak endogenous fluorescence background in typical biological systems. Since there is minimal background fluorescence, weak fluorescence signal from even a few fluorescent exogenous labels can be readily observed.

Third, fluorescence microscopy is a minimally invasive imaging technique. *In vivo* labeling and imaging procedures are well developed. While photodamage may still result from prolonged exposure of shorter excitation radiation, long-term observation of biological processes is possible. Today, a single neuron in the brain of a small animal can be imaged repeatedly over a period of months with no notable damage.

SPECTROSCOPIC PRINCIPLES OF FLUORESCENCE MICROSCOPY

Fluorescence Spectroscopy

An understanding of spectroscopic principles is essential to master fluorescence microscopy (4–6). Fluorescence is a photon emission process that occurs during molecular relaxation from electronic excited states. Historically, Brewster first witnessed the phenomenon of fluorescence in 1838 and Stokes coined the term fluorescence in 1852. These photonic processes involve transitions between electronic and vibrational states of polyatomic fluorescent molecules (fluorophores) by the absorption of either one or more photons. Electronic states are typically separated by energies on the order of $10,000\text{ cm}^{-1}$ and vibrational sublevels are separated by $\sim 10^2\text{--}10^3\text{ cm}^{-1}$. In a one-photon excitation process, photons with energies in the ultraviolet (UV) to the blue–green region of the spectrum are needed to trigger an electronic transition, whereas photons in the infrared (IR) spectral range are required for two-photon excitation. The molecules from the lowest vibrational level of the electronic ground state are excited to an accessible

vibrational level in an electronic excited state. The molecule is quickly relaxed to the lowest vibrational level of the excited electronic state after excitation on the time scale of femtoseconds to picoseconds via vibrational processes. The energy loss in the vibrational relaxation process is the origin of the Stokes shift where fluorescence photons have longer wavelengths than the excitation radiation. The coupling of the ground and excited – state both for the absorption and emission process is governed by the Franck–Condon principle, which states that the probability of transition is proportional to the overlap of the initial and final vibrational wave function. Since the vibrational level structures of the excited and ground states are similar, the fluorescence emission spectrum is a mirror image of the absorption spectrum, but shifted to lower wavelengths. The shift between the maxima of the absorption and emission spectra is referred to as the Stokes' shift. The residence time of a fluorophore in the excited electronic state before returning to the ground state is called the fluorescence lifetime. The fluorescence lifetime is typically on the order of nanoseconds. The Jablonski diagram represents fluorescence excitation and deexcitation processes (Fig. 1).

Fluorescence deexcitation processes can occur via radiative and nonradiative pathways. Radiative decay describes molecular deexcitation processes accompanied by photon emission. Molecules in the excited electronic states can also relax by nonradiative processes where excitation energy is not converted into photons, but are dissipated by thermal processes, such as vibrational relaxation and collisional quenching. Let Γ and k be the radiative and nonradiative decay rates, respectively, and N be the number of fluorophore in the excited state. The temporal evolution of the excited state can be described by

$$\frac{dN}{dt} = -(\Gamma + k)N \quad (1)$$

$$N = N_0 e^{-(\Gamma+k)t} = N_0 e^{-t/\tau} \quad (2)$$

Figure 1. A Jablonski diagram describing fluorescence (F) and phosphorescence (P) emission and excitation processes based on one-photon (1p) and two-photon (2p) absorption. The parameters S0, S1, and T1 are the electronic singlet ground state, singlet excited state, and triplet excited state, respectively. Here VL denotes vibrational levels, IC denotes internal conversion, and IS denotes intersystem crossing.

The fluorescence lifetime, τ , of the fluorophore is the combined rate of the radiative and nonradiative pathways:

$$\tau = \frac{1}{\Gamma + k} \quad (3)$$

One can define the intrinsic lifetime of the fluorophore in the absence of nonradiative decay processes as, τ_0 :

$$\tau_0 = \frac{1}{\Gamma} \quad (4)$$

The efficiency of the fluorophore can then be quantified by the fluorescence quantum yield, Q , which measures the fraction of excited fluorophore relaxing via the radiative pathway:

$$Q = \frac{\Gamma}{\Gamma + k} = \frac{\tau}{\tau_0} \quad (5)$$

Environmental Effect on Fluorescence

A number of factors contributes to the nonradiative decay pathways of the fluorophores and reduces fluorescence intensity. In general, the nonradiative decay processes can be classified as

$$k = k_{ic} + k_{ec} + k_{et} + k_{is} \quad (6)$$

where k_{ic} is the rate of internal conversion, k_{ec} is the rate of external conversion, k_{et} is the rate of energy transfer, and k_{is} is the rate of intersystem crossing.

Internal conversion describes the process where the electronic energy is converted to thermal energy via a vibrational process. The more interesting process is external conversion, where fluorophores lose electronic energy in collision process with other solutes. Several important solute molecules, such as oxygen, are efficient fluorescence quenchers. The external conversion process provides a convenient mean to measure the concentration of these molecules in the microenvironment of the fluorophore. The fluorophore is deexcited nonradiatively upon collision. The collisional quenching rate can be expressed as

$$k_{ec} = k_0[Q] \quad (7)$$

where $[Q]$ is the concentration of the quencher and k_0 is related to the diffusivity and the hydrodynamics radii of the reactants.

When collisional quenching is the dominant non-radiative process, equation 1 predicts that fluorescence lifetime decreases with quencher concentration.

$$\frac{\tau_0}{\tau} = (1 + k_0\tau_0[Q]) \quad (8)$$

Collision quenching also reduces the steady-state fluorescence intensity, F , relative to the fluorescence intensity in the absence of quencher, F_0 . The Stern–Volmer equation describes this effect:

$$\frac{F_0}{F} = 1 + k_0\tau_0[Q] \quad (9)$$

A related process is steady-state quenching, where fluorescence signal reduction is due to ground-state processes. A

fluorophore can be chemically bound to a quencher to form a dark complex, a product that does not fluoresce. In this case, steady-state fluorescence intensity also decreases with quencher concentration as

$$\frac{F_0}{F} = 1 + K_s[Q] \quad (10)$$

where K_s is the association constant of the quencher and the fluorophore. However, since steady-state quenching is a ground-state process that only reduces the fraction of fluorophores available for excitation, fluorescence lifetime is not affected.

Resonance energy-transfer rate, k_{et} , becomes significant when two fluorophores are in close proximity within ~ 5 – 10 nm as during molecular binding. The energy of an excited donor can be transferred to the accepted molecule via an induced dipole–induced dipole interaction. Let D represents the donor and A, the acceptor. Under illumination at the donor excitation wavelength, the number of excited donors and acceptors are N^D , N^A , respectively. Further, define the donor and acceptor deexcitation rates as k_D and k_A . The excited-state population dynamics of the donor and acceptor can be described as

$$\frac{dN^D}{dt} = -(k_D + k_{et})N^D \quad (11)$$

$$\frac{dN^A}{dt} = -k_A N^A + k_{et} N^D \quad (12)$$

Solving these equations provides the dynamics of donor and acceptor fluorescence:

$$N^D = N_0^D \exp[-(k_D + k_{et})t] \quad (13)$$

$$N^A = N_0^D \frac{k_{et}}{k_A - k_D - k_{et}} [\exp(-k_D t - k_{et} t) - \exp(-k_A t)] \quad (14)$$

The donor decay is a shortened single exponential, but the acceptor dynamics is more complex with two competing exponential processes.

The intersystem crossing rate, k_{is} , describes transitions between electronic excited states with wave functions of different symmetries. The normal ground state is a singlet state with an antisymmetric wave function. Excitation of the ground-state molecule via photon absorption results in the promotion of the molecule to an excited state with an antisymmetric wavefunction, another singlet state. Due to spin–orbit coupling, the excited molecule can transit into a triplet state via intersystem crossing. The subsequent photon emission from the triplet state is called phosphorescence. Since the decay of the triplet state to the singlet ground state is forbidden radiatively, the triplet excited state has a very long lifetime on the order of microseconds to milliseconds.

FLUORESCENCE MICROSCOPE DESIGNS

The components common to most fluorescence microscopes are the light sources, the optical components, and the detection electronics. These components can be configured to create microscope designs with unique capabilities.

Fluorescence Excitation Light Sources

Fluorescence excitation light sources need to produce photons with sufficient energy and flux level. The ability to collimate the emitted rays from a light source further determines its applicability in high resolution imaging. Other less critical factors, such as wavelength selectivity, ease of use, and cost of operation, should also be considered.

Mercury arc lamps are one of the most commonly used light sources in fluorescence microscopy. The operation of a mercury arc lamp is based on the photoemission from mercury gas under electric discharge. The photoemission from a mercury arc consists of a broad background punctuated by strong emission lines. A mercury lamp can be considered as a quasimonochromatic light source by utilizing one of these strong emission lines. Since mercury lamps have emission lines throughout the near-UV and visible spectrum, the use of a mercury lamp allows easy matching of the excitation light spectrum with a given fluorophore by using an appropriate bandpass filter. Mercury arc lamps are also low cost and easy to use. However, since the emission of mercury lamps are difficult to collimate, they are rarely used in high resolution techniques, such as confocal microscopy. The advent of high power, energy efficient, light-emitting diodes (LEDs) with a long operation life allows the design of new light sources that are replacing arc lamps in some microscopy applications.

Laser light sources are commonly used in high resolution fluorescence microscopes. Laser light sources have a number of advantages including monochromaticity, high radiance, and low divergence. Due to basic laser physics, the laser emission is almost completely monochromatic. For fluorescence excitation, a monochromatic light source allows very easy separation of the excitation light from the emission signal. While the total energy emission from an arc lamp may be higher than some lasers, the energy within the excitation band is typically a small fraction of the total energy. In contrast, lasers have high radiance: the energy of a laser is focused within a single narrow spectral band. Therefore, the laser emission can be more efficiently used to trigger fluorescence excitation. Furthermore, laser emission has very low divergence and can be readily collimated to form a tight focus at the specimen permitting high resolution imaging. Gas lasers, such as the argon-ion laser and helium-neon lasers, are commonly used in fluorescence microscopy. Nowadays, they tend to be replaced by solid-state diode lasers that are more robust and fluctuate less. Lasers can further be characterized as continuous wave and pulsed. While continuous wave lasers are sufficient for most applications, pulsed lasers are used in two-photon microscopes where high intensity radiation is required for efficient induction of nonlinear optical effects.

Microscope Optical Components

The optical principle underlying fluorescence microscopes can be understood using basic ray tracing (7,8). The ray tracing of light through an ideal lens can be formulated into four rules: (1) A light ray originated from the focal point of a lens will emerge parallel to the optical axis after the lens. (2) A light ray propagating parallel to the optical axis will pass through the focal point after the lens. (3) Light rays

Figure 2. Four basic rules of optical ray tracing. (1) Light emerging from the focal point will become collimated parallel to the optical axis after the lens. And inversely (2) a collimated beam parallel to the optical axis will be focused at the focal plane of the lens. (3) A light source in the focal plane of the lens will become collimated after passing through the lens with an oblique angle determined by the distance from the optical axis and inversely (4) An oblique collimated beam will be focused in the focal plane by the lens. The numerical aperture of an imaging system is a function of the maximum convergence angle, α , as defined in rule 2. The maximum convergence angle is a function of the lens property and its aperture (AP) size.

originated from the focal plane of a lens will emerge collimated. (4) Collimated light rays incident upon a lens will focus at its focal plane (Fig. 2). From these rules, one can see that a simple microscope can be formed using two lenses with different focal lengths (Fig. 3). The lens, L1, with focal length, f_1 , images the sample plane and is called the objective. The lens, L2, with focal length, f_2 , projects the image onto the detector plane and is called the tube lens. From simple geometry, two points P1 and P2 separated by x in the sample plane will be separated by $x(f_2/f_1)$ at the detector plane, where the ratio $M = f_2/f_1$ is called the magnification. One can see that the image in the sample plane is enlarged by the magnification factor at the detector.

By using the common wide-field fluorescence microscope as an example, we can further examine the components of a

Figure 3. The detection path of a microscope. Lenses L1 and L2 are the objective and the tube lens, respectively. L1 has focal length f_1 and L2 has focal length f_2 . For two points, P1 and P2 with separation, x , on the sample plane (S), these points are projected to points P1' and P2' on the detector plane (D).

Figure 4. Two configurations of fluorescence microscopy (a) trans-illumination and (b) epi-illumination. The objective and detection tube lenses are L1 and L2. The condenser is L3. The excitation relay lenses are L4 and L4'. The sample and detector planes are S and D respectively. The light source is LS. The dichroic filter and the barrier filter are DC and BR.

complete fluorescence microscope system (Fig. 4a) (9). In addition to the detection optical path, fluorescence microscope requires an excitation light source. The excitation light source is typically placed in the focal point of a third lens, L3. The lens collimates the excitation light and projects it uniformly on the specimen (Koehler illumination). The lens, L3, is called the condenser. Since the excitation light is typically much stronger than the fluorescence emission, a bandpass filter is needed to block the excitation light. In this trans-illumination configuration, it is often difficult to select a bandpass filter with sufficient blocking power without also losing a significant portion of the fluorescence signal. To overcome this problem, an alternative geometry, epi-illumination, is commonly used (Fig. 4b). In this geometry, lens L1 functions both as the imaging objective and the condenser for the excitation light. A couple of relay lenses (L4, L4') are used to focus the excitation light at the back aperture plane of the objective via a dichroic filter that reflects the excitation light but transmits the fluorescence signal. The excitation light is collimated by L1 and uniformly illuminates the sample plane. The fluorescence signal from the sample is collected by the objective and projected onto the detector via the tube lens L2. Since the excitation light is not directed at the detector, the task of rejecting excess excitation radiation at the detector is significantly easier. A barrier filter is still needed to eliminate stray excitation radiation from the optical surfaces.

From Fig. 2, one may assume that arbitrarily small objects can be imaged by increasing the magnification ratio. However, this is erroneous as the interference of light imposes a resolution limit on an optical system (10). The smallest scale features that can be resolved using fluorescence microscopy are prescribed by the Abbe limit.

For an infinitely small emitter at the sample plane, the image at the detector, the point spread function (PSF), is not a single point. Instead, the intensity is distributed according to an Airy function with a diameter, d :

$$d = M \frac{1.22\lambda}{NA} \quad (15)$$

where M is the magnification of the system, λ is the emission wavelength, and NA is the numerical aperture of the objective, which is defined as (Fig. 2):

$$NA = n \sin \alpha \quad (16)$$

where α is the half-convergence angle of the light and n is the index of refraction of the material between the lens and the sample. Therefore, the images of two objects on the sample plane will overlap if their separation is $< 1.22\lambda/NA$. Since NA is always on the order of 1, an optical system can only resolve two separate objects if their separation is on the order of the wavelength of light.

Fluorescence Detectors and Signal Processing

Since the fluorescence signal is relatively weak, sensitive detectors are crucial in the design of a high performance fluorescence microscope. For a wide field microscope, the most commonly used detectors are charged couple device (CCD) cameras, which are area detectors that contain a rectilinear array of pixels. Each pixel is a silicon semiconductor photosensor called a photodiode. When light is incident upon an individual photodiode, electrons are generated in the semiconductor matrix. Electrodes are organized in the CCD camera such that the charges generated by optical photons can be stored capacitatively during the data acquisition. After data acquisition, manipulating the voltages of the electrodes on the CCD chip allows the charges stored in each pixel to be extracted from the detector sequentially and read out by the signal conditioning circuit. These cameras are very efficient devices with a quantum efficiency up to $\sim 80\%$ (i.e., they can detect up to 8 out of 10 incident photons). Furthermore, CCD cameras can be made very low noise such that even four to five photons stored in a given pixel can be detected above the inherent electronic noise background of the readout electronics.

While CCDs are the detector of choice for wide-field microscopy imaging, there are other microscope configurations (discussed below) where an array detector is not necessary and significantly lower cost single element detectors can be used. Two commonly used single element detectors are avalanche photodiodes (APDs) and photomultiplier tubes (PMTs).

Avalanche photodiodes and photomultiplier tubes have been used in confocal and multiphoton microscopes. Avalanche photodiodes are similar to the photodiode element in a CCD chip. By placing a high voltage across the device, the photoelectron generated by the photon is accelerated across the active area of the semiconductor and collide with other electrons. Some of these electrons gain sufficient mobility from the collision and are accelerated toward the anode of the device themselves. This results in an avalanche effect with a total electron gain on the order

of hundreds to thousands. A sizable photocurrent is generated for each input photon. A normal photodiode or a CCD camera does not have single photon sensitivity because the readout electronic noise is higher than the single electron level. The gain in the avalanche photodiode allows single photon detection. Photomultiplier tubes operate on a similar concept. A photomultiplier is not a solid-state device, but a vacuum tube where the photons impact the cathode and generates a photoelectron using the photoelectric effect. The electron generated is accelerated by a high voltage toward a second electrode, called a dynode. The impact of the first electron results in the generation of a cascade of new electrons that are then accelerated toward the next dynode. A photomultiplier typically has ~ 5 – 10 dynode stages. The electron current generated is collected by the last electrode, the anode, and is extracted. The electron gain of a photomultiplier is typically >1 – 10 million. While APDs and PMTs are similar devices, they do have some fundamental differences. The APD are silicon devices and have a very high quantum efficiency ($\sim 80\%$) from the visible to the near-IR spectral range. The PMT photocathode material has a typical efficient of 20% , but can reach $\sim 40\%$ in the blue–green spectral range. However, PMTs are not sensitive in the red–IR range with quantum efficiency dropping to a few percent. On the other hand, PMT have significantly higher gain and better temporal resolution.

Advanced Fluorescence Microscopy Configurations

In addition to wide-field imaging, fluorescence microscopy can be implemented in other more advanced configurations to enable novel imaging modes. We will cover four other particularly important configurations: wide-field deconvolution microscopy, confocal microscopy, two-photon microscopy, and total internal reflection microscopy.

Wide-Field Deconvolution Microscopy. Wide-field microscopy is a versatile, low cost, and widely used technique. However, cells and tissues are inherently three dimensional (3D). In a thick sample, the signals from multiple sample planes are integrated to form the final image. Since there is little correlation between the structures at different depths, the final image becomes fuzzy. The need for 3D resolved imaging has long been recognized. The iterative deconvolution approach has worked well for relatively thin specimen, such as in the imaging of organelle structures in cultured cells (11) (Fig. 5). In terms of instrument modifications, the main difference between deconvolution microscopy and wide-field microscope is the incorporation of an automated axial scanning stage allowing a 3D image stack to be acquired from the specimen. An initial estimate of the 3D distribution of fluorophores is convoluted with the known PSF of the optical system. The resultant image is then compared with the measured 3D experimental data. The differences allow a better guess of the actual fluorophore distribution. This modified fluorophore distribution is then convoluted with the system PSF again and allows another comparison with experimental data. This process repeats until an acceptable difference between the convoluted image and the experimental data

Figure 5. A comparison between (a) normal wide-field images and (b) deconvoluted images (11). Green fluorescent protein labeled mitochondria of a cultured cell was imaged by a wide-field fluorescence microscope as a 3D image stack. The image stack is deconvoluted and the significantly improved result is shown. The axial position of the image stack is shown below in units of micrometers.

is achieved. The deconvolution process in a wide-field fluorescence microscope belongs to the class of mathematical problems called ill-posed problems (12–14). An ill-posed problem does not have a unique solution, but depends on the selection of approach constraints to reach a final solution. One should consider the deconvoluted images only as the best estimate of the real physical structure given the available data. Furthermore, deconvolution algorithm is computationally intensive and often fails in thick specimens.

Confocal Fluorescence Microscopy. Confocal fluorescence microscopy is a powerful method that can obtain 3D resolved sections in thick specimens by completely optical means (15–18). The operation principle of confocal microscopy is relatively straightforward. Consider the following confocal optical system in the transillumination geometry (Fig. 6). Excitation light is first focused at an excitation pinhole aperture. An excitation tube lens collimates the rays and projects them toward the condenser. The excitation light is focused at the specimen. The emitted light from the focal point is collected by the objective and collimated by the emission tube lens. The collimated light is subsequently refocused at the emission pinhole aperture. The detector is placed behind the aperture. As it is clear in the ray tracing illustration, the fluorescence signal produced at the specimen position defined by the excitation

Figure 6. The configuration of a simple confocal microscope. The objective and the detection tube lenses are L1, L2. The light source is LS. The excitation aperture placed in front of the light source is EXA. The relay lens that images the excitation aperture and projects the image of the pinhole onto the specimen (S) are L3 and L3'. The fluorescence emission from the focal point (red rays) are projected onto the emission aperture (EMA) by L1 and L2. The signal is transmitted through EMA and is detected by the detector (D). Fluorescence generated outside the focal plane in the specimen (blue rays) are defocused at EMA and are mostly blocked.

Figure 7. A comparison between confocal (a) and wide field (b) imaging of a plasmacytoma cell labeled with fluorescent antiendoplasmic reticulum protein that binds mainly to the endoplasmic reticulum. In the wide-field image, it is not possible to determine whether the central nucleic region contains endoplasmic reticulum and the structure of the cisternae are unclear (19).

pinhole aperture is exactly transmitted through the conjugate pinhole in the emission light path. However, for a fluorescence signal generated above or below the focal plane, the light is defocused at the emission pinhole aperture and is largely rejected. Hence, a pair of conjugate pinholes allows the selection of a 3D defined volume. One can show that a confocal microscope can image structures in 3D with a volume resolution of 0.1 fl. This system achieves 3D resolution, at the cost of obtaining fluorescence signal from only a single point in the specimen. It is necessary to raster scan the excitation focus to cover a 3D volume. Confocal microscopy has been used extensively to investigate microstructures in cells and in the imaging of tissues (19) (Fig. 7).

Two-Photon Fluorescence Microscopy. A two-photon microscope is an alternative to confocal microscopy for the 3D imaging of thick specimens. Denk, Webb, and co-workers in 1990 introduced two-photon excitation microscopy (18,20). Fluorophores can be excited by the simultaneous absorption of two photons each having one-half of the energy needed for the excitation transition. Since the two-photon excitation probability is significantly less than the one-photon probability, two-photon excitation occurs only at appreciable rates in regions of high temporal and spatial photon concentration. The high spatial concentration of photons can be achieved by focusing the laser beam with a high numerical aperture objective to a diffraction-limited spot. The high temporal concentration of photons is made possible by the availability of high peak power pulsed lasers (Fig. 8). Depth discrimination is the most important feature of multiphoton microscopy. In the two-photon case, >80% of the total fluorescence intensity comes from a 1 μm thick region about the focal point for objectives with numerical aperture of 1.25. For a 1.25 NA objective using excitation wavelength of 960 nm, the typical point spread function has a fwhm of 0.3 μm in the radial direction and 0.9 μm in the axial direction (Fig. 8). Two-photon microscopy has a number of advantages compared with confocal imaging: (1) Since a two-photon microscope obtains 3D resolution by limitation of the region of excitation instead of the region of detection as in a confocal system, photodamage of biological specimens is restricted to the focal point. Since out-of-plane chromophores are not excited,

they are not subject to photobleaching. (2) Two-photon excitation wavelengths are typically redshifted to about twice the one-photon excitation wavelengths in the IR spectral range. The absorption and scattering of the excitation light in thick biological specimens are reduced. (3) The wide separation between the excitation and emission spectra ensures that the excitation light and Raman scattering can be rejected without filtering out any of the fluorescence photons. An excellent demonstration of the ability of two-photon imaging for deep tissue imaging is in the neurobiology area (21) (Fig. 9).

Total internal reflection microscopy. Confocal and two-photon microscopy can obtain 3D resolved images from specimens up to a few hundred micrometers in thickness. However, both types of microscopy are technically challenging, require expensive instrumentation, and only can acquire data sequentially from single points. Total internal reflection microscopy (TIRM) is an interesting alternative if 3D-resolved information is only required at the bottom surface of the specimen, such as the basal membrane of a cell (22–24). Total internal reflection occurs at an interface between materials with distinct indices of refraction (Fig. 10). If light ray is incident from a high index prism, n_2 , toward the lower index region, n_1 , at an angle θ , the light will be completely reflected at the interface if $\theta > \theta_c$, the critical angle.

$$\sin \theta_c = \frac{n_1}{n_2} \quad (17)$$

While the light is completely reflected at the interface, the electric field intensity right above the interface is nonzero, but decays exponentially into the low index medium. The decay length of the electric field is on the order of tens to hundreds of nanometers. Compared with other forms of 3D resolved microscopy, TIRM allows the selection of the thinnest optical section, but only at the lower surface of the sample. While prism launch TIRM as described is simpler to construct, the bulky prism complicates the routine use of TIRM for cell biology studies. Instead, ultrahigh numerical aperture objectives have been produced (1.45–1.6 N). Light rays focus at the back aperture plane of the objective that are sufficiently off axis will emerge collimated, but at an oblique angle. If a specimen grown on a high index coverglass is placed upon the objective, total internal reflection can occur at the specimen-coverglass interface if the oblique angle is sufficiently large. This approach has been described as the objective launch TIRM and has been very successful in the study of exocytosis processes (23) (Fig. 11).

FLUORESCENT PROBES

Fluorescence microscopy has found many applications in biomedicine. This wide acceptance is a direct result of the availability of an ever growing set of fluorescence probes designed to measure cell and tissue structure, metabolism, signaling processes, gene expression, and protein distribution (25,26). The synthesis of fluorescent probes dates back to 1856, when William Perkin made the first synthetic

Figure 8. Two-photon microscopy optical sections and produces a fluorescent signal originating only from the focal point (a) the geometry of two-photon fluorescence. In traditional one-photon excitation, fluorescence is generated throughout the double inverted cones (blue arrow). Two-photon excitation generates fluorescence only at the focal point (red arrow). (b) The submicron PSF of two-photon excitation at 960 nm: The full-widths at half maximum (fwhm) are $0.3 \mu\text{m}$ radially and $0.9 \mu\text{m}$ axially. (c) An experimental visualization of the small excitation volume of two-photon fluorescence. One- and two-photon excitation beams are focused by two objectives (equal numerical aperture) onto a fluorescein solution. Fluorescence is generated all along the path in the one-photon excitation case (blue arrow), whereas fluorescence is generated only in a 3D confined focal spot for two-photon excitation (red arrow) The reduced excitation volume is thought to lead to less photodamage. (Please see online version for color figure)

probe from coal tar dye. Thereafter, many more synthetic dyes became available: pararosaniline, methyl violet, malachite green, safranin O, methylene blue, and numerous azo dyes. While most of these early dyes are weakly fluorescent, more fluorescent ones based on the xanthene and acridine heterocyclic ring systems soon became available.

Optical Factors in the Selection of Fluorescent Probes

Before providing a survey of the wide variety of fluorescent probes, it is important to first discuss the optical properties of fluorescent probes that are important for microscopic imaging: extinction coefficient, quantum yield, fluorescent lifetime, photobleaching rate, and spectral characteristics.

One of the most important characteristic of a fluorescent probe is its extinction coefficient. Extinction coefficient, ϵ , measures the absorption probability of the excitation light by the fluorophore. Consider excitation light is transmitted through a solution containing fluorophore at concentration c with a path length l . The light intensities before and after the solution are I_0 and I . The extinction coefficient can then

be defined by Beer's law:

$$\log_{10} \frac{I_0}{I} = \epsilon cl \quad (18)$$

Fluorescent probes with high extinction coefficients can be excited by lower incident light intensity allowing the use of lowest cost light sources and reducing the background noise of the images originated from scattered excitation light.

Quantum yield, Q , measures the relative contributions of the radiative versus nonradiative decay pathways. High quantum efficiency maximizes the fluorescent signal for each photon absorbed. The combination of probe extinction coefficient and quantum efficiency quantifies the total conversion efficiency of excitation light into fluorescent signal.

While ϵ and Q determines excitation light conversion efficiency, the maximum rate of fluorescent photon generation also depends on the lifetime, τ , of the probe. Since a molecule that has been excited cannot be reexcited until it returns to the ground state, fluorescent lifetime

Figure 9. Fluorescein dextran labeled blood vessels in the primary vibrissa cortex of a living rat brain imaged using two-photon microscope down to a depth of $>500\ \mu\text{m}$, which demonstrates the ability of this technique to image deep into tissue (21).

Figure 10. The configuration of a total internal reflection fluorescence microscope. L1 and L2 are objective and tube lens, respectively. The barrier filter is BR and the detector is D. The prism is P. The excitation light (green) is incident up the prism at angle, θ , greater than the critical angle. The excitation light is totally internally reflected from the surface. A magnified view is shown on the left. The evanescent electric field induced by the excitation light above the prism surface decays exponentially and only induces strong fluorescence signal for probes close to the surface of the prism. Please see online version for color figure.

Figure 11. Epi-illuminated wide field (EPI) and total internal reflection (TIR) microscopy of bovine chromaffin cells containing secretory granules marked with GFP atrial natriuretic protein (23). Only the lower plane of the cells contributes to the fluorescence signal in TIR set-up.

determines the rate at which a single probe molecule can be recycled. In general, for fluorescent probes with equal ϵ and Q , fluorescent photon production rate is an inverse function of probe lifetime. Further intersystem cross-rate also plays a role in determining photon generation rate. Since the triplet state has a very long lifetime, probes with high intersystem cross-rates are trapped in the triplet state with a relatively lower photon generation rate.

Photobleaching rate measures the probability that a probe will undergo an excited-state chemical reaction and become nonfluorescent irreversibly. Therefore, the photobleaching rate of a probe limits the maximum number of fluorescence photons that can be produced by a single fluorophore. Photobleaching rates of fluorophores vary greatly. For example, rhodamine can survive up to 100,000 excitation, fluorescein a few thousand, and tryptophan can only sustain a few excitation events. Photobleaching can be caused by a variety of processes. Generally, it is the result of a photochemical reaction in the excited state of the probe. For example, a common bleaching pathway is the generation of a triplet state that reacts with oxygen dissolved in solution to generate singlet oxygen and an oxidized molecule incapable of undergoing the same electronic transition as before.

Spectral properties are also important in probe selection for a number of reasons. First, selecting fluorescent probes with well-separated excitation and emission spectra allow more efficient separation of the fluorescence signal from the excitation light background. Second, fluorescent probes should be selected to match the detector used in the microscope that may have very different sensitivity across the

spectral range. For example, most PMTs have maximum efficiency in the green spectral range, but very low efficiency in the red. Therefore, green emitting probes are often better matches for microscopes using PMTs as detectors. Third, probes with narrow emission spectra allow a specimen to be simultaneously labeled with different colors providing a method to analyze multiple biochemical components simultaneously in the specimen.

Classification of Fluorescent Probes

There is no completely concise and definitive way to classify the great variety of fluorescent probes. A classification can be made based on how the fluorophores are deployed in biomedical microscopy: intrinsic probes, extrinsic probes, and genetic expressible probes.

Intrinsic Probes. Intrinsic probes refer to the class of endogenous fluorophores found in cells and tissues. Many biological components, deoxyribonucleic acid such as (DNA), proteins, and lipid membrane are weakly fluorescent. For example, protein fluorescence is due to the presence of amino acids: tryptophan, tyrosine, and phenylalanine. Among them, tryptophan is the only member with marginal quantum yield for microscopic imaging. However, fluorescent imaging based on tryptophan provides very limited information due to the prevalence of this amino acid in many proteins distributed throughout cellular systems and provides no specificity or contrast. The most useful intrinsic probes for microscopy imaging are a number of enzymes and proteins, such as reduced pyridine nucleotides [NAD(P)H], flavoproteins, and protoporphyrin IX. Both NAD(P)H and flavoproteins are present in the cellular redox pathway. The NAD(P)H becomes highly fluorescent when reduced, whereas flavoprotein becomes fluorescent when oxidized, while their redox counterparts are nonfluorescent. These enzymes thus provide a powerful method to monitor cell and tissue metabolism. Protoporphyrin IX (PPIX) is a natural byproduct in the heme production pathway that is highly fluorescent. Certain cancer cells have been shown to have upregulate PPIX production relative to normal tissue and may be useful in the optical detection of cancer. Another class of important intrinsic fluorophores includes elastin and collagen, which resides in the extracellular matrix allowing structural imaging of tissues. Finally, natural pigment molecules, such as lipofuscin and melanin, are also fluorescent and have been used in assaying aging in the ocular system and malignancy in the dermal system respectively.

Extrinsic Probes. Many extrinsic fluorescent probes have been created over the last century. A majority of these extrinsic fluorophores are small aromatic organic molecules (25–28). Many probe families, such as xanthenes, canines, Alexas, coumarines, and acrinides have been created. These probes are designed to span the emission spectrum from near UV to the near-IR range with optimized optical properties. Since these molecules have no intrinsic biological activity, they must be conjugated to biological molecules of interest, which may be proteins or structure components, such as lipid molecules.

Most common linkages are through reactions to amine and thiol residues. Reactions to amine are based on acylating reactions to form carboxamides, sulfonamides, or thiouraeas. Targeting thiol residue in the cysteines of proteins can be accomplished via iodoacetamides or maleimides. Other approaches to conjugate fluorophores to biological components may be based on general purpose linker molecules, such as biotin-avidin pairs or based on photoactivable linkers. A particularly important class of fluorophores conjugated proteins is fluorescent antibodies that allow biologically specific labeling.

In addition to maximizing the fluorescent signal, the greater challenge in the design of small molecular probes is to provide environmental sensitivity. An important class of environmentally sensitive probes distinguishes the hydrophilic versus hydrophobic environment and results in a significant quantum yield change or spectral shift based on solvent interaction. This class of probes includes DAPI, laurdan, and ANS, which have been used to specifically label DNA, measure membrane fluidity, and sense protein folding states, respectively. Another important class of environmentally sensitive probes senses intracellular ion concentrations, such as pH, Ca^{2+} , Mg^{2+} , Zn^{2+} . The most important members of this class of probes are calcium concentration sensitive because of the importance of calcium as a secondary messenger. Changes in intracellular calcium levels have been measured by using probes that either show an intensity or a spectral response upon calcium binding. These probes are predominantly analogues of calcium chelators. Members of the Fluo-3 series and Rhod-2 series allow fast measurement of the calcium level based upon intensity changes. More quantitative measurement can be based on the Fura-1 and Indo-1 series that are ratiometric. These probes exhibit a shift in the excitation or emission spectrum with the formation of isosbestic points upon calcium binding. The intensity ratio between the emission maxima and the isosbestic point allows a quantitative measurement of calcium concentration without influence from the differential partitioning of the dyes into cells.

Quantum dots belong to a new group of extrinsic probes that are rapidly gaining acceptance for biomedical imaging due to a number of their very unique characteristics (29–31). Quantum dots are semiconductor nanoparticles in the size range of 2–6 nm. Photon absorption in the semiconductor results in the formation of an exciton (an electron-hole pair). Semiconductor nanoparticles with diameters below the Bohr radius exhibit strong quantum confinement effect, which results in the quantization of their electronic energy level. The quantization level is related to particle size where smaller particles have a larger energy gap. The radiative recombination of the exciton results in the emission of a fluorescence photon with energy corresponding to the exciton's quantized energy levels. The lifetime for the recombination of the exciton is long, typically on the order of a few tens of nanoseconds. Quantum dots have been fabricated from II–VI (e.g., as CdSe, CdTe, CdS, and ZnSe) and III–V (e.g., InP and InAs) semiconductors. Due to the compounds involved in the formation of these fluorescent labels, toxicity studies have to be realized prior to any experiments. Recent research works have been devoted

to the better manufacture of these semiconductor crystals including methods to form a uniform crystalline core and to produce a surface capping layer that enhances the biocompatibility of these compounds, prevents their aggregation, and can maximize their quantum efficiency. Furthermore, coating the surface of quantum dots with convenient functional groups, including common linkages, such as silane or biotin, has been accomplished to facilitate linkage to the biological molecules. Quantum dots are unique in their broad absorption spectra, very narrow (~ 15 nm) emission spectrum, and extraordinary photostability. In fact, quantum dots have been shown to have photobleaching rates orders of magnitude below that of organic dyes. Quantum dots also have excellent extinction coefficients and quantum yield. While there are significant advantages in using quantum dots, they also have a number of limitations including their relative larger size compared with organic dyes and their lower fluorescence flux due to their long lifetime. Quantum dots have been applied for single receptor tracking on cell surface and for the visualization of tissue structures, such as blood vessels.

Genetic Expressible Probes. The development of genetically expressible probes has been rapid over the last decade (32). The most notable of these genetic probes is green fluorescent protein, GFP (33). The GFP was isolated and purified from the bioluminescent jellyfish *Aequorea Victoria*. Fusion proteins can be created by inserting GFP genes into an expression vector that carries a gene coding for a protein of interest. This provides a completely noninvasive procedure and perfectly molecular specific approach to track the expression, distribution, and trafficking of specific proteins in cells and tissues. In order to better understand protein signaling processes and protein-protein interactions, fluorescent proteins of different colors have been created based on random mutation processes. Today, fluorescent proteins with emission spanning the spectral range from blue to red are readily available. Expressible fluorescent proteins that are sensitive to cellular biochemical environment, such as pH and calcium, have also been developed. Novel fluorescent proteins with optically controllable fluorescent properties, such as photoactivatable fluorescent proteins, PA-GFP, photoswitchable CFP, and pKindling red have been created and may be used in tracing cell movement or protein transport. Finally, protein-protein interactions have been detected based on a novel fluorescent protein approach in which each of the interacting protein pairs carries one-half of a fluorescent protein structure that is not fluorescent. Upon binding of the protein pairs, the two halves of the fluorescent protein also recombine, which results in a fluorescent signal.

ADVANCED FUNCTIONAL IMAGING MODALITIES AND THEIR APPLICATIONS

A number of functional imaging modalities based on fluorescent microscopy have been developed. These techniques are extremely versatile and have found applications ranging from single molecular studies to tissue level experiments. The implementation of the most common imaging

modalities will be discussed with representative examples from the literature.

Intensity Measurements

The most basic application of fluorescence microscopy consists in mapping fluorophore distribution based on their emission intensity as a function of position. However, this map is not static. Measuring intensity distribution as a function of time allows one to follow the evolution of biological processes. The fastest wide-field detectors can have a frame rate in the tens of kilohertz range, unfortunately at the expense of sensitivity and spatial resolution. They are used to study extremely fast dynamics, such as membrane potential imaging in neurons. For 3D imaging, point scanning techniques are typically slower than wide-field imaging, but can reach video rate speed using multi-foci illumination.

Dynamic intensity imaging has been used at the tissue level to follow cancer cells as they flow through blood vessels and extravasate to form metastases, or in embryos to track the expression of a regulatory protein at different developmental stages. One commonly used technique to follow the movements of protein in cellular systems is fluorescent recovery after photobleaching (FRAP). In FRAP studies, a small area of a cell expressing a fluorescently labeled protein is subjected to an intense illumination that photobleaches the dye and leads to a drastic drop in fluorescence intensity. The rate at which the intensity recovers provides a measure of the mobility of the protein of interest.

An important aspect of the fluorescent microscopy technique lies also in the image analysis. Particle tracking experiments are an excellent example. Zuhang and co-workers (34) studied the infection pathway of the influenza virus labeled with a lipophilic dye in CHO cells. Each frame of the movie recorded was analyzed to extract the position of the virus particles with 40 nm accuracy. Three different stages of transport after endocytosis of the virus particle were separated, each involving different transport mechanisms transduced by a different protein as shown in Fig. 12. The first stage is dependant on actin and results in an average transport distance of 2 μm from the initial site of binding at the cell periphery. The second stage is characterized by a sudden directed displacement that brings the virus close to the nucleus with a speed of 1–4 $\mu\text{m s}^{-1}$ that is consistent with the velocity of dynein motors on microtubules. The last stage consists of back and forth motion in the perinuclear region. This is followed by the fusion of the endosome with the virus and the liberation of the genetic material. This event is identified by a sudden increase in the fluorescence intensity due to the dequenching of the fluorescent tags on the virus.

Spectral Measurements

An extremely important feature of fluorescent microscopy is the ability to image many different fluorescent species based on their distinct emission spectra. Dichroic bandpass filters optimized for the dyes used in the experiment can discriminate efficiently between up to four or five different fluorophores.

Figure 12. Particle tracking of virus infecting a cell. (a) Trajectory of the virus. The color of the trajectory codes time from 0 s (black) to 500 s (yellow). The star indicates the fusion site of the virus membrane with the vesicle. (b) Time trajectories of the velocity (black) and fluorescence (blue) of the virus particle (34). Please see online version for color figure.

In a study of connexin trafficking, Ellisman and co-workers (35) used a dual labeling scheme to highlight the dynamics of these proteins. Using a recombinant protein fused to a tetracystein receptor domain, the connexin was stably labeled with a biarsenical derivative of fluorescein or resorufin (a red fluorophore). The cells expressing these modified proteins were first stained with the green fluorophore and incubated 4–8 h. The proteins produced during this incubation period are fluorescently tagged in a second staining step with the red fluorophore. The two-color images highlight the dynamics of the connexin refurbishing at the gap junction. As shown on Fig. 13, the older proteins are found in the center and are surrounded by the newer proteins.

For wide-field fluorescence imaging using a CCD camera, spectral information is collected sequentially while position information is collected at once. Bandpass filters can be inserted to select the emission wavelength in between image frames. This procedure is relatively slow and can result in image misregistration due to the slight misalignment of the filters. This problem can be overcome by the use of electronically tunable filter. Two types of electronically tunable filters are available based either on liquid-crystal technology or on electrooptical crystals. Liquid-crystal tunable filters are made of stacks of birefringent liquid-crystal layers sandwiched between polarizing filters. Polarized light is incident upon the device. The application of a voltage on the liquid-crystal layer produces a wavelength dependent rotation of the polarization of light as the light is transmitted through the liquid-crystal layers. After cumulative rotations through the multiple layers, only the light at a specific spectral range is at the correct polarization to pass through the final polarizer without attenuation. The second type is acousto-optic tunable filters (AOTFs). An AOTF works by setting acoustic vibration at radio frequency (rf) through an electrooptical crystal to create a diffraction grating that singles out the appropriate wavelength with a few nanometer bandwidth. The main advantage of AOTF is that the wavelength selection is realized by tuning the acoustic wave frequency, which can be done in a fraction of a millisecond while the liquid-crystal tunable filters operate with a time constant of hundreds of milliseconds. The latter, however, have a larger clear aperture and selectable bandwidth ranging

from a fraction of a nanometer up to tens of a nanometer. Liquid-crystal filters are more often used for emission filtering while the acousto-optic filters are more commonly used for excitation wavelength selection.

Typical emission spectra from molecular fluorophores have a sharp edge at the blue end of the spectrum, but have a long tail extending far into the red due to electronic relaxation from the excited state into a vibrationally excited ground state. When imaging with a few color channels, where each channel represents a single chromophore, one has to be careful to take into account the spectral bleedthrough of each dye into the neighboring channels. Collecting signal in a larger number of channels allows the use of a linear unmixing technique to account for the real shape of the emission spectra of each dye and accounts more precisely for their contributions in each pixel of the image. This technique can be implemented using tunable filters with a narrow bandwidth and CCD camera detectors. It has also been shown that an interferometer can be used to encode the spectral information in the image on the CCD camera. An image is then recorded for each step of the interferometer and a Fourier transform analysis allows the recovery of the spectral information. Although it requires more advanced postprocessing of the image data, this approach offers a large spectral range and a variable spectral resolution unmatched by the tunable filters.

Figure 13. Connexin trafficking at gap junction. The newly produced proteins are labeled in red after 4 h (a and b) or 8 h (c and d) hours after the first staining step with green. The older proteins occupy the periphery of the gap junction, while the new ones are localized in its center (35). Please see online version for color figure.

In scanning systems, such as confocal microscopes, the use of dichroic beamsplitters can be readily constructed to simultaneously resolve two or three spectral channels in parallel at each scan position. If more spectral channels are desired for spectral decomposition measurement, the emission can be resolved in a multichannel detector using a grating or a prism to separate the different wavelength components. This has been used to separate the contribution of dyes with very similar emission spectra like GFP and fluorescein, or resolve the different intrinsic fluorophores contained in the skin where many fluorophores with overlapping spectra are present.

A particularly promising class of probes for spectral imaging are quantum dots. As discussed previously, the emission spectra of quantum dots are very narrow and can be tuned by changing their size. Further, all quantum dots have a very broad excitation spectrum and a single excitation wavelength larger than the band gap energy can lead to the efficient excitation of many different colored quantum dots simultaneously. In their report, Simon and co-workers (36) used these particles to track metastatic cells injected in the tail of a mouse as they extravasate into lung tissue. Using spectrally resolved measurements, they demonstrate their ability to recognize at least five different cell populations each labeled with different quantum dots. Figure 14 shows an image of cells labeled with different quantum dots and the emission spectra from each of these particles. The difference in emission spectra allows an easy identification of each cell population.

Lifetime Resolved Microscopy

Measurement of the fluorescence lifetime in a microscope provides another type of contrast mechanism and can be used to discriminate dyes emitting in the same wavelength range. It is also commonly used to monitor changes in the local environment of a probe measuring the pH or the concentration of cations *In situ*. The fluorescence lifetime can be shortened by interaction of the probe with a quencher, such as oxygen. Another type of quenching is induced by the presence of the transition dipole of other dyes, which are in close vicinity and lifetime measurements can be used to quantify energy-transfer processes (discussed further in a later section).

There are two methods to measure the fluorescence lifetime in a microscope. One is in the time domain and the other is in the frequency domain. In the time domain, a light pulse of short duration excites the sample and the decay of the emission is timed. The resulting intensity distribution is a convolution between the instrument response and the exponential decay of the fluorophore.

$$I(t) = I_0 \int_0^t G(t-T) \cdot \exp\left(-\frac{T}{\tau}\right) dT \quad (19)$$

In the frequency domain, the excitation light is modulated at frequency ω . The intrinsic response time of the fluorescence acts as a low pass filter and the emitted signal is phase shifted and demodulated. Both the demodulation and the phase shift can be linked to the fluorescence lifetime.

$$\Delta\phi = a \tan(\omega\tau) \quad (20)$$

$$M = \frac{1}{\sqrt{1 + \omega^2\tau^2}} \quad (21)$$

In order to obtain a measurable phase shift and modulation, the frequency has to be on the same order of magnitude as the lifetime (i.e., 10^8 Hz). However, it is difficult to measure these two parameters at such high frequencies. Therefore, one typically uses a heterodyne detection to lower the frequency to the kilohertz range by modulating the detector at a frequency close to the excitation frequency.

For wide-field microscopy, an image intensifier is placed in front of the CCD camera to modulate the gain of detection. In the time domain, a short time gate is generated to collect the emission at various times after the excitation. In the frequency domain, the image intensifier is modulated at high frequencies and a series of images at different phases are acquired. In laser scanning confocal and multiphoton microscopes, time correlated single-photon counting is the method of choice for lifetime measurements in the time domain because it offers an excellent signal/noise ratio at low light levels. Every time a photon is detected, the time elapsed since the excitation of the sample is measured. A histogram of all the times of arrival yields a decay curve of the fluorescence in each pixel of the image. For brighter

Figure 14. Spectral imaging of cells labeled by quantum dots. Cells were labeled with five different quantum dots and imaged in a multiphoton microscope. Each symbol represents a different quantum dot. The symbols on the image match the emission spectra seen on the graph. The spectral imaging set-up allows to discriminate between the different cell populations (36).

Figure 15. Quantification of the pH of the skin by lifetime imaging. (a) Intensity, (b) modulation, (c) lifetime, and (d) pH maps of a mouse skin at different depth. The lifetime measurements allow a determination of the pH independently of the intensity changes recorded between different imaging depth (37).

samples, a frequency domain approach using modulated detectors can also be used to measure the lifetime.

To measure the pH in the skin of a mouse, Clegg and co-workers (37) used a modified fluorescein probe whose lifetime varies from 2.75 ns at pH 4.5 to 3.9 ns at pH 8.5. As they image deeper in the skin, they observe that the average pH increases from 6.4 at the surface up to >7 at 15 μm depth. The extracellular space is mostly acidic (pH 6), while the intracellular space is at neutral pH. Typically, pH is measured in solution by correlating fluorescence intensities with specific pH levels. This approach is not suitable for tissues, as in the skin, since the dye is unevenly distributed throughout the tissue (Fig. 15) due to differential partitioning. A measurement of pH based on fluorescence lifetime is not dependent on probe concentration and thus the pH can be measured in the intra and extracellular space at various depths in the skin.

Polarization Microscopy

Polarization microscopy is a technique that provides information about the orientation or the rotation of fluorophores. Linearly polarized excitation light results in preferential excitation of molecules with their transition dipole aligned along the polarization. If the molecule is in a rigid environment, the emitted fluorescence will mostly retain a polarization parallel to the excitation light. However, if the molecule has time to rotate before it emits a photon, this will randomize the emission polarization. The anisotropy r is a ratio calculated from the intensity parallel I_{\parallel} and perpendicular I_{\perp} to the incident polarization and is a measure of the ability of the molecule to rotate.

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \quad (22)$$

This ratio is mostly governed by two factors, which are the fluorescence lifetime τ and the rotational correlation time θ .

$$r = \frac{r_0}{1 + (\tau/\theta)} \quad (23)$$

where r_0 is the fundamental anisotropy. Molecules with a short fluorescence lifetime and a long rotational correlation time ($\tau < \theta$) will have a high anisotropy. In the opposite case, where molecules can freely rotate during the time they reside in the excited state, the anisotropy will be low. An approximate measurement of the mobility of a molecule can be obtained by exciting the sample at different polarization angles. A proper measurement of the anisotropy requires both a linearly polarized excitation light source and the detection of the parallel and perpendicular component of the fluorescence light using a polarizer. This technique has been used to measure viscosity and membrane fluidity *In vivo*. It has been applied to quantify enzyme kinetics, relying on the fact that the cleavage of a fluorescently labeled substrate leads to a faster tumbling and thus a decrease in anisotropy.

Goldstein and co-workers (38) used polarization microscopy at the single-molecule level to study the orientation of the kinesin motor on a microtubule. A thiol reactive rhodamine dye was attached to cysteines on the motor protein. Microtubules decorated with the modified kinesin were imaged under a different polarization angle. In the presence of adenosine monophosphate (AMP)–(PNP) [a nonhydrolyzable analogue of adenosine triphosphate (ATP)], the fluorescence intensity depends strongly on the angle of polarization of the excitation light (Fig. 16) proving that the kinesin maintains a fixed orientation. In the presence of adenosine 5–diphosphate (ADP), however, the anisotropy is lower (no dependence on excitation polarization angle),

Figure 16. Mobility of single kinesin motors on microtubules probed by polarization microscopy. (a) Image of microtubules sparsely decorated with kinesin motors in presence of AMP-PNP and ADP. (b) Time course of the fluorescent intensity recorded from single molecule excited with linearly polarized light at four different angles. The large fluctuations of the fluorescence intensity as function of the excitation polarization in the AMP-PNP case demonstrate the rigidity of the kinesin motor on the microtubule (38).

leading to the conclusion that the kinesin is very mobile, while still attached to the microtubule.

Fluorescence Resonance Energy Transfer

Förster resonance energy transfer (FRET) is a technique used to monitor interaction between two fluorophores on the nanometer scale. When a dye is promoted to its excited state, it can transfer this electronic excitation by dipole-dipole interaction to a nearby molecule. Due to the nature of this interaction, Förster predicted a dependence of the FRET efficiency on the sixth power of distance that was demonstrated experimentally by Stryer with a linear polypeptide of varying length (39). The efficiency E of the process varies as function of the distance, R , between the two molecules as

$$E = \frac{R_0^6}{R_0^6 + R^6} \quad (24)$$

Where R_0 is called the Förster distance, which depends on Avogadro's number N_A , the index of refraction of the medium n , the quantum yield of the donor molecule Q_D , the orientation factor κ , and the overlap integral J .

$$R_0^6 = \frac{9000 \ln(10) \kappa^2 Q_D}{128 \pi^5 N_A n^4} J \quad (25)$$

κ represents the relative orientation of the transition dipole of the donor and acceptor molecules. In most cases, a random interaction is presumed and this factor is set to two-thirds. The overlap integral J represents the energy overlap between the emission of the donor and the absorption of the acceptor. For well-matched fluorophore pairs, R_0 is on the order of 4–7 nm.

Most FRET experiments are based on the measurement of the intensity of the donor and of the acceptor because the presence of FRET in a system is characterized by a decrease in the emission of the donor and an increase in the acceptor signal. Thus, in principle, a two color channel microscope is sufficient to follow these changes. However, experimental artifacts, such as concentration fluctuation and spectral bleed, complicate the analysis of these images and many different correction algorithms have been developed.

FRET measurements have been used in molecular studies to measure distances and observe dynamic conformational changes in proteins and ribonucleic acid (RNA). In cellular studies, FRET is often used to map protein interactions. By labeling one protein with a donor dye and its ligand with an acceptor dye, energy transfer will occur only when the two proteins are bound such that the dyes come in close proximity of each other.

The addition of fluorescence lifetime imaging provides the additional capability of retrieving the proportion of fluorophore undergoing FRET in each pixel of an image independently of concentration variations. This is possible because the fluorescence lifetime of a FRET construct is shorter than the natural decay of the dye. Thus if one has a mixture of interacting and free protein, fitting a double exponential to the fluorescence decay allows us to retrieve the proportion of interacting protein. This has been applied by Bastiaens and co-workers (40) to the study the phosphorylation of the EGF receptor Erb1. The transmembrane receptor is fused with a GFP protein. The phosphorylation of the protein is sensed by an antibody labeled with a red dye (Cy3). When the Erb1 is phosphorylated, the antibody binds to the protein and FRET occurs due to the short distance between the antibody and the GFP. The Erb1 receptors can be stimulated by EGF coated beads leading to phosphorylation and FRET. The time course of the stimulation is followed and for each cell and the fraction of phosphorylated receptors at various time interval is shown in Fig. 17. After 30 s, the FRET events are localized at discrete locations. But after 1 min, the whole periphery of the cell displays high FRET, demonstrating the lateral signaling of the receptor after activation at discrete location by EGF coated beads.

Figure 17. Time course of the phosphorylation of EGF receptors ERB1 after stimulation by EGF coated beads observed by FRET between a GFP modified EGF receptor and a phosphorylation antibody labeled with Cy3. While the GFP intensity is remains relatively constant, the concentration of the Cy3 tagged antibody clearly increases after the stimulation. This leads to an increase FRET signal as function of time (40).

CONCLUSION

The utility of fluorescence microscopy lies in its ability to study biological structure and function *In vivo*. The exquisite sensitivity and image contrast of fluorescence microscopy allow biological structures to be imaged on the submicron length scale. The greatest power of fluorescence microscopy lies in its ability to determine biochemical functions using assays based on fluorescence spectroscopy. With the availability of more versatile instruments, more fluorophores unit greater molecular and environmental specificity, the impact of fluorescence microscopy technology on biomedical science will only increase.

INTRODUCTION

Recent advances in technology have allowed us to study our world at molecular, even subatomic, resolution. One of the devices in the forefront of such studies is the atomic force microscope (AFM), which is a relatively complex device

with two major applications. It can be used as an imaging device, which allows for the acquisition of atomic-level images of biological structures as well as to measure forces of interactions between two opposing surfaces down to the single-molecule level.

Imaging AFM

The AFM was originally designed as an imaging tool (1). It was modified from the design of the scanning tunneling microscope (STM). The AFM acquires topographic images by methodically scanning a sample with a flexible probe, called a cantilever, which bends according to the contours of the sample's surface. The bending of the cantilever is translated into an image map, which reveals the height differences in the surface being scanned. It is possible to image biological samples under physiological conditions as imaging can be done in both air and liquid. The resulting resolution of such maps is at the atomic level (2,3).

The imaging AFM has been used to image many biological samples ranging from genetic material to cells to bone. A few of these studies will be highlighted. One of the earliest biological materials to be imaged was DNA, which has been imaged in many forms to date, including double- and single-stranded forms as well as more complex structures. The AFM has also been used for many applications including DNA sizing, previously only achieved using gel electrophoresis, DNA mapping, hybridization studies, and examinations of protein-DNA interactions (4). AFM studies of RNA were also conducted. Unlike DNA, which mainly forms a double-helical structure, RNA has the ability to form more advanced structures that do not rely solely on Watson-Crick base pairing. One example are the so-called kissing-loop structures imaged by Hansma et al. (4) (Fig. 1). Not only was the AFM used in imaging of such structures, many of them 3D, but also played an important role in designing them (5). Unlike other imaging techniques, AFM studies can be done under physiological conditions allowing for the imaging of biological processes. Images of transcription complexes have been obtained, for example, *E.coli* RNA polymerase in complex with DNA. These studies are the only of their kind that can answer certain specific questions as to how the RNA transcription process takes place. One is able to visualize how the DNA does not get entangled in the nascent RNA strands. Such studies detailing the structure-function relationship of the transcription process are key in furthering our understanding of gene expression (6,7).

Also, imaging of cells was conducted to examine the structure of the cellular cortex in detail. The cell cytoskeleton is known to be involved in affecting cell shape as well as movement and other cellular responses to biochemical and biophysical signals. At present, relatively little is known about the mechanical organization of cells at a subcellular level. Pesen et al. (8) studied the cell cortex of bovine pulmonary artery endothelial cells (BPAECs) using AFM and confocal fluorescence microscopy (CFM). They were able to identify a coarse and fine mesh that make up the cortical cytoskeleton. These two types of mesh appear to be intertwined (Fig. 2) (8). Such details are not distinguished in imaging studies using fixed cells.

Figure 1. Kissing-loop RNA structures. (a,c) Kissing-loop RNAs at low concentrations. The three arms of the individual RNAs are visible. (B) Kissing-loop RNAs at a concentration 10-fold higher than in a and c. The individual structures are less well-defined. Scale bars = 100 nm for all images.

Other imaging studies have looked at tendon and bone, both of which are composed of type I tropo-collagen, which was done by acquisition of high resolution AFM images of type I collagen in conjunction with force spectroscopy studies, namely protein unfolding, which is described in the following section. Figure 3 reveals these high resolution collagen type I images. They were acquired using two different concentrations of collagen, which resulted in

Figure 2. AFM Images of the cortical mesh of bovine pulmonary artery endothelial cells (BPAEC). (a–d) High magnification deflection AFM images of the cortical mesh of living BPAECs in a physiological saline. The filamentous mesh appears to be organized on two length scales, with coarse mesh (arrowheads) and fine mesh filaments (arrows). The two meshes are likely to be intertwined, although it is possible that the fine mesh is layered over the coarse mesh. Lateral resolution in these images is ~ 125 nm.

slightly different orientations of collagen: random at the lower concentration (Fig. 3a) and oriented unidirectionally in the higher concentration (Fig. 3b). In these studies, the AFM was used to investigate the mechanical properties of this collagenous tissue, which are altered in diseases such as osteoporosis. Being familiar with such properties is important for gaining further understanding as well as preventing and curing bone diseases (9).

Force Spectroscopy

The AFM can also be operated in the force scan mode, which allows for the measurement of adhesion forces

Figure 3. Topographical images (height; tapping mode in air) of type I collagen monomers on a mica substrate. (a) low ($1 \mu\text{g/ml}$) concentration of collagen, (b) high ($10 \mu\text{g/ml}$) concentration of collagen.

between receptors and their corresponding binding partners, or ligands. In studies of ligand-receptor forces, the receptor is immobilized on the surface of a flexible AFM cantilever whereas the ligand is attached to a suitable substrate. The deflection of the cantilever during the approach and withdrawal of the cantilever from the substrate allow for the force of the interaction to be measured. These type of experiments provide information simulating the influence of internal and external forces that these receptors would experience in the body, for example, the shear stress experienced by a blood cell attached to the endothelium while blood rushes past it. Such information was previously unavailable when receptor-ligand interactions were examined using more traditional biochemical techniques. AFM has made it possible to acquire measurements that reveal the mechanical properties of biomolecules under applied force. Measurements of the unbinding force of a single ligand-receptor interaction can now be acquired with the AFM (10–12).

The AFM can also be used in adhesion studies involving whole cells (13,14). In these studies, the interaction between a cell expressing a particular receptor of interest and its ligand protein or another cell expressing the ligand is measured. The cell adhesion experiments allow for the acquisition of both single-molecule measurements, like in the above-mentioned studies, as well as multiple-bond interactions. The advantage of using the AFM in cell adhesion studies is the high specificity and wealth of information that is obtained. The AFM force scans provide information about the individual bond strengths as well as the force and work that is required to separate the entire complex. Combining single-molecule and multiple-bond data allows us to describe the thermodynamic model of the separation of a particular complex in addition to the mechanism of its action on the cellular scale (15,16).

The AFM can also serve as a microindenter that probes soft samples, including cells revealing information about their mechanical properties. The mechanical properties of cells play an important role in such essential physiological processes such as cell migration and cell division. Understanding these properties can later help scientists to identify when certain processes may be taking place. The mechanical properties of cells are chiefly determined by their actin cytoskeleton, which is the cell's "backbone." This type of information, which cannot be obtained using standard cell biology methods, allows for the estimation of the Young's modulus of living cells (16). The Young's modulus is a calculated value, which provides information regarding the compliance or elasticity of a cell. Such experiments may be done with either the imaging AFM or using force spectroscopy. Manfred Radmacher's group has conducted such measurements with an imaging AFM in force mapping mode. The advantage of such measurements is the wealth of information that they provide. These experiments reveal not only the elastic properties of the cells being examined but also topographical information. They can also be performed in conjunction with video microscopy to further confirm what one is visualizing and that cells are not undergoing damage (17,18). In force spectroscopy experiments, the Young's modulus is obtained by poking the cell cantilever tip. This type of

information can be correlated with adhesion data to determine whether elasticity changes in response to drugs or other stimulation have an effect on the strength of cell adhesion (19).

Another application allows scientists to study protein folding. Proteins are composed of amino acid chains, which constitute the primary protein structure. These amino acid chains have to undergo folding into tertiary and secondary, 3D structures, which is essential for the proper functioning of these proteins. Recently, advances in AFM have made it possible to study this fascinating biological process and bring new insight into the energy landscapes of protein folding. Proteins involved in mechanical functions are composed of multiple domains, which fold individually. One of these domains is fibronectin. The most common form of fibronectin is fibronectin type III (FN-III), which is found in an estimated 2% of all animal proteins and has thus been studied extensively. FN-III domains are found in the muscle protein titin, which is responsible for the passive elasticity of muscle. These domains have been found to unravel during forced extension. Understanding the forces required in unfolding events as well as the time it takes for unfolding to happen can be critical for the physiological functions of mechanical proteins such as titin (9,20–22).

Now that a brief overview of the potential applications of the AFM has been provided, it is important to understand the principles behind its operation. The following section focuses on the theory of data acquisition using AFM as well as descriptions of the equipment itself. The last section of this article provides a more in-depth evaluation of the technique in addition to discussing the most recent advances in the field.

THEORY AND EXPERIMENTAL APPROACH

This section focuses on the theory and experimental approaches of AFM. The section begins with a description of the imaging AFM as well as its different modes of operation, which allow for its applications in various experimental protocols. Later, force spectroscopy is described. Focus is placed on the force apparatus used in our laboratory, which relies on the same basic principals as the commercially available AFMs. In addition to a description of its operation, this section also discusses the different applications of the force apparatus.

Imaging AFM

Optical Beam Deflection. An AFM has a force sensor called a cantilever to measure the forces between a sharp tip and the surface (23). Unlike the optical microscope that relies on 2D images, the images acquired with the AFM are obtained in three dimensions: the horizontal xy -plane and the vertical z -direction. As shown in Fig. 4, the tip at the end of the cantilever is brought in close proximity to the sample mounted on a piezoelectric element. The AFM can be compared with a record player such as an old stylus-based instrument (1). It combines the principles of a scanning tunneling microscope (STM) and the stylus profiler. However, the probe forces in the AFM are much smaller than those ($\sim 10^4$ N) achieved with a stylus profiler.

Figure 4. Schematic illustration of an AFM. A force sensor consists of a flexible cantilever with an extremely sharp tip at its end. A ceramic (Si_3N_4) or semiconductor (Si) tip on the cantilever can be brought into close proximity to a sample surface. As the tip is close to the sample surface, it either continuously touches or periodically vibrates on the surface, and bends or changes in its vibration amplitude and frequency. A laser spot is reflected off the top of the cantilever. When the cantilever bends, the laser light is deflected onto a two-panel photodiode. The detected signals are amplified and transformed by electronic circuits and sent to an SPM controller. The SPM controller, the computer, and their interfaces generate an image.

The AFM belongs to the family of scanning probe microscopes (SPMs). Like all other SPMs, the AFM uses an extremely sharp tip that moves over the sample surface with a raster scan (like the movement of the electron beam on the TV screen). In the first AFM, the bending of the cantilever was detected using an STM, but now a sensitive and simple optical method is used in most AFMs (24). As shown in Fig. 4, a laser beam is reflected off the cantilever onto a two-panel photodiode. As the cantilever bends, the position of the reflected laser light changes. Measurements are obtained as a result of the differences in the signal between the two segments of this photo-detector.

Feedback Operation. The AFM uses a piezoelectric element to position and scan the sample with high resolution. A tube-shaped piezoelectric ceramic that has a high stability is used in most SPMs. Application of voltage results in the stretching or bending of the piezoelectric tube, allowing it to move in all three dimensions and to position the cantilever probe with very high precision. For example, by applying a voltage to one of the two electrodes (xy -axis) the tube scanner expands and tilts away from a center position (xy -origin). A corresponding negative voltage applied to the same electrode causes the tube scanner contract, resulting in movements on the xy -plane relative to the origin. The magnitude of the movement depends on the type of piezoelectric ceramic, the shape of the element, and the applied voltage.

Feedback control is used for many common applications, such as thermostats, which are used to maintain a particular temperature in buildings, and autopilot, commonly used in airplanes. In the AFM, a feedback loop is used to

keep the force acting on the tip in a fixed relationship with the surface while a scan is performed. The feedback loop consists of the piezoelectric tube scanner, the cantilever and tip, the sample, and the feedback circuit. The feedback circuit consists of proportional and integral gain controls and provides an immediate response to scanning parameter changes. A computer program acts as a compensation network that monitors the cantilever deflection and attempts to keep it at a constant level.

Contact Mode (Static Mode). The AFM operates by measuring the intermolecular forces between the tip and sample. The most common method used in imaging AFM is contact mode, where the piezoelectric element slightly touches the tip to the sample. The experimental setup is shown in Fig. 4. As a result of the close contact, the tip and sample remain in the repulsive regime of the tip-sample interaction shown in Fig. 5. Thus, the AFM measures repulsive force between the tip and sample. As the raster scan moves the tip along the sample, the two-panel photodiode measures the vertical deflection of the cantilever, which reveals the local sample height. Each contour of the

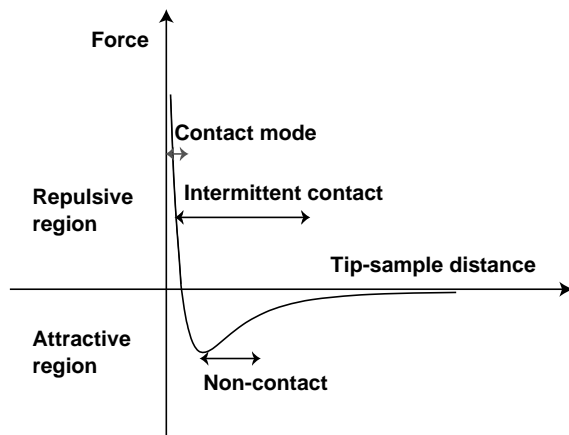

Figure 5. Relationship between the operating modes of AFM and the force regions. The x -axis of the graph is the tip-sample distance and the y -axis is the force or potential. The graph shows the force or potential, as a function of the distance, simply calculated by the Lennard–Jones potential and the DMT approximation. In contact mode AFM, the tip-sample interaction lies in the repulsive region of the curve above the x -axis. As the cantilever is pushed upward, a resulting restoring force occurs, which can be given by Hooke’s Law. The difference between this graph and the measured force-distance curve occurs when the force measurement is not static but dynamic and is quickly affected by the capillary force in the thin surface water layer. In intermittent contact mode, the cantilever is operated by a vibration of an amplitude of 10 to 100 nm. The tip is still in contact with the surface, but it just contacts or “taps” on the surface for a very small fraction of its oscillation period. In this operation mode, the tip-sample interaction is broad, ranging from the repulsive region of the curve to the attractive region due to the long-range van der Waals force. The tip-sample interaction in noncontact mode is much weaker than the one in contact and intermittent contact mode. The force between the tip and sample is several orders of magnitude weaker than in the contact regime. As the cantilever in noncontact mode is vibrated near its resonance frequency with an amplitude less than 10 nm, the spacing between the tip and sample is on the order of several to tens of nanometers.

surface results in a movement of the tip in the xyz -direction, resulting in a change in the deflection angle of the laser beam. This change is measured through the photodiode and translated finally to an image.

Tip-sample Interaction: The cantilever in the AFM is a critical component (1). The force produced by a spring always tends to restore the spring to its equilibrium position. When the spring is pushed upward by a distance z , it has to be pulled downward. This restoring force is given by Hooke’s Law as:

$$F(z) = -k * (z - z_0) \quad ()$$

where k is a spring constant and depends on the material and dimensions of the cantilever, z is the vertical position of the cantilever, and z_0 is the equilibrium position. As a cantilever with a spring constant of 0.1 newton/meter (N/m) is moved by 1 nm, the resulting force is 0.1 nanonewton (nN). The first tip used by the inventors of the AFM was made from diamond glued to a lever of gold foil (1). Microfabricated cantilever tips are now commercially used.

Electromagnetic forces determine the properties of solids, liquids, and gases; the behavior of particles in solution; and the organization of biological structures (25). These forces are also the source of all intermolecular interactions including covalent bonds, Coulomb forces, ionic forces, ion-dipole interaction, and dipole-dipole interaction. In the AFM, the intermolecular interactions between the tip and the sample surface include van der Waals forces, electrostatic forces, water capillary force, and material properties including elasticity. The most common force in the tip-sample interaction is the van der Waals force. The force is calculated using the Lennard–Jones potential, which combines the attractive van der Waals and the repulsive atomic potentials (25). The force depends on the distance between the tip and the sample, as shown in Fig. 5. This calculated force is an estimate of the van der Waals forces and is usually a few nanonewtons in magnitude.

Force-distance Curve: Since the invention of the AFM, many researchers have used it to measure the tip-sample interaction force on the atomic scale. The AFM records the force as the tip is brought in close proximity to the sample surface, even indented into the surface, and then pulled off. The measured force curve is a plot of cantilever deflection versus the extension of the z -piezoelectric scanner (z -piezo). A force-distance curve is a kind of interpretation of the force measurements. It needs a simple relationship between the cantilever deflection and the tip-sample distance. Thus, the force-distance curve describes the tip-sample interaction force as a function of the tip-sample distance rather than as a function of the z -piezo position. It is difficult to measure the quantitative forces with this technique because the spring constant of the cantilever and the shape of the tip are not accurately known. However, this technique has been used to study adhesion, elasticity, bond rupture length, and even thickness of adsorbed layers. These studies of the fundamental interactions between the sample surfaces have extended across basic

science, chemistry, biology, and even material science. The interaction force between tip and sample is typically on the order of tens of pN for biomolecular interactions. Force measurements in solution have the advantages of the AFM due to the lower tip-sample interaction.

Constant Force and Constant Height: In contact mode, the tip is scanned across the surface in contact either at a constant force or at a constant height above the sample. Constant force mode is achieved by use of a z -feedback loop from the deflection signal. The feedback circuits serve to maintain a constant force between the tip and the sample while the tip follows the contours of the surface. The piezoelectric tube can respond to any changes in the cantilever deflection. A computer program acts to keep the cantilever deflection at a constant level. Then, the tip-sample interaction can be kept at a predetermined restoring force. This technique is used to observe the precise topography of the sample surface. If the z -feedback loop is switched off, then the z -direction of the piezoelectric tube is kept constant, and an image is generated based on the cantilever deflection. Using constant height can be useful for imaging very flat samples.

Lateral Force Microscopy: Lateral force microscopy (LFM) is an extension of contact mode, where an additional detected parameter is the torsion of the cantilever, which changes according to the friction force (26). This lateral force induces a torsion of the cantilever, which, in turn, causes the reflected laser beam to undergo a change in a perpendicular direction to that resulting from the surface corrugation. The LFM uses a photodiode with four segments to measure the torsion of the cantilever. When the cantilever is scanned across the surface in contact, differences in friction between tip and sample cause the tip to stick-slip on the surface. This stick-slip behavior creates a characteristic saw-tooth waveform of atomic level in the friction image (27). The LFM can provide material-sensitive contrast because different components of a composite material exert different friction forces. Researchers often call this operation mode friction force microscopy (27,28). Increasing wear with decreasing sliding velocity on the nanometer scale has been observed with this technique. It has been demonstrated with LFM that, on the atomic scale, frictional properties are sensitive to changes in surface properties on chemical modification. The LFM can also be applied to chemical force microscopy (CFM) by a modified tip with chemical functionality (29). It has been demonstrated with CFM that mapping the spatial arrangement of chemical functional groups and their interactions is of significant importance to problems ranging from lubrication and adhesion to recognition in biological systems.

Capillary Force: The thin surface water layer that exists on the sample surface will form a small capillary bridge between the tip and the sample. The capillary force is important when the AFM is operated in air. Examine the effect of surface tension on AFM measurements. At the moment of tip contact with a liquid film on a flat surface, the film surface reshapes producing a ring around the tip. The water layer wets the tip surface because the

water-tip contact (if it is hydrophilic) is energetically advantageous as compared with the water-air contact. If the tip radius is 10 nm and the contact angle is small (i.e., hydrophilic), a capillary force of about 10 nN can result. Thus, the capillary force is the same order of magnitude as the van der Waals interaction. An AFM tip has been used to write alkanethiols with a 30 nm line-width resolution on a gold thin film in a manner analogous to that of a dip pen (30). Recently, this dip-pen nanolithography has also been applied to direct nanoscale patterning of biological materials such as DNA, peptides, and proteins on glass substrates.

Vibration Mode (Dynamic Mode). In dynamic mode, the cantilever is oscillated close to its resonance frequency. This vibration mode operates at a frequency-modulation (FM) mode or the more common amplitude-modulation (AM) mode, which are basically the same as the frequencies used in radio communication. In the FM mode, a z -feedback loop keeps a constant force between the tip and the sample while the tip follows the contours of the surface by maintaining the resonance frequency. In the AM mode, the z -feedback loop keeps the constant tip-sample interaction by maintaining the amplitude of oscillation.

Intermittent Contact Mode: The cantilever in dynamic mode can easily be vibrated by a piezoelectric ceramic called a bimorph actuator. In air, the cantilever is oscillated close to its resonance frequency and positioned above a sample surface. When the vibrating cantilever comes close to the surface, its oscillation amplitude may change and can be used as the control signal. In this AM mode, the tip is still in contact with the surface, but it just contacts or "taps" on the surface for a very small fraction of its oscillation period. This operation mode is best known as tapping mode in commercial AFMs and, more generally, as intermittent contact mode.

As a raster scan moves the tip on the sample, the four-segment photodiode measures the vibration signal of the cantilever. The detected signal can be changed to root mean-square values by an analog-to-digital converter. In constant force mode, the z -feedback loop adjusts so that the averaged amplitude of the cantilever remains nearly constant. Each contour of the surface causes a movement of the tip in the xyz -direction, resulting in a change of the oscillation amplitude of the cantilever. This change is measured through a photodiode and finally translated to an image. In air, friction forces due to the surface water layer are dramatically reduced as the tip scans over the surface. Tapping mode may be a far better choice than contact mode for imaging of biological structures due to their inherent softness. In tapping mode, the cantilever can be vibrated at an amplitude of less than 100 nm. Additionally, changes in the phase of oscillation under tapping mode can be used to discriminate between different types of materials on the surface.

Tip-Sample Interaction: The mechanical resonance of the cantilever plays a major role in the response of the system for an interaction between a tip mounted on a vibrating cantilever and a non-homogeneous external force (23). Although basic equations governing the operation of a

bimorph actuator used to vibrate the cantilever are not introduced here, the position of the bimorph is given by:

$$u = u_0 + A_{ex} \cos(\omega t + \phi)$$

where u_0 is the equilibrium position and the excitation is done with amplitude A_{ex} , a frequency ω , and a phase shift ϕ . The fundamental resonance frequency of the cantilever can be approximately calculated from equating its strain energy at the maximum deflection to the kinetic energy at the point of zero deformation. A more accurate method, which takes into consideration all the resonance frequencies of the cantilever together with the modes of vibration, can be obtained by solving the equation of motion subject to the boundary conditions (23). A basic equation to describe the motion of the cantilever is briefly introduced. If the tip-sample interaction is uniform and includes dissipative force in Newton's second law, the vibration system including the cantilever can be described as follows:

$$F(z) = k(z - u) + \gamma(dz/dt) + m(d^2z/dt^2) \quad (1)$$

where $F(z)$ is the tip-sample interaction force, k is a spring constant of the cantilever, z is the vertical position of the cantilever, u is the motion of the bimorph, γ is the dissipation term (i.e., the friction coefficient of the material or the environment), and m is the effective mass of the cantilever. For the constant amplitude mode, we assume that the frictional force $\gamma(dz/dt)$ is compensated for by the driving force $F_{ex} = k A_{ex} \cos(\omega t + \phi)$. Then, the equation of motion is reduced to $F(z) = k z + m(d^2z/dt^2)$. If a strong tip-sample interaction occurs only at the point of contact, the motion of the cantilever tip can be almost perfect harmonic oscillation, $z = z_0 + A \sin \omega t$.

Resolution and Tip Effects: The resolution obtained by an AFM depends greatly on the sharpness of the cantilever tip. Broadening effects usually develop when imaging biological structures having extremely small surface features like a DNA strand (4). If a tip with a radius of curvature of about 20 nm is used to image DNA on a substrate surface, the observed width is about 20 nm, which is considerably greater than the expected value of 2.4 nm deduced from the van der Waals radii of DNA. When the tip radius is comparable with the size of the feature being imaged, it is important to evaluate the radius of the tip end. As such, the development of sharper tips is currently a major concern for commercial vendors, which is also of interest for biologists whose work would greatly benefit from much faster scanning. Recently, improvement of the scanning speed in AFM is one of the most important topics. The tip-sample interaction also tends to distort biological structures because they are relatively soft (31).

Phase Imaging: Phase imaging is an extension of tapping mode based on the measurement of the cantilever phase lag (32). The dependence of phase angles in tapping mode AFM on the magnitude of tip-sample interactions has been demonstrated. The phase images of several hard and soft samples have been recorded as a function of the free amplitude and the reference of the tapping amplitude. It is thought that the elastic deformation associated with the

tip-sample repulsive force can be estimated by the repulsive contact interaction. In many cases, phase imaging complements the LFM and force modulation techniques, often providing additional information along with a topographic image. Phase imaging like LFM can also be applied to CFM by using a modified tip with chemical functionality.

Pulsed Force Mode: Pulsed force mode (PFM) is a non-resonant and intermittent contact mode used in AFM imaging (33). It is similar to tapping mode in that the lateral shear forces between the tip and the sample are also reduced. In contrast to tapping mode, the maximum force applied to the sample surface can be controlled, and it is possible to measure more defined surface properties together with topography. This mode is similar to the force modulation techniques of CFM in that a chemically modified tip is used. A series of pseudo force-distance curves can be achieved at a normal scanning speed and with much lower expenditure in data storage. A differential signal can be amplified for imaging of charged surfaces in terms of an electrical double-layer force.

Noncontact Mode: A reconstructed silicon surface has been imaged in a noncontact mode by AFM with true atomic resolution (34). The operation of the AFM is based on bringing the tip in close proximity to the surface and scanning while controlling the tip-sample distance for the constant interaction force. The tip-sample interaction forces in noncontact mode are much weaker than those in contact mode, as shown in Fig. 5. The cantilever must be oscillated above the sample surface at such a distance as is included in the attractive regime of the intermolecular force. Most surfaces are covered with a layer of water, hydrocarbons, or other contaminants when exposed to air, which makes it very difficult to operate in ambient conditions with noncontact mode. Under ultrahigh vacuum, clean surfaces tend to stick together, especially when the materials are identical. The FM mode used in noncontact mode can keep the constant tip-sample interaction by maintaining the resonance frequency of oscillation through the z -feedback loop. Nearly ten years following the invention of the AFM, a few groups achieved true atomic resolution with a noncontact mode (35). After that, several groups succeeded in obtaining true atomic-level resolution with noncontact mode on various surfaces. Many important yet unresolved problems, such as determining the tip-sample distance where atomic-level resolution can be achieved, still remain. Experimentally, atomic-level resolution can be achieved only between 0 and 0.4 nm. A stiff cantilever vibrates near resonance frequency (300–400 kHz) with amplitude of less than 10 nm.

In covalently bound materials, the charge distribution of surface atoms reflects their bonding to neighboring atoms (36). These charge distributions have been imaged by noncontact mode with a light-atom probe such as a graphite atom. This process revealed features with a lateral distance of only 77 picometers (pm). However, all of the atomic-scale images have been generated in ultrahigh vacuum, which has limited applications in biology. Recently, several groups have reported obtaining atomic-scale images with FM mode in ambient conditions

and liquid environments. In the near future, true atomic-level imaging by AFM will be commercially available in various environments.

Force Spectroscopy

Equipment

AFM Instrumentation. The AFM that is used in the author's laboratory is a homemade modification of the standard AFM design that is used for imaging and is shown in Fig. 5 (19). It operates on the same basic principles as a commercial AFM. In the author's design, improvement of the signal quality by reducing mechanical and electrical noise and improvement of the instrument's sensitivity by uncoupling the mechanisms for lateral and vertical scans was achieved. The cantilever is moved vertically up and down using a piezoelectric translator (Physik Instrumente, model P-821.10) that expands or contracts in response to applied voltage. The vertical range of the piezo is 0–15 μm . A dish coated with substrate is placed below the cantilever, and the cantilever with a cell or protein attached can be lowered onto that dish using the piezo allowing for the receptor-ligand interaction to take place. During the acquisition of a force scan, the cantilever is bent (Fig. 6) causing the beam of a 3 mW diode laser (Oz Optics; em. 680 nm) that is focused on top of the cantilever to be deflected. A two-segment photodiode (UDT Sensors; model SPOT-2D) monitors these deflections of the laser beam. An 18 bit optically isolated analog-to-digital converter (Instrutech Corp., Port Washington, NY) then digitizes the signal from the photodiode. Custom software is used to control the piezoelectric translator and to time the measurements. The AFM is shielded inside of an acoustic/vibration isolation chamber in order to reduce vibration and aid in keeping a stable temperature. The detection limit of the AFM system is in the range of 20 pN.

Cantilever Calibration. It is necessary to determine the spring constant of the cantilever k_C (i.e., $F = k_C x$) in order to translate the deflection of the cantilever x to units of force F . Calibrating the cantilever can be achieved through theoretical techniques that provide an approximation of k_C (37) or through empirical methods. Using empirical methods to determine k_C involves taking measurements of cantilever deflection with application of a constant known force (38) or measuring the cantilever's resonant frequency (39). The method the author's use for calibrating cantilevers is based on Hutter and Bechhoefer (39). The

Figure 6. AFM experimental set-up. (a) Schematic diagram of the AFM. (b) Photograph of the author's AFM setup. The CCD camera is not in view.

author's use triangleshaped unsharpened gold-coated silicon-nitride cantilever tips that have spring constants ranging from 10 mN/m to 50 mN/m for ligand-receptor force measurements (TM Microscopes, Sunnyvale, CA). The cantilever tip can be treated as a simple harmonic oscillator whose power spectrum of thermal fluctuation can be used to derive the spring constant, which can be achieved by raising the cantilever a few microns from the surface of the experimental dish and monitoring its natural vibrational frequency for 2–3 s. Each vibration mode of the cantilever receives the thermal energy commensurated to one degree of freedom, $k_B T/2$. The measured variance of the deflection $\langle x \rangle^2$, can then be used to calculate the spring constant (i.e., $k_B T = k_C \langle x \rangle^2$, where k_B and T are Boltzmann's constant and temperature, respectively). To separate deflections belonging to the basic (and predominant) mode of vibration from other deflections or noise in the recording system, the power spectral density of the temperature-induced deflection is determined. The spring constant is estimated using only the spectral component corresponding to the basal mode of vibration. The spring constant can be calibrated in either air or solution using this approach. The calculated spring constant k_C can then be used to calculate rupture force F by $F = k_C CD V$. DV is the change in voltage detected by the photodiode just prior to and immediately after the rupture event. C is a calibration constant that relates deflection and photodiode voltage and is determined from the deflection of the cantilever when it is pressed against a rigid surface, such as the bottom of a plastic petri dish (19).

Applications

Receptor-Ligand Adhesion Measurements. *Bell Model:* AFM force measurements (Fig. 7) of ligand-receptor interactions can be used to determine the dynamic strength of a complex and characterize the changes in free energy that the particular complex undergoes (i.e., energy landscape) during its breakage. The Bell model can be used to interpret these measurements (40). The Bell model is based on the assumption that the application of an external mechanical force to a receptor-ligand interaction bond will reduce the activation energy that needs to be overcome in order to break this bond. This unbinding force should increase with the logarithm of the rate at which an external mechanical force is applied toward the unbinding of adhesion complexes (i.e., loading rate), which was confirmed by a number of studies. For example, studies using the biomembrane force probe (BFP) (40) and the AFM have shown that increases in loading rate cause an increase in rupture force between individual complexes of streptavidin/biotin (12,15,41).

AFM Measurements of Adhesive Forces: In order to carry out force measurements, a cell is first attached to a cantilever tip and another cell or substrate proteins are plated on a dish. The method employed to attach cells to the cantilever tip works best on nonadherent items. A cell is attached to the AFM cantilever via concanavalin A (con A)-mediated linkages (15). Most cells have receptors for con A on their surface and will attach to the tip. To prepare the con A-functionalized cantilever, the cantilevers are soaked

Figure 7. Steps in the acquisition of an AFM force measurement. The first step is the approach of the cantilever with a cell bound to the substrate, followed by contact between the cell and substrate and retraction of the cantilever, which results in the separation of the cell from the substrate. The cantilever is bent during this process. The arrows indicate the direction of cantilever movement.

in acetone for 5 min, UV irradiated for 30 min, and incubated in biotinamidocaproyl-labeled bovine serum albumin (biotin-BSA, 0.5 mg/ml in 100 mM NaHCO₃, pH 8.6; Sigma) overnight. The cantilevers are then rinsed three times with phosphate-buffered saline (PBS, 10 mM PO₄³⁻, 150 mM NaCl, pH 7.3) and incubated in streptavidin (0.5 mg/ml in PBS; Pierce, Rockford, IL) for 10 min at room temperature. Following the removal of unbound streptavidin, the cantilevers are incubated in biotinylated Con A (0.2 mg/ml in PBS; Sigma) and then rinsed with PBS.

The actual process of attaching a cell to a cantilever tip is reminiscent of fishing. A cantilever tip is positioned above the center of the cell. The largest triangular cantilever (320 μ m long and 22 μ m wide) with a spring constant of 0.017 N/m on the cantilever chip is usually used in our measurements. The cell is brought into focus, with the cantilever slightly out of focus. Then, the tip is lowered onto the center of the cell and held there motionless for approximately 1 s. When attached, the cell is positioned right behind the AFM cantilever tip. The force required to dislodge the cell from the tip is greater than 2 nN, which is much greater than the forces measured in the receptor-ligand studies that were, at most, 300 pN (15).

A piezoelectric translator is used during measurement acquisition to lower the cantilever with an attached cell onto the sample. The interaction between the attached cell and the sample is given by the deflection of the cantilever. This deflection is measured by reflecting a laser beam off the cantilever into a position sensitive two-segment photodiode detector, as described in the instrumentation section above.

Figure 8. AFM force versus displacement traces of the interaction between cells expressing LFA-1 and immobilized ICAM-1. (a) Multiple-bond measurements acquired with a compression force of 200 pN, 5 s contact, and a cantilever retraction speed of 2 μ m/s. The measurements were carried out with a resting, untreated cell (1st trace), a Mg²⁺-treated cell (2nd trace), and a PMA-stimulated cell (3rd trace). The 4th trace corresponds to a measurement acquired from a PMA-stimulated cell in the presence of LFA-1 (20 μ g/ml FD441.8) and ICAM-1 (20 μ g/ml BE29G1) function-blocking monoclonal antibodies (mAbs). Arrows point to breakage of LFA-1/ICAM-1 bond(s). f_{de} is the detachment force, and the shaded area estimates the work of de-adhesion. (b) Single-molecule measurements of LFA-1/ICAM-1 unbinding forces. Traces 2 and 5 show adhesion. Measurements were obtained under conditions that minimized contact between the LFA-1-expressing cell and the ICAM-1-coated surface. The compression force was reduced to \sim 60 pN and the contact time to 50 ms. An adhesion frequency of less than 30% in the force measurements ensured that a $>$ 85% probability exists that the adhesion event is mediated by a single LFA-1/ICAM-1 complex (42,43). The frequency of adhesion in test and control experiments was examined to confirm the specificity of the interaction. The addition of monoclonal antibodies against either LFA-1 or ICAM-1 significantly lowered the frequency of adhesion of both resting cells and activated cells under identical experimental conditions.

As a result of this process, a force scan is obtained. The studies shown in Fig. 8 (42,43) were conducted on cells expressing the adhesion receptor LFA-1 (leukocyte function-associated antigen-1), an integrin expressed on the surface of T-cells, and its ligand ICAM-1 (intercellular adhesion molecule-1), expressed on the surface of APCs. In these experiments, LFA-1-expressing cells and ICAM-1 protein were used. An example of a few force scans from multiple bond cell adhesion studies can be seen in Fig. 8a. The red trace is the approach trace and the black is the retract trace. As the cantilever is lowered and contact is made between the cell and substrate, an initial increase in force occurs. As the cantilever is retracted back up, the force returns to zero and becomes negative as bonds are stretched and begin to break. The jumps in the force scan, which are pointed out by the arrows, represent bonds breaking. Two parameters can be used in such measurements to assess the level of cell adhesion. One is the detachment force, which is the maximum force required to dislodge the cell. Another is the work of deadhesion, which is the amount of work required to pull and stretch

the cell and for the bonds to break. It is derived by integrating the adhesive force over the distance traveled by the cantilever. In this example, Mg^{2+} and PMA are used, which enhance the adhesion of the cells studied through various mechanisms. It is easily observed that a very pronounced increase occurs in the area under the curve as well as the number of bonds that were broken following the application of these adhesion stimulators (16).

FM Force Measurements of Individual Receptor/Ligand Complexes: A different set of information can be derived from single-molecule adhesion measurements. These type of studies offer insight into the dissociation pathway of a receptor-ligand interaction and the changes in free energy that are associated with this process, which is achieved by measuring single-bond interactions between a receptor and ligand at increasing loading rates (20 pN/s–50,000 pN/s). In the author's setup, it translates to using rates of retraction of the cantilever from 0.1 to 15 $\mu\text{m/s}$.

In order to obtain unbinding forces between a single receptor-ligand pair, the experiments have to be carried out in conditions that minimize contact between the cantilever tip and substrate. A >85% probability exists that the adhesion event is mediated by a single bond if the frequency of adhesion is maintained below 30% (15,42). An example of such measurements can be seen in Fig. 8b.

Depending on the speed at which the cantilever is retracted during the measurements, the collected data usually needs to be corrected for hydrodynamic drag, which is due to the hydrodynamic force that acts in the opposite direction of cantilever movement, and its magnitude is proportional to the cantilever movement speeds. The hydrodynamic force may be determined based on the method used by Tees et al. and Evans et al. (42,43). In single-bond AFM studies, it is found that the data obtained with cantilever retraction speeds higher than 1 $\mu\text{m/s}$ needed to be corrected by adding the hydrodynamic force.

The damping coefficient can be determined by plotting the hydrodynamic force versus the speed of cantilever movement. The damping coefficient is the slope of the linear fit and was found to be about 2 pN $\square\text{s}/\mu\text{m}$ in the author's work (15).

AFM Measurements of Cell Elasticity. The AFM can also be used as a microindenter that probes the mechanical properties of the cell. In these measurements, which enable assessment of cell elasticity, a bare AFM tip is lowered onto the center of the cell surface at a set rate, typically 2 $\mu\text{m/s}$. Following contact, the AFM tip exerts a force against the cell that is proportional to the deflection of the cantilever. The indentation force used is below 1 nN (~ 600 pN) in order to prevent damage to the cell. The deflection of the cantilever is recorded as a function of the piezoelectric translator position during the approach and withdrawal of the AFM tip. The force-indentation curves of the cells are derived from these records using the surface of the tissue culture dish to calibrate the deflection of the cantilever. Then, one can estimate the Young's modulus, which is a measure of elasticity. Estimates of Young's modulus are made on the assumptions that the cell is an isotropic elastic

Figure 9. Acquisition of cell compliance measurements. (a) Tip of the AFM cantilever indenting a 3A9 cell. The cell compliance measurements were based on the assumption that the cell is an isotropic elastic solid and the AFM tip is a rigid cone (44–46). According to this model, initially proposed by Love and Hertz, the force (F)-indentation (α) relation (shown) is a function of Young's modulus of the cell, K , and the angle formed by the indenter and the plane of the surface, θ , as in equation (1). The indenter angle, θ , is assumed formed by the AFM tip and the 3A9 cell to be 55° and the Poisson ratio ν to be 0.5. (b) Force versus indentation traces of resting, PMA-stimulated and Mg^{2+} -treated 3A9 cells.

solid and the AFM tip is a rigid cone (44–46). According to this model, initially proposed by Hertz, the force (F) indentation (α) relation is a function of Young's modulus of the cell, K , and the angle formed by the indenter and the plane of the surface, θ , as follows:

$$F = \frac{K}{2(1-\nu^2)} \frac{4}{\pi \tan \theta} \alpha^2 \quad (1)$$

Young's modulus are obtained in the author's laboratory by least square analysis of the force-indentation curve using routines in the Igor Pro (WaveMetrics, Inc., Lake Oswego, OR) software package. The indenter angle θ and Poisson ratio ν are assumed to be 55° and 0.5, respectively.

In order to determine the cell's elasticity, the force versus indentation measurements are fitted to the curves of the Hertz model. Figure 9 (44–46) illustrates an example of such measurements acquired on cells of varying elasticity. Cells with the greatest degree of indentation at a particular applied force will have the lowest Young's modulus values and will therefore be the "softest."

Protein Folding/Unfolding. The AFM can also be used to study protein unfolding. A cantilever tip is used to pick up proteins attached to a surface, which is followed by retrac-

Figure 10. Consecutive unfolding peaks of a titin polyprotein, composed of FNIII domains. The inset demonstrates the corresponding steps of the unfolding process in correlation to the AFM data.

tion of the cantilever, which results in protein unfolding. The length of the unfolded protein can be over ten times its folded length, depending on the protein being studied (9).

This forced protein unfolding generates an opposing force due to the sudden drop in entropy as the protein is unfolded. Although a lower force is required to begin unfolding the protein, the force required to continue the unfolding is increased rapidly as the protein approaches its full, unfolded length. This phenomenon has been described by the worm-like chain model (WLC) of elasticity. The WLC model is based on two parameters, the total or contour length of the polymer being stretched and the persistence length. The persistence length reflects the polymer flexibility and is the length attained when a polymer is bent. A smaller persistence length is an indication of higher entropy and a polymer that is more difficult to unfold (47). When a multidomain protein is extended using the AFM, the first domain is unfolded at a certain pulling force, followed by a return of the cantilever to zero. Further unfolding meets with resistance once again, resulting in a characteristic saw-tooth profile of the unfolding, with each domain that was unfolded being represented by a peak. Figure 10 from Andreas F. Oberhauser illustrates this process. It is the unfolding of a titin polyprotein, which is composed of FNIII domains (22). The protein can also be refolded following unfolding, which is done by bringing the cantilever back down to the substrate and once again retracting it. If force curves representative of unfolding are observed once again, then refolding most likely took place. It is a much slower process (on the order of seconds) than the forced unfolding (48).

EVALUATION

Imaging AFM

The AFM is an exciting novel technology that enables the study of biological structures under physiological conditions. The AFM is probably the only technique of its kind

that enables image dynamic processes taking place in real time. A number of other techniques are currently available in the biological sciences for imaging studies, however, most result in modifications to the biological sample. One such technique is electron microscopy (EM), which, until recently, provided images of the highest resolutions. In recent years, a number of modifications to the AFM have brought the resolution up to par and even surpassed those of EM.

In recent years, many advances have been made in the field of AFM. Significant improvements in resolution have been gained through cantilever tip modification. The currently available cantilevers are relatively “soft” and flexible with spring constants of 0.01–0.5 N/m. Tip deformation is one aspect that limits resolution. Recently, stiffer cantilevers have been designed improving resolution. One example are quartz cantilevers with spring constants on the order of 1 kN/m allowing for possibly subatomic-level resolution (34). Smaller cantilevers have been designed that increase the possible scanning speed of the AFM. Images of 100 × 100 pixels (240 nm scan size) have been achieved in 80 ms. A sharper, finer tip can also improve resolution, which has been achieved through the use of carbon nanotubes, probably the greatest probe improvement to date, which are seamless cylinders composed of sp²-bonded Carbon (49).

Several characteristics exist that make Carbon nanotubes improved AFM tip materials, including small diameter, a high aspect ratio, large Young’s modulus, and mechanical robustness. They are able to elastically buckle under large loads. All these properties translate into higher sample resolution. Chemical vapor deposition has made it easier to grow Carbon nanotubes on cantilever surfaces, a process that replaces previously more laborious and time-consuming attachment techniques (4,50).

A few techniques also exist worth mentioning that have improved AFM imaging. One such method is cryoAFM. This method addresses the previously mentioned problem of tip and sample flexibility. In this case, samples are imaged at extremely cold temperatures in their cryogenic states, which provides a rigid surface that exhibits a high Young’s modulus, thus reducing cantilever deformation and increasing resolution. CryoAFM images match and surpass EM images. Other improvements address the problem resulting from the vibration induced by the commonly used piezoelectric translator. This vibration is translated to the cantilever holder and the liquid containing the sample being imaged. Magnetic mode (MAC) eliminates the cantilever holder entirely and replaces it with a magnetic cantilever. The cantilever is manipulated via a magnetic field. Photothermal mode (PMOD) uses a bimetallic cantilever that is oscillated via a pulsed diode laser (50,51).

Advances have also been made in single-molecule manipulation with a nanomanipulator. This method relies on a force feedback pen that actually allows the user to touch and manipulate the sample being studied. For example, one can dissect DNA from a chromosome. The interaction forces involved during manipulation of samples can also be studied through oscillating mode imaging. The nanomanipulator can now measure forces in the pN–μN range. For excellent reviews on this technique, see Yang et al. (50) Fotiadis et al. (52).

Progress has also been made in imaging of membrane proteins, which are not ideal candidates for X-ray crystallography, as they do not readily form 3D crystals. Atomic-level resolution images have been obtained of membrane proteins complexed with lipids using EM. However, AFM images of these proteins offer an improvement in that they can be carried out in near physiological conditions and allow for the acquisition of functional and structural information (50,52).

The continued improvements leading to the enhanced imaging capabilities of AFM are reflected in the most recent work being done in the field. We would like to highlight one area where a great deal of progress has been made, which is the field of DNA and RNA assembly of nanostructures in which the imaging AFM plays a pivotal role. Some of the earlier successes in this area included the construction of 2D DNA arrays, which were assembled in a predictable manner (53). Much progress has also been made with RNA in an attempt to design self-assembling building blocks. The goal of such studies is to generate molecular materials, the geometry of which can be determined for applications in nanobiotechnology (54–56). Chworos et al. were able to form stable RNA structures termed “tectosquares” from RNA helices without the presence of proteins (5). “TectoRNAs” can be thought of as RNA Lego blocks that can be used for the formation of supramolecular structures. In order for these structures to be assembled, the right conditions have to be met in terms of divalent ion concentrations, temperature, as well as the strength, length, and orientation of the RNA. The AFM is an essential tool used in this process as it allows the researcher to obtain detailed images of the assembled tectosquares providing the opportunity to compare predicted structures with those that actually formed. The structures formed by Chworos et al. were in good agreement with the predicted structures. Figure 11 demon-

Figure 11. Diagram and AFM images of tectosquare nanopatterns generated from 22 tectosquares. One micrometer square scale AFM images obtained in solution (clockwise from the upper leftmost image) for the ladder pattern, fish net pattern, striped velvet pattern, basket weave pattern, cross pattern, tartan pattern, polka dot pattern, lace pattern, and diamond pattern. Scale bar, 20 nm.

strates the amazing predictability of assembly of these structures, where nine different types of RNA patterns were created (5). Such DNA and RNA structures may have applications in nanotechnology and the material sciences as they could be used to generate nanochips, nanocircuits, and nanocrystals (57). For an excellent recent review of DNA nanomechanical devices, please see Seeman (58).

Force Spectroscopy

Force spectroscopy allows us to measure interaction forces between receptors and their respective ligands. These studies can be carried out with purified proteins or cells, or a combination of both. Traditionally, adhesion measurements have been conducted using adhesion assays, which involve the attachment of cells to dishes coated with substrate. The cells are later dislodged manually or using a centrifuge, which are older yet still viable techniques that provide basic kinetic information about the interaction of a receptor-ligand pair. More advanced techniques for conducting force measurements include the use of microneedles, optical tweezers, magnetic beads, and the biomembrane force probe. These techniques, much like the AFM, provide more advanced information from which energy landscapes of an interacting receptor-ligand pair may be determined (11).

The AFM is also a powerful tool for determining the mechanical properties of cells, which was traditionally done using micropipettes or the cell pocker, which offered much less precision than the AFM. More recently, methods such as the scanning acoustic microscope, optical tweezers, and magnetic tweezers have also been used in addition to the AFM (59).

An important advantage of the AFM over other methods is that it can be used in conjunction with other techniques through relatively simple modifications. Recently, it has been combined with the patch clamp technique to study the mechanically activated ion channels of sensory cells of the inner ear. This strategy allowed the researchers to use the AFM tip to stimulate the mechanosensory hair bundles by exerting force on them and measure the electrical output of the patch clamp simultaneously (9,60). Another example is combining an AFM with a confocal microscope, which could allow one to monitor cellular responses to AFM measurements using fluorescent reporter systems. One could monitor calcium levels, expression of caspases, and so on (61,62). The AFM could also be combined with RICM microscopy as well as FRET.

Other recent advances involve modifications that would allow for more efficient and effective receptor-ligand studies, including the use of more than one cantilever on the same chip simultaneously. In this case, multiple proteins could be attached and their interaction with their ligand could be measured. So far, this approach has been done with two cantilevers, which involves the use of two laser beams. Further modifications could allow for measurements with even more proteins. Improvements can also be made in plating of the ligands proteins. In the ideal scenario, different proteins could be plated so that interaction between different receptor-ligand pairs could be

carried out simultaneously. Current improvements also involve finding better ways to attach cells and proteins to the cantilever that would result in covalent attachment to the tip. Another area that requires improvement is data analysis. The currently available analysis program involves days of rather tedious computer time. Automating analysis would greatly reduce the time required to study a particular interaction. Also, some improvements can be made in data acquisition, where still frequent adjustments of cantilever retraction speed and contact time are required throughout the course of the experiment. Automating data acquisition would allow experiments to be carried out during the night, when noise levels are also minimal.

The applications of AFM technology are vast and too numerous to describe in one review article. The author's have attempted to summarize the technology that was deemed to be of great importance in the developing field of AFM. AFM technology is still limited to a relatively small number of laboratories, which is most likely due to the lack of familiarity with the field, limited expertise in operation, as well as the expense involved in acquiring an AFM. However, it is changing as more and more people are discovering the possibilities that become open to them if they acquire and familiarize themselves with this technology.

MICROSCOPY, SCANNING TUNNELING

VIRGINIA M. AYRES
Michigan State University
East Lansing, Michigan

INTRODUCTION

Four years after its invention in 1982 (1), the scanning tunneling microscope (STM) was awarded the 1986 Nobel Prize for physics, one of only four such prestigious awards given for a truly significant contribution to scientific instrumentation. Since then, the family of scanning probe microscopy (SPM) techniques, which includes scanning tunneling microscopy, atomic force microscopy (2–4), magnetic force microscopy (5), near-field optical microscopy (6), scanning thermal microscopy (7), and others, has revolutionized studies of semiconductors, polymers, and biological systems. The key capability of SPM is that, through a controlled combination of feedback loops and detectors with the raster motion of piezoelectric actuator, it enables direct investigations of atomic-to-nanometer scale phenomena.

Scanning probe microscopy is based on a piezoelectric-actuated relative motion of a tip versus sample surface, while both are held in a near-field relationship with each other. In standard SPM imaging, some type of tip-sample interaction (e.g., tunneling current, Coulombic forces, magnetic field strength) is held constant in z through the use of feedback loops, while the tip relative to the sample undergoes an x – y raster motion, thereby creating a surface map of the interaction. The scan rate of the x – y raster motion per line is on the order of seconds while the tip-sample interaction is on the order of nanoseconds or less. The SPM is inherently cable of producing surface maps with atomic scale resolution, although convolution of tip and sample artifacts must be considered.

Scanning tunneling microscopy is based on a tunneling current from filled to empty electronic states. The selectivity induced by conservation of energy and momentum requirements results in a self-selective interaction that gives STM the highest resolution of all scanning probe techniques. Even with artifacts, STM routinely produces atomic scale (angstrom) resolution.

With such resolution possible, it would be highly desirable to apply STM to investigations of molecular biology and medicine. Key issues in biology and medicine revolve around regulatory signaling cascades that are triggered through the interaction of specific macromolecules with specific surface sites. These are well within the inherent resolution range of STM.

The difficulty when considering the application of STM to molecular biology is that biological samples are non-conductive. It may be more accurate to describe biological samples as having both local and varying conductivities. These two issues will be addressed in this article, and examples of conditions for the successful use of STM for biomedical imaging will be discussed. We begin with an overview of successful applications of STM in biology and medicine.

SCANNING TUNNELING MICROSCOPY IN BIOLOGY AND MEDICINE: DNA AND RNA

The STM imaging for direct analysis of base pair arrangements in DNA was historically the first biological application of the new technique. An amusing piece of scientific history is that the first (and widely publicized) images (8–12) of (deoxyribonucleic acid) DNA were subsequently shown to correspond to electronic sites on the underlying graphite substrate! However, more careful investigations have resulted in an authentic body of work in which the base pairings and conformations of DNA and RNA are directly investigated by STM. One goal of these investigations is to replace bulk sequencing techniques and crystal diffraction techniques, which both require large amounts of material, with the direct sequencing of single molecules of DNA and RNA. Two examples of DNA and RNA investigation by STM are presented here. One is an investigation of DNA and RNA structures, and the other is an investigation of DNA biomedical function.

Recently reported research from the group at The Institute for Scientific and Industrial Research at Osaka University in Japan (13) has shown detailed STM images of well-defined guanine-cytosine (G-C) and adenine-thymine (A-T) base pairings in double- and single-stranded DNA. Four simple samples involving only G-C and only A-T base pairs in mixed (hetero) and single sided (homo) combinations were chosen for analysis (Fig. 1). These were deposited on a single-crystal copper (111)-orientation [Cu(111)] substrate using a technique developed specially by this group to produce flat, extended strands for imaging. An STM image showing the individual A-T base pairs in the hetero A-T sample is shown in Fig. 2. Images of the overall structures indicated repeat distances consistent with interpretation as the double helix. Images from mixed samples of hetero G-C and hetero A-T are shown in Fig. 3. The larger structure is interpreted as hetero G-C and the smaller as hetero A-T, which is consistent with X-ray diffraction data that indicates the A-T combination is more compact.

Only the double helix structure was observed for the hetero G-C samples. However, the homo G-C structures,

Figure 1. (a) Homo A-T, (b) Hetero A-T, (c) Homo G-C, and (d) Hetero G-C. (Figure adapted from Ref. 9, used with permission.)

Figure 2. STM image of portion of Hetero A-T double helix of showing base pairs. (Reproduced from Ref. 9, used with permission.)

hetero A-T structures, and homo A-T structures were observed in two types, and the spot spacings and sizes of the second type would be consistent with interpretation as single-stranded DNA. The observed presence or lack of single-stranded configurations among the samples is consistent with the fact that hetero G-C has a higher melting (unwinding) temperature than the homo G-C and thus is more difficult to unwind. Both hetero and homo A-T pairs have lower melting temperatures than either of the G-C pairs. Images of both hetero A-T and Homo A-T samples often showed sizing and spacings consistent with interpretation as single-stranded DNA, in addition to observed double helix specimens. Thus, the presence/lack of single-stranded versus double helix images is consistent with known melting temperature data for the C-G and A-T base pairings.

The same group has also reported successful STM investigations of transfer-ribonucleic acid (t-RNA) (14). In

Figure 3. Hetero G-C and Hetero A-T mixed sample. The larger specimens are identified as Hetero G-C, and the smaller specimens are identified as Hetero A-T. Both are in a double helix configuration. (Reproduced from Ref. 9, used with permission.)

Figure 4. (a) Model of t-RNA L-shaped conformation. (b) Model base pair arrangement in L-shaped conformation. (c) STM image of L-shaped conformation at physiological pH. (Reproduced from Ref. 10, used with permission.)

RNA, the base pairing is adenine-uracil (A-U) instead of adenine-thymine (A-T). Also the backbone sugars are ribose rather than deoxyribose, but are still linked by phosphate groups. The RNA is very difficult to synthesize as a single crystal and consequently there is a very limited amount of X-ray diffraction data available for RNA. Little is known about its variations, and therefore direct investigations of single molecule RNA would add much to our knowledge.

Transfer RNA is a small RNA chain of ~ 74 –93 nucleotides that transfers a specific amino acid to a growing polypeptide chain at the ribosomal site of protein synthesis during translation (15). It has sites for amino acid attachment, and an anticodon region for codon recognition that binds to a specific sequence on the messenger RNA (mRNA) chain. It has a partial double-helix structure even though it has only one chain, because the single RNA chain folds back, and loops back, on itself, as shown in Fig. 4a.

X-ray diffraction studies (16) have indicated that the t-RNA structure may often assume an L-shaped conformation with a long and a short arm. A model of the *Escherichia Coli* lysine t-RNA macromolecule used by the group for its STM studies is shown in Fig. 4a and b. It shows both the L conformation and the underlying loop and base pair chemistry.

Using STM, the group was able to directly image the L conformation as shown in Fig. 4c. In addition to the first direct statistical data on the lengths of the long and short arms, obtained from analysis of several STM images, an analysis of the influence of pH on conformation was also carried out. Current investigations are focusing on biofunction research issues in addition to structural research issues, using STM to directly image the coupling of the important amino acid molecules at specific t-RNA sites.

The STM investigations of nanobiomedical rather than structural issues are an important emerging research area. One example is the recently reported research from the University of Sydney group in which the local binding of retinoic acid, a potent gene regulatory molecule, to plasmid p-GEM-T easy (596 base pair Promega) DNA fragments on a single-crystal graphite substrate, was directly imaged and reported (17). Retinoic acid has been documented as responsible for a number of profound effects in cell differentiation and proliferation, and is known to accomplish its functions through selective site binding during the transcription process. The STM images of retinoic acid by itself

on a single-crystal graphite substrate were investigated first. These showed sizes consistent with the retinoic acid molecular structure, and a bright head area with a darker tail area. A molecular model of retinoic acid, also shown in Fig. 5a, shows its aliphatic carbon ring head and polymeric tail. For reasons further discussed below, the aliphatic ring head may be expected to have a higher tunneling current associated with it than the polymeric tail, and therefore the observed bright and dark areas are consistent with the expected structure.

At low concentrations, retinoic acid was observed to bind selectively at minor groove sites along the DNA, with some clustering of retinoic acid molecules observed, as shown in Fig. 5b. High resolution STM imaging provided direct evidence for alignment of the retinoic acid molecules head-to-tail structure edge-on with the minor groove and also in steric alignment with each other. From STM height studies, it could also be inferred that the aliphatic ring head was attached to a ring partner along the minor groove surface, but that the tail was not attached. This may suggest a loosely bound on-off functional mechanism. At high concentrations, retinoic acid was observed to bind along the whole length of the DNA double helix, but again selecting the minor grooves. These first direct studies of selective site binding of retinoic acid with the minor groove of DNA should serve as a template for further direct investigations of other known minor groove binders, thereby opening up the direct investigation of an entire

Figure 5. (a) STM image of retinoic acid on a graphite substrate compared with its molecular model showing the aliphatic ring head and polymeric tail. (b) STM image of retinoic acid binding to t-RNA with molecular model overlay. (Reproduced from Ref. 13, used with permission.)

class of regulatory molecule–DNA interactions. The interactions of related structures that are candidate therapeutic drug molecules could be receive similar direct investigation.

Note that both of the above groups have also made important contributions to sample preparation techniques for successful STM analysis of DNA and RNA. These sample preparation techniques will be discussed below in the context of the basic physics of the STM interaction, and the basic chemistry and conductivity of DNA and RNA samples.

BASIC PHYSICS OF THE STM INTERACTION

The STM is based on tip–sample interaction via a tunneling current between filled electronic states of the sample (or tip) into the empty electronic states of the tip (or sample), in response to an applied bias, as shown in Fig. 6. The bias may be positive or negative, and different and valuable information may often be obtained by investigation of the how the sample behaves in accepting, as well as in giving up, electrons. In STM imaging, it is important to recognize that the feature map or apparent topography of the acquired image is really a map of the local density of electronic states. Bright does not correspond to a raised topography; it corresponds to a region with a high density of electronic states. Therefore, in STM imaging of biological samples, an important consideration is that a differential conductivity will be observed from regions, such as rings (usually high) versus regions, such as alkane backbones (usually low). As in all SPM techniques, a z -direction feedback loop maintains some aspect of the tip samples interaction constant (Fig. 6). The readily available choices on commercial machines are to hold either the tunneling distance d constant (constant height mode) or the magnitude of the tunneling current content (constant current mode).

The current in question is a tunneling current, which is a quantum mechanical phenomenon. It is well documented that all electrons within the atomic planes of any material are in fact in such tight quarters that they display the characteristics of a wave in a waveguide, in addition to

Figure 6. Important features of an STM system.

Figure 7. A particle penetrating into and through a wall.

their particle-likeness. An electron at the surface of a material faces a wall (barrier) created by the dissimilar material (e.g., air, vacuum, or a liquid). While a particle would run into a wall and bounce back, a wave can penetrate into and indeed through a wall (as light goes through glass). This is illustrated in Fig. 7. Additionally, all materials have precise energy levels within them, and therefore, electrons will move by going from one energy level at location 0 to another at location d , meeting conservation of energy requirements.

In STM, a tip with empty electronic states is brought physically close to a sample surface. The electrons are given a direction through the application of the bias (positive in this example). Because they are wavelike, when they reach the sample surface, they can tunnel through the barrier created by the 0-to- d gap and reach the empty states of the tip, where they are recorded as a current proceeding from sample to tip. A tunneling current has the known mathematical form: $I \sim V \exp^{-c d}$, where I is the tunneling current, V is the bias voltage between the sample and the tip, c is a constant and d is the tip-sample separation distance. The tunneling current depends sensitively on the size of the 0-to- d gap distance. To observe a tunneling current, the gap must be on the order of tens of nanometers. This is the case in any commercial STM system. It is remarkable, that with the addition of a simple feedback loop, a tip can be easily maintained within nanometers of a sample surface without touching it. Typical STM tunneling currents are on the order of 10^{-9} – 10^{-12} A. With special preamplifiers, currents on the order of 10^{-14} A can be detected.

Because STM is a current-based technique, some situations that can interfere with its current will be briefly discussed. Very common in STM imaging of biological samples is for the tip to acquire a layer of biological material, possibly by going too close to the sample surface while passing over an insulating region where the feedback loop has little to work on. This usually just introduces image artifacts, discussed below, but it can sometimes insulate the tip from the sample, thus terminating the tip–sample interaction. The problem can be minimized through careful consideration of the expected chemistry and local conductivity of the biological specimen to be investigated.

CHEMISTRY, CONFORMATION, AND CONDUCTIVITY OF BIOLOGICAL SAMPLES

Consideration of the basic chemistry involved in a biological sample can help to determine its appropriateness for STM imaging. The building blocks for DNA and RNA are

Figure 8. (a) The deoxyribose (ribose) sugar/phosphate backbone for DNA (RNA) is negatively charged due to phosphate groups. (b) DNA and RNA bases are nitrogenous ring systems.

shown Fig. 8. The sugar-phosphate backbone contains negatively charged phosphate groups for both DNA and RNA. The bases adenine, thymine, uracil, guanine, and cytosine are all nitrogenous ring systems. Thymine, cytosine, and uracil are six-member ring pyrimidine systems, and adenine and guanine are purines, the fusion of a six-member pyrimidine ring to a five-member imidazole ring. Successful STM imaging of monolayers of the individual bases has been reported (18,19). Examples of the high resolution STM imaging that is possible for monolayers of the individual bases are shown in Figs. 9 and 10.

The nitrogenous ring systems, like the classic benzene ring system, which has also been imaged (20), contain *p*-orbital electrons above and below the ring structure plane, which create a conductive electron cloud. Hence, the successful STM imaging of the DNA and RNA systems by the Osaka University and University of Sydney groups might be expected from the charged phosphate groups in the backbones and the ring systems in the base pairs.

However, there are also very difficult issues to resolve in making the local conductivity of, especially, the signature DNA and RNA base pairs available to the STM tip. These are enclosed within the sugar-phosphate backbones, and only partially exposed by the twisting of the helix, as shown in Fig. 11a and b (21,22). Also, the choice of substrate will powerfully influence the molecular structure deposited on it, especially if it is small. An example of this is shown in Fig. 12, taken from Ref. 16. The behaviors of pyridine (a

single-nitrogen close relation to pyrimidine) and benzene on a single crystal (001) orientation copper, Cu(001), substrate were investigated. The pyrimidine monolayers (thymine, cytosine, and uracil) in Figs. 9 and 10 had rings oriented parallel to the substrate surface, but individual pyridine molecules on Cu(001) had rings perpendicular to the surface, due to the strong nitrogen-copper atom interaction, as shown in Fig. 12a. Also, if a single hydrogen atom was dissociated from the pyridine molecule, as can happen during routine scanning, the molecule would shift its position on the copper substrate (Fig. 12b). The STM imaging of an individual benzene molecule indicated a ring system parallel to the copper substrate (Fig. 12c), but hydrogen dissociation would cause the benzene molecule to become perpendicular to the substrate surface (Fig. 12d). Therefore both the substrate choice and interactions with the imaging tip can influence the conformation of the biomolecule and whether its locally conductive portions are positioned to produce a tunneling current.

Now consider the situation of a molecule with a difference in local conductivity, like retinoic acid. The aliphatic ring head would similarly be expected to have a high local conductivity, and separate investigations of just retinoic acid by the University of Sydney group confirmed that this is the case (Fig. 5a). The polymeric tail is basically an alkane system without any *p*-type orbitals. Its conductivity is therefore expected to be less than the ring system and this is experimentally observed. However, results such as those shown in Fig. 13 from a group at California Institute of Technology, demonstrate that high resolution STM imaging even of low conductivity alkane systems is possible (23–26). Therefore, one aspect of STM biomolecular imaging is that there may be large differences in the conductivities of two closely adjacent regions. It then becomes an issue of whether the STM feedback loop will be able to sufficiently respond to the differences to maintain the tip-sample tunneling current interaction throughout the investigation. Prior consideration of the imaging parameters necessary for successful STM imaging of the *least* conductive part of the bio molecule can help.

Figure 12. Influence of the sample-substrate interaction on sample orientation. (a) An individual pyridine molecule on a copper (001)-orientation, (Cu(001)) substrate is perpendicular to the surface due to the strong nitrogen-copper atom interaction. (b) An individual pyridine molecule from which a hydrogen atom has dissociated is also perpendicular to a Cu(001) surface but has a shifted location. (c) An individual benzene molecule on a Cu(001) substrate is parallel to the surface but (d) may become perpendicular if hydrogen dissociation occurs. (Adapted from Ref. 16, used with permission.)

Biomolecules, with only nanometer dimensions, always should be deposited on atomically flat single-crystal substrates. Substrates can also be selected to supply electrons to the biomolecule, for positive bias scanning, or to manipulate the biomolecule into a desired position. Another important sample preparation issue is that biomolecules often have multiple available conformations, including globular conformations that self-protect the molecule under nonphysiological conditions. While STM imaging may be performed in vacuum, air, and even in a liquid-filled compartment (liquid cell), the best resolution may be achieved in vacuum, which is a nonphysiological condition. The less physiological the imaging conditions, the more it will be necessary to use special molecular stretching techniques to investigate an open conformation. A special pressure jet injection technique was developed by the Osaka University group to deposit stretched DNA and RNA on single-crystal copper for vacuum STM imaging, without giving them the chance to close into globular conformations (13,14).

IMAGING ARTIFACTS AND DATA RESTORATION USING DECONVOLUTION

Examination of Fig. 5a shows the ring head of retinoic acid as a large blurred bright spot. Greater resolution of detail would clearly be desirable. As in all SPM imaging systems, tip artifacts versus the surface features will limit the resolution of the experiments performed. This is often cited as an ultimate barrier in STM studies of macromolecular structures and in scanning probe microscopy in general (27). It is therefore necessary to develop techniques for deconvolution of STM tip artifacts for enhancing the resolution of measured STM image data.

A commonly used approach for data restoration or eliminating the smearing effect of tip sample interaction is to assume that the observed signal is a convolution of the true image and the probe response function (PRF). The following equation gives a general degradation model due to the convolution of tip artifacts with true data resulting in the measurement $g(x,y)$. Neglecting the presence of the additive noise, the data can be modeled as

$$g(x,y) = f(x,y) * h(x,y) = \sum_{n,m} f(n,m)h(x-n,y-m)$$

where $g(x,y)$, $f(x,y)$, and $h(x,y)$ are the observed or raw signal, true image, and PRF, respectively. One can then use deconvolution methods to extract the true image from the knowledge of measured data and probe PRF.

Theoretically, the probe response function is derived from the underlying physics of the tip sample interaction process. Hence, there is a need for a theoretical model for the tip sample interaction. Recent advances in formulation and modeling of tip sample interactions allow development of accurate compensation algorithms for deconvolving the effect of tip-induced artifacts.

Figure 14 shows an example of applying a deconvolution algorithm on synthetic degraded images. The degraded image in Fig. 14c is generated from a synthetic image in Fig. 14a blurred by a Gaussian PRF in Fig. 14b. Figure 14d shows the enhanced result obtained using deconvolution. Although the theoretical treatment of STM and related SPM techniques provide major challenges because the atomic structures of the tip and sample have to be modeled appropriately, its potential is clear and this is a strongly developing research area at the present time.

CONCLUSIONS

The STM imaging has the highest resolution of all SPM imaging techniques. As such, it would be highly desirable to apply STM to investigations of molecular biology and medicine. An often described difficulty when considering the application of STM to molecular biology is that biological samples are nonconductive. It would be more accurate to describe biological samples as having both local and varying conductivities. Design of STM experiments in which ring systems are exploited, and/or imaging parameters are set for the least conductive portion of the biomolecules may help produce successful imaging results. New research in applications of powerful deconvolution

techniques to STM imaging will also open up the field of direct STM investigations of the structure and function of important biomolecules.

MICROSURGERY

KEITH J. REBELLO
The Johns Hopkins University
Applied Physics Lab
Laurel, Maryland

INTRODUCTION

Microsurgery is a specialized surgical technique whereby a microscope is used to operate on tiny structures within the body. Fine precision microinstruments are used to manipulate tissue with or without robotic or computer control.

This technique has allowed for significant advances in surgery especially for operations involving the inner ear, eye, brain, nerves, and small blood vessels.

HISTORY OF THE SURGICAL MICROSCOPE

The compound microscope is generally agreed upon to have been invented in the 1590s by the two Dutch opticians Hans and Zacharias Janssen. Their device consisted of a sliding tube with two aligned lenses. In 1624 Galileo Galilei, the famous astronomer and mathematician, demonstrated an inverted telescope to his colleagues of the Lincean Academy. One of them, Giovanni Faber, named it a microscope from the Greek words *micro*, meaning small, and *scope*, meaning to aim or shoot. Microscope lenses were improved in the seventeenth century by Antonie van Leeuwenhoek, a Dutch linen draper who originally was interested in counting the number of threads per square inch in his reams of cloth. How he constructed his spherical lenses still remains a mystery to this day. In the eighteenth century, fine and course adjustments as well as tube inclination were added by Robert Hooke, who first discovered the cell. The microscope was further improved by Joseph Jackson Lister a British wine merchant, school visitor, and histologist, the father of Lord Joseph Lister whom is credited as stating the era of modern surgery. His innovations included the developed achromatic objective lens corrected for chromatic and spherical aberrations and stands designed to reduce vibrations. His jointly published work with Dr. Joseph Hodgkins in 1827, redefined the understanding at the time of arteries, muscles, nerves, and the brain.

In 1848 Carl Zeiss, a German machinist opened a microscope workshop. Ernst Abbé, a physicist working with Zeiss, derived new mathematical formulas and theories that allowed the optical properties to be mathematically predicted for the first time. Prior lenses had always been made by craftsmen who learned their trade by trial and error. Abbé's advancements enabled Zeiss to become the first mass producer of high quality microscopes.

USE IN SURGERY

Edwin Theodor Saemisch, a German ophthalmologist, used loupes in surgery in 1876, but although the microscope was being used in the laboratory medical research environment it was not used the operating room. Zeiss manufactured a binocular microscope specifically designed for dissecting which was used for ophthalmological examinations of the cornea and anterior chamber of the eye. It was not until 1921 that Carl Olof Nylen, a Swedish, otologist and tennis olympian, used his homebuilt monocular microscope for the first time in ear surgery on a case of chronic otitis media, a type of ear infection. His monocular microscope was quickly replaced in 1922 by a binocular microscope developed by adding a light source to a Zeiss dissecting microscope by his chief surgeon, Gunnar Holmgren. He used it to treat diseases otosclerosis, the abnormal growth of temporal bone in the middle ear.

Despite these early successes the surgical microscope was seldom used due to its limited field of vision, very short focal distance, poor light quality, and instability. It was not until the 1950s that the surgical microscope started to become more widely adopted. In 1953, Zeiss released the Zeiss OpMi 1 (Zeiss Operating Microscope Number One), which was specially designed for otological procedures. Its superior coaxial lighting, stability, and ease of operation enabled the advent of tympanoplasty operations to repair ruptured ear drums as well as widespread use in temporal bone surgery.

The success the microscope was having in otology soon spread to other disciplines as well. In the early 1950s, José Ignacio Barraquer adapted a slip lamp to the Zeiss otological surgical microscope for ocular microsurgery. By the 1960s, J. I. Barraquer, Joaquín Barraquer, and Hans Littman of Zeiss, had further modified the surgical microscope and refined microsurgical techniques to make ocular maneuvers in glaucoma microsurgery easier to perform. During this same time frame, Richard Troutman also had Zeiss make a special microscope for his ophthalmic procedures. He made many advances and is credited as adding electric and hydraulic control to surgical microscopes, but possibly his greatest innovation was the first variable magnification, or zoom, surgical microscope.

Around this time neurosurgeons also began using the surgical microscope in the operating room. In 1957, Theodore Kurze removed a neuriloma tumor from the seventh cranial nerve, and then later anastomized it to the hypoglossal nerve. He also developed techniques to use the surgical microscope for aneurysm surgeries. Recognizing that sterilization was a major problem, he developed the use of ethylene oxide gas to sterilize his surgical microscopes for use in the operating room. Dr. R. M. Peardon Donaghy established the first microsurgical training lab at the University of Vermont, where many surgeons were trained. He collaborated with the vascular surgeon Julius Jacobson to remove occlusions from cerebral arteries. Jacobson and his colleague Ernesto Suarez, were responsible for developing small vessel anastomoses techniques. Their procedures required another surgeon's assistance. To meet this need Jacobson invented the diploscope that allowed two surgeons to view the same operative field. Later he and his colleagues worked with Hans Littman of Zeiss to develop a commercial surgical microscope with a beamsplitter enabling two surgeons to operate at the same time. A modern day version of the Zeiss dual head microscope is shown in Fig. 1.

Inspired by the work of the neuroscientists plastic surgeon also started using the surgical microscope. Harold Buncke was one of the first plastic surgeons to use the microscope for digit/limb replantation and free-flap autoplantation. Buncke also developed many of the tools microsurgeons use by borrowing technology from the jewelry, watchmaking, and microassembly industries (Fig. 2.)

The 1960s saw the techniques applied to neurosurgery. Breakthroughs in microneurosurgery included the repair of peripheral nerve injuries, intracranial aneurysm surgeries, embolectomies of middle cerebral arteries, middle cerebral artery bypasses. One of the visionaries of this time was M. G. Yasargil a Turkish neurosurgeon from

Figure 1. Zeiss OpMi Vario S8 surgical microscope. (Courtesy of Carl Zeiss.)

Switzerland. Trained in Donaghy's training lab he further refined and improved the surgical techniques.

The next advancements came with the development of minimally invasive surgical techniques. Traditional surgical techniques used relatively large incisions to allow the surgeon full access to the surgical area. This type of operation, called open surgery, enables the surgeon's hands and instruments to come into direct contact with organs and tissue, allowing them to be manipulated freely. These operations are classified as first generation surgical techniques and most surgeons are trained in this manner. While the large incision gives the surgeon a wide range of motion to do very fine controlled procedures, it also causes substantial trauma to the patient. In fact, the majority of trauma is caused by the incisions the surgeon uses to get access to the surgical site instead of the actual

Figure 2. Modern day microsurgical tools. (Courtesy of WPI Inc.)

surgical procedure itself. For example, in a conventional open-heart cardiac operation, the rib cage must be cracked and split exposing the heart muscle. This trauma not only increases pain to the patient, but adds to recovery times increasing hospital stays, in turn increasing costs.

In 1985, Muhe performed the first laparoscopic cholecystectomy, or gallbladder removal surgery with a fiberoptic scope. The technique he performed is commonly called minimally invasive surgery but also goes by other names, such as micro, keyhole, microscopic, telescopic, less invasive, and minimal access surgery. This microsurgical technique is based on learnings from gynecological pelviscopies and arthroscopic orthopedic operations along with the previous advances made in otology, ophthalmology, neurosurgery, and reconstructive microsurgeries. It has subsequently been applied to many other surgical areas, such as general surgery, urology, thoracic surgery, plastic surgery, and cardiac surgery. These procedures are classified as second generation surgeries as trauma to the patient is drastically reduced by the reducing or eliminating incisions. The shorter hospital stays and faster recovery times for the patient reduce the cost of a minimally invasive procedure 35% compared to its open surgery counterpart.

In a minimally invasive cardiac operation a few small holes, access points, or ports are punctured into the patient and trocars are inserted. A trocar consists of a guiding cannula or tube with a valve-seal system to allow the body to be inflated with carbon dioxide. This is done so that the surgeon has enough room to manipulate his instruments at the surgical site. An endoscope is inserted into one of the trocar ports to allow the surgeon a view the surgical site. Various other surgical instruments, such as clippers, scissors, graspers, shears, cauterizers, dissectors, and irrigators were miniaturized and mounted on long poles so that they can be inserted and removed from the other trocar ports to allow the surgeon to perform the necessary tasks at hand.

While minimally invasive surgery has many advantages to the patient, such as reduced postoperative pain, shorter hospital stays, quicker recoveries, less scarring, and better cosmetic results, there are a number of new problems for the surgeon. The surgeon's view is now restricted and does not allow him to see the entire surgical area with his eyes. While the operation is being performed he must look at a video image on a monitor rather than at his hands. This is not very intuitive and disrupts the natural hand-eye coordination we all have been accustomed to since childhood. The video image on the monitor is also only two dimensional (2D) and results in a loss of our binocular vision eliminating the surgeon's depth perception. While performing the procedure the surgeon does not have direct control of his own field of view. A surgical assistant holds and maneuvers the endoscopic camera. The surgeon has to develop his own language to command the assistant to position the scope appropriately, which often leads to orientation errors and unstable camera handling, especially during prolonged procedures. Since the images from the camera are magnified, small motions, such as the tremor in a surgical assistant's hand or even their heartbeat can cause the surgical team to experience motion induced nausea. To combat the endoscopic problems, some

surgeons choose to manipulate the endoscope themselves. This restricts them to using only one hand for delicate surgical procedures and makes procedures even more complicated.

The surgeon also loses the freedom of movement he has in open surgery. The trocar ports are fixed to the patient's body walls by pressure and friction forces. This constrains the instrument's motion in two directions and limits the motion of the tip of the instrument to four degrees of freedom (in-out, left-right, up-down, and rotation). The trocars also act as pivot points and cause the surgical instruments to move in the opposite direction to the surgeon's hands. When the surgeon is moving left, the image on the monitor is moving to the right. The amount of this opposite movement also depends on the depth of the introduction of the instrument. Again because of the pivot point the deeper an instrument is inserted into the body the more the surgeon's movement is amplified. Even a small movement made by the surgeon on the outside of the patient can translate to a very large movement on the inside of the patient. The seals and valves in the trocars also impede movements which hinders the smoothness of motions into and out of the patient and greatly reduces the already limited tactile feedback the surgeon experiences. These movement behaviors and lack of tactile feedback are counter to what the surgeon is used to in open surgery and require long training to develop the technical skills to perform these operations.

Performing a minimally invasive procedure has been likened to writing your name holding the end of an 18 in. (45.72 cm) pencil (1). The surgeon loses three-dimensional (3D) vision, dexterity, and the sense of touch. The instruments are awkward, counterintuitive, and restricted in movement. The lack of tactile feedback prevents the surgeon from knowing how hard he or she is pulling, cutting, twisting, suturing, and so on. These factors cause a number of adjustments to be made by the surgeon, which requires significant retraining on how to do the procedures in a minimally invasive manner. These difficulties encountered by the surgeon cause degradation in surgical performance compared to open surgery which limits surgeons to performing only simpler surgical procedures.

In an attempt to address some of these shortcomings and allow the surgeon more control during operations a third generation of surgical procedures, robotic surgery was developed. Although these types of procedures are commonly referred to as robotic surgery, the operations themselves are not completely automated and are still carried out by a surgeon. For this reason, robotic surgery is also referred to as computer aided or computer assisted surgery.

The robotic technology was originally developed for telerobotic applications in the late 1980s for the Defense Advanced Research Project Administration (DARPA) by researchers at SRI International. The surgeon of the future would allow surgeons from remote command centers to operate on injured soldiers in the battlefield. In 1995, this technology was spun off into a new company named Intuitive Surgical to commercialize the technology for use in the hospital environment. Near the same time Dr. Yulan Wang was developing robotic technology for NASA to allow

Figure 3. Intuitive Surgical da Vinci robotic surgery system. (Copyright ©2005 Intuitive Surgical, Inc.)

surgeons on earth to deal with medical emergencies on the international space station. He formed Computer Motion in 1989. Both of these companies merged in 2003, and Intuitive Surgical is now the leader in Robotic Surgery. In 2002, Dr. Fredric Mol, one of the original founders of Intuitive Surgical, founded Hansen Medical which brings computerized robotic control of catheters to electrophysiology and interventional cardiac procedures.

Current robotic surgery systems have a number of benefits over conventional minimally invasive surgery. Figure 3 shows an Intuitive Surgical da Vinci robotic system. In this arrangement the surgeon sits comfortably at a computer console instead of having to stand throughout the entire procedure, which can last up to 5 h long. A three-armed robot takes his place over the patient. One arm holds an endoscope while the other two hold a variety of surgical instruments. The surgical team can also look at a video monitor to see what the surgeon is seeing. The surgeon looks into a stereo display in much the same way as looking through a surgical microscope and manipulates joystick actuators located below the display. This simulates the natural hand–eye alignment he is used to in open surgery, (Fig. 4). Since computers are used to control the robot and are already in the operating room, they can be used to give the surgeon superhuman like abilities. Accuracy is improved by employing tremor cancellation algorithms to filter the surgeon's hand movements. This type of system can eliminate or reduce the inherent jitter in a surgeon's hands for operations where very fine precise control is needed. Motion scaling also improves accuracy by translating large, natural movements into extremely precise, micro-movements. A wide variety of surgical instruments or end effectors are available including graspers, cutters, cauterizers, staplers, and so on. Both companies provide end effectors that have special wrist like joints at their tips enabling full seven degree of freedom movements inside the patient, (Fig. 5), but still lack tactile feedback.

These robotic advances allow surgeons to perform more complex procedures, such as reconstructive cardiac operations like coronary bypass and mitral valve repair that cannot be performed using other minimally invasive techniques.

MEMS

Around the same time that minimally invasive surgery was being developed, there was a turning point in microelectromechanical systems (MEMS). This a technology was developed from the integrated circuit industry to create miniature sensors and actuators. Originally, these semiconductor processes and materials were used to build electrical and mechanical systems, but have now expanded to include biological, optical, fluidic, magnetic, and other systems as well. The term MEMS originated in the United States and typically contain a moving or deformable object. In Europe, this technology goes by the name microsystems technology or microstructures technology (MST) and also encompasses the method of making these devices, which is referred to as micromachining. In Japan and Asia MEMS are called micromachines when mechanisms and motion are involved. The MEMS devices first were used in medical applications in the early 1970s with the advent of the silicon micromachined disposable blood pressure sensor (2), but it was not until the mid-1980s when more complicated mechanical structures, such as gears and motors, were able to be fabricated.

FABRICATION TECHNOLOGIES

The fabrication of MEMS devices is based on the merger of semiconductor microfabrication processes and micromachining techniques to create the desired microstructural components. There are four major processes that are used to fabricate MEMS devices: bulk micromachining, surface micromachining, LIGA, and precision machining. Combinations of these technologies are what allow MEMS to be highly miniaturized and integratable with microelectronics. These processes are very sensitive to impurities and environmental conditions such as temperature, humidity, and air quality. Typically, these fabrication steps are performed inside a cleanroom (Fig. 6). Bulk micromachining, surface micromachining, and LIGA have the added advantage of being able to be batch fabricated. This allows many devices to be made in parallel at the same time greatly reducing device cost.

Bulk micromachining utilizes wet- or dry-etch processes to form 3D structures out of the substrate. These subtractive processes produce isotropic or anisotropic etch profiles in material substrates, which are typically but not limited to silicon wafers. Bulk micromachining can create large MEMS structures on the micrometers (μm) to millimeters (mm) scale (tens of μm -to-mm thick). Commercial applications of bulk micromachining have been available since the 1970s. These applications include pressure sensors, inertial sensors such as accelerometers and gyros, and microfluidic channels and needles for drug delivery.

In surface micromachining, MEMS are formed on the surface of the substrate using alternating layers of structural and sacrificial materials. These film materials are repeatedly deposited, patterned, and etched to form structures that can then be released by removing sacrificial layers. The release process allows for the fabrication of complex movable structures that are already assembled,

Figure 6. Cleanroom fabrication facility. (Courtesy of Intel Corp.)

such as motors, switches, resonators, cantilevers, and so on. Surface micromachined structures are typically limited to thicknesses of 2–6 μm and because they use much of the same technology as is used in the integrated circuit industry are readily integrated with electronics. Because so much technology is shared with the IC industry silicon wafers are typical substrates with thousands of devices being able to be fabricated at once (Fig. 7).

Lithographie, Galvanik, Abformung (LIGA) is a German acronym that means lithography, electroforming, and molding. The technology was originally developed in the late-1970s to fabricate separation nozzles for uranium enrichment. This technology uses X rays to fabricate devices with very high aspect ratios. A synchrotron radiation source is used to define small critical dimensions in a poly(methyl methacrylate) (PMMA) mold that can then be electroplated to form high aspect ratio metallic structures. Many parts can be batch fabricated in this manner, but assembly is usually still a serial process.

Precision machining technology, such as micro-EDM (microelectro discharge machining), laser micromachining, and micro stereo lithography, is also used to form complex structures out of metal, plastic, and ceramics that the previous fabrication technologies may be incapable of. Precision machining is typically a serial process, but is

Figure 7. Silicon wafer in the fabrication process. (Courtesy of Intel Corp.)

often better able to deal with the varied shapes and substrates of microsurgical instruments.

Micro EDM is a form of spark machining used to shape conductive materials, such as silicon and metals. An EDM erodes material by creating a controlled electric discharge between an electrode and the substrate. It is a noncontact process and there is no direct mechanical cutting force applied to the substrate. Dielectric fluid is used to remove the erosion particles, as well as to keep the substrate material from oxidizing. Micro-EDMs can be used to make holes, channels, gears, shafts, molds, dies, stents, as well as more complex 3D parts such as accelerometers, motors, and propellers (3).

Lasers can be used to both deposit and remove material. Laser ablation vaporizes material through the thermal noncontact interaction of a laser beam with the substrate. It allows for the micromachining of silicon and metals, as well as materials that are difficult to machine using other techniques such as diamond, glass, soft polymers, and ceramics. Laser direct writing and sintering is a maskless process where a laser beam is used to directly transfer metal materials onto a substrate. This can be used to form metal traces on nonplanar surfaces, which reduces the need for wires on surgical tools (4).

Micro stereo lithography processes generate 3D structures made out of ultraviolet (UV) cured polymers. It is an additive process where complex 3D structures are made from stacks of thin 2D polymer slices that have been hardened from a liquid bath. Conventional systems were limited in that they were a serial process where only one part could be made at a time. MicroTEC has developed a batch fabricated wafer level process called rapid material product development (RMPD), which is capable of constructing structures out of 100 different materials including plastics, sol-gels, and ceramics (5).

APPLICATIONS

The inclusion of MEMS technology in microsurgery, will allow for smaller more miniaturized surgical tools that not

Figure 8. Strain gauges fabricated on surgical sharps. (Courtesy of Verimetra, Inc.)

only overcome many of the limitations of microsurgical procedures, but allow for new more advanced operations to be performed. MEMS are just now being incorporated into microsurgical tools and coming on the market. Most are still at the research level, but the industry is moving in this direction as the need for smaller smarter tools increases.

HAPTIC FEEDBACK

One of the key areas for improvement in microsurgery is tactile feedback. The lack of tactile sensing limits the effectiveness these procedures. Recent work in robotic feedback for minimally invasive surgery has concentrated on force feedback techniques using motors and position encoders to provide tactile clues to the surgeon. In these approaches, the sense element is far removed from the sense area. Verimetra, Inc. has developed strain gauge force sensor fabrication technology which uses the surgical tools themselves as a substrate (6). Prior efforts have focused on fabrication of sensors on silicon, polyimide, or some other substrate followed by subsequent attachment onto a surgical tool with epoxy, tape, or some other glue layer. Attaching a sensor in this manner limits performance, introduces sources of error, limits the sensor's size, and further constrains where the sensor can be placed. By eliminating glue and adhesion layers improved sensitivity and reduces errors due to creep. Figure 8 shows strain gauges fabricated on surgical sharps. Figure 9 is a cut away SEM image of a strain gauge and temperature sensor embedded inside of a robotic microforcep. While this micro-fabrication technology is an improvement in sensor technology, wires are still used to connect the sensor to the outside world. Reliability and the added complexity of adding wires to surgical end effectors with high degrees

Figure 9. Strain gauges and temperature sensor embedded in robotic microgripper. (Courtesy of Verimetra, Inc.)

of freedom limit the effectiveness of the technology. Short-range wireless technology compatible with the operating room environment need to be developed to overcome these limitations.

Recently tactile feedback has been shown to be able to be added to noncontact lasers. Based on optical distance measurements, the systems synthesize haptic feedback through a robotic arm held by the surgeon when the focal point of the laser is coincident with a real surface. This gives the operator the impression of touching something solid. By increasing the power of the laser such a system could also be used for cutting or ablation.

TISSUE SENSING

Taking haptic feedback one step further is the ability to distinguish between different types of tissue in the body. Tissue sensing is of vital importance to a surgeon. Before making an incision into tissue, the surgeon must identify what type of tissue is being incised, such as fatty, muscular, vascular, or nerve tissue. This becomes more complicated because the composition and thickness of different human tissues varies from patient to patient. Failure to properly classify tissue can have severe consequences. For example, if a surgeon fails to properly classify a nerve and cuts it, then the patient can suffer effects ranging from a loss of feeling to loss of motor control. If a neurosurgeon cuts into a blood vessel while extracting a tumor severe brain damage may occur. The identification and classification of different types of tissue during surgery, and more importantly during the actual cutting operation, will lead to the creation of smart surgical tools. If a surgical tool senses that it is too close to or about to cut the wrong type of tissue it can simply turn itself off.

Verimetra, Inc. has developed a device called the data knife, Fig. 10. It is a scalpel, which is outfitted with different strain sensors along the edges of the blade to sense the amount of force being applied. The resistance of the tissue is one of the signals used for classifying tissue. Pressure sensors are used to measure the characteristics of material surrounding the blade. The pressure of the surrounding fluid can be used to help classify the type or location of tissue. Electrodes are used to measure the impedance of different types of tissue, as well as being used to identify nerves by picking up their electrical signals. The tool provides the real-time feedback surgeons

Figure 10. Data Knife smart scalpel. (Courtesy of Verimetra, Inc.)

have been asking for during surgery, and can also be used to record data for later use for tracking purposes.

Sensing the density of tissue can also be used to assist the surgeon in identifying tissue. In open cardiac bypass operations, the surgeons insert their hands inside the body to palpate arteries. For cardiac bypass surgery, surgeons select the bypass location by feeling where the fat and fatty plaque is located in your arteries with their fingers. The lack of tactile feedback in minimally invasive surgery, prevents them from using this technique. The MEMS devices have been developed for the palpation of tissue using strain gauges (7), diaphragms (8), micropositioners (9,10), and load cells (11) and have shown the ability to measure blood pressure, pulse, different kinds of arterial plaque, and distinguish between colon, bowel, stomach, lung, spleen, and liver tissue.

Piezoelectric transducers can also be used to measure density. Macroscale transducers are frequently used in imaging applications to differentiate between tumors, blood vessels, and different types of tissue. These transducers both emit and receive sound waves. By vibrating at a high frequency sound waves are emitted in the direction of the object of interest. The density of the impinged object can then be measured based on the signal that is reflected back by that object. Sound waves are reflected off the interfaces between different types of tissue and returned to the transducer. Present ultrasound systems tend to be large and are not well suited for incorporation into microsurgical devices. The MEMS technology is well suited for this application and many ultrasonic MEMS sensors have been developed for imaging (12–16).

Microelectromechanical systems ultrasound devices for density measurements are shown in Fig. 11. They have been shown to be able to detect the location of bone in tissue and are being applied to atrial fibrillation surgeries. Atrial fibrillation is what causes irregular heartbeats and leads to one out of every six strokes. Drugs can be used to treat this condition, but have dangerous side effects including causing a switch from atrial fibrillation to the more dangerous ventricle fibrillation. Pacemakers and other electrical control devices can be used, but they do not always work for all patients. The most effective treatment is the surgical

Figure 11. Ultrasound transducers next to a dime. (Courtesy of Verimetra, Inc.)

MAZE procedure, but it is an incredibly invasive treatment. The patient is put on a heart lung machine and then their heart is stopped. Next, the surgeon takes a scalpel and actually cuts all the way through the heart making lesions, which physically separate the heart muscle. These lesions break the electrical connections in the heart. The heart is then sewn back together. Recently, there have been a variety of different methods used to address the problem. Instead of physically cutting all the way through the heart with a scalpel, surgeons are using radio frequency, microwave, cryo, and laser energy to create transmural lesions. Transmurality means that the lesions go all the way through the tissue, breaking the heart's electrical connections. One of the problems surgeons encounter is to know how deep the ablation is or if it is transmural. If the lesions are not completely transmural or just partially transmural then the undesirable electrical signals may still be transmitted to the heart muscle. The MEMS ultrasound technology or micromachined electrodes can be used to measure the transmurality.

Temperature can be used to detect if a surgical device is close to a blood vessel, or if the surgical tool is in a diseased or infected area. Temperature can also be used to monitor the usage of a surgical device, by monitoring the time at which the device is at body temperature. Usage is just one of many areas where Auto-ID technologies will benefit microsurgery (17). They can be used to make sure that only the correct surgical tool is used for a procedure and if that tool has been properly sterilized. Keeping track of how many times, how long, and what was done with a surgical tool will improve the reliability and effectiveness of surgical procedures and will greatly impact the entire medical industry.

TRACKING SYSTEMS

Traditionally, a surgeon uses an endoscope in minimally invasive surgery to determine where the surgical instruments are located in the patient. The view the surgeon has of the surgical area is not ideal and the position of surgical instruments outside of the camera view is not known. Ideally, the surgeon would like to know the position and orientation of each of his instruments. Computer-aided surgery has enabled the surgeon to overlay magnetic resonance imaging (MRI) or computed arterial tomography (CAT) scan images of the patient with position and orientation data taken during surgery to create 3D models that the surgeon can use to better visualize the surgical procedure. Computers can be used to simulate the procedure beforehand allowing the surgeon to practice difficult operations ahead of time.

Current technology in this area is predominately optical in nature. Markers are placed on the ends of the surgical instruments that are located outside of the body, as well as on specific locations on the patient's body. A computer registers the location of the surgical tools with the reference markers on the patient so that images of the patient's body can be aligned with the surgical tools. This is done through the use of visible and infrared (IR) cameras. The tips of the surgical tools that are located inside of the body

are then extrapolated. The markers must not interfere with the surgery in any way, and therefore should be as small and lightweight as possible. While these systems are wireless and do not have cords that can get tangled on the surgeon or on the surgical tools, there must be an unobstructed path from the markers to the camera systems. The surgeon must be careful not to block the markers themselves or with other surgical instruments. Precision is compromised because the location of the surgical tips is extrapolated and does not take into account bending of the surgical tools. Markers on the outside of the body do not take into account compression of the tissue.

MEMS based ultrasound tracking systems have been developed to address these issues (18). Constellations of ultrasound sensors can also be placed on the surgical tools themselves to determine position thereby eliminating errors from extrapolation. Reference markers can now be placed inside of the body, closer to the surgical area so that they are less affected by compression and movement of the patient.

Position and orientation can also be estimated using accelerometers and gyroscopes. The signal outputs can be integrated to determine or predict the distance traveled by a surgical tool. Conventional MEMS accelerometers have accuracies in the milligram range, which are not sufficient for measuring accurately the relatively small displacements made during surgery (19). More accurate inertial sensors need to be developed before they can be integrated into surgical tools.

Magnetic field sensors can also be used to determine position and orientation of surgical tools (20,21). A three axis magnetoeffect sensor has been developed for determining the location of catheters. Currently this is done by continually taking X rays of the patient. However X rays only provide a 2D snapshot, a 3D image would be more helpful for navigation.

EYE SURGERY

The leading cause of vision loss in adults > 60 are cataracts. The word cataract comes from the Greek meaning waterfall and was originally thought to be caused by opaque material flowing, like a waterfall, into the eye. The condition is actually caused by the clouding of the eye's intraocular lense. In the eye, light passes through the lens that focuses it onto the retina. The retina converts the light into electrical signals that are then interpreted by the brain to give us our vision. The lens is a hard crystalline material made mostly of water and protein. The protein is aligned in such a way to allow light to pass through and focus on the retina. When proteins in the lens clump together, the lens begins to cloud and block light from being focused on the retina. This causes vision to become dull and blurry, which is commonly referred to as a cataract.

Much like other surgery in other parts of the body, cataract surgery has followed down the minimally invasive path for the same benefits. Cataract surgery is one of the earliest known surgical procedures. The earliest evidence is the written Sanskrit writings of the Hindu surgeon

Susrata dating from the fifth century BC. He practiced a type of cataract surgery known as couching or reclination, in which a sharp instrument was inserted into eye and pushed the clouded lens out of the way. This displacement of the lens enabled the patient to see better. Although vision was still blurred without corrective lenses, many famous people underwent this procedure including the artists Michelangelo, Rembrandt, and Renoir. Couching was still performed until the mid-twentieth century in Africa and Asia.

In 1748, Jacques Daviel of Paris introduced extracapsular surgery where the lens was removed from the eye. Later, very thick pairs of glasses were used to focus the light onto the retina and restore sight, but the glasses were cumbersome and caused excessive magnification and distortion.

By 1949, Dr. Harold Ridley of England, used PMMA as the first intraocular lens. He discovered that PMMA was biocompatible with the eye while treating WWII fighter pilots whose eyes were damaged by shattering plastic from their windshields. In the 1960s and 1970s, extracapsular surgery became the preferred treatment. A large incision (10–12 mm) was made in the eye to remove and replace the lens. This procedure minimized problems with image size, side vision, and depth perception, but the large incisions required longer hospitalization, recovery time, and stitches.

Today, cataracts are removed with a procedure called phacoemulsification with ~1.5 million operations performed yearly. A hollow ultrasonically driven titanium needle is inserted into the anterior chamber of the eye. Ultrasonic energy is then used to liquefy the hard lens and it is then aspirated out of the eye. A foldable lens made of acrylic or silicone is inserted through a (1–3 mm hole) as a replacement. Since the incision size has been reduced compared to conventional extracapsular surgery, hospitalization, general anesthesia, sutures and bandages have all been eliminated. The reduction in incision size has also reduced the risk of infection and postoperative refractions.

During the procedure the surgeon cannot see directly under the needle as the lens is broken up and aspirated. A thin clear membrane or capsule surrounds the lens. The posterior capsule tissue underneath the lens is very delicate and easily cut compared the crystalline lens. To prevent the soft underlying tissue from damage requires a skilled surgeon whom has performed many procedures. If the posterior capsule is ruptured it can lead to glaucoma, infection, or blindness. As the size of the incision has decreased, heat damage to surrounding tissue from the ultrasonic tip has increased that can alter the characteristics of the tissue and change its appearance. In addition positive intraocular pressure must be maintained by balancing the flow of infusion fluid at positive pressure and the aspirated cataract lens fragments. If pressure is not maintained the anterior chamber can collapse. Pressure is currently maintained by sensors located many feet from the surgical area. This distance creates delays in the feedback loop, which can cause dangerous pressure fluctuations leading to damage to the iris and cornea.

Recently, micromachined silicon ultrasonic surgical tools for phacoemulsification have been developed by Lal's

Figure 12. Ultrasonic phacoemulsification tool. (Courtesy of Jeff Miller/University of Wisconsin-Madison.)

research group (22,23) (Fig. 12). Piezoelectric material is attached to a micromachined silicon needle. The needle has a fluid channel for aspiration as well as a horn for amplifying the ultrasonic displacement. These silicon devices are able to generate higher stroke velocities and lower heat generation than their conventional titanium counterparts. High levels of integration has been achieved by integrating pressure and flow sensors directly on the needle for maintaining intraocular pressure, reducing delays and making the phacoemulsification procedure safer.

To prevent damage to the posterior capsule a piezoelectric sensor has been integrated into a phacoemulsification hand piece and undergone clinical trials (24). The device can determine tissue hardness by measuring the impressed loading on the needle tip or by monitoring the resonant frequency at which the ultrasonic system oscillates. Both of these approaches have proven successful in determining when a hard to soft tissue transition has occurred during a phacoemulsification procedure. This technology enables a surgeon to get real-time feedback on the type of tissue he is cutting, and can be applied to other types of surgical procedures such as tumor extraction as well.

Insertion of a replacement lense requires precise movements by the surgeon. Serious postoperative vision problems may occur if the lens is inserted incorrectly and needs to be removed. Precision piezoelectric micromotors have been developed for intraocular delivery of replacement lenses after cataract removal (25). These inchworm actuators use a glider and clamp arrangement to generate large forces over small displacements. An electrostatic clamp made of an oxide dielectric layer sandwiched

between two silicon wafers layer locks the micromotor in place while a PZT actuator generates the force. The inertia of a mass is used to move the clamp. Forces of 3.0 *N* and step sizes of 100 nm to 10 μm have been reported.

In eye surgery there are many times when precision cutting is required. Highly sharpened steel, ceramic, or diamond scalpel blades are used, but are expensive to produce costing up to \$1000 a piece. Disposable silicon micromachined scalpels are an attractive alternative. They can be batch fabricated to reduce cost and sharpened to an atomic edge along their crystal planes. They are already being used in Russia at the Fyodorov Eye Care Center in nonpenetrating deep sclerectomy operations for the treatment of glaucoma (26). BD (Bektan, Dikenson, and Company) is producing Atomic Edge silicon blades for cataract surgery (27). Soon they will be used for eye operations and eventually migrate to procedures on other parts of the body. Smaller incisions made by sharper blades result in less bleeding and tearing. An added advantage of silicon blades is that sensors and electronics can be directly fabricated on them during fabrication. Integrating cauterizing electrodes on the blade itself will prevent the patient from bleeding as well as let the surgeon more clearly see the surgical area.

CATHETERS/GUIDEWIRES/STENTS

Cardiac catheterizations can be referred to as a noninvasive surgical procedure. Specialized tubes or catheters are threaded up through blood vessels in the groin, arm, or neck to an area of the body which needs treatment. The problem is then treated from the inside of the blood vessel. The advantage of these approaches is that the procedures require very small incisions, hospital stays are usually one night or less and the discomfort and recovery times afterwards are minimal. For patients with more complicated ailments, catheter treatments can be used in combination with minimally invasive or open surgery to give the best possible results at the lowest possible risk. Catheters, guidewires, and stents currently represent the most widespread use of MEMS technology in surgery.

Diagnostic catheterizations, which are used to measure pressure in different parts of the body, take blood samples, and to perform detailed angiograms of the heart, can be performed by injecting X-ray dye through the catheters. The MEMS pressure sensors are now commonly found on catheter devices and are the most mature MEMS technology in this area. Even smaller designs are being sold for placement on guidewires, such as those made by Silex Microsystems, shown next to a 30 gauge needle (Fig. 13). Each sensor is but 100 μm thick, 150 μm wide, and 1300 μm long (28). MEMS ultrasound sensors are also starting to be used for both forward looking (16) and side looking intravascular imaging (12,13).

To provide the doctor with more information to make better decisions, additional MEMS sensors are needed to gather additional data for the diagnosis, monitoring of procedures, as well as for checking results of completed operations. Many other types of MEMS sensors are being researched to measure blood flows, pressures, temperatures, oxygen content, and chemical concentrations for placement on diagnostic catheters (29,30).

Figure 13. MEMS pressure sensors next to a 30-gauge needle (Courtesy of Silex Microsystems, Jarfalla, Sweden.)

Heart disease continues to be the leading cause of death in the United States. Interventional catheterization is an increasingly more common way to treat blood vessels which have become occluded (blocked) or stenotic (narrowed) by calcified atherosclerotic plaque deposits. Blood vessels that have become occluded or stenotic may interrupt blood flow, which supplies oxygen and cause heart attacks or strokes. Occluded or stenotic blood vessels may be treated with a number of medical procedures including angioplasty and atherectomy. Angioplasty techniques, such as percutaneous transluminal coronary angioplasty (PTCA), also known as balloon angioplasty are relatively noninvasive methods of treating restrictions in blood vessels. A balloon catheter is advanced over a guidewire until the balloon is positioned in the restriction of a diseased blood vessel. The balloon is then inflated compressing the atherosclerotic plaque. Frequently, the wall of the vessel is weakened after inflation and a metal stent is expanded and deployed against the plaque. The stent helps keep the vessel open. During an atherectomy procedure, the stenotic lesion is mechanically cut or abraded away from the blood vessel wall using an atherectomy catheter.

Microelectrochemical systems pressure sensors can be used to measure the pressure in the balloons during inflation, to make sure damage due to over inflation is minimized. The MEMS temperature sensors can be integrated on catheters and guidewires to determine the location of inflamed plaque. The inflammation causes artery walls in the damaged area to have an increased temperature up to 3°C higher than healthy tissue. Approximately 20–50% of all patients undergoing these therapeutic procedures to clear blocked coronary arteries will suffer restenosis (reblockage) within 6 months of the initial procedure. Drug coated stents have significantly lowered these rates and have been approved for use in Europe for a few years. They are expected to be approved in the United States later this year. The MEMS laser micromachining technology is used in the fabrication of conventional stents and drug coated stents (31). Stainless steel micromachining technology has also been developed at the University of Virginia for piercing structure drug delivery/gene therapy stents for the treatment of restenosis (32). There is potentially a large opportunity for MEMS in embedding sensors into stents to

create a smart stents, which would be able to alert doctors when restenosis occurs or other problems occur (33). The MEMS rotary cutting devices have been fabricated for atherectomy procedures (34), but are not widely used because cut up plaque particles can flow downstream and cause strokes.

FETAL SURGERY

Fetal surgical techniques were first pioneered at the University of California San Francisco (UCSF) in the 1980s to operate on babies while they were still in the womb. The success rate of treating certain birth defects is higher the earlier they are addressed in fetal development. Initially open surgical techniques were used with an incision through the mother's abdomen to allow direct access for the surgeon's hands. After the surgery was complete, the womb was sutured and the mother delivered the baby weeks or months later. In 1981, the first fetal urinary tract obstruction procedure was performed at UCSF. Lately, minimally invasive surgical and robotic surgical techniques have been used that have reduced the risk of complications and premature labor. Other fetal procedures have also been developed to treat cojoined twins, hernias, spina bifida, tumors, and heart defects. One area of interest is in fetal heart.

The development of the cardiovascular system in a developing fetus is typically completed by the twelfth week of gestation. At this stage primary heart defects are small and if repaired will prevent defects from becoming more severe as the heart changes to adapt to the normalization blood flows and pressures in the later periods of gestation.

Fetal heart surgery can be used to treat hypoplastic heart syndrome (HHS), which was often considered fatal. This syndrome causes the heart's left side to fail to grow properly and is caused by an obstruction which restricts blood flow. The heart requires the mechanical stress of blood flow to grow properly, and thus fails to develop normally. Today, three open surgeries are required to allow the remaining single (right) ventricle to support both the pulmonary and systemic circulations. The long-term survival for these patients into adulthood is significantly < 50%. Preserving both ventricles would result in the best chances of long-term survival.

An interventional catheter can be used to treat HHS in a minimally invasive manner. The balloon catheter must first penetrate in through the mother's abdominal wall, the placenta and then the fetus's chest into its heart. It must then locate the fetus's tiny heart and expand to open the blockage. Afterward, the surgeon needs to know whether the operation has succeeded enough for the baby to develop normally. Verimetra, Inc., Carnegie Mellon University, and Children's Hospital of Pittsburgh have embedded a MEMS flow sensor and a series of micromachined bar codes on the tip of a balloon catheter. The bar codes enable the catheter to be visualized with ultrasound allowing surgeons to know its exact position. The flow sensor is a thermistor. As blood flow increases the temperature measured by the thermistor decreases and in this manner blood flow changes as the catheter progresses through the heart's vessels can be monitored. This allows for the measurement of blood flow at or near a constriction

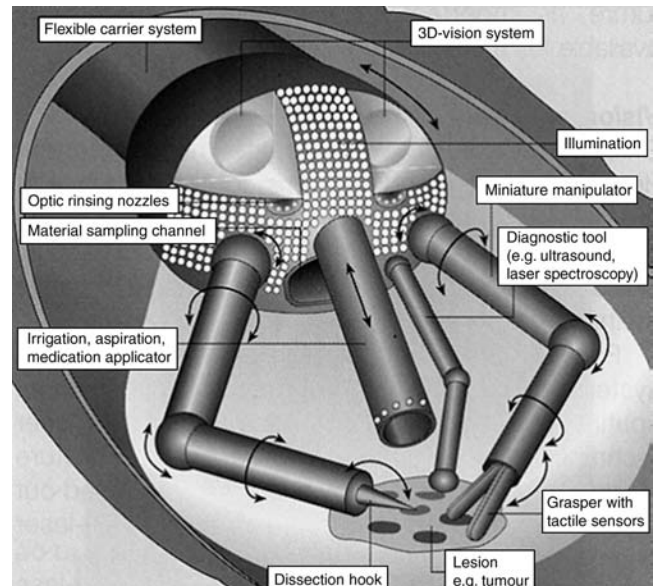

Figure 14. Highly integrated microsurgical probe. (Courtesy of Prof. Dr. M. Schurr, novineon Healthcare Technology Partners GmbH and Prof. G. Buess, Universitätsklinikums Tbingen.)

and then again after the procedure to open the constriction has been performed.

FUTURE SYSTEMS

In 1959, Richard Feynman gave his famous talk *There's Plenty of Room at the Bottom* (35). In it, he talked about being able to put a surgeon in a blood vessel which would be able to look around ones heart. Initially, new microsurgical tools will focus on measuring or detecting a specific parameter be it pressure, blood flow, velocity, temperature, and so on. The MEMS sensor systems will continue to be refined and improved leading to the integration of multiple sensor systems on surgical tool followed by tools with multiple functions. Multifunction surgical tools will reduce the number of tool insertions and removals reducing patient risks. Eventually, this will lead to highly integrated probes, which will do everything a surgeon needs, such as the concept shown in Fig. 14 (36). These tools will fit through a standard 5-mm port and have built in 3D cameras for visualization, biopsy samplers with microfluidic processing capability to do tissue analysis, ultrasound transducers, and tactile sensors for feedback to the surgeon.

MINIMALLY INVASIVE SURGICAL TECHNOLOGY

JAY R. GOLDBERG
Marquette University
Milwaukee, Wisconsin

INTRODUCTION

Most surgical procedures involve the invasion and disruption of body tissues and structures by surgical instrumentation and/or implantable medical devices, resulting in trauma to the patient. Diagnostic imaging procedures, such as magnetic resonance imaging (MRI), computed tomography (CT), X ray, positron emission tomography (PET), and ultrasound do not require disruption of body tissues, and are thus considered to be noninvasive. Extra corporeal shockwave lithotripsy (ESWL) used to disintegrate kidney stones is an example of a noninvasive therapeutic procedure. As shown in Fig. 1, it focuses acoustic energy, generated outside of the patient's body, on kidney stones. No trauma to the patient occurs during this procedure.

Open heart coronary artery bypass and organ transplantation surgery are examples of highly invasive surgery. These procedures require a high level of invasion and disruption of body tissues and structures. Bones, muscle tissue, and blood vessels are cut, and tissue from other parts of the body may be grafted, resulting in a high level of surgical trauma to the patient.

Minimally invasive surgical procedures are less traumatic than corresponding conventional surgical procedures. The use of small instruments placed through intact natural channels, such as the esophagus, urethra, and rectum, is less invasive than conventional open surgical approaches requiring large incisions, significant loss of blood, and trauma to tissues. The use of small instruments, such as biopsy guns and angioplasty balloons placed through small incisions, results in minor trauma to the patient, but is much less invasive than open surgical procedures used to accomplish the same goals. Procedures using small instruments through intact natural channels or small incisions are classified as minimally invasive.

A minimally invasive surgical procedure can be defined as surgery that produces less patient trauma and disruption of body tissues than its conventional open surgical counterpart. For example, conventional appendectomies require a 4 cm long incision made through layers of skin, muscle, and other tissues to gain access to the appendix. Once the appendix is removed, the layers of the wound are sutured together to allow them to heal. This invasive procedure requires a significant level of invasion and disruption of tissues and other structures. The minimally invasive appendectomy is performed with small surgical instruments placed into small incisions in the patient's abdomen. Once the appendix is removed, the small incision is closed with sutures. This procedure results in much less trauma to the patient than the open surgical approach.

Minimally invasive surgery (MIS) is performed with small devices inserted through intact natural orifices or channels, or small incisions used to create an orifice. Some

procedures are performed with devices located outside the body, and thus are noninvasive. The MIS procedures are an alternative to open surgery. The benefits of MIS include reduced patient trauma, postoperative recovery time, and healthcare costs.

INSTRUMENTATION FOR MINIMALLY INVASIVE SURGERY

Many MIS procedures involve flexible or rigid fiber optic endoscopes for imaging surgical sites and delivering instrumentation for diagnostic or therapeutic applications. The term "endoscope" is a generic term used to describe tubular fiber optic devices placed into the body to allow visualization of anatomical structures.

Endoscopes consist of a fiber optic light guide, high intensity light source, coherent fiber optic bundle, steering mechanism, and various working channels for insertion of endoscopic instrumentation and infusion of irrigation fluids or insufflating gases. Glass fibers comprise the fiber optic light guide and coherent bundle and are surrounded by a flexible polyurethane sheath or rigid stainless steel tube. Figure 2 shows the components of a typical endoscope. The light source provides light that is transmitted through the light guide and projected onto the anatomical site to create an image. The coherent fiber bundle transmits the image back to the focusing eyepiece and into the surgeon's eye. The surgeon can move the endoscope proximally (toward the patient) and distally (away from the patient) by pushing and pulling the endoscope into and out of the body, respectively. Steering is accomplished with a handle attached to a cable that pulls and bends the tip of the endoscope in the desired direction. The proximal (closest to the patient) end of the endoscope (shown in Fig. 3) contains lumens for the fiber optic light guide and coherent fiber bundle, and one or more working channels for passage of instruments and irrigation fluid into and out of the operative site. Some endoscopes contain video cameras that display endoscopic images on a video monitor in the operating room, as shown in Fig. 4.

Specialized endoscopes have different names depending on what part of the body they are used to image. Table 1 lists the names of various endoscopes, the procedures for which they are used, and the anatomical location where they are used.

Endoscopic Procedures and Instrumentation

To perform an endoscopic procedure, the surgeon inserts a sterilized endoscope into a natural channel or orifice, such as the urethra, rectum, esophagus, bronchial tube, or nose. If there is no natural channel to provide access to the operative site (as in abdominal surgery), then the surgeon will create one with a small incision, and may insert a hollow trocar into the incision, as shown in Fig. 5. The trocar is left in the wound to provide access to the abdominal cavity. The endoscope is inserted into the access site (natural channel, incision, or trocar) and as it is advanced toward the operative site the surgeon monitors the image produced by the endoscope, either through the objective eyepiece or video monitor (as shown in Fig. 4). Rigid endoscopes are typically used when access is obtained

Figure 1. Schematic diagram of noninvasive extra corporeal shockwave lithotripsy (ESWL) procedure used to disintegrate kidney or biliary stones. Acoustic waves generated from spark plugs are focused with ellipsoidal reflectors on the kidney stone.

through an incision. Flexible endoscopes are used when access is obtained through natural channels (2). Once in position, the surgeon can then manipulate the endoscope to inspect tissues and anatomical structures (Table 1).

If a procedure other than visual inspection is required, the surgeon has a variety of instruments available to grasp, cut, remove, suture, and cauterize tissues, and remove debris through the endoscope. Forceps (Fig. 6) and graspers are used to grasp tissue and other objects such as kidney

stones. Scalpels and scissors (Fig. 7) are used for cutting tissue. Suturing devices are used to repair internal wounds resulting from endoscopic procedures such as appendectomies, cholecystectomies (gallbladder removal), and arthroscopies. Morcellators are used to reduce the size and change the shape of a mass of tissue, such as a gallbladder, allowing it to be removed through a small incision. Electrohydraulic lithotripter (EHL) and laser probes are used to disintegrate objects, such as kidney

Figure 2. Components of a typical endoscope.

Figure 3. Proximal ends of typical endoscopes. Endoscopic instruments (left:scissors, right:forceps) are shown placed through working channels. Two other channels contain the fiber optic light guide and coherent fiber bundle, respectively. A fourth channel can be used for instrumentation or delivery of irrigation fluids to operative site (1). stones, with acoustic and laser energy, respectively, allowing the debris to be passed through the ureter. Stone baskets are used to trap kidney or ureteral stones for endoscopic removal, as shown in Fig. 8. These instruments are placed through the working channel of an endoscope or trocar and are operated by manipulating handles and controls located outside the patient.

Figure 4. Surgeon viewing laparoscopic images of gallbladder on video monitor in operating room. Note use of three trocars in patient's abdomen; one each for video camera and two instruments. (Courtesy ACMI, Southborough, MA.)

Figure 5. Trocar inserted into abdominal incision to provide access to abdominal cavity. Safety shield covers sharp end of trocar (circled) upon insertion to prevent damage to abdominal organs. (1) (Courtesy Ethicon Endo-Surgery Inc., Cincinnati, OH.)

Endoscopes may contain multiple working channels that allow for irrigation of fluids to irrigate and flush out clots and other surgical debris. The presence of the fluid improves visibility through the endoscope by keeping the visual field clear and the lens clean. Laparoscopic surgery requires insufflation of CO_2 or N_2O through the working channel or trocar and into the abdominal cavity to cause the cavity to expand, separating organs, and enlarging the operative site and visual field.

There are typically not enough working channels in a laparoscope to accommodate all of the instruments needed for a particular procedure. In these cases, multiple access sites are created with additional trocars. Typically, a camera is placed through one trocar and used to visualize the work being performed with instruments placed through other trocars.

When an endoscopic procedure is completed, the endoscope and instrumentation are removed from the patient via the natural channel or incision. When a laparoscopic procedure is completed, the laparoscope, camera, instruments, and trocars are removed from the patient. The wounds created by the trocars are sutured and the patient begins the recovery process. Although some of the CO_2 from insufflation may escape the abdominal cavity when all instrumentation is removed, some will be absorbed by body tissues and eliminated via respiration. Patients typically recover and are discharged from the hospital within 24–48 h.

Non-Endoscopic Procedures and Instrumentation

Not all minimally invasive procedures require endoscopic devices for imaging and placement of instruments. Some MIS procedures (listed in Table 2), such as stereotactic radiosurgery, use lasers or gamma radiation in place of scalpels. Others use small catheters to deliver medication, devices, or energy to specific anatomical locations. Balloons and stents, delivered via catheters, are used to access and dilate constricted vessels and maintain patency. Catheter mounted electrodes are used to deliver thermal, micro-

Table 1. Names of Endoscopes, MIS Procedures with Which they are Used, and Anatomical Location Where they are Used

Medical Specialty	Type of Endoscope Used	MIS Procedures	Anatomical Location
Urology	Cystoscope Ureteroscope Nephroscope	Cystoscopy, Transurethral resection of the prostate (TURP) Ureteroscopy, stone removal Nephroscopy, stone removal	Urethra, bladder ureter, kidney
Gastroenterology	Gastroscope Colonoscope Sigmoidoscope	Gastrosopy, gastric bypass Colonoscopy, Sigmoidoscopy	Stomach, colon Sigmoid colon
General surgery	Laparoscope	Laparoscopy, hernia repair, appendectomy, cholecystectomy (gallbladder removal)	Abdomen

Ear, nose, and throat	Laryngoscope, Bronchoscope Rhinoscope	Laryngoscopy, bronchoscopy Rhinoscopy, sinuscopy	Larynx, bronchus, nose, sinus cavities

wave, or radio frequency energy to selectively destroy tissue in ablation procedures used to treat cardiac arrhythmias (3), benign prostatic hypertrophy (BPH) (4), and other conditions. Many of these devices are guided through the body with the help of imaging or surgical navigation equipment.

Image Guided Surgery–Surgical Navigation

Image guided surgery (IGS) allows surgeons to perform minimally invasive procedures by guiding the advancement of instrumentation through the patient’s body with increased accuracy and better clinical outcomes. Preoperatively, an IGS system is used to produce computerized anatomical maps of the surgical site from MRI or CT images of the patient. These maps are then used to plan the safest, least invasive path to the site. During an image guided procedure, the IGS system provides surgeons with a three dimensional image showing the location of instruments relative to the patient’s anatomical structures. It tracks the movement of surgical instruments in the body, correlates these movements with the patient’s preoperative images, and displays the location of the instruments on a monitor in the operating room. This feedback helps the

surgeon safely and accurately guide instruments to the surgical site, reducing the risk of damaging healthy tissue (4,5).

An IGS system includes a computer workstation, localization system, display monitor, and specialized surgical instruments capable of being tracked by the system. Image processing and surgical planning software are also used. Tracking of instruments is accomplished through optical, electromagnetic, or mechanical means. Optical tracking systems use a camera mounted to view the surgical field and optical sensors attached to surgical instruments. These systems required line of sight between the camera and sensor to function properly. Electromagnetic tracking systems include a transmitter located close to the surgical site, and receivers attached to surgical instruments. Line of sight is not an issue with these systems, however, nearby metallic objects may produce interference to signals used to track instruments (4).

To ensure that the patient’s anatomical features (and location of instruments) are accurately displayed by the IGS system, actual anatomical locations must be registered to the preoperative images. This can be accomplished by touching a probe to a marker on the patient’s body and then assigning the location of this marker to its corresponding point in preoperative images (4).

Figure 8. A stone basket used to trap and remove a large ureteral stone. (Courtesy ACMI, Southborough, MA.)

Table 2. Examples of Non-Endoscopic Minimally Invasive Surgical Procedures

Medical Specialty	Non-Endoscopic Minimally Invasive Surgical Procedure
Cardiovascular surgery	Minimally invasive direct coronary artery bypass (MIDCAB) Percutaneous transluminal coronary angioplasty (PTCA) Coronary stenting Radio frequency cardiac ablation Laser angioplasty Microwave catheter ablation for arrhythmias
Ophthalmology	Chemical ablation for ventricular tachycardia Laser photorefractive keratotomy (PRK) Laser ablation of cataracts Laser glaucoma surgery
Orthopedics	Total joint arthroplasty (hips, knees, and others)
Neurosurgery	Stereotactic radiosurgery Stereotactic radiotherapy Laser ablation of brain tissue, tumor tissue
Radiology	Clot removal Aneurism repair Cerebral arterial venous malformation repair Transjugular hepatic portal systemic shunt creation

Most surgical instruments must be adapted for use in image guided surgery by mounting sensors and other devices to allow detection of the instrument's position by the IGS system. Some medical device manufacturers are developing navigation-ready surgical instruments that contain small reflective spheres to act as reference arrays for cameras used in image guided surgery (5).

MINIMALLY INVASIVE SURGICAL PROCEDURES

This section contains a few examples of minimally invasive surgical procedures used in urology, orthopedics, neurosurgery, and general and cardiovascular surgery.

Ureteroscopy

Flexible ureteroscopy is used to perform a variety of diagnostic and therapeutic urological procedures. It involves entry into the body via intact natural channels (urethra and ureter) and does not require an incision. Local anesthesia and sedation of the patient are required.

Ureteroscopy is commonly used to remove ureteral or kidney stones. Initially, a cystoscope is inserted into the urethra. Next, a guidewire is placed through a cystoscope into the ureter, and advanced up into the kidney. While maintaining the position of the guidewire, the cystoscope is removed, and the distal end of the guidewire is placed into a working channel at the proximal end of the ureteroscope. The ureteroscope is then advanced along the guidewire into the ureter or kidney, as shown in Fig. 9. Active (controlled by the cable and handle) and passive deflection of the shaft, along with rotation of the flexible ureteroscope allows visual inspection of the renal calices as shown in Fig. 10. Ureteroscopic instruments are then placed through the working channel into the ureter or kidney. Figure 11 shows two devices used for ureteroscopic removal of ureteral stones. The stone grasper is used to physically grab the stone (Fig. 11). If the stone is small enough to fit into the working channel, it is pulled out of the patient through the ureteroscope. Large stones that will not fit into the working

channel are pulled out with the ureteroscope. The laser lithotripter (Fig. 11) disintegrates the stone into small particles that can easily be passed naturally through the ureter, bladder, and urethra. Collapsed stone baskets can be placed alongside a stone and moved proximally and distally as they are expanded, until the stone is trapped in the basket (as shown in Fig. 8) and pulled out of the urethra.

Laparoscopy

Laparoscopy is commonly used for removal of the gallbladder and appendix, hernia repair, and other abdominal procedures. The basic steps involved in laparoscopy have been previously described. The lack of natural channels located in the abdomen requires the use of trocars to gain access to the operative site. Laparoscopic procedures require insufflation of gas to separate organs and expand the visual field. This is controlled by a separate insufflator that controls the pressure inside the abdomen produced by the flow of insufflating gases (1).

Figure 9. A surgeon views images through a ureteroscope placed through the urethra, bladder, ureter, and into the kidney. (Courtesy ACMI, Southborough, MA.)

Figure 10. Flexibility and steerability of proximal end of ureteroscope allow inspection of upper, middle, and lower renal calices. (Courtesy ACMI, Southborough, MA.)

Total Joint Replacement

Total hip and knee replacements are typically performed with large incisions to expose the joint, allowing for complete visualization of and access to the joint and soft tissues. New surgical approaches using smaller incisions that result in less damage to muscles and other soft tissue limit the view of the joint. To compensate for the limited view, fluoroscopy and IGS systems are often used. Some existing surgical instruments have been modified to enable surgery through smaller incisions (6).

Traditional hip arthroplasty requires a 30–46 cm long incision, which is highly disruptive to muscles and surrounding tissues. Two different techniques can be used for minimally invasive total hip arthroplasty. One technique

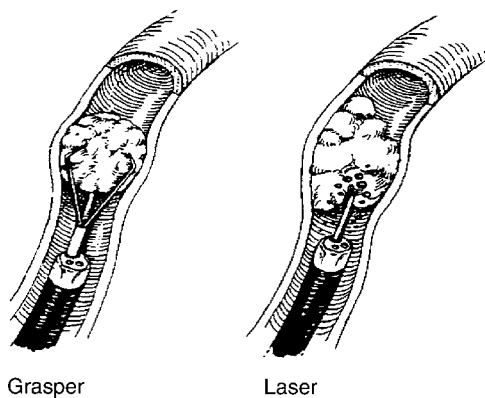

Figure 11. Devices used for endoscopic removal of ureteral stones. (Courtesy ACMI, Southborough, MA.)

Figure 12. Acetabular component inserted with inserter through small incision (top image). Fluoroscopic image of inserter and acetabular component seated in acetabulum (bottom image). Images such as these allow surgeons to ensure proper placement of instruments and implantable components within hip joint when small incisions prevent viewing of entire device (6). (From *MIS for the Hip and Knee: A Clinical Perspective*, 2004, pg. 20, *Minimally Invasive Total Hip Arthroplasty: The Two Incision Approach*, Berger, R.A. and Hartzband, M.A., Fig. 2.11. Copyright 2004, with kind permission of Springer Science and Business Media.)

uses two 5 cm long incisions, one each for preparation and insertion of the acetabular and femoral components, respectively. The other technique involves one 8–10 cm long incision. Modified retractors and elevators are used to gain access and expose the joint. Fluoroscopy and IGS systems are used to provide the surgeon with a view of instruments and components (as shown in Fig. 12) and assist in positioning of instruments designed to enable accurate component alignment and placement. Minimally invasive hip arthroplasty results in less disruption of muscles and tissues, smaller and less noticeable scars, less blood loss and pain, and fewer blood clots and dislocations (6).

Most minimally invasive knee arthroplasties performed through smaller incisions involve a single compartment of the knee. These procedures typically use existing unicompartmental knee implants for resurfacing the medial or lateral femoral condyle and corresponding tibial plateau. Existing instrumentation has been modified to obtain

access to the joint and enable accurate placement and alignment of the unicompartamental knee components through smaller incisions.

Minimally Invasive Direct Coronary Artery Bypass

Coronary arteries may become blocked due to fatty deposits (plaque), blood clots, or other causes. This reduces blood flow to cardiac muscle, depriving it of needed oxygen and other nutrients. This condition can result in a myocardial infarction (heart attack) that can damage cardiac muscle.

Traditional open heart coronary artery bypass graft surgery has been used to restore normal blood flow to cardiac muscle. This procedure involves grafting a new vessel to points on both sides of the blocked coronary artery, thereby bypassing the blockage and restoring normal blood flow. It requires open access to a still heart to allow suturing of the graft to the blocked coronary artery. A sternotomy and separation of the sternum is required to provide access to the heart. The heart is stopped and the patient is attached to a heart–lung machine to maintain circulation of oxygenated blood through the body during the surgical procedure. This procedure is highly invasive

and can result in a variety of complications, many of which are associated with use of a heart–lung machine. Inflammatory responses negatively affecting multiple organ systems have been observed in patients who were perfused with a heart–lung machine during traditional open heart coronary bypass surgery (7). These responses are due to reactions between circulating blood and material surfaces present in the heart–lung machine.

Minimally invasive direct coronary artery bypass is an alternative to open heart surgery. A small 5–10 cm incision made between the ribs replaces the sternotomy to gain access to the heart. A retractor is used to separate the ribs above the heart to maximize access to the operative site (8). Heart positioners and stabilizers (Fig. 13) are used to minimize the motion of the heart, allowing surgeons to perform the procedure on a beating heart, eliminating the need for the heart–lung machine. Some stabilizers grasp the heart with suction cups. Others use a fork like device to apply pressure to the beating heart to keep it steady for anastomosis of the graft (8). A thoracoscope and small endoscopic instruments are used to visualize the surgical site and perform the surgical procedure. The left internal mammary artery is commonly used as the grafted

Figure 13. Heart positioner and stabilizer used in MIDCAB procedures. The positioner attaches to the sternal retractor and holds the heart in position using suction. It provides greater access to the blocked coronary artery. The tissue stabilizer, attached to the sternal retractor, straddles the blocked artery and holds the suturing site steady. This allows surgery on a beating heart, eliminating the need for a heart–lung machine along with its associated complications. (Courtesy of Medtronic, Inc., Minneapolis, MN.)

Figure 14. A PTCA catheter and stent. Stent and balloon in collapsed configuration for insertion and placement into coronary artery (a). Inflated balloon causing stent to expand (b). Expanded stent after collapse of balloon and removal of catheter (c). (Courtesy of Sorin Biomedica Cardio SpA, Italy.)

vessel to bypass the blockage of the coronary artery. The MIDCAB results in fewer complications, less blood loss, and shorter hospital stays.

Percutaneous Transluminal Coronary Angioplasty with Stent Placement

The PTCA method is used to open a blocked, constricted coronary artery instead of bypassing the blockage with a graft. Under local anesthesia, a steerable balloon catheter containing a stent mounted to the balloon (Fig. 14a) is inserted into the patient's femoral artery and guided to the constricted coronary artery under fluoroscopy. Once in position, the balloon is inflated to compress and flatten the plaque against the arterial wall, creating a larger opening for blood to flow through the coronary artery. The balloon is constructed with materials of different stiffness such that pressure from the inflating balloon is radially applied to the constricted area, and not to tissue outside of the constricted region (3). During balloon inflation, the stent is expanded to a larger diameter (Fig. 14b), which is maintained after deflation of the balloon. The catheter is removed, and the expanded stent (Fig. 14c) is left in place to maintain a larger opening and prevent restenosis of the coronary artery.

Most coronary stents are made of stainless steel, nitinol, cobalt chrome molybdenum alloy, or gold (3). Some stents contain coatings to improve biological performance (biocompatibility and resistance to clot formation) and/or elute drugs into surrounding tissues to prevent restenosis of the coronary artery.

The PTCA method does not remove plaque from the coronary artery; it flattens it so it no longer restricts blood flow. Plaque removal methods involve lasers and rotational cutting devices (3).

Stereotactic Radiosurgery

In this noninvasive procedure, focused external beams of radiation are delivered to specific locations in the brain to treat tumors (9). The accuracy of the delivery prevents damage to healthy brain tissue. The patient's head is constrained in a mask or frame during the 30–45 min procedure.

Newer radiotherapy systems include robotic linear accelerators for delivery of radiation at any angle to the patient's head, a beam shaper to match the shape of the beam to the three-dimensional (3D) shape of the tumor, and imaging equipment to provide real-time tracking of tumor location and patient positioning (9).

Treatment of Benign Prostatic Hypertrophy

Benign prostatic hypertrophy causes the prostate to enlarge. An enlarged prostate applies pressure to the prostatic urethra that can occlude the urethra, reduce urinary flow rate, and make urination difficult. The enlarged prostate can be removed with an open surgical approach or less invasive transurethral resection of the prostate (TURP). The TURP procedure involves cutting and removing segments of the prostate through a cystoscope or with a resectoscope inserted into the urethra, and can result in complications, such as incontinence and impotence. Prostatic balloon dilators and prostatic stents inserted into the urethra have been used to expand the narrowed urethra. Transurethral laser incision of the prostate (TULIP) has been used to cut and remove prostate tissue. In this procedure, a catheter mounted laser facing radially outward toward the prostate delivers laser energy that cuts through the enlarged prostatic tissue, relieving pressure on the urethra.

Newer approaches to treating BPH include transurethral microwave therapy (TUMT) and transurethral needle ablation (TUNA) (4). These procedures use microwave and radio frequency energy, respectively, to heat and destroy unwanted tissue without actually removing the tissue. The TUMT method involves insertion of a urethral catheter containing a microwave antenna into the bladder neck. Channels contained in the catheter carry cooling water to prevent thermal damage to the urethra while microwave energy is used to heat the prostate for ~1 h. The TUNA method uses a cystoscope to insert two shielded electrode needles through the urethra and into the prostate. Radio frequency energy is delivered to the prostate, heating the tissue and destroying it. Thermal energy causes the prostate tissue to stiffen and shrink, relieving the pressure on the urethra caused by the enlarged prostate. Both TUMT and TUNA deliver controlled thermal energy to a targeted area to selectively destroy prostate tissue (4).

NEW DEVELOPMENTS IN TECHNOLOGY FOR MINIMALLY INVASIVE SURGERY

New devices and technologies are being developed and clinically evaluated for use in MIS. Robots can be used to enable surgeons to perform more intricate surgical

procedures than can be done with endoscopic devices (10). In robot-assisted surgery, the surgeon operates a console to control mechanical arms positioned over the patient. The arms become an extension of the surgeon's hands. While observing the procedure on viewing screens (one for each eye) that produce a 3D image, the surgeon uses hand, finger, and foot controls to move the mechanical arms containing interchangeable surgical instruments through a small opening in the patient's body (10).

Other new technologies for MIS include 3D video imaging, integrated robotic and surgical navigation systems, devices for mechanical retraction of the abdominal wall (eliminating the need for insufflation), and telerobotics (8).

OUTCOMES OF MINIMALLY INVASIVE SURGERY

Comparison of MIS to Conventional Approaches

Minimally invasive surgical procedures result in reduced patient trauma, less postoperative pain and discomfort, and decreased complication rates. Hospital stays and postoperative recovery times are reduced, resulting in lower hospital costs and allowing patients to return to work earlier.

Studies comparing various MIS procedures to their traditional open surgical counterparts have been conducted. One such retrospective study compared the clinical and economic aspects of laparoscopic and conventional cholecystectomies (11). Results of 153 consecutive traditional procedures and 222 consecutive laparoscopic procedures performed in a German teaching hospital were evaluated. Researchers found that although laparoscopic cholecystectomies required longer operative times (92 vs. 62 min), they resulted in fewer complications (6 vs. 9), shorter hospital stays (3 vs. 8 days), and an 18% decrease in hospital costs, when compared to traditional procedures.

In a Canadian study, the direct costs of conventional cholecystectomy, laparoscopic cholecystectomy, and biliary lithotripsy were compared (12). Researchers concluded that laparoscopic cholecystectomy provided a small economic advantage over the other two procedures and attributed this to a shorter hospital stay.

In the United States, hospital stays following laparoscopic cholecystectomies typically ranged from 3 to 5 days. Now, many of these procedures are performed on an outpatient basis. This additional reduction in hospital stay further reduces hospital costs, resulting in a greater economic advantage over the conventional procedure.

A study comparing results of 125 consecutive off-pump coronary bypass (OPCAB) procedures to a matched, contemporaneous control group of 625 traditional coronary artery bypass graft (CABG) procedures was conducted (7). The OPCAB procedure is a beating heart procedure that does not involve a heart-lung machine. Partial sternotomies were used with some patients in the OPCAB group. Researchers found that the OPCAB procedure resulted in a lower mortality rate (0 vs. 1.4%), reduced hospital stays (3.3 vs. 5.5 days), 24% lower hospital costs, and a reduced transfusion rate (29.6 vs. 56.5%), when compared to the traditional CABG procedure. Excellent graft patency rates

and clinical outcomes were also reported with the OPCAB procedure.

In another study of 67 MIDCAB patients, it was found that average hospital charges for MIDCAB were \$14,676 compared to \$22,817 for CABG and \$15,000 for coronary stenting (13). The significantly lower charges for MIDCAB were attributed to shorter hospital stays, elimination of perfusion expenses, and reduction in ICU, ventilation, and rehabilitation times.

Limitations of Minimally Invasive Surgery

There are several problems and limitations associated with MIS procedures. First, some minimally invasive surgical procedures can take longer to perform than their more invasive counterparts (10). Second, open surgical procedures allow the surgeon to palpate tissue and digitally inspect for tumors, cysts, and other abnormalities. Tactile feedback also assists in locating anatomical structures. The inability of the surgeon to actually touch and feel tissue and structures at the operative site limits the diagnostic ability of some MIS procedures (10). Third, a two-dimensional (2D) image is produced by the endoscope and video monitor. The resulting loss of depth perception combined with restricted mobility of instruments through a small incision make manipulation of endoscopic instruments challenging. Fine hand movements are difficult due to the long distances between the surgeon's hand and working ends of these instruments. Fourth, there is a limit to the number of instruments that can be used at one time through trocars and working channels of a laparoscope. Finally, instrumentation for MIS procedures is more expensive.

Insufflation presents a small risk not associated with open surgical procedures (1,10). If the gas pressure inside the abdominal cavity becomes too high or there is a small defect in a blood vessel, then a gas bubble can enter the bloodstream and travel to the heart or brain, causing unconsciousness or death.

Laparoscopic removal of cancer tissue carries a very small risk of transporting cancer cells to other parts of the body. As tumor tissue is removed through the laparoscope, some cancer cells may remain in the body. They may be displaced from their original location resulting in the spread of cancer cells to other parts of the body (10).

SUMMARY

Minimally invasive surgery is made possible through the use of specialized devices and technologies. These include endoscopes, surgical instruments, imaging and navigation systems, catheters, energy delivery systems, and other devices. The MIS procedures tend to require more time, are more difficult to perform than conventional procedures, and present some unique risks not associated with conventional procedures. Compared to conventional open surgical procedures, MIS procedures demonstrate similar clinical efficacy and reduce trauma and disruption of body tissues and structures. Patients experience less pain and discomfort, fewer complications, and shorter recovery periods. Hospital stays are reduced, resulting in lower hospital costs.

INTRODUCTION

The National Center for Health Statistics estimates that 12.4 million adults are unable to walk a quarter of a mile in the United States, and that 28.3 million adults have moderate mobility difficulty (1). Approximately 4 million Americans use wheelchairs, and about one-half of them use their wheelchairs as their primary means of mobility. About 1.25 million people wear a prosthetic limb due to injuries, birth anomalies, and disease. Once fatal injuries are now survivable due to advancing medical achieve-

ments, prolonging life spans, and the staggering growth in the aging population. Because of this growth, the population of individuals who use mobility aids is sure to grow in the coming decades.

The goal of issuing wheelchairs, prosthetics, walkers or rollators to individuals with mobility impairments independence remains the top priority when prescribing one of these devices, other main concerns include safety, not causing secondary injury (i.e., pressure sores, carpal tunnel syndrome, rotator cuff tear), and the physical design of the device (e.g., weight, size, ease of use). Research has shown that manual wheelchair users commonly report shoulder, elbow, wrist, and hand pain (2). Low back pain and fatigue are also common secondary ailments experience due to exposure of whole-body vibrations (3). Safety research shows that proper fitting and wheelchair skill can reduce injurious tips and fall in wheelchairs (4).

In order to fully maintain an active lifestyle, including recreational activities, participating in the community, and going to work, transportation for people with mobility impairments is essential. With the added technology that is necessary to allow people to use public or private transportation, added safety features must also be included to maintain the security of both the drivers and the passengers.

Besides performing normal activities of daily living, sports, and recreational activity are an important physical and psychosocial aspect of any human being. The case is no different with people who use assistive technology. With dramatic advances in technology, people with mobility impairments are able to go places and participate in activities that were once nearly impossible.

In recent years, wheelchairs, prosthetics, walkers, and rollators have been designed to be stronger, safer, lighter, more adjustable, and smarter than in the past, through the use of materials like titanium and carbon fiber, using advanced electronics, and so on. The technology of wheelchairs, prosthetics, walkers, and rollators has improved dramatically in the past 25 years due largely in part to the increased demand of consumers, their loved ones and others who assist consumers, and the people who recommend and issue these technology devices. The term "recommend" is used because it is crucial that these devices, especially wheelchairs and prosthetics, be issued by a team of professionals to provide the highest levels of independence and safety, and that this team is centered around the client. All of these components are important to the further development of the technology and, in turn, they may result in the increased independence of people with mobility impairments.

CLINICAL ASSESSMENT OF MOBILITY

The ultimate goal and outcome for a clinical assessment of mobility should drive toward a successful wheelchair, prosthetics, walker, or rollator recommendation that enhances the quality of life expectations and their effectiveness as reported by the consumer. Quality of life is specific to and defined by each person and/or family receiving clinical services. The consumer, their family, and care

givers, must be actively included in this process, as they will be most affected by the choice of the mobility aid. Also, people chose their mobility devices based on the features available that facilitate activities or address needs (5), and the clinician should be aware of the consumer preferences and the features of various devices.

The complexity of some of the mobility device components combined at times with involved disease processes can make it virtually impossible for a single clinician to act independently when recommending assistive technology. Therefore, involving an *interdisciplinary team* is recommended in the decision making process (6,7). This team, with the consumer as an involved member and a variety of rehabilitation professionals, includes a physiatrist or similarly trained physician who understands the importance of Assistive Technology, addresses medical issues and assists with mobility decisions; the Occupational or Physical Therapist with RESNA (www.resna.org) certified Assistive Technology Practitioner (ATP) credentials, who is the point person for evaluation and prescription; and the Rehabilitation Engineering (with RE Training and RET Credential) who is a technology expert with the ability to design–modify–tune devices, and who also understands the capabilities and applications of various technologies. Another important team partner is the Assistive Technology Supplier (ATS) or Certified Rehabilitation Supplier (CRTS, National Association of Rehabilitation Technology Suppliers, www.narts.org), who provides or manages demonstration equipment, does routine home and workplace assessments, and orders, assembles, and delivers the equipment. All team members involved in the mobility aid selection process should have knowledge about the technology available on the market. Peer reviewed journal articles (Assistive Technology, Archives of Physical Medicine and Rehabilitation, Journal of Rehabilitation Research and Development etc.), magazine articles and commercial database sources such as ABLEDATA (<http://www.abledata.com/>), or WheelchairNet (www.wheelchairnet.org) are good places to research devices or to direct consumers who want to inform and educate themselves.

Resources available to the team and its members includes a defined and dedicated space for demonstration equipment, assessments, and evaluations, access to common activities and tasks (e.g., ramps, curb cuts, bathroom, countertop), an electronic tracking system to follow clients and their technology, assessment resources (e.g., pressure mapping, SMART^{Wheel}, gait force plate, actigraph), IT Resources (e.g., email, web, databases, medline, paging, cell, wireless), and the facilities–hospital commitment to continuing education.

A mechanism for Quality Measures for AT Clinics will provide valuable feedback on performance quality and areas in need of improvement. An important tool to measure patient satisfaction is the information gained through a satisfaction survey provided to every patient, in order to find out whether the goals and desired outcomes have been met. Feedback on performance quality is provided through tracking mechanism of primary clinician credentials (ATS, ATP, RET), dedicated staffing levels, continuing education (CEUs and CMEs), compliance with the commission on Accreditation of Rehabilitation Facilities (CARF) AT Clinic

Accreditation, as well as tracking of continuous quality improvement.

Assessment

The occupational or physical therapist conducts the initial assessment process and obtains critical information about the consumer and their environment. This part usually involves a structured interview with the consumer and then a physical motor assessment. Establishing a medical diagnosis that requires the mobility aid is vital to assure no ongoing medical problems exist that are not being adequately addressed. To properly specify a mobility device, the intentions and abilities of the consumer must be ascertained (8,9). The intentions and abilities may include how people perform tasks, where the deficits are, and how mobility systems can compensate for the deficits to augment task performance. Some outcome tools that are clinically used to measure the functional impact of mobility aids are the QUEST, the FEW and the Wheelchair Skills Test (WST).

Additional necessary information includes type of insurance, method of transportation, and physical capabilities. Also, if the consumer has been using a chair, historical information about their current chair should be addressed, including problems they are having. The mobility device chosen should also be compatible with the public and/or private transportation options available to the consumer, such as a bus, car, or van. The regularity of the surface, its firmness and stability are important, when, for example, recommending a wheelchair in determining the tire size, drive wheel location, and wheel diameter. The performance of a wheelchair is often dictated by the need to negotiate grades, as well as height transitions, such as thresholds and curbs. The clearance widths in the environment will determine the overall dimensions of the wheelchair. The climates the chair will be operated in, and the need to be able to operate in snow, rain, changing humidity and temperature levels, and other weather conditions, are important considerations as well.

A physical–motor assessment of strength, range of motion, coordination, balance, posture, tone, contractures, endurance, sitting posture, cognition, perception, and external orthoses is an important first step to obtain a basic understanding of an individual's capacity to perform different activities. The history likely provided significant insight related to their physical abilities. To verify this, a physical examination should focus on aspects of the consumer that (1) help justify the mobility aid, (2) help determine the most appropriate mobility aid, and (3) assure that medical issues are appropriately addressed.

Once the examination documents the need, or potential lack of need for the mobility device the remainder of the examination can focus on the appropriate technology. This is best assessed by giving the consumer the opportunity to try equipment to determine how functional and safe they maneuver/operate the device within the clinical space. During this part of the assessment, the consumer and family must be informed of the positive and negative characteristics of devices and services. The team needs to educate the consumer or family to participate in

choosing the device that will meet their needs (Locus of Control) and assure the provision of follow-up services.

The in-home evaluation conducted by the ATS verifies that the device is compatible and will fit within the home environment of the consumer; that may also included recreational and work environment. Once the appropriateness of a device is established, final measurements are taken. For many people, a few simple measurements can be used to determine the proper dimensions for a wheelchair (10). Body measurements are typically made with the consumer in the seated position. A Rehabilitation Technology Supplier, therapist, or other member of the rehabilitation team often completes this.

MANUAL WHEELCHAIRS

When most individuals think of manual wheelchairs they envision the boxy, steel framed, standard wheelchairs commonly seen at airports and shopping malls. These wheelchairs may be acceptable for transport of short distances, but are good for little else. Their heavy weight and complete lack of adjustability makes them poor choices for anyone using a manual wheelchair for an extended period of time.

The development of the lightweight and ultralight wheelchairs evolved in the late 1970s with a select few, extremely motivated, manual wheelchair users choosing to perform modifications on their own wheelchairs to make them faster and easier to propel (11). After these initial steps the demand became far greater for lightweight, adjustable wheelchairs and several companies were created to meet that need.

Research conducted on the new lightweight and then ultralight manual wheelchairs have quantitatively shown the benefits over the heavier, nonadjustable standard style wheelchairs. Cooper et al. (12) reported that when subjected to the fatigue tests described in the ANSI/RESNA standards, ultralight manual wheelchairs were 2.3 times more cost effective than lightweight wheelchairs and 3.4 times more cost effective than depot style wheelchairs.

The benefits of lightweight and ultralight manual wheelchairs do not end with higher cost efficiency and longevity. They are also crucial in preserving the upper extremities of their users. Because of the constant use of the upper extremities by manual wheelchair users, they tend to experience secondary injuries such as joint pain, repetitive strain injury, and nerve damage (2). Compared to standard and lightweight wheelchairs, the ultralight

wheelchairs have two very distinct advantages when attempting to prevent secondary injury in manual wheelchair users: the primary advantage is the lower weight (Fig. 1).

Standard style wheelchairs tend to be greater than 36 lb (16 kg), while lightweight wheelchairs tend to be ~30–34 lb (14 + 18 kg) and ultralight wheelchairs ~20–30 lb (9–14 kg). The second advantage presented by the ultralight wheelchairs is adjustability. Lightweight wheelchairs do have some adjustability, but not to the extent of an ultralight wheelchair. Masse et al. (13) showed that moving the horizontal axle position toward the front of the wheelchair and moving the seat downward created a more efficient position for wheelchair propulsion and resulted in less exertion without loss of speed. Although some studies have been conducted to assess the importance of wheelchair setup in reducing upper extremity injury in manual wheelchair users, the solution has not been clearly defined. However, what is certain is that the adjustability and weight of manual wheelchairs are crucial parameters when selecting a wheelchair for a user that will be propelling for extended periods of time.

Another recent addition to manual wheelchairs has been suspension elements, such as springs or dampeners to reduce the amounts of vibration transmitted to manual wheelchair users. During a normal day of activity for a wheelchair user, they encounter bumps, oscillations, and other obstacles that may subject them to whole-body vibration levels that are considered harmful. VanSickle et al. (3) demonstrated that when propelling over certain obstacles, vibrations experienced at the seat of the wheelchair and the head of the user exceed the safety levels prescribed by the ISO 2631-1 Standard for evaluation of human exposure to whole-body vibration (14). Wheelchair companies have attempted to reduce the amounts of transmitted vibration by adding suspension to manual wheelchairs. Research has been done to evaluate effectiveness of suspension at reducing vibration. Results show that on average, suspension does reduce the vibration levels, however, the designs are not yet optimally effective and may not be as effective based on the orientation of the suspension elements (15,16).

POWERED ASSIST WHEELCHAIRS

Often, people using manual wheelchairs are required to transition to using powered wheelchairs or are at a level of capacity where they must choose between the two. This may be because of increased amounts of upper extremity

Figure 1. (a) Standard, (b) lightweight, and (c) ultralight wheelchairs.

pain, or the progression of a disease such as Multiple Sclerosis or Muscular Dystrophy. Recently, the development of Pushrim Activated Power Assist Wheelchairs (PAPAWs) has provided an alternative for these users. The PAPAW works through the use of a battery and a motor mounted directly into the wheel. The motor provides a supplement to the user so that very little force input from the user will still afford normal momentum. Transitioning from a manual wheelchair to a powered wheelchair may be difficult both physically and psychologically for some people. Users may not want to modify their homes or their cars to accommodate a powered wheelchair and may be used to providing their own mobility. Although the PAPAW provides a good intermediate wheelchair for users who may still benefit from a manual wheelchair, but do not have the strength or stamina, it also has its disadvantages. The added weight of the motor driven wheels dramatically increases the overall weight of the wheelchair and can also be difficult for users during transfers. Additionally, algorithms for the control of the PAPAWs are not yet refined and can lead to difficulty propelling the wheelchair.

POWERED WHEELCHAIRS

Powered wheelchairs represent devices that can provide an incredible amount of independence for individuals who may have extremely limited physical function. Perhaps even more than manual wheelchairs, having the proper elements and setup of a power wheelchair is vital. The lifestyle of the user, the activities in which they would like to participate, the environments to which they would like to be subjected, and ability level have all contribute to the correct prescription of a powered wheelchair. Many adjustments can be made to any particular powered wheelchair to specifically fit the needs of the user. Seating systems, cushions, added assistive technology to name a few. This section will focus on the characteristics that differentiate certain powered wheelchairs from one another (Fig. 2).

Powered wheelchairs come in three drive wheel setups: front, mid, and rear wheel. Each of these setups has different advantages and shortcomings. Powered wheelchair users are each unique and have specific requirements for their activities of daily living, such as maneuverability, obstacle climbing, or driving long distances. Mid-wheel

drive wheelchairs tend to provide greater maneuverability because the drive wheels are located directly beneath the user's center of mass. Front-wheel drive wheelchairs are often associated with greater obstacle climbing ability. Rear-wheel drive powered wheelchairs are good for speed and outdoor travel, but may not provide the maneuverability or stability for some users. The different wheelchair setups provide the means for users to achieve their goals.

For the user, the joystick is probably the most important part of the powered wheelchair. However the standard displacement joystick is not acceptable for all users. Current technologies have allowed almost any user to operate a powered wheelchair as well as other assistive technologies, such as computers. Even the smallest abilities of the user can be translated to powered wheelchair mobility such as foot control, head control, finger control, tongue control and so on.

Like manual wheelchairs, powered wheelchairs also have different classifications. Medicare defines powered wheelchairs in three major categories: Standard weight frame powered wheelchair (K0010), Standard weight framed powered wheelchair with programmable control parameters for speed adjustment, tremor dampening, acceleration control and braking (K0011), other motorized powered wheelchair base (K0014) (17). Pearlman et al. (18) recently conducted a study examining the reliability and safety of standard weight frame powered wheelchairs. Of the 12 wheelchairs tested, only 3 passed the Impact and Fatigue section of the ANSI/RESNA Standards (19,20). Medicare has recently proposed to stop funding these powered wheelchairs, recommending the addition of a programmable controller that would place it in the second category (K0011). However, this may not be acceptable since the problems exist mainly with the drive train or the frame of the wheelchair and these parameters would not change. In order to adequately serve the interests of powered wheelchair users, the frames, drive trains, and control systems all need to perform within the standards put forward by ANSI/RESNA.

WALKERS AND ROLLATORS

Some individuals may have the ability to ambulate, however, they may get tired very easily or have visual

Figure 2. (a) Front-, (b) mid-, and (c) rear-wheel drive powered wheelchairs.

Figure 3. Robotic walker for users with visual impairments.

impairment problems that may result in a fall and injury. Fuller (21) reported that 33% of community-dwelling elderly people and 60% of nursing home residents fall each year. Walkers and rollators represent useful assistive technology devices for these individuals by lending support and weight relief during mobility. They may have zero, two, or four wheels and possibly have hand brakes. They may also contain a small area for sitting if the user becomes fatigued or a basket for carrying items for the user.

Some elderly persons, in addition to having mobility impairment, also have a visual impairment. Recent research has investigated a new robotic walker (Fig. 3) that through the use of sonar and infrared (IR) sensors can detect obstacles as well as provide guidance along a preprogrammed path (i.e., maneuvering around an assisted living home) (22).

SPORTS AND RECREATION DEVICES

As quality of life receives more attention, sports and recreational activities have become more important to individuals with disabilities. Sport and recreational activity participation provides many benefits to individuals with disabilities. Physical activity reduces or slows down the development of cardiovascular disease as well as modifies risk factors including high blood pressure, blood lipid levels, insulin resistance, and obesity (23). In addition, the development of muscular strength and joint flexibility gained through regular exercise improves the ability to perform activities of daily living (24). Regular exercise may help reduce clinical depression and days spent as an in-patient in a hospital, and may improve social interactions and prolong life expectancy (25). With the positive benefits of sports, exercise, and recreational activities in mind, the purpose of this section is to describe some of the more popular sports played by individual with disabilities.

Wheelchair Basketball

Wheelchair users who play basketball may have various diagnoses, such as paraplegia, cerebral palsy, amputations, post-polio syndrome, or a disabling injury. Participants are not required to use a wheelchair for their primary means of mobility or in their activities of daily living. Prior to the actual game, persons who want to play basketball must have their player classification level determined by a qualified referee. To equalize the capability of each team, the classification levels of the competitors are matched (26).

Whether players play zone or person-to-person basketball, the basic rules apply to both. Because different players have varying degrees of disability, rules have been developed that all players need to abide by. Keep firmly seated in the wheelchair at all times. A player may not use a functional leg or leg stump for physical advantage. An infraction of this rule constitutes a physical advantage foul (27).

Wheelchair basketball is similar to an everyday wheelchair, but incorporates features that enhance maneuverability (Fig. 4). Basketball wheelchairs are lightweight to allow for speed, acceleration and quick braking. The wheelchair must have four wheels. Two large, rear wheels and two front casters. The front casters are 2 in. (50 mm) in diameter and typically made from hard plastics, similar to the material used to make inline skate wheels. The rear wheels must be larger than or equal to 26 in. (338 mm) in diameter. The rear wheels must have handrims. Basketball wheelchairs use spoke guards made of high impact plastic. These guards cover the rear wheel spokes to prevent wheel damage and illegal ramming and picking. The spoke guards provide several benefits: First, spoke guards can be used to pick up the ball from the floor. Using a hand, the player pushes the ball against the spoke guard and rolls it onto their lap. Second, spoke guards protect hands and fingers from injury when reaching for the ball near another player's rear wheel. Third, they provide space to identify team affiliations and sponsor names. Camber is an important feature of basketball wheelchair as well. Camber is defined as "the angle of the main wheel to the vertical", or as a situation in which "the spacing between the top

Figure 4. Players competing in a friendly game of wheelchair basketball.

points of the wheels may be less than the spacing between the bottom points". Increasing camber slightly reduces the height of the seat, while it proportionally increases the wheelbase, which corresponds to the width of the wheelchair. In the same way, with negative camber, the center of gravity of the occupied wheelchair moves backward. From a practical point of view, increased wheel camber improves hand protection as chairs pass through doors and, in terms of basketball, camber makes a wheelchair more responsive during turns and protects players' hands when two wheelchairs collide from the sides, by limiting the collision to the bottom of the wheels and leaving a space at the top to protect the hands. Basketball wheelchair seats typically have a backward seat angle slope of 5–15°. The angle of the seat compared to the ground is known as "seat angles". Guards are an exception. Guards are allowed to have lower seat heights and greater seat angles. These modifications make chairs faster and more maneuverable for ball handling.

Wheelchair Racing

Individuals with all levels of SCI as well as lower limb amputees can participate in competitive races. The preferred racing chair among racers is the three-wheel chair (Fig. 5). The three-wheel design is constructed from high pressure tubular tires, light weight rims, precision hubs, carbon disk/spokes wheels, compensator steering, small push rings, ridged aluminum frame, and 2–15° of wheel camber. The camber in a racing chair makes the chair more stable and allows the athlete to reach the bottom of the pushrim without hitting the top of the wheels or pushrim.

Hand-Cycling

Cycling has been a popular outdoor sport for several years. The adaptability of cycling to different terrains makes it a favorite for many. Adaptive equipment for bicycles consists of a hand cycle allows individuals with limited use of their legs to utilize the strength of their arms (28). A handcycle typically consists of a three-wheel setup to compromise for the balance required when riding a two-wheeled bicycle. Two-wheeled handcycles do exist but require a great deal of skill and balance. Handcycle designs allow the user to propel, steer, break, and change gears, all with the upper extremities and trunk. Two types of handcycle designs are

Figure 5. Shows a racing three-wheeled wheelchair.

readily available (1) the upright and (2) the recumbent. In an upright handcycle, the rider remains in an upright position similar to the position the body takes when seated in a touring bike. Upright handcycles use a pivot steer to turn. Only the front wheel turns while the cycle remains in an upright position. Transferring and balancing tend to be easier on the upright cycle. In the recumbent handcycle, the rider's torso reclines and the legs are positioned out in front of the cyclist. These cycles use a lean-to-steer mechanism. The rider leans to turn, causing the cycle to pivot at hinge points. Leaning to turn can be challenging if the rider lacks trunk stability, in which case a pivot steering recumbent handcycle may be more appropriate. Recumbent handcycles are lighter and faster, making them the choice for hand cycle racing. Relatively minimal modifications are needed to accommodate individuals with tetraplegia. Some of the modifications include hand cuffs that can be mounted to the arm crank handles and elastic abdominal binders which can be fitted around the user and the handcycle seat to increase trunk stability.

Wheelchair Rugby

Rugby is played indoors on a large gym on a basketball court surface. Players use manual wheelchairs specifically designed for the sport. Due to the level of contact, the chairs have protective side bars on them and players are strapped in to prevent injury. Most chairs are made of titanium or steel to handle the hits that they sustain. In addition, the low pointers have a high camber (angle of the wheels) so that they can turn fast, as well as "red push rim covers so they can actually stick to the other person's chair and hold them." The high pointers have armor on the front of their chairs resembling a cow catcher so that they can push through the other players without getting stuck (Fig. 6).

To be eligible to play rugby, players must have a combination of upper and lower extremity impairment. Most of the players have sustained cervical level spinal injuries and have some degree of tetraplegia. Like in basketball, players receive a classification number based on their level of impairment (29). Rugby consists of two teams comprised of four players. The object of the game is for a player to have possession of the ball and cross the opponent's goal line.

Rugby wheelchairs are strictly regulated to ensure fairness. However, chairs may vary considerably depending on

Figure 6. Wheelchair rugby.

a player's preferences, functional level and team role. Team roles may be assigned according to ability. Players with upper body limitations tend to perform the defensive blocking and picking roles. They use chairs that have additional length and hardware. All rugby chairs have extreme amounts of camber, 16–20°, significant bucketing, and antitip bars. The camber provides lateral stability, hand protection, and ease in turning. The bucketing (knees held high relative to rear end) helps with trunk balance and protection of the ball.

Tennis

Tennis players compete in both singles and doubles games. Players are required to have a permanent mobility-related physical disability that requires a wheelchair as the primary means of mobility. Tennis is played on the traditional tennis court using the tradition size and height tennis net. However, unlike traditional tennis, the ball is permitted two bounces on the court before it must be returned. Brakes are not permissible as stabilizers and the athlete must keep one buttock in contact with the seat at all times.

Tennis players use a three-wheeled chair with a large amount of camber to maximize mobility around the court. The seat is situated at a steep backwards seat angle slope. The angle helps with balance, keeps players against the seat backs, and gives them greater control over the wheelchair. The knees tend to be flexed with the feet on the footrest behind the player's knees. With the body in a relatively compact position, the combined inertia of rider and wheelchair is reduced, making the chair more maneuverable (30). Handles and straps can also be added to the chair. Many players incorporate plastic rigid handles into the front of the seat. Players use these handles when leaning for a shot or making quick directional changes. Straps can be used around the waist, knees and ankles, to help with balance (31).

Adaptive Skiing

Skis for skiers with disabilities have advanced state-of-the-art skis that offer shock absorption systems, frames molded to body shape, and quick release safety options. Skiers with disabilities can maintain a similar pace to that of unimpaired athletes with the development of adaptive seating, backrests, cushions, tethering ropes, roll bars and outriggers. Outriggers, an adapted version of a forearm crutch with a shortened ski, provide extra balance and steering maneuverability (32). Two types of sit-down adaptive skies are available: Bi and Mono. Bi skis are appropriate for skiers with limited trunk stability. With Bi skis, the skier balances on two skies and angulates and shifts to put the skis on edge. Bi skis have wider base of support, can usually be mastered quickly with few falls and are easier to control than a mono ski. The Mono Ski is the ski of choice for individuals who want high end performance, maneuverability and speed. With a mono ski, the skier sits relatively high on the seat of the ski over the snow. The skier uses upper body, arm and head to guide their movement down the hill. Sit-, Mono- and Bi-skis have loading mechanisms, usually hydraulic, that enable the individual

to raise themselves to a higher position for transferring onto a ski lift.

TRANSPORTATION SAFETY AND ADAPTIVE DRIVING FOR WHEELCHAIR USERS

Wheelchair users, like the entire population, use several forms of transportation to travel from place to place: They are passengers in public transportation systems (bus, subways, and vans) and private vehicles, and are potential drivers of each of these types of vehicles. To ensure the safety of *all* passengers and drivers, certain safety mechanisms must be in place: drivers must be able to safely control the vehicle, and all seated passengers require seats securely fastened to the vehicle and passenger restraints (e.g., seatbelts) which can secure the passenger to the seat. The requirement of passenger restraints is relaxed for passengers in large vehicles, like busses and subways, because of the low likelihood of high velocity crashes (33). In many cases, adaptation of a vehicle is necessary when the original equipment manufacturer (OEM) control and/or securement mechanism cannot provide adequate safety for wheelchair users because either (1) sensory and/or motor impairments of the user requires adaptive driving equipment so the vehicle can be safely controlled, or (2) the user cannot safely or effectively use the OEM seat or passenger restraint system in the vehicle.

Vehicle Control Systems

The complexity of the adaptive equipment required for safe control of the vehicle is correlated to the type and level of impairment of the wheelchair user. Adaptive driving equipment can be as low tech as attaching a knob on a steering wheel, and as high tech as fly-by-wire technology, where computer-controlled actuators are added to all of the controls, and the drive interfaces with the computer (via voice and/or low or no-effort sensors). Adding actuators to all of the driving and operating controls of the vehicle through computer controls.

An example of this range is the types of steering adaptations available for people with disabilities. Figure 7 demonstrates both a typical steering knob for a person with little to no loss of hand sensory-motor function (a), and (b) a knob for someone with loss of some sensory motor function. Both types of steering knobs serve the same purpose: They allow the driver to safely steer the vehicle with one hand while (typically) their other hand is operating a hand control which actuates the fuel accelerator and brake pedals. When upper-extremity sensory-motor function does not allow for safe turning of the OEM steering system (even with a knob), actuators can be used in lieu of upper-extremity function. These systems are named "low-" or "no-effort" steering systems, depending on the type of assistance that the actuators provide. Retrofitted controls for these systems are used and typically require removal of the OEM equipment (e.g., the steering wheel and/or column). Consequently, when this level of technology is used, it usually becomes unsafe for an unimpaired individual to drive the vehicle (without significant training).

Figure 7. Steering knobs.

Common fuel/accelerator and braking system hand controls are bolted to the OEM steering column, and actuate each pedal with mechanical rods (Fig. 8). These types of controls require nearly complete upper extremity function to operate. When upper extremity function is substantially impaired actuators are added to the braking and fuel/accelerator systems and are operated through some switching methods. The types of switches depend on the most viable control mechanism for the user: in some cases, a simple hand-operated rheostat variable resistance switch (i.e., dimmer switch or rheostat) may be used, and in other cases, a breath-activated pressure switch (sip-and-puff) system may be used.

The above steering, fuel/accelerator, and brake adaptive equipment are focused on the primary control systems of the vehicle (those which are required to drive the automobile). Various adaptive equipment can control the secondary control system of the vehicle also (e.g., ignition switch, climate control, windows). Like the primary control adaptive equipment, equipment to modify the secondary controls of the vehicle range from low to high tech. For example, users with impaired hand function may require additional hardware to be bolted to the ignition key so they can insert the key and turn it to start the vehicle. Alternatively, hardware can be added to allow a driver to start the vehicle via a switch, either remotely or from within the cabin. Power windows and door-lock switches can be

Figure 8. Common hand controls.

rewired to larger switches, or in more accessible locations for the driver.

Both primary and secondary control systems must be placed in locations easily accessible to the driver. In some cases, wheelchair riders will transfer out of their wheelchair directly into the OEM seating system, allowing for most controls to remain in their OEM locations. If a wheelchair user remains in their wheelchair and drives the vehicle the controls must be made accessible to their seated position and posture. In these cases, along with the case a wheelchair users remaining in their wheelchair as passenger, provisions must be made to safely secure the wheelchair to the vehicle, and to provide adequate passenger restraints.

Wheelchair Tie-Down and Occupant Restraint Systems (WTORS)

For both practical and safety reasons, when a wheelchair user remains in wheelchair while riding in a vehicle they must be safely secured to the vehicle. An unsecured wheelchair will move around, causing the user to be unstable while the vehicle is moving. Being that power wheelchairs can be in excess of 200 lb (91 kg) in weight, This instability could cause harm to the wheelchair rider and/or the surrounding other passengers vehicle occupants. If the wheelchair user is driving, they may lose control of the vehicle if they accidentally roll away from the vehicle controls. Another important concern for an unsecured wheelchair rider is in the case of an accident. An unsecured wheelchair and user can easily be ejected out of the vehicle if they are not secured. The WTORS systems are currently governed by the ISO 7176-19 (34).

Several types of tie-down systems exist, including a four-point belt system and various latching-type mechanisms which typically require hardware to be attached to the wheelchair. The four-point belt systems are most common, and are found on public busses, and also private vehicles. These systems are the most widely used tie-down system because they can be attached to a wide variety of wheelchairs. In some cases, manufacturers incorporate attachment rings for these tie-down systems into their wheelchair. When no points of attachment are available (most common situation), points at the front and rear of the seat or frame be used. These attachment points must be sufficiently strong to secure the wheelchair in the event

of a crash, and be in locations which will allow the straps to be oriented within a specified range of angles with the horizontal (front straps: 30–60°, rear: 30–45°).

Unfortunately, tie-down systems as they are not convenient to use: a second person (other than the wheelchair user) is typically needed to help secure the wheelchair, making the operation laborious, and in some cases awkward for the wheelchair users who may not be comfortable with another person touching their wheelchair or encroaching on their personal space. Consequently, and especially on public transportation, these systems are commonly unused and the wheelchair user relies on their brakes wheel-locks for stability, risking their own safety in a crash.

Other mechanisms have been used to secure a wheelchair to the vehicle. These included wheel-clamps and t-bar systems. With these mechanisms, wheelchairs are secured to the vehicle through a mechanical clamp that adjusts to the wheelchair size. These systems are quicker to attach to the wheelchair, but are still difficult or impossible for a user to use independently.

A variety of wheelchair tie-down systems have been developed that allow the wheelchair users to independently lock and unlock their wheelchair to the vehicle. A common one used for personal vehicles is the EZ-Lock System, which is a hitch system for the wheelchair. This system allows the wheelchair user to maneuver the wheelchair so a specialized hitch attached to the wheelchair is captured into a latch bolted to the vehicle; both electric and manual release mechanisms can be used to unhitch the wheelchair from the device, allowing for custom placement of a hitch for easy accessibility to the wheelchair user. A drawback to this system is the specialized hardware that must be attached to the wheelchair that restricts folding a manual wheelchair and reduces ground clearance.

Because this system is designed to allow the user to drive forward into the device, it works well and is common in private vehicles where the wheelchair user drives the vehicle. In larger vehicles, such as public busses, it is typically more convenient for a user to back into a spot and lock their wheelchair.

An ideal system for public transportation would be one that a user can operate independently and that does not require specific hardware to be attached to the wheelchair that may not work on *all* wheelchair models. A system is currently being developed at the University of Pittsburgh that tries to achieve these goals.

Occupant restraint systems are the last requirement to allow a wheelchair user to safely travel in a vehicle. These restraint systems mimic the function of a seat belt, and can be either attached to the wheelchair (integrated restraint) or to the vehicle (Fig. 4). In both cases, the placement of the restraints with respect to the body is critical to prevent injury in a crash—either through direct insult of the seatbelt with the body, or because of submarining (where the torso slides down under the pelvic belt).

To ensure these WTORS systems and the wheelchair themselves can safely survive a crash, standards testing is in place. Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), International Standards Organization (ISO), and Society of Automotive

Engineers (SAE) have worked in parallel to establish minimum standards and testing methods to evaluate wheelchairs and WTORS systems (35). These tests mimic those performed on OEM seat and occupant restraint systems, which suggest the system should be able to withstand a 20 g crash (36). To encourage and guide wheelchair manufacturers to build their wheelchairs to these standards researchers have developed a website to inform all relevant stakeholders of the latest information (<http://www.ercwts.pitt.edu/WC19.html>).

LOWER EXTREMITY PROSTHETICS

Prosthetics are devices that replace the function of a body organ or extremity, unlike orthotic devices, which support existing extremities. Prosthetics range from simple cosmetic replacements to complicated structures that contain microprocessors for controlling hydraulic and pneumatic components. Commonly used prosthetic devices primarily include artificial limbs, joint implants, and intraocular lenses. Approximately, 29.6–35.4% of the U.S. population use prosthetic limbs (37) with >2% of them aged between 45 and 64 years using lower extremity (LE) prosthetics for mobility (U.S. Bureau of Census, 2000). Amputation, resulting from peripheral vascular diseases in the older population (60 years and older) and trauma in young population can be considered factors for the use of LE prosthetics.

Research and development in clinical practice has resulted in recent advances in the area of prosthetics designs and controls technology. Examples of these advances include the use of injection molding technology for socket manufacturing, shock absorbing pylons, the incorporation of neuro-fuzzy logic microprocessor-based controllers for myoelectric prostheses, and microprocessor-controlled prosthetic knees and ankles (38,39).

Prosthetic feet classified as "uniaxial" allow for movement at a single axis in one plane, such as plantarflexion and dorsiflexion of the ankle. In this type of prosthetic foot, the heel is typically composed of the same density materials as the rest of the foot, with an option of different heel height. Also, uniaxial feet have different options at the rubber toe section in terms of flexibility, which depends on the weight of the individual. Multiaxial prosthetic feet (MPFs) have five degrees of motion in three planes: plantarflexion–dorsiflexion, inversion/eversion, and rotation. This feature provides stability to the user, while walking on uneven surfaces and also aid in shock absorption lowering intensity of shear forces on residual limb. Elastomer or rubberized material is used to alter, resist, or assist with the different degrees of motion in the prosthetic foot. MPFs also provide options for different heel heights [0.5–1 in. (13–26 mm)] and different degrees of toe material resistance, while split internal structures in the heel assist with inversion/eversion on uneven ground. The MPFs are prescribed by the weight and shoe size of the consumer.

The solid ankle, cushion heel (SACH) prosthetic foot is the most commonly prescribed prosthetic foot for lower extremity amputations. The SACH foot is constructed out of eurothene (plastic) materials with a less dense material

Table 1. Functional Level and Devices

	Functional Level	Type of Device
K0	No ability to ambulate or transfer safely; prosthesis does not enhance mobility	Cosmesis
K1	Transfers and ambulates on level surfaces; household use	SACH
K2	Able to negotiate over low level environmental barriers; limited community ambulation	Low level energy storage feet
K3	Prosthetic usages are beyond simple ambulation; able to traverse MOST environmental barriers and is a community ambulator	Energy storage prosthesis
K4	Able to perform prosthetic ambulation exceeding basic skills (i.e., high impact); child, active adult and athlete	Energy storage prosthesis

incorporated at the heel. Use of materials with different densities permits proper positioning while standing, as softer heels aides in enhancement of the walking efficiency after heel strike, by shifting center of gravity forward. A device known as durometer is used to measure the density of plastics used in prosthetic devices. The weight and activity level of the individual using the prosthesis determines which heel density is selected, as heavier user require firmer heel cushion. The stiffness of heel, also determine amount of knee flexion and shock absorption. Greater the heel stiffness more the knee flexion and lower shock absorption during heel strike and vice versa. The SACH foot also contains a keel made out of a hard wood or composite material. Belting material is applied to the keel, which prevent the keel it from breaking through the eurothene cover. During ambulation, the foot simulates plantar flexion movement and prevents the loss of anterior support during the push off at the toe.

Individuals who use foot prosthetic devices are assessed for weight, potential activity levels, and type of use for which they anticipate using their prosthetic devices. Based on this assessment, clients are then categorized into four functional levels:

Energy Storage and Return (ESAR) prosthetic feet are fabricated to assist with the dynamic response of feet, acting as a diving board from which a person can push off during walking. These feet have capability to store energy during stance phase and return it to the user to assist in forward propulsion in late stance phase. The ESAR has flexible keels and are prescribed by the anticipated activity level and weight of the person. Also, limited evidence suggests use of ESAR as their use results in increasing ambulation speed and stride length $\sim 7\text{--}13\%$ greater than with a conventional (SACH) foot in both traumatic and vascular transtibial amputees (40).

Macfarlane et al. (40) compared energy expenditure of individuals with transfemoral amputations who walked with a SACH foot versus a Flex-Foot prosthetic. The SACH has a solid ankle and cushioned heel construction, while the Flex-Foot prosthetic has a hydraulic knee joint. The authors determined that Flex-Foot walking resulted in significantly lower exercise intensity, reduced energy expenditure and improved gait efficiency. These findings are significant considering the SACH foot is the most commonly used foot prosthetic in the U.S. today (41). Lower

energy expenditure was also reported for individuals with trans-tibial amputation with the use of Flex-Foot as compared with a SACH foot.

Higher level of limb loss results in addition of more prosthetic components. Prostheses for transfemoral amputations comprised of four basic components: the socket, the knee joint, the pylon, and the foot. Pylons are classified as: exoskeleton in which the weight of the individual is supported by the external structure of the prostheses (i.e., a crustacean shank), or endoskeleton that is comprised of an internal, weight-bearing pylon encased in moldable or soft plastics (i.e., modular pylon). The knee mechanism use, a conventional damping system, where a flow of (fluid or air) is controlled by a valve and its operation is set for a particular walking speed according to user's preference. The system described as intelligent prosthesis (IP), where a diameter of damping controlling valve is changeable according to varying speed of walking (42). Romo provided guidance on the selection of prosthetic knee joints and indicated that proper alignment impacts the effectiveness of matched and adjusted knee joints for smooth and reliable gait (43). Taylor et al. (44) compared effectiveness of an intelligent prosthesis (IP), and pneumatic swing-phase, control-dampening systems while walking on a treadmill at three speeds of 1.25, 1.6, and 2 mph (2, 2.6, and $3.2 \text{ km} \cdot \text{h}^{-1}$). The results indicated lower VO_2 consumption for individuals using IP compared to controls-damping system at 2 mph ($3.2 \text{ km} \cdot \text{h}^{-1}$). The question often raised by critiques concerns the cognitive demands by the high end technology on the users. The results of the study by Heller et al. (42) that investigated cognitive demand when using the IP compared to a conventional prosthesis indicated no significant differences while using these prostheses for ambulation. Though not uncommonly prescribed high rejection rates has been described for prostheses after hip disarticulation and hemipelvectomy. These prostheses consist of an addition of hip joint mechanism to other parts similar to prostheses prescribe after transfemoral amputation.

Modular systems were first developed in the 1960s by Otto Bock, which consisted of shock absorbing pylons that contained with shock absorbers. Also, a reverse-pyramid fixture at the ends of the pylon permits angular adjustments to the alignment of these devices with the residual limb. Modular systems are lighter than the earlier wooden

systems, allow for 15° of movement gain in either the frontal or sagittal plane, and also permit internal and external rotational adjustments. Modular systems can extend the life of a prosthetic device, as worn parts can be replaced. In addition, individuals using these systems experienced less need for maintenance.

A significant improvement in the design procedure of the prosthetics considers the interaction of forces between prosthesis and residual limb can be found in the literature. Jia et al. (45) studied the exchange of loads and forces between the residual limb and prosthetic socket in transtibial amputation using the Finite Element Analysis (FEA) method. Lee et al. (46) used FEA to determine contact interface between the transtibial residual limb and prosthetic socket. The study determined the need for sameness of shapes for both the residual limb and socket in order to decrease peak normal and shear stresses over the patellar tendon, anterolateral and anteromedial tibia, and popliteal fossa. Winson et al. investigated the interaction between socket and residual limb during walking using a FEA model for transtibial prosthesis. Pylon deformities and stress distribution over the shank were problems identified during walking and results indicated need for pylon flexibility for better optimization and need of future studies identifying fatigue life of these prostheses (47).

With advancement in the area of prosthetics designs and development, simultaneous factors that need to be considered, use of these devices in clinical practice for targeted population and cost containment. Premature abandonment of mobility assistive devices, which might be due to poor performance and/or changes in the need of the user, is not uncommon and adds to the expense of these devices (48). Improved quality of service delivery for LE prostheses, which include identifications of reasons for successful use or non-use of LE prostheses, is needed (49). Also, incorporation of standardized performance testing procedure to ensure durability of LE prosthetics is vital to the appropriate prescription of, and satisfaction with, prosthetic devices.

Prosthetic devices of today incorporate advancements from the aerospace and engineering fields and include the use of new materials, such silicone elastomer gel sleeves in to assist in the fit of prosthetic sockets, prosthetic feet made from carbon-fiber composite components that are lighter in weight, and surgical implantation of titanium prosthetic attachment devices directly to bones of residual limbs (50,51). Neuro- and microprocessors and sensors are now incorporated on-board the prosthetic device to control knee joint movement to improve the symmetry of different gait patterns across a variety of cadence speeds. Hydraulic or pneumatic devices are also used to dampen the swing-through phase of walking with the prostheses to assist with walking at difference cadences (52,53). Manufacturers are now using computer-aided design and manufacturing techniques to improve the fit of the prosthetic sockets as well as component designs (54,55).

Because of the growing population of people in need of mobility aids, and their demand to maintain their lifestyle, whether that includes going to and from work, participating in extracurricular activities, or maneuvering around their environment, continuing information must be gathered and disseminated to make these goals achievable.

Through technological advancements people who require mobility aids can accomplish more of their goals than ever before, however there are still people for whom the technology is not yet developed enough or cannot obtain the proper devices to meet their needs. It is for this reason that problems must continually be studied and innovations must advance so that mobility aids will serve anyone who requires them to meet their goals.

MONITORING IN ANESTHESIA

TARMO LIPPING

 Technology
 Pori, Finland

INTRODUCTION

Anesthesia is one of the most complex and mysterious phenomena in clinical work. The main feature of anesthesia

is the loss of consciousness, which suggests its relatedness to sleep, epilepsy, and various kinds of brain trauma. In the case of anesthesia and sedation, consciousness is manipulated deliberately to prevent the patient from being aware of their state and the medical procedures carried through.

Recent decades have seen significant advancements in mapping various psychological functions to corresponding brain areas, however, the knowledge of the formation of human consciousness is still based on uncertain hypothesis. This complexity makes anesthesia monitoring extremely challenging.

This article first addresses the problem of anesthesia monitoring from the clinical, as well as from the physiological, point of view. The main emphasis is on monitoring anesthetic depth as this is the most discussed topic in anesthesia monitoring today. It starts with clinical indicators of anesthetic depth, gives an overview on the methods used in commercially available depth-of-anesthesia monitors, and describes some new algorithms proposed and evaluated for anesthesia electrocardiograms (EEG) monitoring in recently published works. Finally, the feasibility of monitoring brain function is argued using neurophysiological parameters like EEG, Auditory Evoked Potentials (AEPs), and so on, in the Intensive Care Unit (ICU) and the Emergency Room (ER).

ANESTHESIA AS A PROCESS AND A PROCEDURE

Anesthesia can be seen from the clinical point of view as a procedure, carried out according to certain protocol. From the physiological point of view anesthesia is a process evolving in the nervous system as the dose of an anesthetic agent increases.

Anesthesia as a Procedure

The goal of general anesthesia in the operating room (OR) is to render the patient unaware so that they do not feel pain during the surgery or recall the events afterward. It is also important that the patient does not react to surgical stimuli by movement. In the ICU, the goal of sedation is to keep the patient calm and painless. Too deep anesthesia causes prolonged awakening times after surgery in OR and longer treatment times in the ICU. The goals of anesthesia and sedation can be achieved by hypnotics (unconsciousness producing drugs), analgesics (antinociceptive drugs), and neuromuscular blocking agents. The choice of drugs is mainly made based on experience and clinical signs during the treatment.

Although general anesthesia is considered a safe procedure, various complications like postoperative nausea, vomiting, and pain are relatively frequent. The incidence of recall of events and awareness during anesthesia is rare ($\sim 0.1\%$), however, the consequences may be traumatic for the patient (1). Anesthesia-related mortality has decreased significantly during past decades having recently been estimated at 1 death per 200,000–300,000 cases of anesthesia (2–4).

Anesthetic agents can be divided into inhalation anesthetics (e.g., halothane and isoflurane) and intravenous

anesthetics (e.g., thiopental and propofol). Intravenous drugs are becoming more popular as they are short acting, do not cause gas pollution, are easy to administer, and do not cause airway irritation. Desirable properties of anesthetic agents include rapid, smooth and safe induction of and emergence from anesthesia, no accumulation in the body, minimal effects on cardiovascular functions, no irritation to tissues and veins, low potential to hypersensitivity reactions.

Anesthesia as a Process

During the last decades, it has become obvious that different anesthetic and sedative agents produce their effects with different mechanisms, and therefore from the physiological point of view depth of anesthesia is a vague notion (5). It is more meaningful to talk about components forming the state we usually call anesthesia. These include amnesia, unconsciousness (hypnosis), antinociception, and neuromuscular blockade (paralysis). Different neurophysiological modalities should be used in order to assess these components. In the operating room, the patient is said to be anesthetized while the term sedation is used in the ICU. Some drugs, like propofol, are useful in producing both anesthesia and sedation at different concentrations, while some others are most useful as anesthetics or sedatives. There is evidence that anesthesia and sedation can be produced via different structures in the brainstem. Hypnosis and sedation cause similar changes in the EEG signal (described in the section changes in Neurophysiological Variables During Anesthesia). As all the available depth-of-anesthesia monitors are either fully or partly based on the EEG, the terms depth of hypnosis and depth of sedation are used depending on the corresponding clinical situation and are, in the context of available monitoring devices, roughly equivalent.

The action of anesthetics can be studied at various levels of neuronal function (6). The models underlying these studies can be divided into those operating at the molecular–cellular level and those explaining anesthetic processes at higher levels (generator models). State-of-the-art knowledge on the molecular and neuronal substrates for general anesthesia has recently been reviewed in Ref. 7. The model proposed by Flohr describes the action of anesthetics as disruption of computational processes dependent on the NMDA receptors (8). The activation state of these receptors in cortical neurons determines the complexity of representational structures that can be built-up in the brain and thus the level of consciousness. Steyn-Ross et al. performed numerical simulations of a single-macrocolumn model of the cerebral cortex and found that the effects of anesthetics can be modeled by cortical phase transition (9). Their simulations explain several trends in the EEG caused by anesthetic actions and predict the decrease in spectral entropy of the EEG signal with deepening anesthesia. This model has supported the development of the Entropy module, described in the section Recently Developed Methods, Applied in Commercial Anesthesia Monitors. Great caution must be taken, however, in interpretation of the models operating at molecular level, because they include only a small part of the neurophysiological functions known to be involved in consciousness and generation of anesthesia-induced EEG patterns.

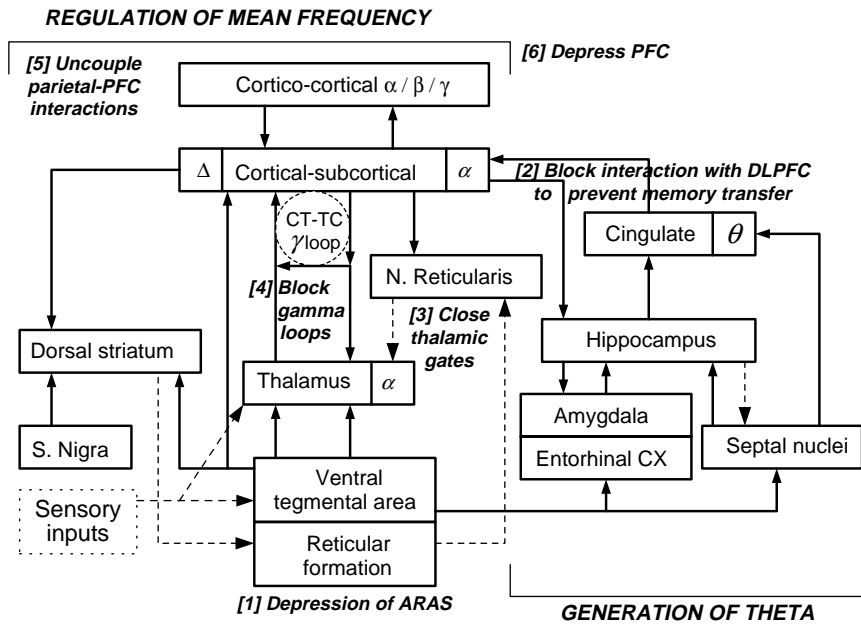

Figure 1. The Anesthetic Cascade model (redrawn with permission from: E. R. John and L. S. Prichep, "The anesthetic cascade: A theory on how anesthesia suppresses consciousness," *Anesthesiology*, Vol. 102, Fig. 11 (p. 468), 2005).

John et al. developed a higher level model based on a complex neuroanatomical system described in (10). This model, described and thoroughly discussed in volume 10 of Ref. 11, incorporates and explains an extensive bulk of results obtained from EEG, evoked potential and magnetic resonance imaging (MRI) image analysis, as well as laboratory studies. Loss of consciousness is described as the following cascade of events, called the Anesthetic Cascade by the authors, involving various brain regions (Fig. 1) (6): (1) depression of the brainstem; (2) depression of mesolimbic-dorsolateral prefrontal cortex interactions leading to blockade of memory storage; (3) inhibition of the nucleus reticularis of the thalamus, resulting in closure of thalamic gates (seen as increasing θ rhythm in the EEG); (4) blocking of thalamocortical reverberations (γ loop) and perception; (5) uncoupling of parietal-frontal transactions (coherence in γ frequency band decreases); (6) depression of prefrontal cortex to reduce awareness (increase in frontal θ and δ rhythm).

Definitions of the EEG rhythms used in the description of the Anesthetic Cascade are given in Table 1.

The model by John et al. underlies the Patient State Index for depth-of-anesthesia monitoring, described in the section Recently Developed Methods, Applied in Commercial Anesthesia Monitor. Although the Anesthetic Cascade model covers a large set of neurophysiological functions, it does not explain patterns like burst suppression, for example.

Table 1. Definition of the EEG Rhythms^a

EEG Rhythm	Frequency Range, Hz
Delta (δ)	< 4
Theta (θ)	4–8
Alpha (α)	8–12
Beta (β)	12–25
Gamma (γ)	25–50

^aExact frequencies may vary slightly from source to source.

MONITORING ADEQUACY OF ANESTHESIA

Clinical Indicators and Measures of Anesthetic Depth

The verb monitor originally means to check systematically or to keep watch. Thus, monitoring actually does not necessarily involve medical equipment, but refers also to clinical inspection. As clinical indicators of anesthetic depth are often used as a reference for automated depth-of-anesthesia monitoring methods, they are shortly described here.

In the case of inhalation anesthetics, drug concentration can be monitored by measuring the partial pressure of the anesthetic in exhaled air (end-tidal concentration). Due to the variation of the potency of anesthetic agents, a universal unit of minimum alveolar concentration (MAC) has been applied. The value 1 MAC is the partial pressure of an inhaled anesthetic at which 50% of the unparalyzed subjects cease to express protective movement reaction to skin incision. The primary rationale behind the development of the term MAC was the need to compare the potency of different volatile anesthetics, not the effort to monitor the anesthetic state of an individual patient.

For intravenous anesthetics, no such direct measure can be derived and the effect of anesthetics can be estimated using pharmacokinetic models (effect-site concentration). In this case, the accuracy of the estimate depends on the adequacy of the model. If all subjects would react to anesthetics in exactly identical ways these concentration measures would provide a perfect indicator of adequacy of anesthesia. However, there is an intersubject variability in the effect of anesthetics, and therefore other indicators are needed.

Clinical indicators of the adequacy of surgical anesthesia can be divided into those measuring hypnosis and those measuring nociceptive–antinociceptive balance. The indicators measuring hypnosis include pupillary light reflex, tested by allocating a flashlight to one eye and observing both pupils for constriction; corneal reflex,

Table 2. Ramsay Score for Assessment of Level of Sedation^a

Score	Clinical Status
1	Patient anxious and/or agitated
2	Patient cooperative
3	Patient responds to commands only
4	Brisk response
5	Sluggish response
6	No response to loud auditory stimulus

^aSee Ref. 13.

tested by applying a wisp of cotton wool to the cornea or by electrical stimulation using special electrodes (12); Eyelash reflex, tested by brushing the eyelashes with a moving object or by electrical stimulation; loss of counting, tested by letting the subject count slowly as long as they can from the onset of infusion-injection; syringe dropping, tested by letting the subject hold a syringe between their thumb and forefinger as long as they can; loss of obeying verbal commands.

The indicators measuring nociceptive-antinociceptive balance include avoidance reaction to nociception. This is mainly a spinal reflex, however, it correlates well with the concentration of most anesthetics; electrical tetanic stimulation, applied using needle electrodes or adhesive skin electrodes to the upper or lower limb; autonomic nervous system-mediated reactions or motor reactions to laryngoscopy and endotracheal intubation. This is a natural stimulus in many clinical situations in the operating room.

These indicators test the functioning of different neural pathways and their applicability depends on the anesthetic used. For example, ketamine leaves corneal and pupillary light reflexes intact.

For more graded and standardized clinical assessment of sedation and hypnosis, several scoring systems have been developed. Probably the most widely used such systems are the Ramsay score (Table 2) and the Observer's Assessment of Alertness and Sedation Scale (OAAS; Table 3). These scoring systems are developed for use in the ICU as they include scores for agitated states and cover mainly lighter levels of anesthesia. Therefore, they do not necessarily indicate the adequacy of anesthesia for surgical procedures. Also, the assessment obtained using these scoring systems is subjective.

Table 3. OAAS Score for Assessment of Level of Sedation^a

Score	Clinical Status
5	Responds readily to command spoken in normal tone
4	Lethargic response to command spoken in normal tone
3	Lethargic response to command spoken loudly and repeatedly
2	Appropriate response to loud tone and mildly painful stimulus
1	Appropriate response to loud tone and moderately painful stimulus
0	No response

Changes in Neurophysiological Variables with Deepening Anesthesia

All the commercial monitors of hypnosis employ the EEG signal. Although different anesthetic agents induce specific features and patterns in the EEG, certain common trends in signal properties with deepening anesthesia can be seen. At subanesthetic levels, several agents produce oscillations at beta frequency range, sometimes called beta buzz. This activity is seen dominantly in the frontal brain areas. With increasing anesthetic concentrations, the activity becomes more widespread, decreases in frequency and increases in amplitude. Around concentrations, causing the subjects to stop responding to stimuli (1 MAC for inhalation anesthetics), the EEG activity slows further and high amplitude theta and delta waves occur. With further increasing concentration, the burst-suppression (BS) pattern occurs, finally turning into continuous suppression. The dynamics of this pattern, as well as the waveforms of bursts, varies for different anesthetic agents (Fig. 2). Several anesthetic agents tend to induce epileptiform seizure activity in patients with a prior history of seizures and even in subjects with no previous history of seizures (15,16).

In addition to the EEG signal, AEPs have been used for anesthesia monitoring. The latency of early cortical responses Pa and Nb increases and the amplitude decreases with deepening anesthesia (17). Also, late cortical responses to auditory stimuli, specifically the amplitude and latency of the N100 peak have been found to improve the assessment of the level of consciousness in ICU patients (18). A commercially available brain monitor, the AEP Monitor/2 by Danmeter A/S, combines AEPs with EEG parameters to calculate the cAAI index (see the next section).

In most commercially available monitoring devices, the EEG signal is obtained from the electrodes placed at the forehead. This makes the recording procedure easier in clinical situations. The electrodes tend to pick up frontal EMG, which is an artifact from the point of view of the EEG signal but may be used as a valuable indicator of nociception in light anesthesia (19). The EMG component of the measurement is either explicitly or implicitly incorporated into most of the available monitoring devices (see the section Discussion).

Another neurophysiological variable proposed for anesthesia monitoring is the respiratory sinus arrhythmia (RSA) component of the heart rate (HR) signal (20). Although potentially valuable addition to the assessment of the level of consciousness, this variable has not made its way to anesthesia monitoring devices to date.

Short History of Brain Monitoring in Anesthesia

Since the first measurements of human electroencephalogram, performed by Hans Berger in 1920s, this modality has been applied to studying the effects of various drugs, including anesthetics. The emergence of microprocessors and digital techniques for signal analysis opened new perspectives for anesthesia monitoring.

The first commercial brain monitoring device based on digital signal analysis was the *Cerebral Function Analyzing Monitor* (CFAM1), developed in 1975 by Prior and

Figure 2. Samples of BS pattern in EEG during deep propofol (a) and sevoflurane (b) anesthesia. Detection of BS suppression and calculation of BS ratio is an important part of all modern depth-of-hypnosis monitors. The pattern varies significantly among anesthetic drugs. In the case of propofol anesthesia, spindles can be observed (marked by boxes in the figure). Note that the scale of the time axes is different for upper and lower curves.

Maynard (21). This device used the Motorola 6808 8-bit microprocessor. The display of the CFAM1 was divided into two sections, one showing the 10th and 90th percentile as well as the mean of the EEG amplitude distribution while the other showing the percentage of weighted (prewhitened) EEG activity per hertz in the beta, alpha, theta, and delta frequency bands (Fig. 3). In addition, muscle activity, EEG suppression ratio, and electrode impedance were displayed. An important feature of the CFAM1 was the possibility of monitoring averaged evoked potentials. Since the introduction of CFAM1, the CFAM family of brain monitors has been continuously developed with the recently introduced CFAM4 being the latest member of this product family. Comprehensive list of publications referring to the CFAM family can be found at www.cfams.com/references/a4a.htm.

In 1982 Datex-Ohmeda (Helsinki, Finland) introduced its first EEG monitor for anesthesia, the *Anesthesia Brain Monitor* (ABM). Like in most of the later monitoring devices, the location of the EEG electrodes in the ABM monitor was on the forehead. The monitor displayed the root-mean squared (rms) value of the EMG and the RMS, as well as the zero-crossing frequency of the EEG signal. The EMG and EEG signals were obtained from the same electrodes—bandpass filter of 65–300 Hz was applied to obtain the EMG while frequencies 1.5–25 Hz were used to obtain the EEG. The ABM monitor is described in (22).

At the beginning of 1990s Thomsen et al. took a different approach to anesthesia monitoring in their *Advanced Depth of Anesthesia Monitor* (ADAM) (23). They divided the signal into consecutive 2 s segments, applied a prewhitening filter, and derived 11 parameters: the rms value and 10 correlation coefficients from each segment. Either the values of the first 10 autocorrelation lags or the coefficients of the 10th-order autoregressive model were suggested as features. To create a set of reference classes, an unsupervised repetitive hierarchical cluster analysis was applied to the data bank of preannotated recordings of

halothane and isoflurane anesthesia. Six clusters were defined, corresponding to anesthetic levels from drowsiness to very deep anesthesia. The classification was adjusted according to the anesthetic agent used. Burst-suppression was detected separately and the suppression ratio in 2 s segments was incorporated into classification. Anesthetic depth was displayed as the class probability histogram: A plot where each line represented the clusters

Figure 3. Layout of the screen of the CFAM1 monitor (with permission from D. Maynard).

obtained for 10 s period of the recording. The clusters were color coded. In spite of its advanced approach, ADAM was never implemented in a commercial anesthesia monitoring device.

Recently Developed Methods, Applied in Commercial Anesthesia Monitors

The *Bispectral Index Score* (BIS), developed by Aspect Medical Systems Inc. in 1997, marked a breakthrough in anesthesia monitoring. The output of the BIS monitor is a single number between 0 and 100 achieved by combining in a nonlinear fashion from the following parameters (24): relative beta ratio calculated in spectral domain as $\log\left(\frac{P_{30-47}}{P_{11-20}}\right)$, where P_{30-47} and P_{11-20} denote signal power in frequency ranges 30–47 and 11–20 Hz, respectively; SynchFastSlow measure calculated in bispectral domain as $\log\left(\frac{B_{0.5-47.0}}{P_{40.0-47.0}}\right)$, where $B_{0.5-47.0}$ and $B_{40.0-47.0}$ denote the sum of magnitudes of the bispectrum values in the corresponding frequency ranges; BS ratio. Bispectrum (the third-order spectrum), is defined as the two-dimensional (2D) Fourier transform (FT) of the third-order cumulant sequence $c_3(k_1, k_2)$ of the signal:

$$B(\omega_1, \omega_2) \stackrel{\text{FT}}{\leftrightarrow} c_3(k_1, k_2) \quad (1)$$

If the direct current (dc) component of the signal has been removed (as is usually the case), $c_3(k_1, k_2)$ equals to the third order moment sequence $m_3(k_1, k_2)$, defined as:

$$m_3(k_1, k_2) = \varepsilon\{s(n)s(n+k_1)s(n+k_2)\} \quad (2)$$

where $\varepsilon\{\cdot\}$ denotes expected value. Overview on the estimation of higher order spectra can be found in (25).

The weighting of the three parameters forming the BIS depends on signal properties and is not disclosed. In light anesthesia, relative beta ratio is dominating while SynchFastSlow measure becomes more important with deepening anesthesia. The function combining the parameters was developed empirically, based on thousands of EEG records. An important part of BIS is its careful artifact rejection scheme, dealing with heartbeat artifacts, eyeblinks, wandering baseline, muscle artifacts, and so on. BIS has become very popular among anesthesiologists; the bulk of literature dealing with the behavior of BIS in various clinical situations, discussing its advantages as well as disadvantages, incorporates more than 1000 papers. Comprehensive bibliography can be found on the web-pages of Aspect Medical Systems Inc.

At the beginning of this decade Physiometrix Inc. brought to market the PSA 4000 depth-of-hypnosis monitor, based on the *Patient State Index* (PSI) (26). The development of the PSI was based on a library of 20,000 cases of EEG records. In addition, a library of surgical cases, a library of artifacts and results from volunteer studies (for calibration), were used. In PSI, the EEG signal is measured from four electrodes: Fp1, Fpz, Cz, and Pz, with the reference at linked ear electrodes. Signal analysis is based on power in standard EEG frequency bands (see Table 1) and incorporates the calculation of the following parameters: absolute power gradient between Fp1 and Cz leads in the

gamma frequency band (25–50 Hz); absolute power changes between Fpz and Cz leads in beta (12–25 Hz) and between Fpz and Pz; leads in alpha (8–12 Hz) frequency bands; total spectral power (0.5–50 Hz) at the Fp1 lead; mean frequency of the total spectrum at Fpz lead; absolute power in delta frequency band (0.5–4 Hz) at Cz; relative power at Pz lead in slow delta frequency band;

The calculated parameters go through a mathematical transformation that guarantees their Gaussian distribution in order to be rescaled into the Z-score (Fig. 4). The Z-score sets the calculated parameters into relation with the parameter values obtained for reference population giving the percentage of the reference population that lies more standard deviations away from the mean than the calculated parameter (6). The Z-scored parameters are fed into discriminant analysis with adaptive discriminant functions. EEG suppression is detected separately: The suppression ratio is included in the discriminant analysis. The discriminant analysis yields the PSI index: a scalar between 0 and 100 with higher level of hypnosis corresponding to lower PSI value.

The *Narcotrend* anesthesia monitoring system was developed by a German group and first introduced in 2000 (27,28). This system has its roots in sleep analysis: A five-stage sleep scoring system was further developed into a system of 6 stages and 14 substages for level-of-hypnosis monitoring. These stages are mapped to a scale of 0–100 in the Narcotrend algorithm. The EEG signal is derived from one or two electrodes; the most common electrode location is on the forehead, however, according to the authors other electrode locations are possible. The signal is sampled at 128 Hz and prefiltered using lower and upper cutoff frequencies of 0.5 and 45 Hz, respectively. The principal idea underlying the method is similar to that of the PSI: Several variables calculated from the EEG signal are fed to discriminant analysis with separate detection of BS (Fig. 5). The variables are classified as time- and frequency-domain ones and contain signal power, autoregressive coefficients, relative power in standard EEG frequency bands, median frequency (the frequency dividing the signal spectrum into two parts of equal energy), spectral edge frequency (SEF95, the frequency below which 95% of signal energy is contained), and spectral entropy. The algorithm also contains plausibility check to ensure that the signal segment is actually similar to a typical EEG sample of corresponding stage and to detect patterns in the EEG signal untypical for general anesthesia (e.g., epileptic activity). The detailed algorithm of the Narcotrend index is proprietary.

Another EEG-based depth-of-anesthesia monitoring device is the recently introduced *M-Entropy* module for the Datex-Ohmeda S/5 anesthesia monitor. As the name indicates, the method is based on the idea that the entropy of the EEG signal decreases with deepening anesthesia. Signal entropy can be defined and calculated in many different ways (see also the next section) of which spectral entropy is employed in the M-Entropy module. Spectral entropy in the frequency range f_1 – f_2 is expressed as

$$S(f_1, f_2) = \sum_{f_i=f_1}^{f_2} P_n(f_i) \log \frac{1}{P_n(f_i)} \quad (3)$$

Figure 4. Schematic of the calculation of the PSI index. (Redrawn with permission from D. R. Drover et al., "Patient State Index: Titration of delivery and recovery from propofol, alfentanil, and nitrous oxide anesthesia," *Anesthesiology*, Vol. 97, Fig. 3 (p. 88), 2002).

where $P_n(f_i)$ is the normalized power spectrum of the signal. $S(f_1, f_2)$ is again normalized by $\log N(f_1, f_2)$, where $N(f_1, f_2)$ is the number of frequency components in the range f_1-f_2 , to give a value between 0 and 1. In the original version of the device, the analysis was performed on a single EEG channel measured from the forehead. In this derivation, muscle activity dominates over the EEG at frequencies higher than ~ 30 Hz. The algorithm of the M-Entropy module, like that of the early ABM-monitor by Datex-Ohmeda, employs these high frequency components to detect the early response of the patient to nociceptive stimuli. This is done by calculating spectral entropy over two frequency ranges: 0.8–32 Hz (called state entropy) and 0.8–47 Hz (called response entropy). The difference between these two entropies indicates the contribution of the EMG component to the response entropy. As in the other described monitors, BS is detected separately. The details of the algorithm (variable window length, obtaining the output value in the case of BS, etc.) are described in (29).

The Danmeter AEP Monitor/2 (further development of the A-Line monitor) employs the composite AAI Index,

combining the middle latency auditory evoked potentials in 20–80 ms latency range, calculated from the 25–65 Hz bandpass filtered signal, with spontaneous EEG. The purpose of combining the two modalities is to get a better response to the lightening of hypnosis due to, for example surgical stimuli (achieved by using AEPs) while retaining sensitivity during deep anesthesia (achieved by using the EEG). The schematic of the cAAI index calculation is presented in Fig. 6. Using evoked potentials poses a problem in on-line monitoring due to the long delay needed for obtaining the averaged response. This problem has been solved in the cAAI calculation by applying the autoregressive model with exogenous input (the ARX model). The ARX model enables to calculate the response to stimuli based on the average of 18 sweeps using the average of 256 sweeps as a reference. The algorithm is described in detail in (30) and compared with conventional evoked potential averaging techniques in Ref. 31. In addition to AEPs, the cAAI index incorporates logarithmic EEG power ratio $[\log(P_{30-47}/P_{10-20})]$ and the burst suppression ratio. The EMG is extracted and monitored

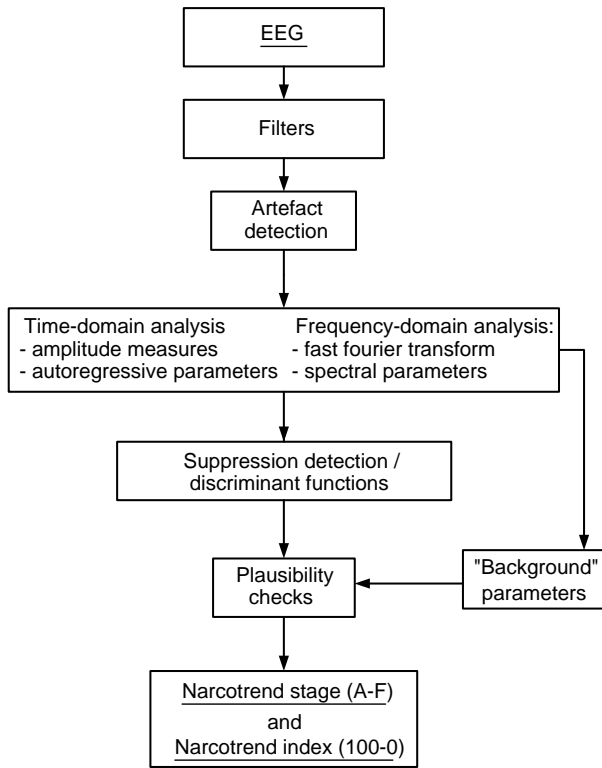

Figure 5. Schematic of the calculation of the Narcotrend index (with permission from B. Schultz).

separately based on the 65–85 Hz bandpass filtered signal.

A somewhat different concept of anesthesia monitoring has been used in the *Cerebral State Monitor* (CSM; Danmeter A/S, Odense, Denmark) and the *SNAP* monitor (Everest

Biomedical Instruments Inc). These monitoring devices come in the form of a handheld wireless PDA-type tool, convenient to use in a clinical situation. The CSM displays the Cerebral State Index, calculated based on the 6–42 Hz bandpass filtered EEG, the EMG component calculated from the same signal, but in 75–85 Hz frequency range, as well as the burst suppression ratio. The algorithm of the second version of the SNAP index is described in (32). Two variables, the low frequency variable *LF* (0.1–40 Hz) and the high frequency variable *HF* (80–420 Hz) are derived from a single frontal EEG channel. The HF and LF are scaled to fit into the intervals 0.0–1.0 and 0.0–100, respectively. The SNAP index is expressed as $SI = 100 - (HF * LF)$; thus the index can be thought of as the reversed version of HF-modulated LF.

New Parameters Proposed for Monitoring Anesthetic Depth

In spite of the large selection of available methods, new parameters for quantifying depth of hypnosis are being proposed continuously. This is mostly due to the following reasons: the variety of procedures and combinations of drugs in surgical anesthesia is wide. No method performs well in all cases; monitoring in anesthesia is closely related to monitoring brain dysfunction and detection of brain ischemia and hypoxia: important tasks faced in cerebral function monitoring in the ICU and emergency room (see the section Monitoring Outside the Operating Theater). The available depth-of-hypnosis monitors are generally not suitable for these applications; the neurophysiological basis of consciousness is still an unsolved problem: applying modern signal analysis tools to neurophysiological measurements during anesthesia can hopefully offer new insight to the problem.

Several groups have recently published studies on the behavior of various complexity–entropy measures during

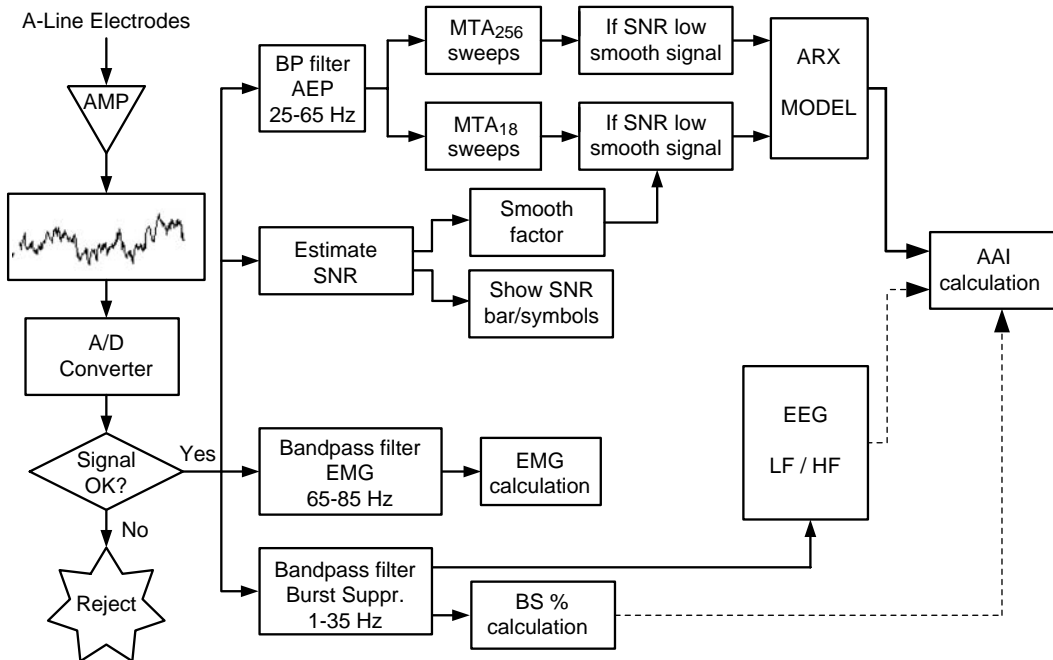

Figure 6. Schematic of the calculation of cAAI index (with permission from E. W. Jensen).

anesthesia and sedation. These measures come from different signal analysis frameworks.

Correlation dimension is a measure for quantifying the behavior of chaotic signals in the phase space (33). The signal s of finite length N is divided into $N-m+1$ time series: $s_m(i) = \{s(i), s(i+1), \dots, s(i+m-1)\}$, where m is the embedding dimension. After that, for each i the quantity $C_i^m(r)$ is calculated:

$$C_i^m(r) = \frac{\text{number of such } j \text{ that } d[S_m(i), S_m(j)] \leq r}{N - m + 1} \quad (4)$$

where the distance d between the phase space vectors $s_m(i)$ and $s_m(j)$ is defined as

$$d[S_m(i), S_m(j)] = \max_{k=1,2,\dots,m} (|s(i+k-1) - s(j+k-1)|) \quad (5)$$

Correlation dimension D can be estimated as

$$D = \frac{d \log(C^m(r))}{d \log(r)} \quad (6)$$

where $C^m(r) = \sum_i C_i^m(r) / N - m + 1$. Although EEG cannot be considered strictly chaotic, except in the case of some abnormal conditions, this measure has, for example, been found to have good correlation with the end-site concentration of sevoflurane (34).

Probably the most intensively studied complexity/entropy measure for the assessment of depth of hypnosis is Approximate entropy (ApEn). In general, entropy measures information-richness, regularity and randomness of a signal. The intuitive idea behind anesthesia monitoring using signal entropy is that with deepening anesthesia EEG becomes more regular and its entropy decreases. Approximate entropy, like correlation dimension, is calculated in the phase space. First, $\Phi^m(r)$ is defined based on $C_i^m(r)$ in Eq. 4 as

$$\Phi^m(r) = \frac{1}{N - m + 1} \sum_{i=1}^{N-m+1} \log C_i^m(r) \quad (7)$$

Approximate entropy is then defined as

$$ApEn(m, r) = \Phi^m(r) - \Phi^{m+1}(r) \quad (8)$$

Approximate entropy has been studied and compared to other methods as an indicator of anesthetic depth in (35–37).

The classical entropy measure, introduced for information theory by Claude Shannon in 1948 (38), the Shannon entropy (ShEn), is calculated as $ShEn = -\sum_i p_i \log p_i$, where p_i is the probability that signal amplitude obtains the range of values a_i . In practice, ShEn can be estimated based on the histogram of the values of signal samples, and therefore long signal segments are needed to achieve smooth histograms. An important property of Shannon entropy is that signal samples are considered as independent trials of some experiment, taking no notice on the time order of the samples. Signals having equal probability for all possible amplitude values have the highest Shannon entropy. In Ref. 39, it has been found that Shannon entropy of the EEG recorded between frontopolar electrodes increases with increasing concentration of desflurane: A behavior opposite to other entropy measures.

Other measures of the EEG, found to correlate well with depth of hypnosis, include Lempel–Ziv complexity and Higuchi fractal dimension (35,40). Lempel–Ziv complexity is calculated by transforming the signal into symbols and calculating the reoccurrence rate of these symbols (41). Higuchi fractal dimension is calculated as the average rate of increase in the difference of signal amplitude values as the separation between the samples increases in logarithmic scales (42).

These studies demonstrate that although different measures of entropy or complexity quantify different phenomena, many of them may correlate with concentrations of selected anesthetics when electrode positions and signal bandwidth are selected properly.

MONITORING OUTSIDE THE OPERATING THEATER

Development of digital EEG equipment, increase in processing speed and memory capacity, and advancements in telecommunication technology have made cerebral function monitoring feasible in ICU and ER. Brain monitoring in ICU and ER has much in common with monitoring in anesthesia as the changes in the EEG caused by intoxication, metabolic disturbances and brain ischaemia are similar to those induced by general Anesthesia. Also, in the ICU the assessment of depth of sedation is desirable. The advantages offered by EEG monitoring in the ICU are based on the following findings (43): EEG is tightly linked to cerebral metabolism; EEG is sensitive to brain ischemia and hypoxia; EEG detects neuronal dysfunction at a reversible stage; EEG detects neuronal recovery when clinical examination cannot; continuous EEG provides dynamic information; EEG provides useful information about cerebral topography.

However, from the monitoring point of view, the situation in ICU and ER is a lot more complicated compared to that of OR. The patients may need various medication having effect on the EEG signal and misleading automated EEG analysis, the clinical situation of the patients is often complex, and the surrounding is hostile for interference-sensitive equipment. In ICU, recordings often need to last for several days and nights without disturbing the normal care of the patient. In ER, the EEG recording equipment needs to be extremely flexible and easy-to-use. In both situations the interpretation of the recordings poses a problem as no experienced EEG readers are usually around. The solution to the last problem is the usage of telecommunication protocols to transfer the data for interpretation.

Although the above described depth-of-anesthesia monitoring methods are sometimes applied to sedation monitoring and even to the detection of brain dysfunction in ICU, their performance in this situation is questionable. It is difficult to differentiate between the effects of hypoxia, ischemia and sedative drugs. The importance of having the underlying raw EEG signal available for review to confirm the significance of any trends and changes suggested by automatic analysis methods, especially in complex situations like ICU, has been repeatedly emphasized (44,45). A comprehensive brain monitor for ICU, especially for neuroscience ICU, should also be able to detect epileptic

patterns in EEG and desirably have the option for synchronous video recording (46). All this suggests that an adequate brain monitor for ICU or ER should be a much more complex device than today's depth-of-anesthesia monitors.

DISCUSSION

Several considerations are appropriate concerning the available commercial depth-of-anesthesia monitors. First, different modalities should be used to assess the different components of anesthesia (see the section Anesthesia as a Process). Selecting EEG and AEPs as the basis for the assessment, the primary component of anesthesia considered would be hypnosis.

But even in this case there still remain other physiologically separate end-points like subcortically controlled reactions to nociceptive input (e.g., autonomic reactions), increased muscle tone, and movement response to surgery. Adding the fact that there are many anesthetic agents of different cell-level actions and that the interplay of hypnotic and antinociceptive medication modulates the anesthetic state (47), we are left with a complex situation that makes the comparison of the available algorithms for anesthesia monitoring a real challenge.

Another difficulty in comparing the results obtained with different methods is posed by the frequency band used for the calculation. All the commercial methods operate at least partly in the frequency domain although BIS applies third-order spectrum and in the Entropy module a nonlinear transformation follows the calculation of the power spectrum. For anesthesia, monitoring frequency domain can roughly be divided into the following physiologically meaningful areas: δ (and partly θ) frequencies, indicative of pre-BS deep anesthesia (~ 0.5 – 6 Hz); α and β frequencies; the EMG component, overlapping with the EEG and extending to > 100 Hz.

The devices differ in the usage of δ frequencies and in the way the EMG component is incorporated. While most of the methods employ frequency band starting from 0.1 Hz (SNAP)–0.8 Hz (Entropy), the Cerebral State Index and cAAI by Danmeter do not make use of δ rhythms. Several devices like the A-2000 monitor by Aspect Medical Systems Inc., the AEP Monitor/2 and the Cerebral State Monitor by Danmeter as well as the PSA 4000 monitor by Physiometrix Inc. display the EMG power separately from their corresponding depth-of-anesthesia indices. The frequency band the EMG component is obtained from varies from device to device, falling into the range from 65 to 110 Hz. The SNAP index, the Entropy module and the Narcotrend index incorporate the information on EMG activity into their depth-of-anesthesia indexes in different ways. In SNAP, the high frequency band used is 80–420 Hz, while the other two monitors use frequencies up to 47 Hz. The various entropy–complexity measures proposed for the assessment of anesthetic depth are sensitive to the prefilter settings as well (40). Thus it can be concluded that while comparing the performance of various algorithms, the following matters should be considered: the properties of the algorithm itself, the frequency band of the EEG signal it employs, and the location of the EEG electrodes.

In the future, it seems to be inevitable that brain monitoring becomes more common in ICU and emergency room. There is a compromise between the simplicity of the presentation of the output and versatility of the method. Monitoring such complex phenomenon as anesthesia by a single number is clearly an oversimplification. On the other hand, a device requiring sophisticated configuration and displaying a lot of parameters difficult to interpret gets easily rejected by clinicians. Connecting the algorithms to physiological models would certainly help the interpretation of the monitor output. Future will show if any of the new approaches such as measures of signal complexity find their way into the commercial devices. Operating in the frequency domain has the advantage of long-term experience in EEG analysis by means of frequency domain methods. Another advantage is the solid signal processing theory of frequency analysis. On the other hand, the theory of nonlinear systems is developing rapidly having made its way to physiological signal analysis in various applications.

INTRODUCTION

The word monitor has a variety of meanings, depending on the context. A monitor can be any device for checking on or regulating the performance of a machine, aircraft, or a patient. A patient monitor is usually thought of as something that watches, warns, or cautions if there is a life-threatening event. A more rigorous definition of patient monitoring is Repeated or continuous observations or

measurements of the patient, his or her physiological status, and the functions of life support equipment for the purpose of guiding management decisions, including when to make therapeutic interventions and assessment of those interventions (1). As a result, a monitor should not only alert physicians and nurses to potentially life-threatening events, but perhaps should also control devices that maintain life. The primary emphasis of this section deals with hemodynamic monitoring of the critically ill patient who is in an intensive care unit (ICU), but many of the principles apply to all hospitalized patients.

Hemodynamic monitoring relates to monitoring of the blood pressure and blood flow in the cardiovascular system. The cardiovascular system consists of the heart, lungs, and blood vessels, and has a most important function in maintaining life in complex animals, such as humans. Oxygen and fuel must be transported from their source to the individual cells that consume them. The resulting waste products of metabolism must then be disposed of. Thus, the heart and blood vessels transport nutrients to the body and remove the waste products. Clearly, if this system does not function properly, the organism could be compromised. As a consequence clinically applicable methods have been developed to assess the function of the cardiovascular system. Hemodynamic monitoring is one part of this complex monitoring strategy. Typical parameters measured when performing hemodynamic monitoring are heart rate and rhythm, measured through analysis of the electrocardiogram (ECG), blood pressure measurements in various locations in the cardiovascular system, and estimates of blood flow usually using cardiac output as a measure.

THEORY

Hemodynamic monitoring permits minute-to-minute surveillance of the cardiovascular system and provides physiologic data to assist in diagnosis as well as to guide therapy (2–5). The cardiovascular system consists of the heart, lungs, and blood vessels that supply blood to the body and return blood from the peripheral tissue.

It is beyond the scope of this section to describe the detailed anatomy of the cardiovascular system. However, to understand the principles of hemodynamic monitoring knowledge of the functional aspects of the cardiovascular system is essential.

HEART

The heart is made up of four chambers: the right atrium and the right ventricle and the left atrium and the left ventricle (see Fig. 1). The right atrium accepts blood from the systemic circulation (head, arms, and legs) via the superior and inferior vena cava. On atrial contraction the tricuspid valve between the right atrium and right ventricle opens and blood flows into the right ventricle. On ventricular contraction the right ventricle pumps blood through the pulmonic valve into the pulmonary artery and to the lungs where oxygen is added and carbon dioxide is removed. Blood flows from the lungs to the pulmonary veins and then into the left atrium. On atrial contraction

Figure 1. Outline drawing of the heart with its chambers and typical pressures (expressed in mmHg) for each area of the heart. Note the pressures are systolic (SP), diastolic (DP), and mean (MP), as shown on the arterial pressure waveform.

the blood flows into the left ventricle through the mitral valve. On ventricular contraction the left ventricle pumps blood through the aortic valve to the systemic circulation (aorta and the systemic vasculature).

The basic contractile element of the heart is the sarcomere, which is composed of myofilaments, contractile proteins that interdigitate and slide along one another during contraction. Shortening of the sarcomere is the functional unit of heart contraction. Physiologic and pharmacologic agents can change the contractile characteristics of the sarcomeres. Rate and contractility of the heart are controlled by sympathetic and parasympathetic innervation, as well as circulating catecholamines.

Control of Heart Performance

Mechanisms regulating cardiac (heart) output involve not only factors controlling performance of the heart as a pump, but also factors affecting the systemic vascular system and its resistance. Typically, the heart can increase its output to a level of almost five times its resting value. There are two methods by which the heart regulates its cardiac output in response to stress, injury, or disease: by changing heart rate and stroke volume.

Heart Rate Control

Heart rate can be changed rapidly and is thus one of the most effective ways for the heart to change its cardiac output. For a healthy person, an increase in heart rate can more than double the cardiac output when the heart rate increases to near $180 \text{ beats} \cdot \text{min}^{-1}$. However, if a patient with heart disease increases their heart rate to $>120 \text{ beats} \cdot \text{min}^{-1}$ they may have deleterious responses because of the increased demand for oxygen by the heart muscle. Blood flow in the heart muscle occurs primarily

during diastole (the relaxation phase of heart contraction). Increasing heart rate decreases the time for cardiac circulation during diastole. In normal subjects, decreasing the heart rate to $\sim 50 \text{ beats} \cdot \text{min}^{-1}$ may not decrease cardiac output because there is increased diastolic filling time that increases stroke volume.

Stroke Volume Changes

The stroke volume of an intact ventricle is influenced by (1) ventricular end-diastolic volume (called preload), (2) ventricular afterload, and (3) contractility.

Preload. Preload is the term used to define the end-diastolic stress in the wall of the ventricle. For example, zero preload would result in the ventricle ejecting no blood. However, with increased preload, ventricular ejection generally increases linearly until the capacity of the pump (heart) is exceeded. Since the end-diastolic volume so profoundly influences the myocardial fiber length it has a great influence on the myocardial performance. The Frank–Starling law describes this principle and is illustrated graphically in Fig. 2. The most accessible measure of right ventricular preload is the right atrial pressure. Left atrial pressure is used to estimate left ventricular preload. Since the left ventricle does most of the work of the heart, it is usually the first part of the heart muscle to fail. Consequently, the measurement or estimation of the left atrial pressure is important in assessing a patient's hemodynamic status.

Afterload. Afterload is a measure of the impedance (resistance) against which the right or left ventricles must

eject blood. Resistance (R) is calculated by measuring blood flow and pressure and then using Ohm's law {Eq. 1}.

$$R = \frac{\text{mean blood pressure}}{\text{cardiac output}} \quad (1)$$

Systemic Circulation

Blood flow to the periphery of the body is controlled by local autoregulation and by the autonomic nervous system. Local autoregulation of blood flow helps tissue meet its oxygen requirements. For example, with decreased blood flow, metabolic byproducts increase, causing local vasodilatation that tends to increase blood flow. There are baroreceptors, similar to blood pressure transducers, located in the aortic arch and the carotid sinus which sense blood pressure. Via the baroreceptor reflex mechanism, the body regulates the blood pressure. In addition, chemoreceptors in the carotid sinus and other locations regulate respiration by responding to changes in CO_2 and O_2 .

Pulmonary Circulation

The pulmonary arterial vessels differ markedly from systemic arterial vessels; they have thinner walls, less muscle, and have a resistance to blood flow about one-sixth that of the systemic circulation.

Contractility. Contractility is a measure of how a healthy heart performs. A healthy heart pumps vigorously and nearly empties its ventricles with each beat and is said to have excellent contractility. On the other hand, a compromised heart may not be able to empty effectively.

HEMODYNAMIC MONITORING

Bedside hemodynamic monitoring makes use of data gathering procedures that were formerly only done in diagnostic cardiac catheterization laboratories. Understanding the relationship between the pressure and blood flow in the cardiovascular system is the primary reason for performing hemodynamic monitoring. The cardiovascular system responds to many and varied stimuli and can be affected by physical conditioning, drugs, disease, blood loss, injury, and myocardial insult such as a heart attack. Because of the complexity of factors controlling the body, it is necessary to make hemodynamic measurements on the system to understand disease processes and provide optimum therapy to the patient.

Electrocardiogram

Electrocardiogram (ECG) monitoring is used to determine heart rate and detect arrhythmias, pacemaker function, and myocardial ischemia (lack of blood flow to the heart muscle). To permit optimum ECG monitoring the signal quality must be excellent (6). Since the ECG electrical signal from the heart is only 0.5–2.0 mV at the skin's surface, it is best measured by properly preparing the skin and optimally placing the electrodes. Skin can be properly prepared by removing oil from the surface and abrading the skin to remove the dry dead outer layer (stratum

Figure 2. Frank–Starling curve of the heart showing the ventricular performance (cardiac index) plotted against the end-diastolic volume typically estimated by using pulmonary artery wedge pressure. Note to the right of these curves, there is a pulmonary wedge pressure above which the heart is ineffective in producing increased flow.

granulosum). In 90% of patients, proper skin preparation reduces electrode resistance from as high as 200 to as low as 10 k Ω . Good electrode placement allows the electrodes to receive the maximum ECG signal with minimum noise. By placing the electrodes over bony prominence, such as the sternum or clavicles, muscle artifact (EMG) can be reduced. Motion artifact caused by movement of electrodes can be minimized not only by proper skin preparation, but also by taping a strain-relieving loop in the lead wires to prevent movement artifact. Shielded wire on the ECG leads helps minimize pickup of alternating current (ac) electrical fields from 60 Hz power sources, electrosurgical units, and other sources like radio transmitters. The two leads that connect the patient form a loop through which magnetic fields pass and can induce unwanted voltages. Pickup from magnetic fields can be minimized by decreasing the loop area, by keeping the lead wires close together (usually twisted pairs), and by avoiding draping the lead wires over motors, lights, or other electrically powered instruments.

Electrocardiogram Arrhythmia Monitoring

Early in the development of monitoring techniques, the application of computer technology to detect patterns of the electrocardiogram caught the attention of those who sought to improve care of the critically ill. The computer appeared to be a logical candidate for relieving the nursing and medical staff of the tedious chore of continuously visually monitoring a multichannel oscilloscope.

Arrhythmia monitoring is one of the most sophisticated of the bedside monitor's tasks. People-based arrhythmia monitoring is expensive and unreliable, and those who do it find the task to be tedious and stressful. Today virtually every bedside monitor has rhythm monitoring built in. These monitors use computers and a variety of algorithms to detect and classify ECG rhythm abnormalities. Classifying these rhythm abnormalities is important to hemodynamic monitoring since irregular rhythms can cause dramatic inefficiencies in how the heart works as a pump. For example, Fig. 3 shows three strip recordings of the ECG and the corresponding pressure waveform from three different arrhythmias (ventricular tachycardia, couplet, and bigeminy where every other beat is from abnormal electrical origin). Note that several of the abnormal beats are hardly effective at creating any change in the arterial pressure. Those same beats deliver small stroke volumes to the patient's systemic circulation. As a consequence, one cannot assume that the cardiac output remains constant or increases just because the heart rate increases.

MEASUREMENTS

Blood Pressure Monitoring

Arterial blood pressure can be measured by both direct and indirect methods. However, central venous pressure (CVP), pulmonary artery (PA), and pulmonary capillary wedge pressure (PCWP) used to estimate left atrial pressure, at present, can only be measured by direct invasive methods.

Figure 3. Electrocardiogram and arterial pressure waveforms with three different abnormal rhythms. (a) Ventricular tachycardia (VT), which occurs during the last two beats of the strip. (b) Couplets where two successive beats have an abnormal electrical origin. (c) Bigeminy where every other beat is from an abnormal electrical origin. Pressures are expressed in millimeters of mercury. For example, the patient in (a) has a systolic arterial pressure of 109 mmHg, a diastolic pressure of 53 mmHg, and a mean arterial pressure of 75 mmHg.

Arterial Blood Pressure: Indirect Measurement; Using a Cuff. Recently, the American Heart Association has updated its recommendations on accurate "indirect" measures of blood pressure (7). The update reports that the auscultatory technique with trained observer and mercury manometer continues to be the method of choice for measurement of a patient's blood pressure in a physician's office. The report also suggests that hybrid devices that use electronic transducers rather than mercury have promise. The report indicates that oscillometric devices can also be used, but only after careful validation.

Unfortunately, the indirect measurement of arterial pressure has serious limitations for patients in shock usually signaled by low blood pressure. Also, since virtually all reliable indirect pressure measurement techniques require cuff inflation, such measurements can only be made intermittently.

Direct Blood Pressure Measurements. The direct measurement of blood pressure allows for continuous and accurate assessment of blood pressures. Direct and continuous pressure monitoring allows detection of dangerous hemodynamic events and provides the information necessary to initiate and regulate patient therapy to prevent catastrophic events. However, monitoring of pressures provides valuable information only when it is obtained in a technically satisfactory manner.

To accomplish direct blood pressure measurements, it is necessary to insert a catheter directly into the cardiovascular system (8). This invasive technique has risks that must be weighted against the benefits that can be obtained. These risks include, infection, blood loss, insertion site damage and other factors (9,10). For many patients who are in shock or who have cardiac disease, the benefits far outweigh the risks. Formal methods for assessing these risks have been published by the Coalition for Critical Care Excellence (11).

Blood pressure can be measured on both the pulmonary (right heart) and systemic (left heart) sides of the circulatory

system. Measurements of both pulmonary and systemic parameters yield different and important cardiovascular status. The CVP reflects the patient's circulating blood volume or venous tone, and right atrial and ventricular pressures (right ventricular preload). To measure the right atrial pressure accurately a catheter must be placed in a major vein within the chest or directly in the right atrium. The CVP values fluctuate about atmospheric pressure. The level of the right heart is usually taken as the zero reference point from which all other blood pressures are measured. The CVP gives an indication of only the function of the right heart, and not left heart's performance.

To measure the left atrial pressure, it is necessary to place a catheter tip through the atrial septum from the right atrium (usually done only with fluoroscopic control in the cardiac catheterization laboratory) or estimating it by placing a pulmonary artery (Swan-Ganz) catheter in the wedged position by inflating its balloon near the catheter tip.

EQUIPMENT

Components of Direct Pressure Monitoring Systems

The components of a direct blood pressure monitoring system for critically ill patients are shown in Fig. 4 (6,8). The components numbered 1-7 in the figure are known as

Figure 4. The 10 components used to monitor direct blood pressure. The monitoring components are nearly independent of whether the catheter is in an artery (radial, brachial, or femoral) or in the pulmonary artery. Size of transducer and plumbing components are enlarged for illustration purposes. [Reproduced from Ref. 6, with permission.]

the “plumbing” system and must always be sterile because the fluid contained therein comes in direct contact with the patient’s blood. Today virtually all of these components are disposable or single-use items to minimize patient infection. Components 8–11 in Fig. 4 are used for processing and displaying pressure waveforms and derived hemodynamic parameters.

1. Catheter. Arterial and pulmonary artery catheters provide access to the patient’s blood vessels to (a) monitor intravascular pressure and (b) provide a site for samples for blood to allow determination of blood gas and other laboratory testing parameters. These catheters are typically placed by the percutaneous method, either by the Seldinger “over-the-needle” technique or by introducing the catheter through a needle (8).
2. Sampling stopcock. Stopcock 1 is used as a site for withdrawing blood for analysis. When filling the catheter-tubing-transducer system with fluid, precautions must be taken to be sure all central switching cavities of the stopcock are filled and that entrapped air bubbles are removed. Because stopcocks are especially vulnerable sources of patient contamination, these devices must be handled with extreme care; ports not in active use should be covered with sterile caps and medical personnel should never touch open ports of the stopcocks.
3. Pressure tubing. The catheter and stopcock are normally attached to a continuous flush device and transducer by noncompliant pressure tubing. To optimize the dynamic response of the catheter-tubing-transducer system, long lengths of tubing must be avoided.
4. Stopcock 2. This stopcock is usually put in place to allow disconnection of the flush device and transducer from the patient when the patient is moved or when initially filling the system with fluid.
5. Continuous flush device. This device is used not only when initially filling the pressure monitoring system, but also to help prevent blood from clotting in the catheter. These devices provide a “continuously flush” of fluid at a rate of from 1 to 3 mL · h⁻¹.
- 6,7. Transducer dome and Pressure transducer. Today virtually all transducers used for monitoring are highly reliable, standardized, disposable devices (12,13).
8. Amplifier system. The output voltage required to drive an oscilloscope or strip-chart recorder is provided by an amplifier system inserted between the transducer and display. Pressure transducer excitation is provided either from a direct current (dc) or ac source at a voltage of 4–8 V revolutions per second (rms). Most amplifier systems include low pass filters that filter out unwanted high frequency signals. Pressure amplifier frequency response should be flat from 0 to 50 Hz to avoid pressure waveform distortion.
9. Oscilloscope. Pressure waveforms are best visualized on a calibrated oscilloscope or other similar display panel.

10. Digital processing and display. Digital displays provide a simple method for presenting quantitative data from the pressure waveform. They are found on most modern pressure monitoring equipment. Systolic, diastolic, and mean pressure are typically derived from the pressure waveforms.
11. Strip-chart recorders. Frequently, strip-chart recorders are used to document dynamic response characteristics, respiratory variations in pulmonary artery pressures, and aberrant rhythms and pressure waveforms.

STATIC CALIBRATION

Zeroing and calibrating the transducer are two important steps in setting up the direct pressure-monitoring system.

Zeroing the Transducer

The accuracy of blood pressure readings depends on establishing an accurate reference point from which all subsequent measurements are made. The patient’s midaxillary line (right heart level) is the reference point most commonly used (14). The zeroing process is used to compensate for offset caused by hydrostatic pressure differences, offset in the pressure transducer, amplifier, oscilloscope, recorder, and digital displays. Zeroing is accomplished by opening an appropriate stopcock to the atmosphere and aligning the resulting fluid-air interface with the midaxillary reference point.

Once the system is zeroed the stopcock can be switched to allow the patient’s waveform to be displayed. Pulmonary artery and pulmonary artery wedge pressure are especially susceptible to improper zeroing and should be measured only after the zero point has been verified.

Sensitivity Calibration

The sensitivity of most pressure transducers is fixed at 5.0 $\mu\text{V} \cdot \text{V}^{-1}$ of excitation applied per 1 mmHg (0.13 kpa) and calibrated by the manufacturers to within $\pm 1\%$. This degree of accuracy is adequate for clinical purposes. As a consequence standardized transducers need only to be zeroed to obtain accurate pressure measurements (12,13).

CHECKING DYNAMIC RESPONSE

In the critical care setting, where most hemodynamic monitoring is carried out, the catheter-tubing-transducer systems used can usually be characterized as an underdamped second-order dynamic system analogous, for example, to a bouncing tennis ball. A second-order dynamic system can be expressed mathematically by a second-order differential equation with characteristics determined by three mechanical parameters: elasticity, mass, and friction. These same parameters apply to a catheter-tubing-transducer system where the natural frequency (f_n in Hz) and damping coefficient determine the dynamic characteristics for a catheter-tubing-transducer system. For an underdamped second-order system f_n and define the system’s

Figure 5. Family of frequency versus amplitude ratio plots for five different damping coefficients ζ and natural frequencies f_n of the plot shown is 10 Hz. When $\zeta=0.1$, the system is very underdamped, and when $\zeta=2.0$, it is overdamped. The dashed line shows the frequency versus amplitude characteristic that would occur if the system had a flat frequency response. Along the frequency axis are plotted the harmonics of the pressure wave if the heart rate were $120 \text{ beats} \cdot \text{min}^{-1}$ ($2 \text{ beats} \cdot \text{s}^{-1}$). Note that by the fifth harmonic (10 Hz) if $\zeta=0.1$ the true signal would be amplified five times. If $\zeta=2.0$ there would be an attenuation to about one-fourth of the amplitude. In both cases there would be a gross waveform distortion because neither situation reflects a high fidelity system dynamic response. Fidelity of the system can be improved by increasing the f_n or adjusting ζ to be in the range of 0.5–0.7. [Reproduced from Ref. 6, with permission.]

dynamic characteristics. In the clinical setting f_n and can be measured easily and conveniently by using the “fast-flush” method.

Dynamic response characteristics of catheter-tubing-transducer systems have been defined by two interrelated techniques. The first technique specifies the frequency bandwidth and requires that the system frequency response must be flat up to a given frequency so that a specified number of harmonics usually 10 of the original pulse wave can be reproduced without distortion (Fig. 5).

The second technique specifies f_n and The plot of f_n and in Fig. 6 has five areas (6,15). If the characteristics of the catheter-tubing-transducer “plumbing” system fall in the adequate or optimal area of the graph, the pressure waveforms will be adequately reproduced. If the characteristics fall into one of the remaining three areas, there will be pressure waveform distortion. Most catheter-tubing-transducer systems assembled under optimal conditions are underdamped, but a few fall into the unacceptable areas of the chart. Methods for optimizing the catheter-tubing-transducer system components have been outlined (15–20). In the clinical setting, there are dramatic differences between each patient setup; therefore it is mandatory to verify the adequacy of each pressure-monitoring system by testing them. The testing can be done easily using the fast-flush technique.

A fast flush is produced by opening the valve of the continuous flush device, for example, by pulling and quickly releasing the pigtail valve on a continuous flush

Figure 6. Plot of f_n versus ζ illustrating the five areas into which catheter-tubing-transducer systems fall. Systems in the optimal area will reproduce even the most demanding (fast heart rate and rapid systolic upstroke) arterial or pulmonary artery waveforms without distortion. Systems in the adequate area will reproduce most typical patient waveforms with little or no distortion. All other areas will cause serious and clinically important waveform distortion. Note the scale on the right can be used to estimate ζ from the amplitude ratio determined during fast flush testing (11). See Fig. 8 for an example of waveforms. [Reproduced from Ref. 6, with permission.]

device. The rapid valve closure generates a near square wave pressure signal from which f_n and of the catheter-tubing-transducer system can be measured.

Once the fast-flush test has been executed two or three times, the dynamic response characteristics (f_n and) can quickly and easily be determined. Natural frequency f_n can be estimated by measuring the period of each full oscillation on a strip-chart recorder following a fast flush (Fig. 7a) and calculating the frequency from the period. Damping coefficient can be determined by using the amplitudes of any two successive peak-to-peak values measured after a fast flush. The amplitude ratio is calculated by dividing the measured height of the smaller peak-to-peak value by that of the amplitude of the larger peak-to-peak value (Fig. 7b). The amplitude ration can then be converted to a damping coefficient by using the scale in the right side of Fig. 6.

Once f_n and have been determined, these data can be plotted on the graph of Fig. 6 to ascertain the adequacy of dynamic response. Some bedside monitors and recorders may compromise the clinical user’s ability to use the fast-flush technique because the monitors have built-in low-pass filters. These filters should be expanded to at least 50 Hz or be eliminated.

Several factors lead to poor dynamic responses: (1) air bubbles in the system usually caused by a poor initial catheter-tubing-transducer system setup, (2) pressure tubing that is too long, too compliant, or a diameter that is too small, and (3) pressure transducers that are too compliant. The best way to enhance the system’s dynamics is to improve f_n .

Invasive pressure monitoring systems have patient risks, such as a source of infection and air embolism. In addition, great care is required by clinical users to optimize

Figure 7. Measuring dynamic response parameters from the fast-flush waveform, (a) The natural frequency f_n can be determined by using a strip-chart recording to measure the period of one full oscillation, as shown. In this example, one full cycle is 2 mm and at a paper speed of $25 \text{ mm} \cdot \text{s}^{-1}$ this results in $f_n = 12.5 \text{ Hz} = 25 \text{ mm} \cdot \text{s}^{-1} / 2 \text{ mm}$. (b) Determining the damping coefficient ζ required measuring two successive peak-to-peak values of the resulting oscillations. The amplitude ratio of the two successive peaks is taken, giving a value of $0.58 = 13/22.5$. With use of the amplitude ratio and the scale on the right side of Fig. 6, the damping coefficient $\zeta = 0.17$. Plotting the natural frequency and damping coefficient on Fig. 6 shows that this system is underdamped.

dynamic response and proper zeroing to provide accurate and reliable data. Merely looking at pressure waveforms will not provide the information required to determine the adequacy of the system's dynamic response (see Fig. 8). Fast-flush testing to determine these parameters is essential.

SIGNAL AMPLIFICATION, PROCESSING, AND DISPLAY

Once the pressure signal has been transmitted to the transducer, the bedside monitor operates on that signal. Most monitors not only display the heart rate and systolic, diastolic, and mean pressure, but they also display the processed waveform on an oscilloscope and provide an analog output for a recorder or for transmission to a central display.

Placement of the Pulmonary Artery Catheter

The balloon-tipped, flow-directed, pulmonary artery catheter (Swan-Ganz) came into widespread use in 1970 (21).

Figure 8. Arterial pressure waveforms were obtained from the same patient. Shown are Systolic/Diastolic and Mean Pressure (MP). In panel (a) Patient's actual arterial pressure waveform as if recorded with a catheter-tipped transducer is shown, (b) shown the same patient's arterial waveform recorded with an overdamped system ($\zeta = 3.5$). Note the fast-flush signal (upper left) returns slowly to the patient waveform. Systolic pressure is underestimated, diastolic pressure is overestimated, and MP is unchanged, (c) An underdamped condition ($\zeta = 0.1$) with low $f_n = 7 \text{ Hz}$. After the fast flush, the pressure signal oscillates rapidly (rings). Systolic pressure is overestimated, diastolic is slightly underestimated, and MP is correct, (d) shows an underdamped condition ($\zeta = 0.15$), but with high $f_n = 25 \text{ Hz}$. The pressure waveform is slightly distorted and systolic, diastolic, and mean pressures are close to the actual pressures, (e) shown an ideally damped pressure monitoring system ($\zeta = 0.5$). The undershoot after the fast flush is small and the original patient waveform is adequately reproduced. [Reproduced from Ref. 6, with permission.]

The follow-up development by Ganz of a practical thermal dilution attachment to the pulmonary artery catheter permitted convenient and easy measurement of cardiac output (22). Since these early developments with the Swan-Ganz catheter, the pulmonary artery catheter has been fitted with optical fibers which allow measurement of mixed venous oxygen saturation (23).

The pulmonary artery catheter is inserted into the right side of the circulation using the percutaneous technique typically using entry from either the internal jugular or the subclavian vein. The catheter is floated into the pulmonary artery without use of fluoroscopy, using the hemodynamic pressure waveforms as a guide (Fig. 9).

Accurate Measurement of Pulmonary Artery Pressure.

Since it was introduced, the balloon-tipped, flow-directed, pulmonary artery catheter (Swan-Ganz) has been widely used in intensive care units. The ease with which it is

Figure 9. Composite illustration showing normal pressure waveforms obtained as a fiber optic balloon flotation pulmonary artery catheter (Swan-Ganz) is advanced from the right atrium to the pulmonary artery wedge position. [From Daily and Tilkian in Reading List (1986), with permission.]

usually inserted may lead one to conclude that the measurements of pulmonary artery and wedge pressure (PCWP) are easily and reliably measured. However, such is not the case.

Pulmonary artery pressures can be measured accurately only if the following steps are taken (24–27):

1. The monitor is properly zeroed.
2. Strip-chart recordings of all PA pressures for a time period covering at least three respiratory cycles are obtained. Using only the monitor's digital displays is insufficient.
3. Dynamic response testing (fast flush) should be obtained when the catheter is in each position (i.e., wedge and PA). If the dynamic response is not adequate, the problems with the catheter-tubing-transducer system must be resolved before accurate pressures can be measured.
4. Pressures (i.e., systolic, diastolic, and mean pressures) should be assessed from a monitor's display or a strip-chart recording. The pressure measures should be made at the end expiration when the transmural pressure is nearest zero.

CARDIAC OUTPUT DETERMINATION

Cardiac output is the volume of blood ejected by the heart every minute. Cardiac output is a helpful measurement since it can be used to evaluate the overall cardiac status of the critically ill patient, as well as help make the diagnosis

of cardiovascular disease. Ideally a cardiac output measurement system would be continuous, automatic, minimally invasive, accurate, fast, inexpensive, and easy to use clinically. The most common method used to measure cardiac output in critically ill patients is still the indicator dilution method. The pulmonary artery catheter (Swan-Ganz) introduced in the 1970s revolutionized the ease with which cardiac output could be measured.

The thermal dilution method requires injection of cold physiological solution, usually normal saline, into the superior vena cava or right atrium. Cardiac output is determined by measuring the area under the time-temperature curve measured in the pulmonary artery that results from the injection of the cold solution.

The thermal dilution method for determining cardiac output relies on several assumptions that are not always correct. First, the exact amount of thermal indicator injected cannot be quantitated precisely. Second, indicator is lost at various stages and this loss of indicator (heat loss) leads to errors.

A block diagram of the thermal dilution measuring system with typical thermal dilution curves and time of injection indicated are shown in Fig. 10. Figure 10c and d show the transit time for the cooled blood moving from the injection site in the right atrium to the pulmonary artery measurement site. Calculation of cardiac output requires measuring the area under the curve. Consequently, a baseline temperature must be established before the injection. In turn, the end point is usually determined by extrapolating to the baseline temperature.

Figure 10. Schematic diagram of the thermal dilution measurement of cardiac output. A recorder of some type should always be used to verify the quality of the thermal dilution curve, (a) shows the thermal dilution catheter placed into the pulmonary artery. Note the location of injection site and thermistor, (b) shows the connection of the thermal dilution catheter connected to a cardiac output processor and recorder, (c) shows a typical temperature-time plot sensed by the thermistor near the catheter tip after an iced saline injection. The cardiac output determined in this case was $4.36 \text{ L} \cdot \text{min}^{-1}$. (d) Shows a similar temperature-time plot for a patient with low cardiac output ($2.18 \text{ L} \cdot \text{min}^{-1}$). Note the larger area and broader dispersion of the waveform caused by the lower flow. [Reproduced from Ref. 9, with permission.]

To ensure that accurate thermal dilution cardiac output results are obtained, it is recommended that the thermal dilution curves be presented on a monitoring screen or on a strip-chart recorder. Studies have shown that synchronizing the injections with the respiratory cycle improves the technique's reproducibility (28). Since there is considerable variability in cardiac output between measures, at least three reproducible curves are usually obtained. Averaging the findings from these three curves gives a more representative assessment of cardiac output.

In recent times, the complexities of using the Swan-Ganz pulmonary artery catheter have resulted in controversies. Some clinicians feel that such systems should only be used only when needed and then only sparingly while others have a differing viewpoint (29,30). Still others have questioned the ability of making accurate central venous and pulmonary artery occlusion pressures and whether it matters (26,27). Many of those issues will be resolved in the future when there might be better methods for measuring hemodynamic parameters. Until that time, physicians and nurses caring for critically ill patients who require hemodynamic monitoring should be aware of several how to oriented publications (31–34).

Alarming Based on Hemodynamic Parameters. Clinical hemodynamic monitoring is now several decades old.

What started from a simple beginning has since seen many dramatic changes in both the development of new medical devices and skills of the clinicians to use those devices. However, it is my feeling that we are not yet at optimum hemodynamic monitoring. Some recent publications on the topic are illustrative. Sander and colleagues in Germany have recently looked at categories of patients with elevated heart rates who are at higher risk of cardiac complications (35). Their work resulted in an editorial comment Vital are vital signs (36). Additional recent work at Vanderbilt University indicates that volatility in vital signs is a good predictor of death in trauma patients (37). Finally, the problem of false alarms continues to be a huge problem with current bedside monitors. As part of a Master of Science thesis in Medical Informatics at the University of Utah, an investigator found that only about one-third of the standard alarms for patients in a variety of ICU care were true alarms. Thus about two-thirds of the alarms are false. However, if the alarming system used heart rates determined from both the ECG and the Arterial Blood Pressure, the number of alarms decreased by $\sim 50\%$ and the false alarm rate was only $\sim 25\%$ (38). Having smarter and better hemodynamic monitoring with better and smarter alarming systems will be crucial for to future monitoring systems.

COMPUTERIZED DECISION SUPPORT

Much has been learned about hemodynamic measurements and how to use the data to calculate derived patient parameters. These parameters can then be used to determine patient status and augment patient therapy (39–42).

Using hemodynamic data available from bedside monitors and combining that data, in a structured and coded electronic patient record allows for optimal computerized decision support (42–44). Morris and his colleagues have stated the value of computerized decision support well (45). Only adequately explicit protocols contain enough detail to lead different clinicians to the same decision when faced with the same clinical scenario. Guidelines of care provide only general guidance to patient care and require clinicians considerable latitude in which care decision should be made. Computerized protocols, on the other hand, can be patient-specific and evidence based (46). Using computerized decision-support tools variation in clinical practice can be reduced and favorable effects on improve patient outcomes can be accomplished (45,46).

FUTURE

There are still needs for improvement in hemodynamic monitoring. Being able to make the measurements continuously, less invasively, and more reliably are areas where progress is needed. Clearly, using computer aided decision-support technology to help reduce false alarms and to guide clinicians in making better patient diagnosis and more timely and more optimal and effective treatment decision offer ample opportunity for future research and progress.

MONITORING, INTRACRANIAL PRESSURE

MICHAEL L. DALEY
IAN PIPER
The University of Memphis
Memphis, Tennessee

INTRODUCTION

Intracranial pressure (ICP) monitoring is a form of pressure monitoring used in patients with pathologies that might give rise to raised ICP. The definition of raised ICP depends on the underlying pathology and, for example in adult patients who have sustained a severe head, injury is defined as pressure greater than 20 mm Hg. Over the past 50 years there has been an active and wide ranging research into the causes and consequences of raised ICP that, to date, has been the subject of 11 international symposia embracing such diverse disciplines as neurosurgery, anesthesia, radiology, biophysics, electrical and mechanical engineering, mathematics, and computer science. This article reviews the underlying physiology pertinent to measurement of ICP as well as gives an overview of some of the current technology used to measure ICP. Then, a brief review follows of the clinical literature underlying the case for ICP measurement, with an emphasis on the main clinical condition of patients with a head injury. The last two sections focus on the use of waveform analysis and mathematical modeling techniques to research into mechanisms underlying raised ICP.

PHYSIOLOGY

ICP is the pressure recorded within the tissue (parenchyma) or fluid-filled spaces and is not uniformly distributed within the craniospinal axis. The craniospinal axis consists of all neural tissue and contiguous fluid-filled spaces within the cranium and spinal sac. The central neural tissue is encapsulated within bone and three-layered tissue coverings or *meninges*. From outside in the meninges are the dura, arachnoid, and pia membranes. The meninges provide a physical barrier between neural tissue and the external environment but also serve both a structural and a physiological function as an architecture for supporting cerebral vessels and maintaining a space for flow of cerebrospinal fluid (CSF). CSF cushions the delicate neural tissues, supports the weight of the brain, and acts as a transport media for nutrients, chemical messengers, and waste products. Except at the choroid plexus, the CSF is freely permeable

to the appendymal lining and is in chemical communication with the interstitial fluid and the CNS. ICP is a reflection of the relationship between alterations in craniospinal volume and the ability of the craniospinal axis to accommodate added volume. The craniospinal axis is essentially a partially closed box with container properties including both viscous and elastic elements. The elastic or, its inverse, the compliant properties of the container will determine what added volume can be absorbed before ICP begins to rise. So an understanding of raised ICP encompasses an analysis of both intracranial volume and craniospinal compliance.

The history of the subject of ICP has been well reviewed (1,2) and starts from the doctrine named after *Monro* (3) and *Kellie* (4), which proposed that the brain and its contained blood were incompressible, enclosed in a rigid and inextensible skull, of which the total volume remained constant. In its original form, the *Monro-Kellie* doctrine did not take into account the CSF as a component of the cranial compartment. The concept of reciprocal volume changes between blood and CSF was introduced in 1846 by *Burrows* and later extended in the early twentieth century by *Weed et al.* (5,6) to allow for reciprocal changes in all craniospinal constituents. *Kocher* (7) in 1901 translated into clinical terms the four stages of cerebral compression proposed almost 25 years earlier by the experimental studies of *Duret* (8). *Kocher* described four stages of cerebral compression related to the expansion of intracranial brain tumours. In stage 1, the initial increase in tumor volume is compensated by a reduction in volume of the other intracranial components, chiefly CSF and venous blood. This spatial compensation results in no net increase in intracranial volume or pressure and hence no clinical symptoms. In stage 2, the compensatory mechanisms are exhausted, ICP increases, and the patient becomes drowsy with a headache. Stage 3 is characterized by a considerable increase in ICP, an associated deterioration in conscious level, and intermittent elevations of blood pressure (BP) accompanied by bradycardia. In the fourth and final stage, the patient is unconscious, with bilateral fixed dilated pupils and falling BP usually leading to death.

Cushing (9–11), then a research worker for *Kocher*, described in both experimental and clinical studies the close relationship between increases in ICP and BP and proposed that the BP rose to maintain adequate blood supply to the hind brain, the stimulus to this vasopressor response believed to be medullary ischemia (12,13). At about this time, a false confidence developed in the lumbar CSF pressure technique (lumbar puncture), which caused *Cushing's* findings to be challenged. Reports emerged (14–16) that some patients showing clinical signs of brain compression had normal lumbar CSF pressures and that in other patients elevations in BP were found at times when ICP was well below the level of BP.

Partly because of this apparent dissociation between ICP and clinical symptoms, emphasis switched away from ICP measurement toward the relationship between craniospinal volume and pressure, particularly the importance of the elastic properties of the craniospinal system. The relationship between ICP and intracranial volume is often described graphically by an exponential function that is relatively flat at low ICPs but rises rapidly as pressure

increases much above 20 mm Hg. Under normal conditions, at the low ICP end of this curve, compliance (the ratio of added volume to pressure) is high. When the patient's volume–pressure status changes to move further up the curve, compliance will fall rapidly. Measurement of craniospinal compliance in brain-injured patients may, therefore, offer the potential for early detection of raised ICP before it rises to levels damaging to brain parenchyma. The most commonly used methods of measuring craniospinal compliance were developed by *Marmarou* (17,18) and depend on the rapid injection of known volumes of fluid into the CSF space with immediate measurement of the resultant increase in CSF pressure. One of these methods is the pressure volume index (PVI); this value being the volume that when added to the CSF space would produce a tenfold rise in ICP. *Miller et al.* (19,20) defined a further measure of the craniospinal volume–pressure relationship, the volume pressure response (VPR). The VPR, also calculated from the ICP response resulting from a rapid bolus injection of saline into the CSF space, is a direct measure of the inverse of compliance: elastance. Although both are measures of compliance, some confusion remains as to what exactly is the difference between the VPR and the PVI. The PVI, which assumes a mono-exponential pressure versus volume relationship, is a single index that characterizes the patient's entire volume–pressure relationship and is, numerically, a measure of the slope of the logarithm of the ICP versus intracranial volume relationship. Its strength lies in its ability to define the whole volume–pressure status of the patient with a single index. It was the late *J. Douglas Miller* who pointed out that if there was only a single volume–pressure curve, then no new information would be gained by measuring compliance or elastance, and a knowledge of absolute ICP alone would suffice in determining the state of a patient's craniospinal volume decompensation. However, several studies (21,22) have shown that the shape of the volume–pressure relationship changes under a variety of conditions both between patients and within patients at different times. Under these circumstances, it is likely that the PVI will provide the more useful information. One weakness of the PVI is that if a patient's pressure–volume relationship remains stable, single measurements will not detect movement along a given pressure–volume curve and thus may not detect slow increases in volume of a space-occupying lesion before it causes significant increases in ICP. It is in this situation where a continuous measure of absolute compliance (or its inverse: elastance as measured by the VPR) provides, potentially, more useful information. It is for this reason that, in head-injured patients, *Miller et al.* found that the VPR correlated better to the degree of brain mid-line shift, as imaged on CT scan, than it did to absolute ICP alone. They subsequently demonstrated that the VPR could serve as an indicator for surgical decompression, critical levels being between 3 and 5 mm Hg/mL (19,23). However, in clinical practice, both circumstances (movement along the pressure–volume curve and shift of the curve along the pressure axis) may occur within a patient at different times and thus shows the need for ICP monitoring capable of both continuous compliance measurement and derivation of the PVI.

Few clinicians would argue over the theoretical utility of monitoring compliance in brain-injured patients; what has limited its use in practice has been the inherent problems associated with manual volume–pressure testing. It is difficult to inject equal volumes of fluid manually at a constant and rapid rate of injection. As a result, repeated measures are usually required that can result in a lengthy and time-consuming procedure. Also, even with stringent maintenance of the sterile procedure, repeated addition or removal of CSF from patients carries an increased risk of infection to the patient. Despite the reported benefits of compliance measurement, it has been largely these limitations that have prevented widespread adoption of compliance measurement in clinical practice.

It was not until the 1960s when Lundberg (24) published his now classic monograph that interest in clinical ICP measurement was rekindled. Using ventricular fluid pressure recording in brain tumor patients, Lundberg was the first to delineate the frequency with which raised ICP occurs clinically, at times reaching pressures as high as 100 mm Hg. Lundberg also described three types of spontaneous pressure wave fluctuations: “A” waves or plateau waves of large amplitude (50–100 mm Hg) with a variable duration (5–20 min), “B” waves that are smaller (up to 50 mm Hg), and sharper waves with a dominant frequency of 0.5–2 cycles per min.

DEVICES

ICP was first measured experimentally in animals by Baylis (25) in 1897 using an early form of strain gauge. The most common form of strain gauge use specially prepared alloys that change their resistance in proportion to the amount they are elongated or stretched in cross section due to applied strain.

The Wheatstone Bridge and the Strain Gauge

Most common strain gauge transducers are used in a Wheatstone Bridge configuration, where the resistive strain elements are placed on diagonally opposite arms of the bridge. Should the strain gauge change its resistance (for example, due to an applied strain—perhaps caused by a pressure acting on the strain gauge to cause it to elongate), then the bridge will become unbalanced and a potential difference will be generated in proportion to the degree of strain.

Fluid-Filled Catheter Transducer Systems

The standard intraventricular catheter connected to an external strain gauge transducer is called a catheter-transducer system because it behaves, in many ways, like a mechanical system with a *mass* of fluid that acts against the spring-like “elastic” properties of the catheter walls and the transducer diaphragm. A typical catheter-transducer system is one used for the measurement of arterial pressure comprising a silicon strain gauge, fluid-filled catheter, three-way tap, and an arterial cannulae. Modern transducers are semiconductor fabricated and normally disposable. If a flushing device is attached to the transducer,

extreme care must be used to avoid accidental flushing into the cranium. The older catheter-transducer system included long tubing and therefore had different frequency characteristics than modern transducers. The older transducer first found widespread use in the 1960s and 1970s following the pioneering work on long-term ICP monitoring by Nils Lundberg (24). Most publications in this field still refer to intraventricular monitoring as the “Gold-Standard” method of measuring ICP for several reasons. First, this method allows checking for zero and sensitivity drift of the measurement system *in vivo*. Second, pressure measurement within the CSF space transduces pressure within a medium that is an incompressible fluid and, provided CSF flow is not blocked, is not subject to the development of intracompartmental pressure gradients. Finally, access to the CSF space provides a method for ICP treatment via CSF drainage. However, concerns are often expressed about the increased risks of infection associated with ventriculostomy. Although a range of infection rates has been reported, some as high as 40% (26), recent reports confirm infection rates to be in the region of 1%, which is not considered a prohibitive risk (27).

The Head Injury Management Guidelines published by the Brain Trauma Foundation in 1994 recommend intraventricular ICP measurement as the first-line approach to monitoring ICP. They state that “A ventricular catheter connected to an external strain gauge transducer or catheter tip pressure transducer device is the most accurate and reliable method of monitoring ICP and enables therapeutic CSF drainage. Clinically significant infections or haemorrhage associated with ICP devices causing patient morbidity are rare and should not deter the decision to monitor ICP” (28). Despite the existence of these guidelines (27,28), catheter-tip intraparenchymal pressure monitoring remains popular, particularly in the United Kingdom, as it does not require catheter placement in the operating theater and thus carries significantly lower resource implications. However, the routine use of fluid-filled catheter-transducer systems is not without difficulties. A catheter-transducer system can be described as a second-order mechanical system and, if under-damped, will oscillate at its own natural frequency producing significant amplitude and phase distortion of the pressure signal. The degree of distortion will depend on the damping factor (β) of the system. For most purposes, a damping factor of 0.64 is optimal as the amplitude error will be less than 2% for up to two thirds of the natural frequency of the system (29). Typically, most pressure catheter-transducer systems used in patients tend to be under-damped with a damping factor (β) less than 0.4 (29,30). Manipulating a catheter-transducer system from under-damped ($\beta < 0.3$) to over-damped ($\beta > 0.8$) can cause a decrease in mean pressure of 7 mm Hg. Commercial devices are available, however, such as the acodynamic adjustable damping device (31) that can alter the damping characteristics of external strain gauge pressure transducers and bring them within the range of optimal damping. Another problem with fluid-filled catheter-transducer systems is correcting for the presence of hydrostatic pressure gradients when measuring cerebral perfusion pressure (CPP). Typically, the external strain gauge transducer is zeroed at the same

level as the arterial pressure (BP) transducer, usually at the level of the right atrium. Although the patient is managed in the horizontal position, there is no column of fluid between the site of ICP and BP measurement. However, when the patient is managed with head-up tilt and if the BP transducer is not moved to the same horizontal level as the head, a hydrostatic fluid column will be created. This can produce a significant error between the observed CPP and the actual CPP, which, in the worst case, can produce an error of as much as 15 mm Hg.

The Spiegelberg ICP monitoring system (Spiegelberg KG, Homburg, Germany) largely overcomes these problems. This system is a special case of a fluid-filled catheter-transducer system. With this device, ICP is measured using a catheter with an air pouch balloon situated at the tip. By maintaining a constant known volume within the air pouch, the pressure within the air pouch balloon is equivalent to the surrounding pressure or ICP. The internal air pouch balloon is transduced by an external strain gauge transducer, and because the fluid used for pressure transduction is air, the pressure error caused by an "air column" is clinically insignificant. The design of this device also allows automatic *in vivo* zeroing of the ICP system and, in laboratory bench tests, showed the least zero drift in comparison with standard catheter-tip ICP devices (32). This system now has versions for use in epidural, subdural, intraparenchymal, and intraventricular sites. The intraventricular catheter is a double lumen catheter that allows access to the CSF space for drainage. The Spiegelberg system, although having many attractive features, is, as yet, a relatively little used system outside of Germany and its long-term clinical utility and robustness require evaluation.

Catheter-Tip Transducer Systems

Now several catheter-tip ICP monitoring systems are available, including the Camino (33–36) systems. The Gaeltec ICP/B solid-state miniature ICP transducers, for use in the epidural space, are reusable, and the zero reference can be checked *in vivo*. However, reports of measurement artifacts (37) and decay in measurement quality associated with repeated use (35) have limited the widespread adoption of this technology.

The InnerSpace OPX 100 system (InnerSpace Medical, Irvine, CA) is, like the Camino system, a fiber optic system. Bench test reports on this system show it to have good zero drift and sensitivity stability (32). However, a recent clinical evaluation of this system in 51 patients reported a high (17%) incidence of hematoma formation around the ICP sensor (36). The authors concluded that improved fixation of the catheter is required to minimize micro-movements.

The two catheter-tip systems most frequently used in the management of head-injured patients are the Codman and Camino systems. Neither allows a pressure calibration to be performed *in vivo*. After these systems are "zeroed," relative to atmospheric pressure during a pre-insertion calibration, their pressure output is dependent on zero drift of the sensor. For this reason, it is critical that these devices exhibit good long-term zero drift characteristics. These devices provide an electrical calibration, to calibrate external monitors, but they cannot be corrected for inher-

ent zero drift of the catheter once placed. For the Camino system, the manufacturers specify the zero drift of the catheter to be ± 2 mm Hg for the first day and ± 1 mm Hg per day thereafter. Czosnyka et al. (32) have confirmed these zero drift findings in bench tests studies although they also reported that the temperature drift of the device was significant (0.3 mm Hg/ $^{\circ}$ C). They reported that if the manufacturers specify the zero drift of the catheter to be ± 2 mm Hg for the first day and ± 1 mm Hg per day thereafter. In clinical practice, the reported zero drift upon removal of the Camino device from the patient has been reported to be greater than the manufacturer's specifications. Munch (38) assessed 136 Camino sensors in a clinical study and found an average *daily* drift rate of 3.2 mm Hg. Chambers (39), in a comparative study of the Camino ventricular catheter with an external fluid-filled catheter-transducer system, reported that only 60% of the readings were within 2 mm Hg of the gold-standard method. There are also reports of Camino probe failure because of technical complications (cable kinking, probe dislocation), with reported failure rates ranging from 10% to 25% (39,40).

The Codman transducer is a micro-miniature strain gauge within a titanium housing side mounted at the tip of a catheter. Similar to other transducers, bench test reports on this technology have been favorable (32,41). However, clinical evaluations have reported the presence of inter-patient and intra-patient biases that are independent on whether the device is compared against the Camino transducer or an intraventricular catheter-transducer system (42). A report by Fernandes (43) found that in 24% of the recordings, the Codman sensor over-read the Camino system by 5 mm Hg or more.

The Rehau System

The technology of miniaturization is allowing the development of catheter-tip pressure sensors. Catheter-tip systems, due to their small diameter, are likely to cause less damage to tissue upon placement than larger fluid-filled catheters and are not affected by hydrostatic pressure differences. However, they are potentially more prone to problems of robustness and *in vivo* zero drift. Several similar technologies, although performing well in bench test studies, have been shown to exhibit unacceptable zero drift, fragility, or both during trials conducted under clinical conditions (38,43–45). *In vivo* drift is especially important in catheter-tip strain-gauge technology as it is impossible to check if the calibration has altered after being placed in the patient. Until recently, to reduce the physical size of the catheter-tip strain gauge catheters, often only a partial Wheatstone bridge is employed at the catheter-tip. Recently, a new technology has become available, the Neurovent-P (REHAU AG+CO, REHAU, Germany), in which a full Wheatstone bridge is fabricated in the probe tip, and this solution should, in theory, provide improved zero drift characteristics. One potential advantage of the Rehau NeuroVent system seems to be the incorporation of a full Wheatstone bridge into the catheter-tip electronics. This Wheatstone technological improvement should enhance the zero drift characteristics by reducing temperature sensitivity and the effects of non-pressure-related external

strains. Until recently, this approach was only possible in the much physically larger external strain gauge systems. Through advances in miniaturization technology, it has now been able to incorporate this technology into its catheter-tip systems. In the bench studies performed (46), each catheter was tested for days, from a minimum of 3 to more than 8 days. This timeframe typically covers the period in which an ICP transducer is used in the clinical setting. The results from this bench test study confirm the manufacturer's claim that pre-insertion calibration is not required as the drift was within manufacturer's specifications (± 1 mm Hg). This advantage is very important in the clinical arena because the first pre-insertion zeroing is a crucial step conducted by the surgeons and potentially, if incorrectly performed, could generate erroneous readings during the period of monitoring. Both long-term zero drift and the dynamic pressure test results also confirm that this system performs well in bench test studies and meets manufacturer's specifications. Mean zero drift, after 5 days, was very small and long-term continuous recording of a stable pressure was precise. The response to dynamic tests, i.e., the changes of pressure over a wide range, was excellent. The average bias of the Rehau catheter compared with a hydrostatic pressure column is very small. Despite these promising bench test study results, further work is required to determine the performance of this measurement device in the clinical environment. Following on from these bench tests, the next and most critical step will be to conduct a trial of this promising technology under the more demanding clinical environment. The BrainIT group (<http://www.brainit.org>) as a multicenter collaborative group of neurointensive care scientists and clinicians are well placed to design and conduct such a trial (47). Should this technology demonstrate, under clinical conditions, the required robustness and low drift as indicated by these bench test studies, it may lead to more precise and reliable measurement of ICP.

CLINICAL LITERATURE

Raised ICP has been found to be associated with a poorer outcome from injury with the higher the level of ICP, particularly the peak ICP level, which has been found to correlate with the expected prognosis for mortality and morbidity (48–51). There has, however, been controversy over the usefulness of monitoring raised ICP with some groups, with a “no ICP monitoring” policy, finding in their studies of head injury mortality and morbidity that outcome is similar to other groups that do monitor ICP (52). Reported differences in the utility of ICP monitoring could be due to variability both in management and in monitoring protocols between different neurosurgical centers. Variation in type of ICP pressure monitor, site of placement, treatment thresholds, patient referral characteristics, and in outcome measures can all combine to produce a large variability both in measured ICP and in outcome irrespective of whether ICP is monitored or how it is treated. Another source of variation in terms of raised ICP is the inherent variability of the head-injured population with outcome being dependant on several other factors. For

example, mass lesions are generally accompanied by elevations in ICP of greater than 40 mm Hg and are associated with poorer outcome, whereas diffuse injuries tend to have lower ICP levels associated with a similar poor outcome (50,53). Age is also an important factor with an age-dependent distribution of ICP for both type of injury and outcome. This is particularly so for pediatric cases (54–56). ICP can even be raised in the absence of overt signs of swelling or mass lesions on CT. In a small study of severely head-injured patients, O'Sullivan (57) demonstrated that some comatose head-injured patients whose initial CT scan was normal, with no mass lesion, midline shift, or abnormal basal cisterns, developed raised ICP greater than 20 mm Hg that lasted longer than 5 min. This included a subset of patients showing pronounced raised ICP of greater than 30 mm Hg.

Data from large prospective trials carried out from single centers and from well-controlled multicenter studies have provided the most convincing evidence for a direct relationship between ICP and outcome (58–61). Narayan et al. (58) in a prospective study in 133 severely head-injured patients demonstrated that the outcome prediction rate was increased when the standard clinical data such as age, Glasgow Coma Score on admission (GCS), and pupillary response with extraocular and motor activity was combined with ICP monitoring data. Marmarou et al. (60), reporting on 428 patients' data from the National Institute of Health's Traumatic Coma Data Bank, showed that following the usual clinical signs of age, admission motor score, and abnormal pupils, the proportion of hourly ICP recordings greater than 20 mm Hg was the next most significant predictor of outcome. Outcome was classified by the Glasgow Outcome Score (GOS) at 6 months follow-up. They also found, using step-wise logistic regression, that after ICP, arterial pressure below 80 mm Hg was also a significant predictor of outcome. Jones et al. (61) studied prospectively 124 adult head-injured patients during intensive care using a computerized data collection system capable of minute by minute monitoring of up to 14 clinically indicated physiological variables. They found that ICP, above 30 mm Hg, arterial pressure below 90 mm Hg, and cerebral perfusion pressure below 50 mm Hg significantly affected patient morbidity.

Although differing opinions remain about the contribution of continuous monitoring of ICP to reduction in mortality and morbidity after head injury, there is now sufficient evidence to remove doubt about the value of ICP monitoring toward improving the detection and preventative management of secondary cerebral injury.

Raised Intracranial Pressure: Relationship to Primary and Secondary Injury

Both experimental and clinical studies have clearly shown that after traumatic brain injury, normal physiological mechanisms for maintaining cerebral perfusion can become impaired (62–65). These studies demonstrate that brain injury can cause impairment or loss of autoregulation defined as the ability of the cerebral vessels to respond to changes, in arterial gases or to arterial pressure. As a result of these changes, there can, at times, be a decrease

in cerebrovascular resistance that can lead to raised ICP in both adults and children (66–70). Although brain-injured patients are being managed in intensive care, there are, superimposed on to the primary injury, periods of reduced arterial PO₂ or episodes of arterial hypotension often as a result of other injuries or treatment by hypnotic drugs (50,53,60,61,71,72). With an impaired physiological mechanism unable to respond adequately to these adverse changes in physiological parameters (or “secondary insults”), ischemic brain damage can occur. These secondary, chiefly ischemic brain insults are common, with Graham et al. (74) reporting, in a series of 151 fatal cases of severe head injury, a 91% incidence of ischemic brain damage found on autopsy. A second study carried out by the same group over 10 years later found a similar high incidence (>80%) of ischemic brain damage despite subsequent improvements in intensive care of head-injured patients (74).

There has been much interest in the relationship among ICP, CPP, and CBF. The landmark study of Miller and Garibi (75) produced some of the first experimental evidence confirming the concept that changes in ICP affect cerebral blood flow not directly but through changes in CPP, where CPP is defined as the difference between mean arterial pressure and ICP. Strictly speaking, the actual cerebral perfusion outflow pressure would be cerebral venous pressure, although this pressure is, in most situations, impractical to measure routinely. However, it has been established that over a wide range of pressures cerebral venous pressure is well approximated (within 3–4 mm Hg) by ICP (76–78). In an experimental study of CBF as determined by the venous outflow technique in dogs, Miller and Garibi (75) also demonstrated that when MAP and ICP rise in parallel so that CPP remains constant at 60 mm Hg, CBF increases with MAP in animals found to be non-autoregulating. It was further shown that as CPP drops in autoregulating animals, the breakpoint at which CBF starts to decrease is at a higher level if CPP is reduced through hemorrhagic arterial hypotension than through intracranial hypertension. This work suggests that cerebral perfusion is more sensitive to arterial hypotension than to intracranial hypertension.

The clinical significance of this information is that in the management of head injury, it is often necessary to employ therapy to lower raised ICP. Therapeutic agents for reducing raised ICP often do so at the expense of reduced MAP, and as a consequence, CPP may not improve. If autoregulation is preserved, CBF should remain unchanged despite parallel changes in MAP and ICP. However, clinically, autoregulation is likely to be impaired in those conditions in which ICP is increased such as head injury or subarachnoid hemorrhage (68,69,79–82). Under these circumstances, it is important that reduction in ICP should not be achieved at the expense of lowering CBF and provoking brain ischemia.

This earlier work of Miller and Garibi was later extended by Chan et al. (83) to include CPP ranges of 60, 50, and 40 mm Hg. At CPP levels of 50 and 60 mm Hg, when autoregulation was intact, CBF remained unchanged. However, with loss of autoregulation, there was a trend for CBF to increase as MAP and ICP were

increased in parallel at a CPP of 50 and 60 mm Hg. Absolute CBF levels were significantly different between the autoregulating and non-autoregulating groups. At a CPP of 40 mm Hg CBF showed a linear correlation with BP. This work demonstrates that when autoregulation is impaired, there is a functional difference between autoregulating and non-autoregulating cerebral vessels despite similar MAP and CPP, and that when autoregulation is impaired, CBF depends more on arterial driving pressure than on cerebral perfusion pressure.

The importance of arterial pressure as the prime factor governing CPP-related secondary insults has been well demonstrated by the work of Jones et al. (61), where they carried out a prospective study over 4 years of the frequency and severity with which secondary insults occur to head-injured patients while being managed in intensive care. They developed a microcomputer-based data collection system that allows the acquisition of data from up to 15 monitored variables minute by minute (84). At each bed space, data collection was under the control of a microcomputer where serial links between the patient monitors and the microcomputer allow the controlled transfer of multiple channels of physiological data once per minute. The controlling software allowed medical staff to add comments to the current active computer file at any time, precisely annotating significant events. The software performs artifact detection, calculates derived data, and highlights valid data that falls outside normal physiological levels. Collected data were stored to disk and could be printed either locally or remotely. Later work by Chambers et al. (85) found that both raised ICP and lowered ABP are major factors in producing secondary insults.

From the valid physiological data produced, manual processing of data was used to identify secondary insults that are defined at one of three grades of severity and that must last for 5 min or longer to be recorded as an insult. This permits calculation of the frequency, severity, and total duration of insults, measured in minutes.

An analysis was made of 124 adult head-injured patients who were monitored during intensive care using the computerized data collection system. Information was logged at 1 min intervals and scanned to identify insults when values fell outside threshold limits for 5 min or longer. Three grades of insult were defined for each variable (Table 1). The duration of insults has been analyzed in relation to the GOS of these patients at 12 months after injury. The monitored patients included 68 with severe head injury (GCS 8 or less with no eye opening), 36 with moderate head injury (GCS 9–12), and 20 with minor head injury (GCS 13–15 but with multiple injuries, scoring 16 or more on the Injury Severity Scale).

Insults were found in 91% of patients at all degrees of severity of head injury. Overall, 10% of patients had insults that were only at the lowest grade 1 level, 31% had insults at both grade 1 and grade 2 levels, and 50% of patients had at least one insult at grade 3 level in addition to grades 1 and 2 insults. Overall, the majority (77%) of all insults detected in the ITU were at grade 1 level, and these represented 85% of the total duration in minutes of insult measured. Differences in the duration of insult between outcome groups 12 months post-injury were compared with

each grade of insult using Kruskal–Wallis one-way analysis of variance and Mann–Whitney U tests. Significant differences in the distribution of hypotensive insults were found between the outcome grades at all levels of severity of insult. Similar results were found for cerebral perfusion pressure insult duration. These data confirm the important adverse effect of even moderate reductions in arterial pressure (systolic BP less than 90 mm Hg or mean BP less than 70 mm Hg).

Although the occurrence and clinical significance of severe and long-lasting secondary insults in head-injured patients is not disputed. The incidence, severity, and duration of shorter acting “minute by minute” cerebral perfusion pressure insults, as defined by the Edinburgh secondary insult detection methodology, has not been defined outside of the Edinburgh study population. In addition, the strong association between the occurrence of specific insult types and the subsequent patient morbidity and mortality found by the Edinburgh study (61) needs to be reproduced in other centers. From the Edinburgh group, Signorini et al. (86,87) developed and validated a model for predicting survival in head-injured patients based on collection of simple demographic features. When the minute by minute secondary insult data were added to the baseline model, they found only ICP insults significantly improved the fit of the model.

Almost all of the evidence for a CPP management is based on single-center cohort studies, often compared with historical controls. For example, Rosner and Becker (26) reported on clinical results of a CPP management protocol where approximately 40% of patients received vasopressor support. They reported a greatly improved incidence of favorable outcome in patients' $GCS \geq 7$ compared with historical controls. Despite evidence from single-center studies as described above, a critique of the literature for the purposes of defining head injury management guidelines published by the Brain Trauma Foundation in 1994 states that there is not sufficient evidence to establish either a standard or a guideline for the management of CPP; however they indicate management of CPP greater than 70 mm Hg as a management option (28). Since then, Robertson et al. (88) performed one of the first randomized controlled single-center trials of the CPP management approach. They defined two management cohorts, one based on their normal practice of CPP management and the other CBF, guided practice that included the aggressive management of CPP above 70 mm Hg, together with restricted use of significant hyperventilation. Conversely, their trial has shown that aggressive management of CPP > 70 mm Hg, although reducing the incidence of jugular venous desaturation < 50%, demonstrated no difference in neurological outcome possibly due to the increased incidence of acute respiratory distress syndrome in the CBF management group. Thus, secondary insults are common, result in mainly ischemic brain damage, and are a major contribution to disablement. Moreover Chambers et al. (89) has reported that the critical CPP thresholds for insults of pediatric patients varies with age. For both adult and pediatric patients, insults are important because they are common and yet so potentially avoidable. Clearly a critical challenge facing us is to develop patient monitoring

systems and protocols that will lead to rapid detection and resolution of secondary insults. However, detection is not enough; we need also improved and clinically proven methods of treating secondary insults—further evidence is required. In Signorini et al.'s article (87), they conclude that the questions posed by such observational studies can only be answered definitively within the context of a randomized clinical trial. However, to design such a multicenter randomized clinical trial will require improved standards in the monitoring and analysis of secondary insult data. In Europe, improved standards for high-resolution collection and analysis of multicenter data from head-injured data is now being addressed by the *Brain-IT* group (90). The *Brain-IT* group (<http://www.brainit.org>) is an open consortium of clinicians and basic scientists working toward improving the infrastructure for conducting both observational and controlled trials of medical devices and patient management.

INTRACRANIAL PRESSURE ANALYSIS METHODS

Since the early 1990s, clinical monitoring of ICP has generally become part of the intensive care management of patients with brain injury. Several methods of analysis have been designed to extract pathophysiological information from the ICP and the corresponding ABP recordings. As noted, one particular computation used in clinical practice is the determination of mean CPP, the pressure across the brain. CPP is calculated as the difference between mean ABP and mean ICP and is based on the assumption that cerebral venous pressure is approximately equal to ICP. CPP is a useful parameter because it provides some insight as to whether the blood flow through brain capillaries is regulated. In the uninjured brain, cerebral blood flow is regulated to match the metabolic demand of the brain cells. Regulation of flow is primarily done by active dilation and constriction of cerebral arterioles in response to changes of CPP and/or biochemical vasoconstrictive or vasodilator agents that interact with the vascular endothelium. The steady-state relationship between cerebral blood flow and CPP is termed static pressure regulation and is illustrated by the graphical relationship between cerebral blood flow and CPP shown in Fig. 1.

In the steady state, cerebral blood flow is laminar and computed as the ratio of CPP to hemodynamic resistance, which is inversely proportional to the fourth power of the radius of the vessel. In the autoregulatory range, the arterial–arteriolar bed actively adjusts the resistance of its vessels by dilating when CPP decreases and constricting when CPP increases to maintain a relatively constant cerebral blood flow during changes in CPP. When CPP is below the lower limit of the autoregulatory range, vessels within the arterial–arteriolar bed tend to passively vasoconstrict. When CPP is above the upper limit of autoregulation, passive vasodilation occurs. One proposed intensive care therapeutic procedure designed to prevent secondary complications during recovery is CPP-oriented therapy (91). This therapy requires pressure autoregulation and the ability to manipulate CPP within the autoregulatory range (91). During intact pressure regulation, increases of

Figure 1. Illustration of static pressure regulation. Within the autoregulatory range, changes in arteriolar diameter, represented here as circles at the top of the graph, are primarily responsible for the regulation of cerebral blood flow. The arterial-arteriolar bed actively constricts with increasing CPP and dilates with decreasing CPP. Hypoperfusion occurs when CPP falls below the lower limit of regulation. As CPP falls below this limit, the vasocompression of the arterioles and resistance increases markedly. The lower limit of regulation is not precisely known and varies with age, with 40–50 mm Hg for young pediatric cases (90) and 60–70 mm Hg for an adult (61,86).

CPP cause constriction of the arterial-arteriolar vascular bed and lowering of ICP by a reduction in cerebral blood volume. In addition, the resulting decrease of pre- and post-capillary pressure lessens fluid filtration and increases absorption, thus reducing the effects of edema. The application of CPP-oriented therapy when autoregulation has been lost may result in an imbalance of Starling forces at the capillaries, leading to increased net filtration and further brain injury by increased production of vasogenic edema.

In contrast to clinical cardiology, where the physiological mechanism underlying the dynamic features of the arterial pressure recording are fairly well understood, very little is known about the mechanism that underlies the shape of pulsations of intracranial pressure and how they are influenced by changes in CPP. Past studies have indicated that pulsations in the cerebrospinal fluid develop from either pulsations of the choroids plexus (92,93) or the arterial vasculature (94,95). Depending on the dilatatory state of the cerebrovascular bed, ABP, ICP, and whether the autoregulation is intact, at times the primary component of the ICP pulse may be due to pulsations of venous or arterial origin (94–96). Although the origin of the ICP pulsation is not completely understood, possibly useful methodologies involving the pulsation have been developed. Over two decades ago, Avezatt and van Eijnhoven developed a procedure for distinguishing the occurrence of the loss of regulation of cerebral blood flow through numerical analysis of the pulsation of intracranial pressure (96,97). From laboratory studies, they found that within the autoregulatory range, the relationship between the mean amplitude of the pulsation of ICP increased linearly with mean ICP with a high slope value. At mean ICP above 30 mm Hg, the slope of this relationship decreased. They

proposed that the flattening of the slope of this relationship was an indication of loss of autoregulation (97). A weakness of this technique is that it is dependent on heart rate (98). A low heart rate reflects an increase in the volume, of pulsatile cerebral blood inflow resulting from increased cardiac stroke volume, and the converse is likely for high heart rates. Thus, the variability in the amplitude of the ICP due to heart-rate variability can complicate the analysis (98). However, one modification of the analysis technique is to examine the correlation value between amplitude-pressure and mean ICP rather than the slope of the respective regression line (99). Positive values of this correlation value, which has been called RAP, indicate the ability of the vasculature to regulate cerebral blood flow, and negative values indicate poor cerebrovascular reserve and impaired cerebrovascular reactivity (99,100). Statistical analysis revealed that patients with a fatal outcome were associated with a negative RAP value (99). Most recently, the RAP index has been used to predict the achievable reduction in intracranial pressure a patient can obtain by the implementation of moderate hyperventilation (101). A modification of the mean amplitude of ICP and mean ICP characteristic has been proposed as a means of predicting which patients with idiopathic adult hydrocephalus will have a good outcome after shunting surgery (102). In this application, the amplitude of B-wave of ICP is used instead of the amplitude of the ICP pulsation (102).

In addition to relatively synchronous pulsations of ICP associated with the cardiac cycle, the ICP recording obtained during mechanical ventilation contains a low-frequency component at the rate of ventilation. Generally during mechanical ventilation, inhalation is produced by positive pressure and expiration occurs during zero pressure. Changes in pulmonary volume produce changes in intrathoracic pressure that mechanically modulate arterial and venous blood flow and produce a cyclic compression of the craniospinal sac. Evidence for this mechanical modulation by intrathoracic pressure can be observed in the spectra of an ICP recording obtained during mechanical ventilation. Because the pulsation in ICP associated with the cardiac cycle produced is quasi-periodic and the rate of ventilation is relatively constant, the spectra of the ICP pressure recording contains salient peaks at the cardiac frequency and its higher harmonics. In addition, each of the spectra associated with cardiac cycle has sidebands with a deviation at the ventilation frequency (103). Such a result is consistent with the premise that intrathoracic pressure changes mechanical modulated arterial and venous blood pressure and volume of the craniospinal sac (103).

Over the last few decades, several clinical and laboratory studies of the correlative relationship between ABP and ICP have been completed. Portnoy et al. reported that during normal vascular tone and intact regulation of cerebral blood flow, the ICP and ABP recordings do not look similar, but during maximum vasodilation of the arterial-arteriolar bed and impaired autoregulation induced by severe hypercapnia, these pressure recordings look remarkably similar (104–106). To numerically quantify the correlation between ABP and ICP, this group examined changes in the coherence function. Specifically, they found

that the frequency domain coherence function approached unity when the ICP and ABP recording became similar. Generally, their observations and the observations of others using a spectral analysis systems approach have suggested that the more similar the spectral components of the ICP recording are to those of the ABP recording, the more likely cerebral autoregulation is impaired (106–108). The physical process describing the ABP as the input to the craniospinal sac and the ICP as the corresponding output has been termed cerebrovascular pressure transmission (106). An observational clinical study determined that four types of frequency descriptions of the transmission characteristic could be identified. Two types were associated with high ICP and the other two with low ICP (47).

More recent studies using time-domain correlation analysis on the ICP and ABP pressure recordings have been completed. As correlation analysis of two signals in the time domain is analytically equivalent to coherence analysis in the frequency domain, it was not unexpected that studies on the normocapnic/hypercapnic piglet model found that as the ICP and ABP recordings became more similar, the maximum value of the correlation function approaches unity, the pial arterioles became more dilated, and cerebral blood flow increased (109,110). Consistent with clinical reports that indicate that unlike adult patients, brain-injured pediatric patients often demonstrate cerebral hyperemia and increased ICP (82,109,111), correlation analysis of pressure recordings obtained from pediatric patients have been found to often approach unity, indicating the occurrence of inappropriate vasodilation and cerebral hyperemia (112). Most recently, Czosnyka et al. have reported the clinical use of a pressure reactivity index (PRx). This index is a moving correlation coefficient between 40 consecutive samples of values for intracranial and arterial pressures averaged for a period of 5 s (113,114). They have concluded that when slow waves in the ABP and ICP recordings are present, the proposed clinical index provides a continuous index of cerebrovascular reactivity (114,115). In particular, the PRx was designed to evaluate the integrity of the cerebrovascular response and estimate cerebrovascular autoregulatory reserve reactivity (114,115). The hypothesis is that because of the sluggish nature of the cerebrovascular system, naturally occurring slow-varying oscillations of ABP can be used to evaluate the autoregulatory reserve reactivity (114,115). Unlike the coherence and correlation indices described above, this index cannot be related to a linear system model. By employing averaging over a 5 s interval, most of the frequency changes above 0.2 Hz in the ABP and ICP recordings are filtered out. In addition, Nyquist's sampling theorem dictates that the highest frequency that can be represented by a signal sampled every 5 s is 0.1 Hz or six oscillations per minute. As a result, aliasing occurs, and the dynamical system relationship between ABP and ICP is not precisely defined by this index. Nevertheless, the PRx has been found to be a very useful tool. Clinical observations demonstrate that the PRx is high both during the occurrence of plateau waves and during refractory ICP hypertension (115). In addition, the PRx has been used to guide proposed therapies (116) and while variable seems to provide a reliable index of autoregulation (117).

Most recently, the regressive relationship between mean ICP and mean CPP has been used to assess whether autoregulation of cerebral blood flow is intact. In these studies, ABP is pharmacologically elevated and the regressive relationship between ICP and CPP during the test period is obtained (118). If pressure regulation of cerebral blood flow is intact, then increases of CPP will cause vasoconstriction, a decrease of ICP, and the regressive relationship should have a negative slope parameter. A marked positive slope parameter of this regressive relationship is an indication of passive pressure regulation; increases of CPP cause dilation and increased ICP (119).

ANALYSIS METHODS BASED ON MODELS OF ICP

Models of ICP dynamics are based on the modified Monroe–Kellie doctrine (see the Physiology section), which assumes that the total volume of intracranial substance, tissue, blood, and CSF, is constant. Initial mathematical models described the relationship between the formation of CSF and absorption of CSF in equilibrium. Specifically, in these models, laminar flow of CSF is assumed during steady-state conditions (120–123) and the parameters of the mathematical model are presented as an electrical circuit (Fig. 2).

Using this circuit and manipulating the volume of CSF by bolus either by withdrawal, injection, or constant infusion, it is possible to estimate R_o , C , the volume–pressure response, and the PVI. The latter two parameters have been discussed previously in the Physiology section. All parameters have been used to guide the management of hydrocephalous and traumatic brain injury.

Higher order mathematical models of intracranial hydrodynamics that incorporate the arterial and venous blood volume compartments into the analog electric circuit model have been developed to simulate the pulsatility, which is present in the ICP recording. To account for the reciprocal relationship between cerebral blood volume and volume of CSF, Agarwal et al. (124) constructed a model that connected vascular compliance to intracranial compliance in a series configuration. This modeling effort was further developed in detail by Ursino's proposed fourth-order analog circuit model of overall human intracranial

Figure 2. Electric circuit analog model of CSF system. In this model, current represents flow of CSF fluid, and voltage represents pressure. The capacitance C , represents intracranial compliance, and the resistance R represents resistance of CSF fluid flow into the venous system.

hydrodynamics (125,126). A feature of this model is that the arterial–arteriolar vascular bed consists of vasomotor regulating resistance and compliance elements. Dilatory and constrictive responses are primarily simulated by a corresponding decrease or increase of vascular resistance. This initial model has been modified by synchronously modulating the terminal venous bed resistance to account for cyclic variation of ICP produced by positive pressure ventilation (127). The modified model demonstrates that both the depth of modulation and the cerebrovascular venous terminal bed resistance seem to be progressively reduced with increasing levels of vasodilation induced by increasing the levels of partial pressure of arterial blood carbon dioxide. Numerical modeling of cerebrovascular pressure transmission, the relationship between ABP and CPP, has been used to assess changes in the modes of pressure transmission before and after injury. Specifically, a proposed third-order model of ICP dynamics (128) was used to define the mathematical structure to construct a numerical identification model of cerebrovascular pressure transmission from laboratory pressure recordings (112). Consistent with active vasoconstriction before brain injury, during intact regulation of cerebral blood flow, the highest modal frequency of cerebrovascular pressure transmission decreased with increasing CPP. Conversely, consistent with passive vasodilation with loss of autoregulation induced by fluid percussion injury, the highest modal frequency demonstrated a direct relationship with increasing CPP (112).

SUMMARY

Although the subject of intracranial pressure dates back to over 200 ago, both the invasive monitoring procedure required to measure ICP with its accompanying risk of infection and the nonunique nature of the extravascular pressure measurement have retarded the development of knowledge in this area. As a result, the intent of this article is to provide the reader with a broad perspective of ICP monitoring by providing background material on (1) the physiological and anatomical characteristics of the craniospinal, (2) a history of instrumentation techniques including the most recent advances, (3) a brief review of significant clinical ICP monitoring studies with an emphasis on severe head injury, (4) a review of analysis methods, and (5) models of ICP dynamics related to analysis.

INTRODUCTION

In the neonatal intensive care unit (NICU), monitoring is an integral part of patient care. The primary goal of monitoring is to ensure that early and appropriate intervention can be initiated before to the onset of complications. Monitoring is also a means by which the effect of interventions and therapies may be recorded, evaluated, and controlled. The NICU staff have to deal with a full range of conditions that can arise in the preterm or critically ill neonate, including hypoxemia, hypoglycemia, hypotension, acidosis, and other serious problems. This has led to the evolution and development of several monitors and different sensor-based technologies for use in NICU monitoring including umbilical vessel monitoring. These sensors may provide more accurate and reliable monitoring of neonatal physiological and biochemical changes with a rapid response time. The umbilical vessels may be directly accessed in the first few days of life. An umbilical artery catheter (UAC) may be used for blood pressure monitoring, blood sampling, and fluid or drug infusion. An umbilical vein catheter (UVC) may be used for central venous pressure monitoring, blood sampling, and fluid or drug infusion. Different types of commercially available umbilical catheters are used for these purposes. These catheters differ in their length, size, number of ports, and their material (such as silicone and polyurethane). Blood pressure (BP) monitoring is an important part of neonatal intensive care both for the acutely ill and the convalescing neonate. The most accurate method of measuring BP is by direct intra-arterial recordings, which

usually use an umbilical catheter to access the umbilical artery. As blood gas measurement methods and monitors have progressed in adult critical medicine, most of the new techniques and sensors have been used in the NICU by using umbilical artery catheterization. This article addresses the potential benefits of umbilical vessel catheters and associated monitoring devices. It sheds light on the catheters and monitors available on the market and explains the complications and the risks of these catheters. Furthermore, this article looks at the direction of this technology in the future, and it tries to stimulate development of new technology for use in the monitoring of critically ill newborn infants (1–3).

Historical Aspects

In 1946, Louis K. Diamond, a pediatrician from Boston, and F. H. Allen, Jr. developed a technique that allowed blood transfusion to take place through the infant's umbilical cord vein. Regular transfusions were difficult because of the small size of blood vessels in newborns, and there was a further complication due to the use of steel needles and rubber catheters. Diamond used plastic tubing on the umbilical vein, which was larger than average and remained open for several days after birth (4). By the 1960s, electronic monitors came into use and blood gases began to be measured. By the 1970s, the use of umbilical catheters and arterial pressure transducers was routine (5). The first organized NICU opened its doors at Yale-New Haven Hospital in 1960. The first successful use of extracorporeal membrane oxygenation (ECMO) was in 1975. ECMO eventually reduced infant mortality from 80% to 25% for the critically ill infants with acute reversible respiratory and cardiac failure unresponsive to conventional therapy (6).

Anatomical and Physiological Aspects

The umbilical cord is a cordlike structure about 56 cm long, extending from the abdominal wall of the fetus to the placenta. Its chief function is to carry nutrients and oxygen (O₂) from the placenta to the fetus and return waste products and carbon dioxide (CO₂) to the placenta from the fetus. It consists of a continuation of the membrane covering the fetus and encloses a mucoïd jelly (Wharton's jelly) with one vein and two arteries (7). Examination of the umbilical cord (after cut) normally reveals two umbilical arteries (UA) and one umbilical vein (UV) (Fig. 1). At skin level, the UV is usually in the 12 o'clock position and has a thinner wall and wider lumen than do the UAs (2). Before birth, blood from the placenta, about 80% saturated with O₂, returns to the fetus by way of the UV. On approaching the liver, most blood flows through the ductus venosus directly into the inferior vena cava (IVC), short-circuiting the liver. A smaller amount enters the liver sinusoids and mixes with blood from the portal circulation. After a short course in the IVC, it mixes with deoxygenated blood returning from the lower limbs before it enters the right atrium. The blood leaves the heart to the descending aorta, where it flows toward the placenta by way of the two UAs (7). The O₂ saturation in the umbilical arteries is approximately 58%. Changes in the vascular system at birth are caused by

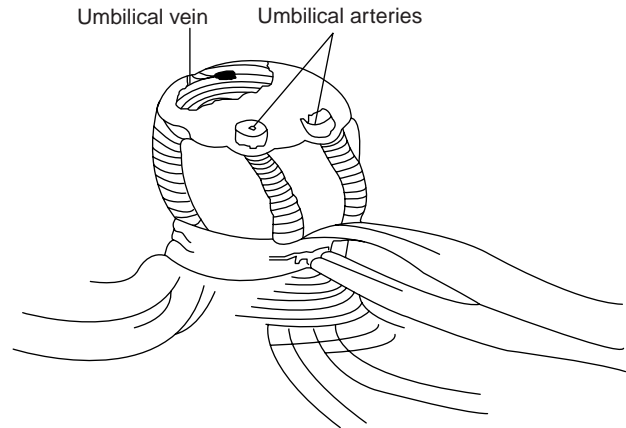

Figure 1. Umbilical cord after it was cut.

cessation of placental blood flow and the beginning of respiration. These changes are summarized in closure of the umbilical arteries, closure of the umbilical vein and ductus venosus, significant reduction in the pulmonary vascular resistance and right ventricle and right atrium pressures, and significant increase in the systemic vascular resistance, left ventricle, and left atrium pressures (8). After birth, the blood volume of the neonate is about 300 mL, the cardiac output averages 500 mL/min, and the arterial blood pressure is about 70/50 during the first day, which increases slowly over the next several months. Arterial blood pressure of the neonate has been best correlated with birth weight. Moreover, systolic and diastolic pressures in the neonate are significantly correlated to blood pressure levels in the mother (9).

Indications and Contra-Indications for Umbilical Artery Catheterization

The primary indications for umbilical artery catheterization include frequent or continuous blood gas measurements, continuous monitoring of arterial blood pressure, and resuscitation (umbilical venous line may be the first choice) (10). Secondary indications include infusion of maintenance glucose-electrolyte solutions or medications, exchange transfusions, angiography, and a port for frequent blood sampling, especially in a very low-birth-weight neonate. These catheters should stay in place only as long as a primary indication exists, with the exception of the very low-birth-weight neonate who may need it for vital infusions and frequent blood sampling. Contraindications include evidence of local vascular compromise in lower limbs or buttock areas, peritonitis, necrotizing enterocolitis, omphalitis, gastroschisis, and omphalocele.

Indications and Contra-Indications for Umbilical Vein Catheterization

The most frequent indications for umbilical venous catheterization include emergency medication administration, exchange transfusion, and partial exchange transfusion (10). This catheter is also used for frequent blood sampling and central venous pressure monitoring. Contraindications for the this catheter include routine fluid infusion

Figure 2. Commercially available umbilical catheters: (a) single-lumen catheter and (b) dual-lumen catheter.

(relative contraindication), omphalitis, omphalocele, gastroschisis, necrotizing enterocolitis, peritonitis, and extrophy of the bladder.

Description of Available Catheters (Design and Material)

Catheters must be made of nontoxic materials that are the least injurious to the vascular intima and least likely to cause thromboses and early atherosclerotic lesions (11). Commercially available umbilical catheters are usually latex-free, made of silicon or high-quality aliphatic polyurethane elastomer (Tecoflex). Silicone catheters are soft, not-irritating, usually not reactive to body tissues and body fluids, not supportive of bacterial growth, and less problematic with blood clotting. Tecoflex is an advanced medical formulation of polyurethane. Its physical characteristics are very close to silicone; however, it is slightly stiffer during insertion, which makes it easier to insert and better to conduct arterial pressure. Tecoflex is thermosensitive, softens at body temperature (12), and significantly reduces the trauma to the vascular intima. These catheters have a rounded tip, which makes them less likely to perforate through the vessel during insertion. They have depth markings at every centimeter for more accurate placement and encased radiopaque stripes to confirm placement by X ray after placement. Umbilical catheters are available with single-lumen, dual-lumen, and triple-lumen catheters (13) (Fig. 2,a,b) in different sizes ranging from 2.6 to 8.0 Fr. (Table 1) Umbilical artery catheter tips are designed in two different ways: end-hole and side-hole tips. The side-hole catheters use a special electrode to measure blood gases and biochemicals. A Cochrane review by Barrington (14) showed that end-hole catheters are associated with a much decreased risk of aortic thrombosis compared with side-hole catheters. Therefore, umbilical artery catheters designed with a side-hole should not be used routinely for umbilical artery catheterization in the newborn. Furthermore, manufactures have made sterile, ready-to-go umbilical catheterization trays. These trays contain

everything needed for umbilical catheterization, including drapes, towels, suture, umbilical tape, skin preparation materials, needles, forceps, syringes, and other instruments.

Umbilical Vessel Catheterization Procedure

The infant must be supine and restrained (2). A field around the umbilicus is sterilized and draped, and a silk suture is looped around the base of the umbilical stump. The distal end of the stump is cut off, leaving 2 cm of stump, and the vessels are occluded to prevent blood loss. For the umbilical artery catheterization (15), the stump is firmly grasped with the gloved fingers of one hand, and one of the two thick-walled umbilical arteries is dilated with a curved iris forceps; then the umbilical artery catheter is inserted into the artery. Some resistance may be encountered when the catheter has been advanced 3 to 5 cm into the vessel, but this resistance can usually be overcome by applying steady downward pressure on the catheter. If the catheter cannot advance, a second catheter can be inserted into the other artery while leaving the first catheter in place. This maneuver often causes one or the other vessel to relax and permits one catheter to be advanced into the aorta. Advancement of an UAC should place the tip above the celiac axis but below the ductus arteriosus. All air should be removed from the system. The accidental injection of small amounts of air (<0.1 mL) may obstruct blood flow to the legs for several hours. The catheter should be attached to a pressure transducer and the arterial pressure measured. For the umbilical vein catheterization, the single, large, thin-walled umbilical vein is grasped with an iris forceps, and the air-free catheter, which is connected to a closed stopcock, is inserted 3 to 5 cm into the vessel with a twisting motion. The UVC tip should lie a few centimeters into the umbilical vein or inferior vena cava. The stopcock must be closed to prevent aspiration of air through the catheter should the patient take a deep breath. It is imperative that no air be injected through venous catheter, because the air may enter the systemic circulation through the foramen ovale and occlude a coronary or cerebral artery. If it does, the neonate may die or suffer central nervous system damage. If the catheter “tickles” the atrial septum, the neonate may suffer arrhythmias. Withdrawal of the catheter a short distance can solve the problem. Plain radiographs should be taken to confirm placement (Fig. 3). “High” placement of the UAC is defined in one major review of the literature as one with “the tip in the descending aorta above the level of the diaphragm and below the left subclavian artery” and “low” placement of the UAC as one with “the tip above the aortic bifurcation and below the renal arteries” (16).

Neonatal Blood Gas and Biochemical Measurement

The blood gas measurement is the most widely used clinical method for assessing pulmonary function in the neonate. It forms the basis for diagnosis and management of neonates with cardiorespiratory disease (17). The physiology of blood gases is discussed in other parts of this Encyclopedia. We will discuss in this section some issues related to the neonatal blood gas measurement. The dissociation curve of fetal hemoglobin (as compared with adult) is shifted to

Table 1. Neonate Weight and Umbilical Catheter Size

Neonate Weight (g)	UAC Size (Fr)	UVC Size (Fr)
<1500 g	3.5 Fr	3.5 Fr
>1500 g	5.0 Fr	5.0 Fr

Figure 3. Anteroposterior roentgenogram shows the position of umbilical artery and vein catheters. Lateral roentgenogram is needed to distinguish the umbilical artery from the umbilical vein catheter and to determine the appropriate level of insertion. A=endotracheal tube; B=umbilical venous catheter. C=umbilical artery catheter passed up the aorta to T12.

the left, and at any arterial O_2 partial pressure (PaO_2) below 100 mm Hg (13332.2 Pa) fetal blood binds more O_2 . This shift seems to be the result of the lower affinity of fetal hemoglobin for 2,3-diphosphoglycerate (DPG). Shunting is a common occurrence in the neonate, such as in congenital cyanotic heart disease, persistent fetal circulation, or atelectasis. O_2 supplementation does not prevent the hypoxia produced by such a shunt. Arterial carbon dioxide partial pressure ($PaCO_2$) is an important measure of pulmonary function in neonatal respiratory disease. The initiation of ventilation with the first breath after normal delivery results in a rapid fall in $PaCO_2$ within minutes of birth. PO_2 rises rapidly to levels of 60 to 90 mm Hg (17). Immaturity of the kidney in the newborn affects the basal acid-base status and the response to additional acid and alkali loads (18). The blood bicarbonate (HCO_3^-) concentration is typically lower than in the adult (18–21 mEq/L). However, the blood pH (7.35–7.43) is only marginally decreased because of the compensatory increase in the neonatal respiratory rate. Table 2 lists the normal values of pH, $PaCO_2$, and total CO_2 in the adult and in preterm and term neonates (19). The transition from fetal to neonatal life, which is associated with rapid changes in fluid

Table 2. Acid-base Parameters in Neonates and Adults (mean \pm SD)

	Preterm	Term	Adult
pH	7.40 \pm 0.08	7.40 \pm 0.06	7.40 \pm 0.03
PCO_2	34.0 \pm 9.0	33.5 \pm 3.6	39.0 \pm 2.6
Total CO_2	21.0 \pm 2.0	21.0 \pm 1.8	25.2 \pm 2.8

and electrolyte balance, and the neonate's small size make the electrolytes and glucose assessment difficult and complicated (20), especially in the first week of life. A physiologic decrease in extracellular water volume, as well as a transient increase in serum potassium and transient decreases in plasma glucose and total plasma ionized calcium concentrations, must be taken into account when monitoring neonatal electrolytes and glucose. Frequent and even continuous monitoring of physiological parameters is indicated in some cases, including glucose and calcium monitoring in the premature newborn (limited hepatic glycogen storage) and in newborns of diabetic mothers (21). Before birth, fetal glucose is slightly higher than maternal glucose. With cord clamping, neonatal plasma level plummets over the first 60–90 min of life (23), (23). Neonatal hormonal changes later leads to an increase in endogenous glucose production and stabilization of its level.

Technical Aspects of Neonatal Blood Gas and Biochemical Measurement

Technologic innovations in the development of biosensors and microprocessors have led to development of bedside small and accurate point-of-care (POC) devices (24). POC devices have been used widely in critical care units, including the NICU. These devices are divided into two groups: "Analyzers," which are not attached to the patient blood source and require blood sampling, and "monitors," which are continuous or near-continuous patient-attached POC monitors (25). Neonatal biochemical measurement may include several important blood parameters, such as sodium, potassium, calcium, glucose, and even lactate Table 3.

Intermittent Blood Gas and Biochemical Measurement (Sampling). This is the most common technique used in the NICU for invasive neonatal blood gas and biochemical measurement. Usually a small blood sample is withdrawn from a blood vessel, such as an umbilical vessel through an umbilical catheter. This sample is analyzed by using a bedside point-of-care analyzer or sent to a small satellite laboratory unit in the NICU or to the central laboratory. Blood gas analyzers are discussed in other articles in this Encyclopedia. These analyzers use the principles of Clark's electrode for PO_2 measurement and Severinghaus's electrode for PCO_2 measurement. Some blood-sample collecting systems are commercially available, such as the Edward VAMP Jr. system manufactured by Edward (Fig. 4), which are manufactured specifically for neonate and small children use. This system is latex-free, disposable, closed, with small volume systems. Such systems are designed to decrease the risks of blood loss, infection, and air bubbles (26).

Continuous Intravascular Neonatal Blood Gas and Biochemical Sensors. There are several drawbacks for using frequent arterial blood gas (ABG) sampling in the neonate (27). This method may result in blood loss that can necessitate blood transfusion. Moreover, in this method, rapid changes in blood gas values may be missed, especially

Table 3. The Main Blood-Chemistry Parameters Monitored in the Neonatal Care Unit, With Typical Sensing Principles and Transducers

Parameter	Sensing Principle(s)	Transducer(s)
Invasive Blood Pressure	Electrical, impedance	Strain gauge, piezoresistor
PO_2	Optical, reflection	Photodetector and emitter
	Optical, fluorescent	Photomultiplier tube
PCO_2	Electrochemical, amperometric	Clark oxygen electrode
	Optical, fluorescent	Photomultiplier tube
Glucose	Electrochemical, potentiometric	Ion-sensitive electrode
	Optical, colorimetric	Photodetector
Lactate	Electrochemical, amperometric	Enzyme modified biosensor
	Optical, colorimetric	Photodetector
Electrolytes (K, Na, Ca, Cl)	Electrochemical, amperometric	Enzyme modified biosensor
	Optical, colorimetric	Photodetector
pH	Electrochemical, potentiometric	Ion-selective electrode (ISE)
	Optical, colorimetric	Photodetector
Hemoglobin	Electrochemical, potentiometric	Ion-sensitive electrode
	Optical, absorption	Photodetector and emitters

in conditions needing quick and close ABG monitoring, such as after surfactant administration (28) and during high-frequency ventilation (29). These drawbacks dictate the need for a more efficient real-time way to monitor ABGs (30). For the last two decades, intra-arterial PaO_2 monitoring has been available with the use of a Clark electrode (31)

or a multiparameter sensor with an umbilical artery catheter (32). New fiber-optic continuous blood gas monitoring sensors have been validated and used in the neonate with an UAC, such as Neotrend. These devices promise to be safe, easy to use, and accurate in newborns. However, the cost-effectiveness of these devices is still not well established (33) (refer to the blood gas measurement article in this Encyclopedia for details about Neotrend). The *ex vivo* in-line VIA Low Volume Mode blood gas and chemistry monitoring system (VIA LVM Monitor; Metracor Technologies, Inc., San Diego, CA) is an in-line, low-volume POC monitor for neonates and children. Studies have shown promising results in using this monitor in the neonate. However, its cost-effectiveness has not been established yet (25,34). This device measures pH, $PaCO_2$, PO_2 , Na^+ , K^+ , and hematocrit (Hct) by automatically drawing blood (almost 1.5 mL) from a patient's arterial catheter, analyzing it, and reinfusing the blood sample back into the patient. Results are usually displayed in 1–2 min. The operator performs an initial calibration, and then the device performs self-calibration after each sample and at least every 30 min. This machine is compatible with all sizes of UACs and peripheral arterial catheters. Figure 5 shows a diagram of the VIA LVM monitor and its components at the neonate bedside.

Figure 4. Edward VAMP Jr. blood-sample collecting system.

Figure 5. Diagram of the VIA LVM in-line *ex vivo* monitor and its components at the neonate bedside.

Neonatal Hemodynamic Monitoring

Direct arterial blood pressure monitoring is the most accurate technique for determining arterial pressure in the neonate (9). This method is best done by using umbilical artery catheterization. It is an easy and quick procedure in comparison with other neonatal artery catheterizations, such as radial and femoral artery catheterization. After the umbilical artery catheterization is done as described above, it is connected to a pressure transducer and a continuous flow device, as well as stopcock and manometer tubing.

Basic Concepts. Hemodynamic pressure monitoring requires several basic components to accurately measure the physiologic pressures. These components are: (1) an intravascular catheter, (2) connecting tubing and stopcocks to connect that catheter and the patient's blood vessels to the monitoring system, (3) a pressure transducer to convert the mechanical impulse of a pressure wave into an electrical signal through movement of a displaceable sensing diaphragm, (4) a continuous flush device that fills the pressure tubing with fluid and helps prevent blood from clotting in the catheter, (5) an amplifier that increases the low-voltage signal from the pressure transducer to a signal that can be displayed on a display device, (6) an oscilloscope to display waveforms and a digital readout to display numerical data, and (7) a processor or microcomputer that is used to calculate various hemodynamic parameters based on the measured variables.

Pressure Transducers. Pressure transducers are divided in two groups: (1) External transducers located away from the intravascular catheter and connected to that catheter via fluid-filled pressure tubing, and (2) catheter-tip transducers. The external transducers use three types of sensing elements: (1) strain gauges. These consist of an electrically conductive elastic material that responds reversibly to deformation by a change in electrical resistance. The resistance is converted into a voltage signal by connecting the elements to form a Wheatstone bridge circuit. The output voltage is proportional to the applied pressure and the excitation voltage. Strain gauges are the most common method of pressure transduction. (2) Silicon strain gauges. These are thin slices of silicon crystal bonded onto the back of a diaphragm. The movement of the diaphragm causes a change in the resistance of the crystal, which can be converted into an output signal. Silicon strain gauges are more sensitive than standard strain gauges, but they are affected by temperature and are non-linear. (3) Optical sensors: These are also diaphragms, but in this case, the movement of the diaphragm is sensed by reflecting a beam of light off the silver back of the diaphragm onto a photoelectric cell. The intensity of light sensed by the photoelectric cell changes with the diaphragm position, causing a decrease in its electrical output.

The Pressure Measurement System. The arterial waveform can be characterized as a complex sine wave, which is the summation of a series of simple sine waves of different amplitude and frequencies. The fundamental frequency (or first harmonic) is equal to the heart rate. The first 10

harmonics of the fundamental frequency contribute to the waveform. Any measurement system responds to a restricted range of frequencies only. Within this range, the system may respond more sensitively to some frequencies than to others. The response of the system plotted against the signal frequency is the *frequency response* of the system. However, the measurement system may possess *natural frequencies* or resonances determined by the inertial and compliant elements in a mechanical system. These resonances can distort the output signals. Therefore, it is essential that the natural frequencies do not lie in the operating frequency range of the instrument. Moreover, the output signal of a measurement may differ from the input signal created by the bloodstream because of the inertial components, frictional effects of movement, viscous forces of fluids, and electrical resistance. The property that determines these effects is called the *damping* of the system (35).

Technical Management of Pressure Monitoring System.

These are some significant practical points in operating this system:

1. *Removal of all air bubbles from system:* Air is more compressible than fluid, and it tends to act as a "shock absorber" within the pressure monitoring system, leading to an overdamped waveform, which may lead to false readings of the blood pressure. Moreover, air bubbles may cause serious air embolism, especially in neonates and small children.
2. *Zeroing the transducer:* The accuracy of invasive pressure measurements is dependent on the establishment of an accurate reference point (Zeroing). This is done by opening the stopcock to atmospheric pressure and zeroing the measurement system to eliminate the effect of the atmospheric pressure, and by leveling the transducer to the level of the upper portion of the right atrium (the patient's "mid-axillary line" or "phlebostatic axis") to eliminate the effect of the blood hydrostatic pressure.
3. *Fast-flush technique:* A "fast-flush" or "square wave test" is performed by opening the valve of the continuous flush device, which leads to an acute increase in the fluid flow rate through the catheter-tubing system from the usual 1–3 mL/h to 30 mL/h. This generates an acute rise in pressure within the system such that a square wave is generated on the monitor. With closure of the valve, a sinusoidal pressure wave of a given frequency and progressively decreasing amplitude is generated. A system with appropriate dynamic response characteristics will return to the baseline pressure waveform within one to two oscillations. If the fast-flush technique produces dynamic response characteristics that are inadequate, the clinician should troubleshoot the system (i.e., remove all air bubbles, minimize tubing length and stopcocks, etc.) until an acceptable dynamic response is achieved. The above-explained basic concepts in hemodynamic monitoring are used in pressure monitoring in neonates as well as in adults. Because of

Figure 6. Neonatal/Pediatric Deltran pressure tubing with needleless blood collection system.

the small size of a neonate (or premature newborn) and because of the different indications and expected complications from adults and older children, these monitors have been modified to fit these requirements. These modifications and changes include (1) using a more simple tubing system with fewer stopcocks to reduce the risk of air embolism and infection, (2) using a smaller volume tubing system with small syringes to decrease blood loss and the need for blood transfusion, and (3) using a special constant-low-rate flush system to decrease the risk of fluid overloading. After correct placement of the umbilical artery catheter, a stopcock (free of air bubbles) is connected to its distal end. Then a fluid-filled, well-flushed pediatric/neonatal blood pressure tubing is connected to that stopcock (or directly to the catheter). The transducer is zeroed and leveled to the midaxillary level. There are several commercially available neonatal/pediatric pressure transducers and tubing systems. Figure 6 shows a disposable, latex-free neonatal/pediatric Deltran blood pressure monitoring and needleless blood collection system (36). For central venous pressure (CVP) monitoring, a dual-lumen or triple-lumen umbilical vein catheter may be used. Figs. 2 and 7 show some of the currently available catheters. Neonatal/pediatric pulmonary artery catheters (PACs) have been used through the umbilical vein. However, they are difficult to place and have numerous complications and risks associated with their placement. Other noninvasive cardiac monitors, such as echocardiography, can assess cardiac output and other physiological cardiac parameters. Thus, use of the neonatal PAC has decreased significantly. The most common indications for pediatric PACs are for cardiogenic shock, for severe distributive shock, for the use of very high ventilator pressures to achieve ade-

Figure 7. Catheter.

quate oxygenation, and for the perioperative management of patients who have undergone complex cardiac or other major surgeries (37). The smallest thermodilution catheter available is 5 Fr in size, although a single-lumen 4-Fr catheter exists and is useful for measuring pulmonary artery pressure (PAP) or obtaining mixed venous saturation (MvO_2). Potential complications of pulmonary artery catheterization include pulmonary artery erosion or infarction, dysrhythmia, damage to the pulmonic valve, coiling in the right ventricle, and cardiac perforation (38).

Complications and Risks

Umbilical Artery Catheter. Many complications and risks are associated with UAC placement (39). Therefore, these catheters should not be used solely for fluid and medication administration. If an infant does not require frequent arterial blood sampling or continuous blood pressure monitoring, there is almost no justification for leaving a UAC inserted. The advantages and disadvantages of “high” versus “low” UAC are still debated. Recent studies (40–43) have found that “high” catheters are associated with a decreased incidence of complications without a statistically significant increase in any adverse sequelae. Therefore, one major review of the literature has concluded that “there appears to be no evidence to support the use of low placed umbilical artery catheters. High catheters should be used exclusively” (40). It is clear that UACs that are located between the “high” and “low” positions are never appropriate. Catheters in these positions have been associated with refractory hypoglycemia (infusion into the celiac axis), paraplegia (infusion into the artery of Adamkiewicz)

Table 4. Care of Indwelling Umbilical Catheter

-
- Change all tubings and connections daily.
 - Secure and label all tubing, and connections should be secured and labeled appropriately.
 - Use only appropriate filters.
 - Maintain catheter, connections, and tubing free of blood to prevent clot formation, or inadvertent flushing of preexisting clots into the neonate.
 - Flush catheter with 0.5 mL of flush solution each time blood sample is drawn.
 - Chart fluids infused in intake/output record.
 - Infuse heparinized parenteral solution continuously through catheter, interrupting only to obtain blood samples.
-

(44), and thromboses that affect the kidneys (infusion into the renal arteries) or the gut (infusion into the mesenteric arteries). A catheter that is found in this intermediate position should be pulled to a “low” position or removed. Similarly, catheters should not be placed below the level of L5 because of the risk of gluteal skin necrosis (45) and sciatic nerve damage (45). Catheters that are placed below the level of L5 should be removed promptly. Other complications may include catheter occlusion, infection, air embolism, breaks or transection of the catheter, electrical hazards, intravascular knots in the catheters, bladder injury, peritoneal perforation, Wharton’s jelly embolus, and others.

Umbilical Venous Catheter. Thromboembolic events and infections are common complications of UVC use. These complications are similar to those of other central catheters, although UVCs are associated with an increased risk of localized infections of the liver and heart. Complications that are specific to UVC commonly are the result of malposition of the catheter. Nearly all experts recommend placement of the catheter outside the heart in the IVC (46). Complications occur as a result of placement of the catheter in the right side of the heart or the left side (via the foramen ovale). Cardiac arrhythmias are common complications, but these arrhythmias usually resolve after catheter withdrawal from the heart. Cardiac perforation with subsequent pericardial effusion and cardiac tamponade has been reported (47). Quick diagnosis (high index of suspicion, chest radiograph, and ultrasonography) and prompt treatment with pericardiocentesis decrease mortality significantly in these neonates. Placement of the catheter in the portal system can result in serious hepatic injury. Hepatic necrosis can occur from thrombosis of the hepatic veins or infusion of hypertonic or vasospastic solutions into the liver. Necrotizing enterocolitis and perforation of the colon also have been reported after positioning of the catheter in the portal system. Other complications of umbilical venous catheters have been reported and include perforation of the peritoneum, electrical hazards, and digital ischemia.

Umbilical Catheter Removal and Maintenance

According to the American Academy of Pediatrics (AAP) guidelines (48), umbilical artery or venous catheters should be removed and not replaced if there is any sign of catheter-related bloodstream infections, vascular insufficiency, or thrombosis. Moreover, umbilical catheters must be removed as soon as possible when no longer needed or when any sign of vascular insufficiency to the lower extremities is observed. An umbilical artery catheter should not be left in place more than 5 days. However, an umbilical

venous catheter can be used up to 14 days if managed aseptically. Umbilical venous catheters may be replaced only if the catheter malfunctions. Table 4 lists the important tasks for daily care of umbilical indwelling catheters.

FUTURE TRENDS IN INVASIVE NEONATAL MONITORING

Providing real-time, accurate, reliable, compact, at the bedside, and safe neonatal monitoring devices is the future goal of researchers and manufacturers involved with neonatal critical care (3). However, the cost issue is still outstanding and is going to be a major factor in directing this industry. The market demand for integrated critical care units and the clinical demand for continuous and rapid biochemical monitoring at the bedside, especially in critically ill patients, will lead to a closer integration between the vital signs monitors and POC analyzers. The monitor and POC analyzer manufacturers have been separate companies. This will slowly change through the formation of strategic alliances and mergers. Therefore, new devices will combine continuous vital signs, blood gases, and blood chemistry in the critical care units, including the NICU. The demand for continuous monitoring of biochemical parameters is at the same time bounded by the requirement for low-blood-loss systems, especially in the NICU. This is where the in-line and indwelling analyzers can offer a major advantage over the POC analyzers. Fortunately, technology is also moving in the right direction to minimize iatrogenic blood loss and decrease the risk of infection through the advances made in sampling, preparation, and handling of liquids using microfluidic techniques and closed systems (49). It is likely that in-line monitors that interface to umbilical artery catheters will become more widespread and will require decreasing sample-volumes. The continuing application and refinement of established optical assay methods, such as absorption and fluorescence spectroscopy, onto fibre-optic cables will enable the detection of increasing numbers of analytes by indwelling probes encased within the umbilical catheters (50,51).

SUMMARY

The use of umbilical vessel catheterization and associated monitoring techniques and devices has been advanced dramatically since Dr. Louis K. Diamond of Boston used plastic tubing on the umbilical vein for blood transfusion in 1946. Advances in invasive neonatal monitoring and neonatal intravascular access have led to a significant reduction in the incidence of complications and have increased the number of indications for umbilical catheters. Umbilical vessel catheterization is now a routine and safe procedure

in the NICU. Moreover, with the increase in the survival rate of low- and very low-birth-weight neonates, the need for these catheters has increased. Sometimes these catheters are the only intravascular access that can be established in this new group of patients. The innovation and development of medical applications of silicone and polyurethane enable the manufacturers to make soft, small catheters with adequate lumen size. These catheters cause minimal adverse reaction to the newborn body. To decrease the risk of blood loss and infection, new blood sampling devices have been developed. These systems are closed and have small volume tubing. New technologies for continuous monitoring of blood gases and neonatal chemistries in-line have been integrated with the umbilical catheters by using special sensors encased in the tip of the catheters. The future trend is to use smaller, compact, real-time, bedside monitors combined with pulse oximetry and other vital signs monitors. However, the issue of the cost-effectiveness of these machines has yet to be determined.

INTRODUCTION

This article outlines the association of antibodies within the human immune system, the structural and binding characteristics of antibodies, and the development and production of monoclonal antibodies. Recent advancements in recombinant DNA techniques and genetic engineering are described, including the use of plants to increase the production capacity of Mabs. Their usefulness as biological and medical reagents is further elaborated in a description of the various instrumentation, techniques,

and assays employed in the diagnosis and treatment of diseases as well as their utility in the research laboratory.

THE IMMUNE SYSTEM AS IT APPLIES TO ANTIBODIES (1)

The immune system is normally directed at foreign molecules borne by pathogenic microorganisms. However, the immune system can also be induced to respond to simple nonliving molecules. Any substance that can elicit an immune response is said to be immunogenic and is called an immunogen. There is a clear operational distinction between an immunogen and an antigen. An antigen is defined as any substance that can bind to a specific antibody (see below), but is not necessarily able to elicit an immune response by itself.

Immunization

The deliberate induction of an immune response is known as immunization. To determine whether an immune response has occurred and to follow its course, the immunized individual is usually monitored for the appearance of antibodies directed at the specific antigen. Monitoring the antibody response usually involves the analysis of relatively crude preparations of sera. The serum is the fluid phase of clotted blood, which contains a variety of specific antibodies against the immunizing antigen as well as other soluble serum proteins.

Cells Participating in an Immune Response

B lymphocytes (or simply B cells) are one of the two major types of lymphocytes that enable the adaptive immune response. When activated, B cells differentiate into plasma cells that secrete antibodies. T lymphocytes or T cells consist of three main classes. One class differentiates upon activation into cytotoxic T cells, which may kill foreign tissues, cancer cells, and cells infected with virus. The second class of T lymphocytes is T helper cells that differentiate into cells that activate and enable the proper function of other cells, such as B cells. The third class is the T suppressor cells that limit the extent of the immune response.

Antigen Recognition

Both T and B lymphocytes bear receptor proteins on their surface that allow them to recognize antigen. Collectively, these receptors are highly diverse in their antigen specificity, but each individual lymphocyte is equipped with membrane-bound receptors that will recognize only one particular antigen. Each lymphocyte therefore recognizes a different antigen. Together, the receptors of all the different lymphocytes are capable of recognizing a very wide diversity of antigens, which encompass most of the different antigens an individual will meet in a lifetime. These include those antigens that are exclusively synthesized in the laboratory. The B cells do not secrete antibody until they have been stimulated by specific antigen. The B-cell antigen receptor (BCR) is a membrane-bound form of the same antibody that they will secrete when activated by antigen. Thus the antigen recognized by both the BCR and

the secreted antibody present in the same B cell, are identical.

Antibodies

Antibody molecules as a class are now generally known as immunoglobulins (Ig), and the antigen receptor of B lymphocytes is known as surface immunoglobulin. The T cell antigen receptor (TCR) is related to immunoglobulins, but is quite distinct from it in structure and function.

Structure and Function of Antibodies

Antibodies are the antigen-specific products (proteins) secreted by B cells. The antibody molecule has two separate functions: one is to bind specifically to molecules from the immunogen (pathogen) that elicited the immune response; the other is to recruit various cells and molecules in order to remove and destroy the pathogen once the antibody is bound to it. These functions are structurally separated in the antibody molecule. One region of the antibody specifically recognizes antigen and the other engages the effector mechanisms that will dispose of it.

The antigen-binding region varies extensively among antibody molecules and is thus known as the variable region or V region, labeled as VH (heavy chain) and VL (light chain). It is this variability that allows each antibody molecule to recognize and bind a particular antigen. The total repertoire of antibodies made by a single individual is large enough to ensure that virtually any structure can be bound. The association between the antibody and the antigen depends on their steric conformation. That is, depending on the size and interatomic distance of these reacting molecules, a tight fit between the antibody combining sites and the antigenic determinant can occur.

The region of the antibody molecule that engages the effector functions of the immune system, but is not associated with antibody binding and does not vary in the same way is known as the constant region or C region. It is typified by the IgG antibody shown in Fig. 1 and is designated CL (light chain) and CH (heavy chain). It has five main forms, or isotypes, that are specialized for activating the different immune effector mechanisms.

The remarkable diversity of antibody molecules is the consequence of a highly specialized mechanism by which

Figure 1. Basic immunoglobulin structure. [Courtesy of Sigma-Aldrich (www.sigmaaldrich.com/img/assets/8181/AntibodyExp).]

the genes that code for antibody production and that are expressed in any given B cell are assembled by DNA rearrangements that join together two or three different segments to form a V region gene during the development of the B cell. Subsequent DNA rearrangement can attach the assembled V-region to any C-region gene and thus produce antibodies of any of the five isotypes.

Antibodies are roughly Y-shaped molecules. All antibodies are constructed in the same way from paired heavy and light polypeptide chains. In Fig. 1, one can observe that the innermost regions of the Y-shaped molecule are the heavy chains; the light chains are the outermost regions. Within this general category, however, five classes (isotypes) of immunoglobulin -IgM, IgD, IgG, IgA, and IgE- can be distinguished biochemically as well as functionally. The five classes are defined by the structure of their heavy chain. Their distinctive functional properties are conferred by differences in the amino acid sequences of the carboxy-terminal part of the heavy chain (COOH in Fig. 1) in the region that is not associated with the light chain. IgG (Fig. 1) will be used to describe the general structural features of immunoglobulin molecules.

The IgG antibodies are large molecules (~150 kDa) composed of two different polypeptide chains. One of these polypeptide chains, ~50 kDa in size, is termed the heavy or H chain. The other, is 25 kDa in size, and is termed the light chain or L chain. The two chains are present in an equimolar ratio, and each IgG molecule contains two heavy chains and two light chains. The two heavy chains are linked to each other by disulfide bonds and each heavy chain is linked to a light chain by a disulfide bond. In any one immunoglobulin molecule, the two heavy chains and the two light chains are identical, enabling them to bind two identical antigenic determinants.

The amino-terminal sequences of both the heavy and light chains vary greatly among different antibodies. The variability in sequence is limited to approximately the first 110 amino acids on the chain, corresponding to the first domain, whereas the carboxy-terminal sequences are constant between immunoglobulin chains, either light or heavy, of the same isotype.

Fragmentation of Antibodies

The antibody molecule can be readily cleaved by different proteases into functionally distinct fragments. For example, Fab fragments, each of which consists of two identical fragments, each containing the antigen binding region. Additionally, an Fc fragment can be extracted that interacts with effector molecules and cells, or one F(ab')₂ fragment that contains both arms of the antigen binding region. Figure 1 shows the sites of the derivation of these fragments. Genetic engineering techniques now permit the construction of designed variations of the antibody molecule such as a truncated Fab that comprises only the V region of a heavy chain linked to a V region of a light chain. This is called a single-chain Fv. A broad range of genetically engineered molecules are now becoming valuable therapeutic agents because their smaller size readily permits their penetration into tissue. Useful antibodies from animal sources have been engineered in a process referred

to as "humanization". This avoids their recognition as foreign, and prevents their rapid clearance from the body. The process utilizes the variable region of a mouse antibody coupled to the Fc region from human antibodies. Antibody fragments may also be coupled to toxins, radioactive isotopes and protein domains that interact with effector molecules or cells.

MONOCLONAL ANTIBODIES

Antibody Heterogeneity

The antibodies generated in a natural immune response or after immunization in the laboratory are a mixture of molecules of different antigen specificities and affinities. Because of their multiple specificities they are termed polyclonal antibodies. Some of this heterogeneity results from the production of antibodies that bind numerous different antigenic determinants (epitopes) present on the immunizing antigen. However, even antibodies directed at a single antigenic determinant can be markedly heterogeneous. Antisera (serum containing antibodies against specified antigens) are valuable for many biological purposes, but they have certain inherent disadvantages that relate to the heterogeneity of the antibodies they contain. First, each antiserum is different from all other antisera, even when raised in a genetically identical animal while using the identical preparation of antigen and immunization protocol. Second, antisera can be produced in only limited volumes, and thus it is impossible to use the identical serological reagent in a long or complex series of experiments, or in clinical tests or therapy. Finally, even purified antibodies may include minor populations of antibodies that give unexpected cross-reactions that confound the analysis of experiments and can be harmful in therapy. To avoid these problems, and to harness the full potential of antibodies, it became necessary to develop a method for making an unlimited supply of antibody molecules of homogeneous structure and known specificity. This has been achieved through the production of monoclonal antibodies from hybrid antibody forming cells or, more recently, by genetic engineering.

Production of Monoclonal Antibodies

In 1975, using cell culture techniques, Kohler and Milstein (2) found a way to grow an immortal B-cell-like lymphocyte that continuously produced an antibody with a predetermined specificity. The procedure required the immunization of a mouse in order to produce a large population of B-cells in the spleen that would secrete a specific antibody. However, in cell culture, the life span of spleen cells is only a few days. To produce a continuous source of antibody, the B cells had to grow continuously. This was achieved by fusing the spleen cells that contained a particular gene, the hypoxanthine-guanine phosphoribosyl transferase (HGPRT) gene with immortal myeloma cells (cancerous plasma cells). In general, plasma cells are mature-antibody secreting B cells. The myeloma cells were preselected to ensure three specific properties. First, immortality in cell culture; second, that they were sufficiently altered so that

Figure 2. Schematic of hybridoma protocol. [Courtesy of Prof. John Kimball (<http://users.rcn.com/jkimball.ma.ultranet/Biology/Pages/M/Monoclonals.html>).]

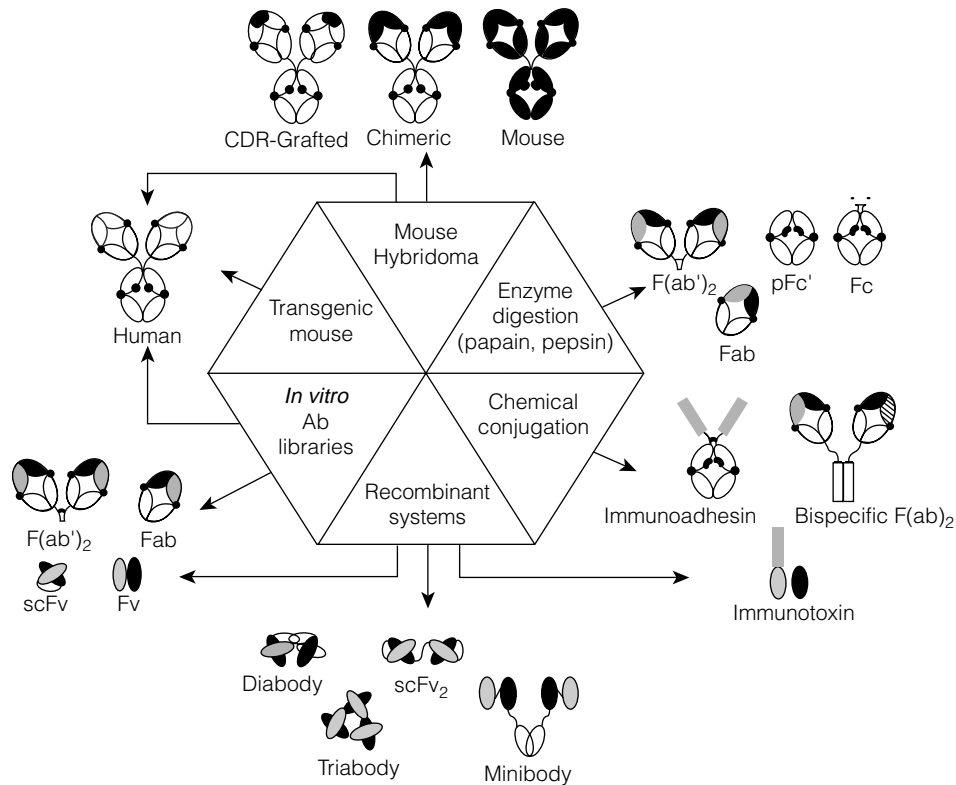

they did not secrete antibody, and third, that they would not flourish in a particular growth medium containing hypoxanthine, aminopterin and thymidine (HAT). The HAT medium was previously shown to be a highly selective medium for those specific hybrid cells that lack the gene for the enzyme, HGPRT. Consequently, all unfused myeloma and spleen cells would not survive in the HAT medium. The HGPRT gene that was contributed by the spleen cell

permitted only hybrid cells to survive in the HAT medium, because only hybrid cells would be able to grow in the culture due to the conferral of immortality by the myeloma cells. Therefore, the immune spleen cells conferred both antibody specificity and the HGPRT gene to the hybrid cell, while the myeloma cell conferred immortality to the spleen cell and they were able to survive indefinitely in culture. This is the method that is used today to produce individual hybridomas (the hybrid cells) that are then screened for antibody production. Single antibody-producing cells that produce an antibody with the desired specificity are cloned. These cloned hybridoma cells are grown in bulk culture to produce large amounts of antibody that are used in a variety of ways. Since each hybridoma is descended from a single B cell, all cells of a particular hybridoma cell line produce the same hybridoma molecule. This is the monoclonal antibody (Mab). The procedure is shown as a schematic outline in Fig. 2.

Recombinant Genetic Engineering

The field of antibody engineering endeavors to improve the target specificity and effector function of the antibodies by altering their construction, while retaining their binding characteristics. This is achieved by using new recombinant engineering technologies to redesign the molecular architecture of the antibodies. Examples of this are shown in Fig. 3, where in a process called genetic engineering, recombinant DNA (spliced DNA that is formed from two or more sources and then rejoined) is produced by putting genes from one species into the cells of an individual organism of another species. The foreign DNA becomes

Figure 3. Antibody engineering: examples of antibody-based constructs and respective routes for their generation. Hybridoma technology provides a way of producing mouse monoclonal antibodies. Genetic engineering has encouraged the creation of chimeric, humanized, and human antibodies, antibody fragments (traditionally obtained by partial digestion of immunoglobulins with proteases), multimeric antibody fragments, fusion (immunoadhesins and immunotoxins) and bispecific antibodies. Multimeric antibody fragments (diabody, triabody, and tetrabody) are represented as multivalent structures, although they can also be engineered to be multispecific. The minibody depicted is a dimer that can be linked to the CH₃ fragment via a LD linker or a flexible linker (FlexMinibody). Bispecific F(ab)₂ is shown as a Fab dimer linked noncovalently via interaction of amphipathic helices. (Courtesy of American Chemical Society and American Institute of Chemical Engineers, Copyright © 2004.) (See Ref. 3.)

part of the host's genome (its genetic content) and is replicated in subsequent generations descended from that host. An alternative technique for producing antibody-like molecules is the Phage Display Libraries for Antibody V-region Production (4). In this approach, gene segments that encode the antigen-binding variable region of antibodies are fused to genes that encode the coat protein (outside surface) of a bacteriophage (viruses that infect bacteria). In essence, mRNA from primed human B-cells is converted to cDNA. The large variety of diverse antibody genes are expanded by the polymerase chain reaction (PCR) to generate a highly diverse library of antibody genes. Bacteriophage containing such gene fusions are then used to infect bacteria, resulting in phage particles that have outer surfaces that express the both antibody-like fusion protein, and the same antigen-binding domain displayed on the outside of the bacteriophage. The collection of such recombinant phages, each displaying a different antigen-binding domain on its surface, is known as a phage display library. A particular phage can be isolated from the mixture and can be used to infect fresh bacteria. Each phage isolated in this way produces a monoclonal antigen-binding particle analogous to a monoclonal antibody. A complete antibody molecule can then be produced by fusing the V region of a particular phage with the invariant part of the immunoglobulin gene. These reconstructed antibody genes can be introduced (transfected) into a suitable host cell line. These genes will become part of the cell's genome and will secrete antibodies akin to hybridomas.

Monoclonal Antibodies Produced in Plants, Plantibodies

After undergoing genetic engineering techniques, plant cells are capable of assembling and producing unlimited quantities of antibodies, referred to as plantibodies (5). This trademark name for human antibodies manufactured in plants has functionally limitless production capacity and lower costs than those associated with the yeast fermentation process that is currently being used to produce mass quantities of human antibodies. This fairly recent finding might prove to be of benefit in the medical, consumer, and industrial applications of monoclonals. For example, it has been postulated that the development of plantibodies with a capability of sequestering heavy metals or radioactive compounds might have a very positive impact on the environment, particularly because their production is very inexpensive and large supplies are easily produced. Because the corn crop is so readily available worldwide, and its kernel stores natural plantibodies, these can be purified as needed by standard milling procedures. Potato and tomato crops are also being used. The first clinical use of the effectiveness of a plantibody was against the bacterium, *Streptococcus mutans*. This organism produces lactic acid that erodes tooth enamel. The plantibody was brushed onto human teeth for 3 weeks and tooth decay was prevented for up to 4 months. The action of the antibody was to prevent the bacterium from binding to the tooth surface. Plantibody-containing gels are being developed to prevent genital herpes infections and to protect newborn babies during delivery against transmission of the Herpes virus from infected mothers. Plantibodies against human immu-

nodeficiency verus (HIV) and the production of sperm are also being developed. Concerns have been expressed about the use of genetically engineered food crops because of the potential dangers of their getting into the wrong hands, or disturbing the ecological balance.

The aforementioned technologies have revolutionized the use of antibodies by providing a limitless supply of antibodies with single and known specificity. Monoclonal antibodies are now used in most serological assays, as diagnostic probes and as therapeutic agents.

TECHNIQUES FOR USING MONOCLONAL ANTIBODIES AS SEROLOGICAL AND DIAGNOSTIC PROBES

Monoclonal antibodies can serve as tools for diagnosing and treating disease and are valuable agents in the research laboratory. Their utility required the development of procedures that would permit them to be viewed at the particular region of interest. Some of the most widely used techniques are described in the following sections (1).

Immunofluorescence

Since antibodies bind stably and specifically to their corresponding antigen, they are invaluable as probes for identifying a particular molecule in cells, tissues, or biological fluids. Monoclonal antibody molecules (Mabs) can be used to locate their target molecules accurately in single cells or tissue sections by a variety of different labeling techniques. When either the antibody itself, or the anti-Mab that is used to detect it, is labeled with a fluorescent dye the technique is known as immunofluorescence. As in all serological techniques, the antibody binds stably to its antigen, allowing any unbound antibody to be removed by thorough washing. The fluorescent dye can be covalently attached directly to the specific antibody, but more commonly, the bound antibody is detected by a secondary fluorescent anti-immunoglobulin; that is, the first antibody binds to the antigen and a fluorescent secondary antibody (antibody) is targeted to the primary antibody-antigen complex. The technique is known as indirect immunofluorescence, which is demonstrated in Fig. 4, where the binding of the first antibody to the antigen is followed by the binding of the antibody. The dyes chosen for immunofluorescence are excited by light of a particular wavelength, and emit light of a different wavelength in the visible spectrum. By using selective filters that can permit only certain wavelengths of light to pass, only that light coming from the dye or fluorochrome used is detected in the fluorescence microscope. Therefore, the antibody can be located by virtue of its emission of fluorescent light. The recently developed confocal fluorescent microscope considerably enhances the resolution of the technique. If different dyes are attached to different antibodies, the distribution of two or more Mabs can be determined in the same cell or tissue section. Differentiating between the antibodies occurs because either the dye or the fluorochrome will excite at different wavelengths or because they will emit their fluorescence at different wavelengths. An example of the immunofluorescence technique is shown in Fig. 4, whereby, through the use of monoclonal antibodies targeted to

Figure 4. Indirect immunofluorescence. The primary antibody binds to the antigen and the fluorescent anti-antibody binds to the primary thereby increasing the signal. [Courtesy of Prof. v. Sengbusch (<http://www.biologie.uni-hamburg.de/b-online/d00/copyrig.htm>).]

intracellular proteins, certain structures within the cell become visible. The structure shown in Fig. 5 is that of the spindle, which appears during cell division. During certain phases of cell division, the chromosomes arrange themselves in the equatorial plane of the spindle. The spindle is made up of microtubules that, in turn, are composed of proteins. Monoclonal antibodies that would bind to two specific proteins, α and γ -tubulin, of the microtubule were synthesized and labeled with two different fluorochromes. During cell division, the cells were exposed to the fluorescent-labeled Mabs that formed a complex with the proteins and permitted visualization of the spindle.

Immunohistochemistry

An alternative to immunofluorescence for detecting a protein in tissue sections is immunohistochemistry, in which the specific Mab is chemically coupled to an enzyme that converts a colorless substrate into a colored reaction pro-

Figure 5. Dividing cells (mitosis: metaphase, anaphase, and telophase) were stained with monoclonal antibodies against two intracellular proteins, α -tubulin in green, and γ -tubulin in red. Because these proteins constitute the spindle, the intracellular structure upon which chromosomes line up during mitosis, the structure is visualized by virtue of the difference in the fluorochromes tagged to the Mabs that were bound to the proteins. Chromosomes were stained with a blue dye. (www.img.cas.cz/dbc/gallery.htm.)

duct *in situ*. The Enzyme-Linked ImmunoSorbent Assay (ELISA) is a technique that detects and quantifies specific antigens from a mixture. It is widely used in procedures that screen blood for viral or bacterial contamination, to detect infections, toxins, illegal drugs, or allergens, and in measuring hormone levels, such as in pregnancy or thyroid function. The assay involves the binding of an antibody to a solid surface and exposing it to the antigens. A second complex, consisting of the same antibody, but additionally tagged with a particular enzyme, is exposed to the initial antibody-antigen conjugate and binds. After washing the surface to remove excess unbound antigen, a colorless substrate is added that permits the antigen to be converted into a colored product that can be read and measured using absorption spectrometry. The intensity of color is proportional to the concentration of bound antigen. A schematic of the ELISA assay is shown in Fig. 6. A more detailed description of the Elisa procedure can be found in (Kimball’s Biology Pages <http://biology-pages.info>). Horseradish peroxidase and alkaline phosphatase are also used as enzymes in immunochemistry assays. An example of the utility of these enzymes for protein detection is shown in Fig. 7.

Immunoelectron Microscopy

Antibodies can be used to detect the intracellular location of structures or particular molecules by electron microscopy, a technique known as immunoelectron microscopy. After labeling Mabs with gold particles and targeting them to samples, they can then be examined in the transmission electron microscope. Since electrons do not penetrate through gold particles, the regions in which the antibodies bind appear as dark dots.

Figure 7. Detection of the measles virus (MV) P-protein by Western Blot in MV infected and noninfected cells. Whole-cell lysates were prepared from MV that was either persistently infected (NS20-MV) or notinfected (NS20) mouse neuroblastoma cells. The proteins in the lysates were separated by SDS-PAGE and blotted onto nitrocellulose paper. The blot was incubated with a Mab against the MV P-protein, followed by a secondary antimouse immunoglobulin antibody linked to horseradish peroxidase. The P-protein band was detected when a substrate was added that was modified by peroxidase on the blot and caused light to be released. Light was detected on a specific band after exposure to film. The results show that only the measles-infected cells express the viral protein. (Courtesy of Jacob Gopas.)

Blotting Techniques

Immunoblotting or Western blotting is used to identify the presence of a given protein in a cell lysate. Cells are placed in detergent to solubilize all cell proteins and the lysate (the material resulting from the ruptured cells) is run on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), which enables protein migration and separation by size. Further resolution is achieved if the proteins are initially separated by charge according to their isoelectric point and then by size. This technique is referred to as two-dimensional (2D) gel electrophoresis. The proteins are then transferred (blotted) from the gel to a stable support, such as a nitrocellulose membrane for easier handling. Specific proteins of interest in the lysate's mixture are detected by incubating the membrane with a Mab that can react with a defined protein on the membrane. An example of the technique is shown in Fig. 7. The proteins

bound to the antibodies are revealed by enzyme-labeled, anti-immunoglobulin antibodies. By this technique the presence or absence, as well as the amounts of specific proteins, can be monitored following a variety cell treatments. Specific DNA labeled with antigen (haptent)-bound nucleotides can be blotted onto a membrane and detected with Mabs against the haptent. This allows the detection of viral or bacterial DNA in tissues or body fluids, as generated by PCR.

Purification Techniques

Affinity chromatography and immunoprecipitation are techniques that enable purification of molecules and their characterization. A mixture of molecules can be incubated with a Mab, which is chemically attached to a solid support. The bound antibody-antigen complex is washed from unbound molecules by centrifugation, and then the molecule of interest is eluted for further characterization. These techniques are useful for protein purification, for determining its molecular weight, its abundance, distribution, and whether it undergoes chemical modifications as a result of processing within the cell.

Immuno-electrophoresis

Two-dimensional electrophoresis is used to separate different antigens that might be present in one solution. The antigens are separated on the basis of their electrophoretic mobility. The currents are run at right angles to each other, driving the antigens into the antiserum (containing Mabs). Peaks are obtained when the antigen forms a complex with the antibody; the area under the peaks gives the concentration of antigen as shown in Fig. 8. Rocket electrophoresis is a similar technique. Here, after a current is applied, the antigens are separated based upon their ionic charge by their differential migration through a gel that contains antibody. As shown in Fig. 9, concentration is determined by the migration distance. In countercurrent electrophoresis, the greater internal osmotic pressure drives the antibody backwards into a gel after a current is applied. An antigen that is negatively charged will form a complex with the antibody in the gel in a pH-dependent process.

Instrumentation

An immensely powerful tool for defining and enumerating and isolating cells is the use of the fluorescence-activated

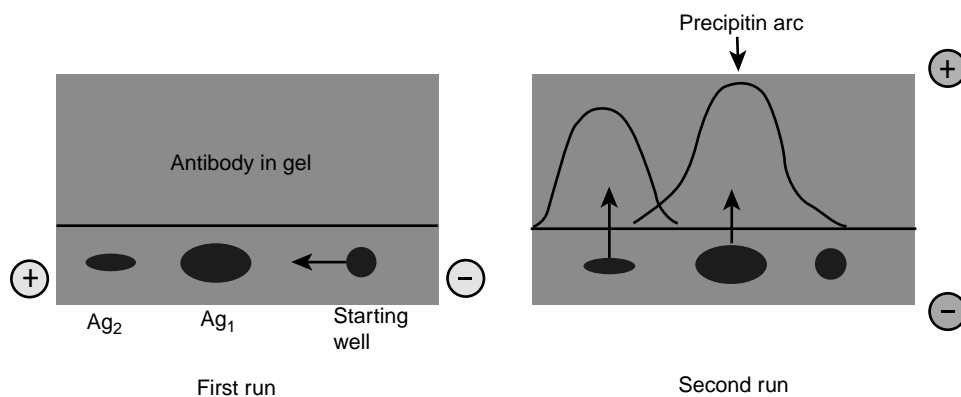

Figure 8. Two-dimensional immunoelectrophoresis. Antigens are separated on the basis of electrophoretic mobility. [Courtesy of the Natural Toxins Research Center at Texas A&M University – Kingsville (<http://ntri.tamuk.edu/>).]

Figure 9. Rocket electrophoresis. Antigen is electrophoresed into gel containing antibody. The distance from the starting well to the front of the rocket shaped arc is related to antigen concentration. [Courtesy of the Natural Toxins Research Center at Texas A&M University – Kingsville (<http://ntri.tamuk.edu/>).]

cell sorter (FACS). This instrument is used to study the properties of cell subsets identified using Mabs to cell surface proteins. Individual cells are first tagged by treatment with specific fluorescent Mabs. The mixture of labeled cells is then forced with a much larger volume of fluid through a nozzle, creating a fine stream of liquid containing cells spaced singly at intervals. As each cell passes through a laser beam it scatters the laser light, and any dye molecules bound to the cell will be excited and fluoresce. Sensitive photomultiplier tubes detect both the scattered light, which gives information on the size and granularity of the cell, and the fluorescence emission, provide quantification of the binding of the labeled Mabs, and on the expression of cell-surface proteins by each cell. In the cell sorter, the signals passed back to the computer are used to generate an electric charge, which is passed from the nozzle through the liquid stream. Droplets containing a charge can then be deflected from the main stream as they pass between plates of opposite charge. In this way a specific population of cells, distinguished by the binding of the labeled antibody and its defined electrical charge, can be extracted and purified from a mixed population of cells. Alternatively, to deplete a population of cells, a labeled antibody directed at marker proteins expressed by undesired cells will direct the cells to a waste channel, retaining only the unlabeled cells. Several Mabs labeled with different fluorochromes can be used simultaneously. FACS analysis can give quantitative data on the percentage of cells bearing different molecules, and the relative abundance of the particular molecules in the cell population, 10,000 cells in a typical experiment demonstrates the retrieval of data after FACS analysis. An example of data output from FACS is shown in Fig. 10.

Mabs as Molecular Probes

Mabs can also be used to determine the function of molecules. Some antibodies are able to act as agonists, when the binding of the Mab to the molecule mimics the binding of the natural ligand (antigen) and activates its function. For example, antibodies to the CD3 antigen present on mature human T cells have been used to stimulate the T cells. This

Figure 10. FACS analysis. Characterizing cells at different stages of development through the use of fluorescent labeled monoclonal antibodies against cell surface markers is one of the most common applications of flow cytometry. Changes in the relative numbers, absolute counts, or in the ratio of cell types can provide valuable information as to the status of the immune system in human disorders or animal models. Different cell types can be detected and quantified from a mixed population by the use of monoclonal antibodies labeled with different fluorescent dyes that have nonoverlapping emission spectra. In this example experiment, blood lymphocytes were incubated with two different Mabs, CD19, and CD3. CD19 was labeled with the fluorochrome phycoerythrin (PE) and binds a cell membrane molecule specific for B-lymphocytes. The CD3 was labeled with fluorescein isothiocyanate (FITC) that detects a cell membrane protein specific for T-lymphocytes. Three populations of cells were detected in this experiment according to the antibody bound to the cells. The logarithmic x and y axis represent relative amounts of fluorescence detected on cells labeled with FITC or PE, respectively. The blue dots represent cells unstained by either of the antibodies, the red dots represent B-lymphocytes that were detected by CD19 and the green dots represent T-lymphocytes, CD3 positive cells. No cells were detected that bound both antibodies (top right quadrant).

occurs because CD3 is associated with the T-cell receptor and is responsible for signal transduction of the receptor. Conversely, Mabs can function as antagonists, inhibiting the binding of the natural ligand and thus blocking its function. For example, antibodies that block the epidermal growth factor receptor (a growth stimulating protein) function as antagonists.

THE USE OF MONOCLONAL ANTIBODIES AS THERAPEUTIC AGENTS

Mabs against cell-surface molecules have been used to remove specific lymphocyte subsets or to inhibit cell function *in vitro*. Cytotoxic drugs kill proliferating cells indiscriminately. In contrast, antibodies can interfere with immune responses in a nontoxic and much more specific manner. For example, Mabs can be used to remove undesirable lymphocytes from donor bone marrow cells prior to transplantation. This treatment selectively removes lymphocytes that recognize the host tissues as “foreign” and induce a potentially fatal condition known as Graft versus Host reaction (6).

Mabs are being tested experimentally to inhibit transplant rejection, to alleviate and suppress autoimmune disease and in cancer detection and treatment. The major impediment to therapy with monoclonal antibodies in humans is that these antibodies are mostly of mouse origin, and humans rapidly develop antibody responses to mouse antibodies. This not only blocks the actions of the mouse antibodies, but leads to allergic reactions. If this occurs, future treatment of the same patient with any mouse Mab is unacceptable. In principle, the problem can be avoided by producing antibodies that are not recognized as foreign by the human immune system. Several strategies are being explored for their construction. One approach is to clone human V regions into a phage display library (see above) and select for its ability to bind human cells. With this method, Mabs that are entirely human in origin can be obtained. Second, mice that lack endogenous immunoglobulin genes can be made "transgenic" (chimeric). That is, they can have human genes put into their genome through recombinant DNA techniques. When this occurs, they will then express human immunoglobulin heavy and light genes and eventually antibody molecules. A third approach is to graft the variable region of a mouse Mab into the rest of the human immunoglobulin molecule, in a process known as humanization. These recombinant antibodies are far less immunogenic in humans than the Mabs of the parent mouse, therefore, they can be used for more efficient and repeated treatment of humans with far less risks. In some cases even humanized antibodies may evoke an immune response and must be administered with immunosuppressive drugs.

THE USE OF MONOCLONAL ANTIBODIES IN THE DETECTION, FOLLOW-UP, AND TREATMENT OF CANCER

Tumor-Specific Antigens

For the greater part of the twentieth century, it was assumed that any antigens present on the cell surface of tumor cells would also be present in normal cells; therefore, few investigations were undertaken to elicit any autoimmune response against cancer cells. However, once inbred mouse strains bearing transplanted syngeneic (genetically identical) tumors became available, research studies validated that immune reactions against these tumors could be induced with no toxic effects on normal tissues, and scientists began to pursue the identification of "tumor specific antigens". Shared tumor antigens were found in many of the same types of cancers in different patients, and unique antigens were isolated that were specific for a particular cancer in a particular patient. The SEREX database lists the antigens that have been isolated from humans (7). These antigens have the ability to generate an immune response when introduced into a patient.

The advent of monoclonal antibodies suggested the possibility of targeting and destroying tumors by making antibodies against tumor-specific antigens. However, this relies upon the identification of a tumor-specific antigen that is located on the surface of cancer cells. Because of their ability to differentiate between normal and malignant tissues and to exact a variety of antitumor responses,

Mabs offer a significant advantage to conventional forms of therapy. Several monoclonal antibodies have already been proven to be relatively well tolerated and effective for the treatment of many different malignant diseases.

Approaches to Cancer Immunotherapy

Approaches to cancer immunotherapy can be either active or passive. For example, in the active category, tumor vaccines that immunize against particularly defined tumor antigens, can be used. In the passive category is the use of monoclonal antibodies that are either conjugated, unconjugated, or radiolabeled. These same approaches can also be categorized as specific, wherein antigens are directly targeted, or nonspecific, where immune cells are used to directly target tumor cells. Other approaches are taken that elicit antitumor effects with different mechanisms, such as using antibodies to block growth factors or receptors on cells; targeting specific tissue components of the tumor or its blood vessels; interfering with cell signals; or with apoptosis (programmed cell death) (8).

Magic Bullets

While such Mab-based therapies offer a high potential to fulfill the promise of "magic bullets" for the treatment of malignant disease, successful application of these therapies is often impaired by several impediments. Factors inhibiting the therapeutic benefit of Mabs may include low or heterogeneous expression of target antigens by tumor cells, high background expression of antigen on normal cells, host antibody immune responses to the Mabs themselves, insufficient anti-tumor response after Mab binding, as well as physical obstructions preventing antibody binding, such as crossing to and from blood vessels as well as tissue barriers en route to the solid tumor mass (9). These factors influence the ability of the Mabs to penetrate to the tumor.

IMAGING TUMORS WITH MONOCLONAL ANTIBODIES

Mabs in Nuclear Medicine

The presence of malignant tumors can be detected through the use of monoclonal antibodies radiolabeled most frequently with the isotopes technetium-99m (^{99m}Tc) or indium-111 (^{111}In). The particular label selected depends upon the size of the antibody. For example, large fragments or whole antibodies require a longer half-life isotope, such as ^{111}In ($T_{1/2} = 2.8$ days), whereas smaller Fab fragments, that are cleared from the body more quickly, can be labeled with ^{99m}Tc ($T_{1/2} = 6$ h). Imaging is performed by a Single Photon Emission Computed Tomography (SPECT) camera whose detectors scan the body and register the radioactive counts. The counts are then mathematically transformed into an image that displays the sites of radioactivity. The nuclear medicine procedure that utilizes this procedure is known as Tumor-Specific Monoclonal Antibody Radio-scintigraphy. Because of occasional difficulties with these techniques, such as inadequate tumor perfusion, inadequate amounts of antigen on the surface of the tumor cells, antigen heterogeneity, and nonspecific uptake, new

approaches are being investigated. However, due to limited clinical experience, it is too early to predict whether they will improve imaging performance (10). Among these methods is the use of other imaging techniques, such as bone scans or computed tomography (CT), in conjunction with SPECT. In other approaches, attempts are being made to augment surface tumor cell antigens by prestimulation with growth factors, such as cytokines (11).

TREATMENT OF HEMATOLOGICAL MALIGNANCIES

Blood-Cell Cancers

Surface antigens on B- and T-cell lymphocytes are also useful targets for the treatment of blood cell (hematopoietic) malignancies, such as leukemias and lymphomas. These antigens are also expressed at high levels on the surface of various populations of malignant cells, but not on normal tissues. With few barriers present to impede Mab binding, hematologic malignancies are well suited to Mab-based therapy. In recent years, several promising Mab-based therapies for the treatment of hematologic malignancies have been developed and either have already received U.S. Food and Drug Administration (FDA) approval or are in the advanced phases of clinical testing (12). The chimeric antibody, rituxan (rituximAb, Genentech, San Francisco, CA) was among the first Mabs awarded Food and Drug Administration approval for the treatment of non-Hodgkin's lymphoma (13,14). This chimeric (human-mouse) antibody binds CD20, a cell surface antigen expressed on mature B lymphocytes and over 90% of non-Hodgkin's lymphoma cells, but not on hematopoietic progenitor or stem cells. Rituxan has proven to be well tolerated and effective in the treatment of non-Hodgkin's lymphoma either by itself, or in combination with traditional chemotherapy, particularly in patients who are refractory to other types of therapy (15). Campath-1 (alemtuzumAb, Ilex Oncology, San Antonio, TX) is another antibody that has also received FDA approval for the treatment of patients suffering from chronic lymphocytic leukemia. A third Mab to receive FDA approval for the treatment of hematologic malignancies is the chimeric Mab, mylotarg (gemtuzumAb ozogamicin, Wyeth-Ayerst Laboratories, Philadelphia, PA). This antibody targets the CD33 antigen expressed on myeloid (white cells) precursors and leukemic cells, and is absent from normal tissues and pluripotent hematopoietic (blood-cell producing) stem cells.

TREATMENT OF SOLID TUMORS

In comparison to the management of hematologic malignancies, successful treatment of solid tumors with Mabs has proven more elusive; however, some significant therapeutic benefits have been achieved. Herceptin (trastuzumAb, Genentech) is a humanized antibody that has received FDA approval for the treatment of metastatic breast cancer. This Mab recognizes an extracellular domain of the HER-2 protein. Clinical trials with herceptin have shown it to be well tolerated both as a single agent for second or third line therapy, or in combination with chemotherapeutic agents as

a first line of therapy. Combination therapy resulted in a 25% improvement of overall survival in patients with tumors that overexpress HER-2, and that are refractory to other forms of treatment (16).

The anti-epithelial cellular adhesion tumors Mab molecule, Panorex (eclrecolomAb, GlaxoSmith-Kline, United Kingdom), is another Mab-based therapy that is currently being used for the treatment of colorectal cancer. Panorex has shown tangible benefit for cancer patients and has received approval in Germany for the treatment of advanced colorectal cancer. Like other Mabs used for the treatment of solid tumors, Panorex has proven more efficacious in the treatment of micrometastatic lesions and minimal residual disease in comparison to bulky tumor masses (17).

The failure of Mabs in the treatment of bulky lesions is primarily attributable to the low level of injected Mabs that actually reaches its target within a sizable solid-tumor mass. Studies using radiolabeled Mabs suggested that only a very small percentage of the original injected antibody dose, ~0.01–0.1/g of tumor tissue, will ever reach target antigens within a solid tumor (18). This low level of binding is due to the series of barriers confronted by an administered Mab en route to antigens expressed on the surface of tumor cells.

ELICITING ANTITUMOR RESPONSES

After successfully negotiating the gauntlet of obstacles obstructing access to the target cells within a tumor, a therapeutic Mab must still be capable of eliciting a potent antitumor response. Although it is often ambiguous as to the exact mechanisms by which a particular Mab may mediate an antitumor response, both direct and indirect mechanisms can potentially be involved.

Antibodies of the IgG₁ and IgG₃ isotypes can support effector functions of both antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity. Antibody-dependent cell-mediated cytotoxicity is triggered by interaction between the Fc region of a cell-bound antibody and Fc receptors on immune effector cells such as neutrophils, macrophages, and natural killer cells. This mechanism is critical for the antitumor effects of several therapeutic Mabs.

Many early studies showed that murine Mabs had limited potential to elicit a potent antitumor response, because the murine Fc regions are less efficient at recruiting human effector cells than their human counterparts. This problem has been largely alleviated by the use of chimeric and humanized antibodies. Genetic engineering techniques have also been used to improve the immunologic effects of therapeutic Mabs by altering antibody shape and size, increasing the valency (bonds of affinity) of Mabs, and creating bifunctional antibodies with two antigenic receptors, one to a tumor antigen and another to an effector cell to increase efficiency of antibody-dependent cell-mediated cytotoxicity (19).

In addition to immunologic effects, Mabs can induce antitumor effects by a variety of direct mechanisms, including the induction of apoptosis (programmed cell

death) (20), or the prevention of soluble growth factors from binding their cognate receptors, such as epidermal growth factor (EGF-R) (21) and HER-2 (22). Additionally, Mabs can also be engineered to deliver a cytotoxic agent directly to the tumor. This offers the potential to combine the biological effects of Mabs with the additional effect of a targeted cytotoxic response. The anti-CD33 Mabs, mylotarg, is one such antibody. Combined with the cytotoxic agent, calicheamicin, mylotarg has been reported to be relatively well tolerated, and effective in the treatment of chronic lymphocytic leukemia (23). Antibodies can also be engineered to deliver ionizing radiation directly to tumor cells. Mabs have been conjugated to both α - and β -particle emitting radionuclides (24). Clinical trials in humans also portend the promise of radiolabeled Mabs for the treatment of cancer. In a recent phase III randomized study, patients with relapsed or refractory non-Hodgkin's lymphoma were treated with yttrium-90 and iodine-131 labeled Mabs targeting the CD20 antigen (ibritumomAb, tiuxetan, and tositumomAb, respectively). Patients treated with these radiolabeled Mabs showed a statistically significant increase in overall response compared with those treated with an unlabeled version of the Mab (rituximAb) (25).

OTHER USES FOR MONOCLONAL ANTIBODIES

Proteomics

After having sequenced the entire human genome, the current task is to understand the "proteome" by identification and quantification of all proteins in a given sample. So far, DNA microarrays have been employed to detect the transcription level [production of messenger ribonucleic acid (mRNA)] of genes in cells. However, it has been found that there is no stringent correlation between transcription level and protein abundance. Furthermore, the status of a protein in terms of its modification and structure cannot be determined by DNA microarrays. To solve this problem, antibody microarrays are envisioned to replace DNA microarrays in proteome research. These arrays consist of a multitude of different antibodies that are immobilized on a solid support and allow characterization of the protein repertoire of a given sample. However, the production of such antibody microarrays and its application require the provision of highly specific and stable antibodies, possessing high affinity and showing no cross-reactivity. Protein and antibody microarrays can be made to encompass as many as 10,000 samples on a chip within the dimensions of a microscope slide (26).

Monoclonal Antibodies in the Food Industry

Monoclonal antibodies are being used in the wine industry. Odors sometimes observed in spoiled food or corked wines are often the result of microbes present in the wood packaging materials. However, this phenomenon has also been observed in bottled water, suggesting that there may be secondary contaminants, such as residues of pesticides that can affect the quality of any packaged food or beverage. To further the quality assurance of products in the

wine industry, a project is being carried out to raise antibodies against a TCA molecule (2,4,6-trichloroanisole) that is thought to be present in cork stoppers and is responsible for the musty taste in wine. The ELISA assay will be employed to detect trace amounts of the contaminating molecule. Also an immunosensor will be used to electrochemically detect the antibody levels present (27). Monoclonal antibodies have also been developed against the vegetative cells and spores of *Bacillus cereus* (28). This bacterium seems to be implicated in food poisoning and is also responsible for food spoilage. It is impossible for the food industry to exclude *B. cereus* from its products because *B. cereus* cells can survive heat processing and can grow in foods kept at refrigerated storage conditions. Two different antibodies were developed. One was used as a specific capture antibody to destroy the bacterium; the other as a detector antibody that would simply identify the presence of *B. cereus*. The ELISA assay was used to detect and quantify the vegetative cells of this pathogenic organism.

Potato cyst nematodes are pests that destroy the potato food crops. Monoclonal antibodies are being used to assist in the development of the plant's resistance to the nematode (29). Recombinant plant monoclonal antibodies have been engineered to protect poultry against coccidiosis infections (30).

Monoclonal Antibodies and Bioterrorism

The same plant biotechnology described above is being developed to create strategic reserves of vaccines and antibodies for infectious agents that could be used in biowarfare. Multiple genes can be engineered in plants intended to provide prolonged immunity against new strains of pathogens that have different mechanisms of action. With this technology, every plant cell will produce the signature protein of a particular biowarfare agent. That protein, in turn, will trigger an immune response in a person who consumes the plant material in an unprocessed or lightly processed form, but it will not cause the disease. These antibodies can prevent infection on surface areas, including nasal passages; clear infectious organisms from the body; identify foreign organisms for destruction; and neutralize and remove toxins. Among the disease-causing substances are several potential bioterrorism agents, such as the botulism toxin, anthrax, Ebola virus, plague, and ricin, a poisonous protein found in the seeds of the castor oil plant. Vaccines for anthrax (*Bacillus anthracis*) and bubonic and pneumonic plague (*Yersinia pestis*), two potentially deadly diseases that can be delivered as airborne agents, are being developed. Preliminary data predicts success in using these plant-derived vaccines (31).

CONCLUDING REMARKS

Antibodies, monoclonal antibodies and antibody derivatives constitute ~20 % of biopharmaceutical products currently in development. Antibodies represent an important and growing class of biotherapeutics. Progress in antibody engineering has allowed the manipulation of the basic antibody structure into its minimal essential functions, and multiple methodologies have emerged for raising

and tailoring specificity and functionality. The myriad of monoclonal antibody structures that can be designed and obtained in different formats from various production systems (bacterial, mammalian, and plants) represents a challenge for the recovery and purification of novel immunotherapeutics (3). However, the general use in clinical practice of antibody therapeutics is dependent not only on the availability of products with required efficacy but also on the costs of therapy. As a rule, a significant percentage (50–80%) of the total manufacturing cost of a therapeutic antibody is incurred during downstream processing. The critical challenges posed by the production of novel antibody therapeutics include improving process economics and efficiency to reduce costs, and fulfilling increasingly demanding quality criteria for FDA approval.

CONTRIBUTOR LIST

- ABDEL HADY, MAZEN**, *McMaster University, Hamilton, Ontario Canada*, Bladder Dysfunction, Neurostimulation of
- ABEL, L.A.**, *University of Melbourne, Melbourne, Australia*, Ocular Motility Recording and Nystagmus
- ABREU, BEATRIZ C.**, *Transitional Learning Center at Galveston, Galveston, Texas*, Rehabilitation, Computers in Cognitive
- ALEXANDER, A.L.**, *University of Wisconsin-Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- ALI, ABBAS**, *University of Illinois, at Urbana-Champaign, Bioinformatics*
- ALI, MÜFTÜ**, *School of Dental Medicine, Boston, Massachusetts*, Tooth and Jaw, Biomechanics of
- ALPERIN, NOAM**, *University of Illinois at Chicago, Chicago, Illinois*, Hydrocephalus, Tools for Diagnosis and Treatment of
- ANSON, DENIS**, *College Misericordia, Dallas, Pennsylvania*, Environmental Control
- ARENA, JOHN C.**, *VA Medical Center and Medical College of Georgia*, Biofeedback
- ARIEL, GIDEON**, *Ariel Dynamics, Canyon, California*, Biomechanics of Exercise Fitness
- ARMSTRONG, STEVE**, *University of Iowa, Iowa City, Iowa*, Biomaterials for Dentistry
- ASPEN, R.M.**, *University of Aberdeen, Aberdeen, United Kingdom*, Ligament and Tendon, Properties of
- AUBIN, C.E.**, *Polytechnique Montreal, Montreal Quebec, Canada*, Scoliosis, Biomechanics of
- AYRES, VIRGINIA M.**, *Michigan State University, East Lansing, Michigan*, Microscopy, Scanning Tunneling
- AZANGWE, G.**, Ligament and Tendon, Properties of
- BACK, LLOYD H.**, *California Institute of Technology, Pasadena, California*, Coronary Angioplasty and Guidewire Diagnostics
- BADYLAK, STEPHEN F.**, *McGowan Institute for Regenerative Medicine, Pittsburgh, Pennsylvania*, Sterilization of Biologic Scaffold Materials
- BANDYOPADHYAY, AMIT**, *Washington State University, Pullman, Washington*, Orthopedic Devices, Materials and Design for
- BANERJEE, RUPAK K.**, *University of Cincinnati, Cincinnati, Ohio*, Coronary Angioplasty and Guidewire Diagnostics
- BARBOUR, RANDALL L.**, *State University of New York Downstate Medical Center, Brooklyn, New York*, Peripheral Vascular Noninvasive Measurements
- BARKER, STEVEN J.**, *University of Arizona, Tucson, Arizona*, Oxygen Monitoring
- BARTH, ROLF F.**, *The Ohio State University, Columbus, Ohio*, Boron Neutron Capture Therapy
- BECCHETTI, F.D.**, *University of Michigan, Ann Arbor, Michigan*, Radiotherapy, Heavy Ion
- BELFORTE, GUIDO**, *Politecnico di Torino - Department of Mechanics*, Laryngeal Prosthetic Devices
- BENKESER, PAUL**, *Georgia Institute of Technology, Atlanta, Georgia*, Biomedical Engineering Education
- BENNETT, JAMES R.**, *University of Iowa, Iowa City, Iowa*, Digital Angiography
- BERSANO-BEGEY, TOMMASO**, *University of Michigan, Ann Arbor, Michigan*, Microbioreactors
- BIGGS, PETER J.**, *Harvard Medical School, Boston, Massachusetts*, Radiotherapy, Intraoperative
- BIYANI, ASHOK**, *University of Toledo, and Medical College of Ohio, Toledo, Ohio*, Human Spine, Biomechanics of
- BLOCK, W.F.**, *University of Wisconsin-Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- BLUE, THOMAS E.**, *The Ohio State University, Columbus, Ohio*, Boron Neutron Capture Therapy
- BLUMSACK, JUDITH T.**, *Disorders Auburn University, Auburn, Alabama*, Audiometry
- BOGAN, RICHARD K.**, *University of South Carolina, Columbia, South Carolina*, Sleep Laboratory
- BOKROS, JACK C.**, *Medical Carbon Research Institute, Austin, Texas*, Biomaterials, Carbon
- BONGIOANNINI, GUIDO**, *ENT Division Mauriziano Hospital, Torino, Italy*, Laryngeal Prosthetic Devices
- BORAH, JOSHUA**, *Applied Science Laboratories, Bedford, Massachusetts*, Eye Movement, Measurement Techniques for
- BORDEN, MARK**, *Director of Biomaterials Research, Irvine, California*, Biomaterials, Absorbable
- BORTON, BETTIE B.**, *Auburn University Montgomery, Montgomery, Alabama*, Audiometry
- BORTON, THOMAS E.**, *Auburn University Montgomery, Montgomery, Alabama*, Audiometry
- BOSE SUSMITA.**, *Washington State University, Pullman, Washington*, Orthopedic Devices, Materials and Design for
- BOVA, FRANK J.**, *M. D. Anderson Cancer Center Orlando, Orlando, FL*, Radiosurgery, Stereotactic
- BRENNER, DAVID J.**, *Columbia University Medical Center, New York, New York*, Computed Tomography Screening
- BREWER, JOHN M.**, *University of Georgia*, Electrophoresis
- BRIAN, L. DAVIS**, *Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio*, Skin, Biomechanics of
- BRITT, L.D.**, *Eastern Virginia Medical School, Norfolk, Virginia*, Gastrointestinal Hemorrhage
- BRITT, R.C.**, *Eastern Virginia Medical School, Norfolk, Virginia*, Gastrointestinal Hemorrhage
- BROZIK, SUSAN M.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- BRUNER, JOSEPH P.**, *Vanderbilt University Medical Center, Nashville, Tennessee*, Intrauterine Surgical Techniques
- BRUNSWIG NEWRING, KIRK A.**, *University of Nevada, Reno, Nevada*, Sexual Instrumentation
- BRUYANT, PHILIPPE P.**, *University of Massachusetts, North Worcester, Massachusetts*, Nuclear Medicine, Computers in
- BUNNELL, BERT J.**, *Bunnell Inc., Salt Lake City, Utah*, High Frequency Ventilation
- CALKINS, JERRY M.**, *Defense Research Technologies, Inc., Rockville, Maryland*, Medical Gas Analyzers
- CANNON, MARK**, *Northwestern University, Chicago, Illinois*, Resin-Based Composites

- CAPPELLERI, JOSEPH C.**, *Pfizer Inc., Groton, Connecticut*, Quality-of-Life Measures, Clinical Significance of
- CARDOSO, JORGE**, *University of Madeira, Funchal, Portugal*, Office Automation Systems
- CARELLO, MASSIMILIANA**, *Politecnico di Torino – Department of Mechanics, Laryngeal Prosthetic Devices*
- CASKEY, THOMAS C.**, *Cogene Biotech Ventures, Houston, Texas*, Polymerase Chain Reaction
- CECCIO, STEVEN**, *University of Michigan, Ann Arbor, Michigan*, Heart Valve Prostheses, In Vitro Flow Dynamics of
- CHAN, JACKIE K.**, *Columbia University, New York, New York*, Photography, Medical
- CHANDRAN, K.B.**, *University of Iowa, Iowa City, Iowa*, Heart Valve Prostheses
- CHATZANDROULIS, S.**, *NTUA, Athens, Attiki, Greece*, Capacitive Microsensors for Biomedical Applications
- CHAVEZ, ELIANA**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CHEN, HENRY**, *Stanford University, Palo Alto, California*, Exercise Stress Testing
- CHEN, JIANDE**, *University of Texas Medical Branch, Galveston, Texas*, Electrogastrogram
- CHEN, YAN**, *Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio*, Skin, Biomechanics of
- CHEYNE, DOUGLAS**, *Hospital for Sick Children Research Institute, Biomagnetism*
- CHUI, CHEN-SHOU**, *Memorial Sloan-Kettering Cancer Center, New York, New York*, Radiation Therapy Treatment Planning, Monte Carlo Calculations in
- CLAXTON, NATHAN S.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- CODERRE, JEFFREY A.**, *Massachusetts Institute of Technology, Cambridge, Massachusetts*, Boron Neutron Capture Therapy
- COLLINS, BETH**, *University of Mississippi Medical Center, Jackson, Mississippi*, Hyperbaric Medicine
- COLLINS, DIANE**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CONSTANTINOU, C.**, *Columbia University Radiation Oncology, New York, New York*, Phantom Materials in Radiology
- COOK, ALBERT**, *University of Alberta, Edmonton, Alberta, Canada*, Communication Devices
- COOPER, RORY**, *University of Pittsburgh, Pittsburgh, Pennsylvania*, Mobility Aids
- CORK, RANDALL C.**, *Louisiana State University, Shreveport, Louisiana*, Monitoring, Umbilical Artery and Vein, Blood Gas Measurements; Transcutaneous Electrical Nerve Stimulation (TENS); Ambulatory Monitoring
- COX, JOSEPHINE H.**, *Walter Reed Army Institute of Research, Rockville, Maryland*, Blood Collection and Processing
- CRAIG, LEONARD**, *Feinberg School of Medicine of Northwestern University, Chicago, Illinois*, Ventilators, Acute Medical Care
- CRESS, CYNTHIA J.**, *University of Nebraska, Lincoln, Nebraska*, Communicative Disorders, Computer Applications for
- CUMMING, DAVID R.S.**, *University of Glasgow, Glasgow, United Kingdom*, Ion-Sensitive Field-Effect Transistors
- CUNNINGHAM, JOHN R.**, *Camrose, Alberta, Canada*, Cobalt 60 Units for Radiotherapy
- D'ALESSANDRO, DAVID**, *Montefiore Medical Center, Bronx, New York*, Heart-Lung Machines
- D'AMBRA, MICHAEL N.**, *Harvard Medical School, Cambridge, Massachusetts*, Cardiac Output, Thermodilution Measurement of
- DADSETAN, MAHROKH**, *Mayo Clinic, College of Medicine, Rochester, Minnesota*, Microscopy, Electron
- DALEY, MICHAEL L.**, *The University of Memphis, Memphis, Tennessee*, Monitoring, Intracranial Pressure
- DAN, LOYD**, *Linköping University, Linköping, Sweden*, Thermocouples
- DAS, RUPAK**, *University of Wisconsin, Madison, Wisconsin*, Brachytherapy, High Dosage Rate
- DATTAWADKAR, AMRUTA M.**, *University of Wisconsin, Madison, Madison, Wisconsin*, Ocular Fundus Reflectometry
- DAVIDSON, MICHAEL W.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- DE LUCA, CARLO**, *Boston University, Boston, Massachusetts*, Electromyography
- DE SALLES, ANTONIO A.F.**, *UCLA Medical School, Los Angeles, California*, Stereotactic Surgery
- DECAU, SABIN**, *University of Maryland, School of Medicine*, Shock, Treatment of
- DECHOW, PAUL C.**, *A & M University Health Science Center, Dallas, Texas*, Strain Gages
- DELBEKE, JEAN**, *Catholique University of Louvain, Brussels, Belgium*, Visual Prostheses
- DELL'OSSO, LOUIS F.**, *Case Western Reserve University, Cleveland, Ohio*, Ocular Motility Recording and Nystagmus
- DELORME, ARNAUD**, *University of San Diego, La Jolla, California*, Statistical Methods
- DEMENKOFF, JOHN**, *Mayo Clinic, Scottsdale, Arizona*, Pulmonary Physiology
- DEMIR, SEMAHAT S.**, *The University of Memphis and The University of Tennessee Health Science Center, Memphis, Tennessee*, Electrophysiology
- DEMLING, ROBERT H.**, *Harvard Medical School*, Skin Substitute for Burns, Bioactive
- DENNIS, MICHAEL J.**, *Medical University of Ohio, Toledo, Ohio*, Computed Tomography
- DESANTI, LESLIE**, *Harvard Medical School*, Skin Substitute for Burns, Bioactive
- DEUTSCH, STEVEN**, *Pennsylvania State University, University Park, Pennsylvania*, Flowmeters
- DEVINENI, TRISHUL**, *Conemaugh Health System*, Biofeedback
- DI BELLA EDWARD, V.R.**, *University of Utah*, Tracer Kinetics
- DIKIDES, NICHOLAS A.**, *Advanced Concepts Analysis, Inc., Falls Church, Virginia*, Thermography
- DOLAN, PATRICIA L.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- DONOVAN, F.M.**, *University of South Alabama*, Cardiac Output, Indicator Dilution Measurement of
- DOUGLAS, WILSON R.**, *Children's Hospital of Philadelphia, Philadelphia, Pennsylvania*, Intrauterine Surgical Techniques
- DRAPER, CRISSA**, *University of Nevada, Reno, Nevada*, Sexual Instrumentation
- DRZEWIECKI, TADEUSZ M.**, *Defense Research Technologies, Inc., Rockville, Maryland*, Medical Gas Analyzers
- DURFEE, W.K.**, *University of Minnesota, Minneapolis, Minnesota*, Rehabilitation and Muscle Testing
- DYRO, JOSEPH F.**, *Setauket, New York*, Safety Program, Hospital

- DYSON, MARY**, *Herts, United Kingdom*, Heat and Cold, Therapeutic
- ECKERLE, JOSEPH S.**, *SRI International, Menlo Park, California*, Tonometry, Arterial
- EDWARDS, BENJAMIN**, *University of Wisconsin-Madison, Madison, Wisconsin*, Codes and Regulations: Radiation
- EDWARDS, THAYNE L.**, *University of Washington, Seattle, Washington*, Chromatography
- EKLUND, ANDERS**, *University of Illinois at Chicago, Chicago, Illinois*, Hydrocephalus, Tools for Diagnosis and Treatment of
- EL SOLH, ALI A.**, *Erie County Medical Center, Buffalo, New York*, Sleep Studies, Computer Analysis of
- ELMAYERGI, NADER**, *McMaster University, Hamilton, Ontario, Canada*, Bladder Dysfunction, Neurostimulation of
- ELSHARYDAH, AHMAD**, *Louisiana State University, Baton Rouge, Louisiana*, Ambulatory Monitoring; Monitoring, Umbilical Artery and Vein, Blood Gas Measurements
- FADDY, STEVEN C.**, *St. Vincents Hospital, Sydney, Darlinghurst, Australia*, Cardiac Output, Fick Technique for
- FAHEY, FREDERIC H.**, *Childrens Hospital Boston*, Computed Tomography, Single Photon Emission
- FAIN, S.B.**, *University of Wisconsin-Madison, Madison, Wisconsin*, Magnetic Resonance Imaging
- FELDMAN, JEFFREY**, *Childrens Hospital of Philadelphia, Philadelphia, Pennsylvania*, Anesthesia Machines
- FELLERS, THOMAS J.**, *The Florida State University, Tallahassee, Florida*, Microscopy, Confocal
- FERRARA, LISA**, *Cleveland Clinic Foundation, Cleveland, Ohio*, Human Spine, Biomechanics of
- FERRARI, MAURO**, *The Ohio State University, Columbus, Ohio*, Drug Delivery Systems
- FONTAINE, ARNOLD A.**, *Pennsylvania State University, University Park, Pennsylvania*, Flowmeters
- FOUST, MILTON J., JR.**, *Medical University of South Carolina Psychiatry and Behavioral Sciences, Charleston, South Carolina*, Electroconvulsive Therapy
- FRASCO, PETER**, *Mayo Clinic Scottsdale, Scottsdale, Arizona*, Temperature Monitoring
- FRAZIER, JAMES**, *Louisiana State University, Baton Rouge, Louisiana*, Ambulatory Monitoring
- FREISLEBEN DE BLASIO, BIRGITTE**, *University of Oslo, Oslo, Norway*, Impedance Spectroscopy
- FRESTA, MASSIMO**, *University of Catanzaro Magna Græcia, Germaneto (CZ), Italy*, Drug Delivery Systems
- FREYTES, DONALD O.**, *McGowan Institute for Regenerative Medicine, Pittsburgh Pennsylvania*, Sterilization of Biologic Scaffold Materials
- FROELICHER, VICTOR**, *VA Medical Center, Palo Alto, California*, Exercise Stress Testing
- FUNG, EDWARD K.**, *Columbia University, New York, New York*, Photography, Medical
- GAGE, ANDREW A.**, *State University of New York at Buffalo, Buffalo, New York*, Cryosurgery
- GAGLIO, PAUL J.**, *Columbia University College of Physicians and Surgeons*, Liver Transplantation
- GARDNER, REED M.**, *LDS Hospital and Utah University, Salt Lake City, Utah*, Monitoring, Hemodynamic
- GEJERMAN, GLEN**, *Hackensack University Medical, Hackensack, New Jersey*, Radiation Therapy, Quality Assurance in
- GEORGE, MARK S.**, *Medical University of South Carolina Psychiatry and Behavioral Sciences, Charleston, South Carolina*, Electroconvulsive Therapy
- GHARIEB, R.R.**, *Infinite Biomedical Technologies, Baltimore, Maryland*, Neurological Monitors
- GLASGOW, GLENN P.**, *Loyola University of Chicago, Maywood, Illinois*, Radiation Protection Instrumentation
- GLASGOW, GLENN**, *University of Wisconsin-Madison, Madison, Wisconsin*, Codes and Regulations: Radiation
- GOEL, VIJAY K.**, *University of Toledo, and Medical College of Ohio, Toledo, Ohio*, Human Spine, Biomechanics of
- GOETSCH, STEVEN J.**, *San Diego Gamma Knife Center, La Jolla, California*, Gamma Knife
- GOLDBERG, JAY R.**, *Marquette University Milwaukee, Wisconsin*, Minimally Invasive Surgery
- GOLDBERG, ZELENNA**, *Department of Radiation Oncology, Davis, California*, Ionizing Radiation, Biological Effects of
- GOPALAKRISHNAKONE, P.**, *National University of Singapore, Singapore*, Immunologically Sensitive Field-Effect Transistors
- GOPAS, JACOB**, *Ben Gurion University of the Negev, Beer Sheva, Israel*, Monoclonal Antibodies
- GORGULHO, ALESSANDRA**, *UCLA Medical School, Los Angeles, California*, Stereotactic Surgery
- GOUGH, DAVID A.**, *University of California, La Jolla, California*, Glucose Sensors
- GOUSTOURIDIS, D.**, *NTUA, Athens, Attiki, Greece*, Capacitive Microsensors for Biomedical Applications
- GRABER, HARRY L.**, *State University of New York Downstate Medical Center, Brooklyn, New York*, Peripheral Vascular Noninvasive Measurements
- GRACA, M.**, *Louisiana State University, Baton Rouge, Louisiana*, Boron Neutron Capture Therapy
- GRANT, WALTER III**, *Baylor College of Medicine, Houston, Texas*, Radiation Therapy, Intensity Modulated
- GRAYDEN, EDWARD**, *Mayo Health Center, Albertlea, Minnesota*, Cardiopulmonary Resuscitation
- GREEN, JORDAN R.**, *University of Nebraska, Lincoln, Nebraska*, Communicative Disorders, Computer Applications for
- HAEMMERICH, DIETER**, *Medical University of South Carolina, Charleston, South Carolina*, Tissue Ablation
- HAMAM, HABIB**, *Université de Moncton, Moncton New Brunswick, Canada*, Lenses, Intraocular
- HAMMOND, PAUL A.**, *University of Glasgow, Glasgow, United Kingdom*, Ion-Sensitive Field-Effect Transistors
- HANLEY, JOSEPH**, *Hackensack University Medical, Hackensack, New Jersey*, Radiation Therapy, Quality Assurance in
- HARLEY, BRENDAN A.**, *Massachusetts Institute of Technology*, Skin Tissue Engineering for Regeneration
- HARPER, JASON C.**, *Sandia National Laboratories, Albuquerque, New Mexico*, Microbial Detection Systems
- HASMAN, ARIE**, *Maastricht, The Netherlands*, Medical Education, Computers in
- HASSOUNA, MAGDY**, *Toronto Western Hospital, Toronto, Canada*, Bladder Dysfunction, Neurostimulation of
- HAYASHI, KOZABURO**, *Okayama University of Science, Okayama, Japan*, Arteries, Elastic Properties of
- HENCH, LARRY L.**, *Imperial College London, London, United Kingdom*, Biomaterials: Bioceramics
- HETRICK, DOUGLAS A., Sr.** *Principal Scientist Medtronic, Inc., Minneapolis, Minnesota*, Bioimpedance in Cardiovascular Medicine
- HIRSCH-KUCHMA, MELISSA**, *University of Central Florida NanoScience Technology Center, Orlando, Florida*, Biosurface Engineering

- HOLDER, GRAHAM E.**, *Moorfields Eye Hospital, London, United Kingdom*, Electroretinography
- HOLMES, TIMOTHY**, *St. Agnes Cancer Center, Baltimore, Maryland*, Tomotherapy
- HONEYMAN-BUCK, JANICE C.**, *University of Florida, Gainesville, Florida*, Radiology Information Systems
- HOOPER, BRETT A.**, *Areté Associates, Arlington, Virginia*, Endoscopes

- HORNER, PATRICIA I.**, *Biomedical Engineering Society Landover, Maryland*, Medical Engineering Societies and Organizations
- HOWITZ, PAUL M.**, *University of Texas, San Antonio, Texas*, Fluorescence Measurements
- HOU, XIAOLIN**, *Risø National Laboratory, Roskilde, Denmark*, Neutron Activation Analysis
- HOVORKA, ROMAN**, *University of Cambridge, Cambridge, United Kingdom*, Pancreas, Artificial
- HUANG, H.K.**, *University of Southern California*, Teleradiology
- HUNT, ALAN J.**, *University of Michigan, Ann Arbor, Michigan*, Optical Tweezers
- HUTTEN, HELMUT**, *University of Technology, Graz, Australia*, Impedance Plethysmography
- LAIZZO, P.A.**, *University of Minnesota, Minneapolis, Minnesota*, Rehabilitation and Muscle Testing
- IBBOTT, GEOFFREY S.**, *Anderson Cancer Center, Houston, Texas*, Radiation Dosimetry, Three-Dimensional
- INGHAM, E.**, *University of Leeds, Leeds, United Kingdom*, Hip Joints, Artificial
- ISIK, CAN**, *Syracuse University, Syracuse, New York*, Blood Pressure Measurement
- JAMES, SUSAN P.**, *Colorado State University, Fort Collins, Colorado*, Biomaterials: Polymers
- JENSEN, WINNIE**, *Aalborg University, Aalborg, Denmark*, Electroneurography
- JIN, CHUNMING**, *North Carolina State University, Raleigh, North Carolina*, Biomaterials, Corrosion and Wear of
- JIN, Z.M.**, *University of Leeds, Leeds, United Kingdom*, Hip Joints, Artificial
- JOHNSON, ARTHUR T.**, *University of Maryland College Park, Maryland*, Medical Engineering Societies and Organizations
- JONES, JULIAN R.**, *Imperial College London, London, United Kingdom*, Biomaterials: Bioceramics
- JOSHI, ABHIJEET**, *Abbott Spine, Austin, Texas*, Spinal Implants
- JUNG, RANU**, *Arizona State University, Tempe, Arizona*, Functional Electrical Stimulation
- JURISSON, SILVIA S.**, *University of Missouri Columbia, Missouri*, Radionuclide Production and Radioactive Decay
- KAEDING, PATRICIA J.**, *Godfrey & Kahn S.C., Madison, Wisconsin*, Codes and Regulations: Medical Devices
- KAMATH, CELIA C.**, *Mayo Clinic, Rochester, Minnesota*, Quality-of-Life Measures, Clinical Significance of
- KANE, MOLLIE**, *Madison, Wisconsin*, Contraceptive Devices
- KATHERINE, ANDRIOLE P.**, *Harvard Medical School, Boston, Massachusetts*, Picture Archiving and Communication Systems
- KATSAGGELOS, AGGELOS K.**, *Northwestern University, Evanston, Illinois*, DNA Sequencing
- KATZ, J. LAWRENCE**, *University of Missouri-Kansas City, Kansas City, Missouri*, Bone and Teeth, Properties of
- KESAVAN, SUNIL**, *Akebono Corporation, Farmington Hills, Michigan*, Linear Variable Differential Transformers
- KHANG, GILSON**, *Chonbuk National University*, Biomaterials: Tissue Engineering and Scaffolds
- KHAODHIAR, LALITA**, *Harvard Medical School, Boston, Massachusetts*, Cutaneous Blood Flow, Doppler Measurement of
- KIM, MOON SUK**, *Korea Research Institutes of Chemical Technology*, Biomaterials: Tissue Engineering and Scaffolds
- KIM, YOUNG KON**, *Inje University, Kimhae City, Korea*, Alloys, Shape Memory
- KINDWALL, ERIC P.**, *St. Luke's Medical Center, Milwaukee, Wisconsin*, Hyperbaric Oxygenation
- KING, MICHAEL A.**, *University of Massachusetts, North Worcester, Massachusetts*, Nuclear Medicine, Computers in
- KLEBE, ROBERT J.**, *University of Texas, San Antonio, Texas*, Fluorescence Measurements
- KLEIN, BURTON**, *Burton Klein Associates, Newton, Massachusetts*, Gas and Vacuum Systems, Centrally Piped Medical
- KNOPER, STEVEN R.**, *University of Arizona College of Medicine*, Ventilatory Monitoring
- KONTAXAKIS, GEORGE**, *Universidad Politécnica de Madrid, Madrid, Spain*, Positron Emission Tomography
- KOTTKE-MARCHANT, KANDICE**, *The Cleveland Clinic Foundation, Cleveland, Ohio*, Vascular Graft Prosthesis
- KRIPFGANS, OLIVER**, *University of Michigan, Ann Arbor, Michigan*, Ultrasonic Imaging
- KULKARNI, AMOL D.**, *University of Wisconsin-Madison, Madison, Wisconsin*, Ocular Fundus Reflectometry, Visual Field Testing
- KUMARADAS, J. CARL**, *Ryerson University, Toronto, Ontario, Canada*, Hyperthermia, Interstitial
- KUNICKA, JOLANTA**, *Bayer HealthCare LLC, Tarrytown, New York*, Differential Counts, Automated
- KWAK, KWANJ JOO**, *University of Miami Miller School of Medicine, Miami, Florida*, Microscopy, Scanning Force
- LAKES, RODERIC**, *University of Wisconsin-Madison*, Bone and Teeth, Properties of
- LAKKIREDDY, DHANUNJAYA**, *The Cleveland Clinic Foundation, Cleveland, Ohio*, Hyperthermia, Ultrasonic
- LARSEN, COBY**, *Case Western Reserve University, Cleveland, Ohio*, Vascular Graft Prosthesis
- LASTER, BRENDA H.**, *Ben Gurion University of the Negev, Beer Sheva, Israel*, Monoclonal Antibodies
- LATTA, LOREN**, *University of Miami, Coral Gables, Florida*, Rehabilitation, Orthotics in
- LEDER, RON S.**, *Universidad Nacional Autonoma de Mexico Mexico, Distrito Federal*, Continuous Positive Airway Pressure
- LEE, CHIN**, *Harvard Medical School, Boston, Massachusetts*, Radiotherapy Treatment Planning, Optimization of; Hyperthermia, Interstitial
- LEE, HAI BANG**, *Korea Research Institutes of Chemical Technology*, Biomaterials: Tissue Engineering and Scaffolds
- LEE, SANG JIN**, *Korea Research Institutes of Chemical Technology*, Biomaterials: Tissue Engineering and Scaffolds
- LEI, LIU**, *Department of General Engineering, Urbana, Illinois*, Bioinformatics

- LEI, XING**, *Stanford University, Stanford, California*, Radiation Dose Planning, Computer-Aided
- LEWIS, MATTHEW C.**, *Medical College of Wisconsin, Milwaukee, Wisconsin*, Hyperbaric Oxygenation
- LI, CHAODI**, *University of Notre Dame, Notre Dame, Indiana*, Bone Cement, Acrylic
- LI, JONATHAN G.**, *University of Florida, Gainesville, Florida*, Radiation Dose Planning, Computer-Aided
- LI, QIAO**, *University of Michigan, Ann Arbor, Michigan*, Immunotherapy
- LI, YANBIN**, *University of Arkansas, Fayetteville, Arkansas*, Piezoelectric Sensors
- LIBOFF, A.R.**, *Oakland University, Rochester, Michigan*, Bone Ununited Fracture and Spinal Fusion, Electrical Treatment of
- LIGAS, JAMES**, *University of Connecticut, Farmington, Connecticut*, Respiratory Mechanics and Gas Exchange
- LIMOGE, AIME**, *The René Descartes University of Paris, Paris, France*, Electroanalgesia, Systemic
- LIN, PEI-JAN PAUL**, *Beth Israel Deaconess Medical Center, Boston, Massachusetts*, Mammography
- LIN, ZHIYUE**, *University of Kansas Medical Center, Kansas City, Kansas*, Electrogastrogram
- LINEAWEAVER, WILLIAM C.**, *University of Mississippi Medical Center, Jackson, Mississippi*, Hyperbaric Medicine
- LIPPING, TARMO**, *Tampere University of Technology, Pori, Finland*, Monitoring in Anesthesia
- LIU, XIAOHUA**, *The University of Michigan, Ann Arbor, Michigan*, Polymeric Materials
- LLOYD, J.J.**, *Regional Medical Physics Department, Newcastle-upon-Tyne, United Kingdom*, Ultraviolet Radiation in Medicine
- LOEB, ROBERT**, *University of Arizona, Tucson, Arizona*, Anesthesia Machines
- LOPES DE MELO, PEDRO**, *State University of Rio de Janeiro, Terreo Salas, Maracaná, Thermistors*
- LOUDON, ROBERT G.**, Lung Sounds
- LOW, DANIEL A.**, *Washington University School of Medicine, St. Louis, Missouri*, Radiation Therapy Simulator
- LU, LICHUN**, *Mayo Clinic, College of Medicine, Rochester, Minnesota*, Microscopy, Electron
- LU, ZHENG FENG**, *Columbia University, New York, New York*, Screen-Film Systems
- LYON, ANDREW W.**, *University of Calgary, Calgary, Canada*, Flame Atomic Emission Spectrometry and Atomic Absorption Spectrometry
- LYON, MARTHA E.**, *University of Calgary, Calgary, Canada*, Flame Atomic Emission Spectrometry and Atomic Absorption Spectrometry
- MA, C-M CHARLIE**, *Fox Chase Cancer Center, Philadelphia, Pennsylvania*, X-Ray Therapy Equipment, Low and Medium Energy
- MACIA, NARCISO F.**, *Arizona State University at the Polytechnic Campus, Mesa, Arizona*, Pneumotachometers

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

LIST OF ARTICLES

ALLOYS, SHAPE MEMORY
AMBULATORY MONITORING
ANALYTICAL METHODS, AUTOMATED
ANESTHESIA MACHINES
ANESTHESIA, COMPUTERS IN
ANGER CAMERA
ANORECTAL MANOMETRY
ARRHYTHMIA ANALYSIS, AUTOMATED
ARTERIES, ELASTIC PROPERTIES OF
AUDIOMETRY
BIOCOMPATIBILITY OF MATERIALS
BIOELECTRODES
BIOFEEDBACK
BIOHEAT TRANSFER
BIOIMPEDANCE IN CARDIOVASCULAR MEDICINE
BIOINFORMATICS
BIOMAGNETISM
BIOMATERIALS, ABSORBABLE
BIOMATERIALS: AN OVERVIEW
BIOMATERIALS: BIOCERAMICS
BIOMATERIALS: CARBON
BIOMATERIALS, CORROSION AND WEAR OF
BIOMATERIALS FOR DENTISTRY
BIOMATERIALS: POLYMERS

ABBREVIATIONS AND ACRONYMS

AAMI	Association for the Advancement of Medical Instrumentation	ALS	Advanced life support; Amyotropic lateral sclerosis
AAPM	American Association of Physicists in Medicine	ALT	Alanine aminotransferase
ABC	Automatic brightness control	ALU	Arithmetic and logic unit
ABET	Accreditation board for engineering training	AM	Amplitude modulation
ABG	Arterial blood gases	AMA	American Medical Association
ABLB	Alternative binaural loudness balance	amu	Atomic mass units
ABS	Acrylonitrile–butadiene–styrene	ANOVA	Analysis of variance
ac	Alternating current	ANSI	American National Standards Institute
AC	Abdominal circumference; Affinity chromatography	AP	Action potential; Alternative pathway; Anteroposterior
ACA	Automated clinical analyzer	APD	Anterioposterior diameter
ACES	Augmentative communication evaluation system	APL	Adjustable pressure limiting valve; Applied Physics Laboratory
ACL	Anterior chamber lens	APR	Anatomically programmed radiography
ACLS	Advanced cardiac life support	AR	Amplitude reduction; Aortic regurgitation; Autoregressive
ACOG	American College of Obstetrics and Gynecology	Ara-C	Arabinosylcytosine
ACR	American College of Radiology	ARD	Absorption rate density
ACS	American Cancer Society; American College of Surgeons	ARDS	Adult respiratory distress syndrome
A/D	Analog-to-digital	ARGUS	Arrhythmia guard system
ADC	Agar diffusion chambers; Analog-to-digital converter	ARMA	Autoregressive-moving-average model
ADCC	Antibody-dependent cellular cytotoxicity	ARMAX	Autoregressive-moving-average model with external inputs
ADCL	Accredited Dosimetry Calibration Laboratories	AS	Aortic stenosis
ADP	Adenosine diphosphate	ASA	American Standards Association
A-D-T	Admission, discharge, and transfer	ASCII	American standard code for information interchange
AE	Anion exchange; Auxiliary electrode	ASD	Antisiphon device
AEA	Articulation error analysis	ASHE	American Society for Hospital Engineering
AEB	Activation energy barrier	ASTM	American Society for Testing and Materials
AEC	Automatic exposure control	AT	Adenosine-thiamide; Anaerobic threshold; Antithrombin
AED	Automatic external defibrillator	ATA	Atmosphere absolute
AEMB	Alliance for Engineering in Medicine and Biology	ATLS	Advanced trauma life support
AES	Auger electron spectroscopy	ATN	Acute tubular necrosis
AESC	American Engineering Standards Committee	ATP	Adenosine triphosphate
AET	Automatic exposure termination	ATPD	Ambient temperature pressure dry
AFO	Ankle-foot orthosis	ATPS	Ambient temperature pressure saturated
AGC	Automatic gain control	ATR	Attenuated total reflection
AHA	American Heart Association	AUC	Area under curve
AI	Arterial insufficiency	AUMC	Area under moment curve
AICD	Automatic implantable cardiac defibrillator	AV	Atrioventricular
AID	Agency for International Development	AZT	Azido thymidine
AIDS	Acquired immune deficiency syndrome	BA	Biliary atresia
AL	Anterior leaflet	BAEP	Brainstem auditory evoked potential
ALG	Antilymphocyte globulin	BAPN	Beta-amino-propionitril
		BAS	Boston anesthesia system
		BASO	Basophil
		BB	Buffer base
		BBT	Basal body temperature

BCC	Body-centered cubic	CCTV	Closed circuit television system
BCD	Binary-coded decimal	CCU	Coronary care unit; Critical care unit
BCG	Ballistocardiogram	CD	Current density
BCLS	Basic cardiac life support	CDR	Complimentary determining region
BCRU	British Committee on Radiation Units and Measurements	CDRH	Center for Devices and Radiological Health
BDI	Beck depression inventory	CEA	Carcinoembryonic antigen
BE	Base excess; Binding energy	CF	Conversion factor; Cystic fibrosis
BET	Brunauer, Emmett, and Teller methods	CFC	Continuous flow cytometer
BH	His bundle	CFR	Code of Federal Regulations
BI	Biological indicators	CFU	Colony forming units
BIH	Beth Israel Hospital	CGA	Compressed Gas Association
BIPM	International Bureau of Weights and Measurements	CGPM	General Conference on Weights and Measures
BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMi	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDI	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCMII	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength
RTT	Revised token test	SISI	Short increment sensitivity index
r.v.	Random variable	SL	Surgical lithotomy
RV	Residual volume; Right ventricle	SLD	Sublethal damage
RVH	Right ventricular hypertrophy	SLE	Systemic lupus erythemotodes
RVOT	Right ventricular outflow tract	SMA	Sequential multiple analyzer
RZ	Return-to-zero	SMAC	Sequential multiple analyzer with computer
SA	Sinoatrial; Specific absorption	SMR	Sensorimotor
SACH	Solid-ankle-cushion-heel	S/N	Signal-to-noise
SAD	Source-axis distance; Statistical Analysis System	S:N/D	Signal-to-noise ratio per unit dose
SAINT	System analysis of integrated network of tasks	SNP	Sodium nitroprusside
SAL	Sterility assurance level; Surface averaged lead	SNR	Signal-to-noise ratio
SALT	Systematic analysis of language transcripts	SOA	Sources of artifact
SAMI	Socially acceptable monitoring instrument	SOAP	Subjective, objective, assessment, plan
SAP	Systemic arterial pressure	SOBP	Spread-out Bragg peak
SAR	Scatter-air ratio; Specific absorption rate	SP	Skin potential
SARA	System for anesthetic and respiratory gas analysis	SPECT	Single photon emission computed tomography
SBE	Subbacterial endocarditis	SPL	Sound pressure level
SBR	Styrene-butadiene rubbers	SPRINT	Single photon ring tomograph
SC	Stratum corneum; Subcommittees	SPRT	Standard platinum resistance thermometer
SCAP	Right scapula	SPSS	Statistical Package for the Social Sciences
SCE	Saturated calomel electrode; Sister chromatid exchange	SQUID	Superconducting quantum interference device

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

§Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

NANOPARTICLES

O.V. SALATA
University of Oxford
Oxford, United Kingdom

INTRODUCTION

Nanoparticle (From a Greek word “ο νάνος” meaning “dwarf”), “nano” is a prefix defining a billion times reduction (10^{-9}) in magnitude. Intuitively, a nanoparticle is an object that is a “nano” times smaller than just a particle. The generally accepted size range for the objects to be called “nanoparticles” is between 1 and 100 nm in at least in two dimensions. This broad definition can be narrowed by defining a nanoparticle of a certain material as a particle that is smaller than a critical size for this material (Fig. 1). The critical size is defined as a cross-point size for the transition from bulk to sized-dependent material property or properties, for example, solubility, melting point, magnetization, light absorption, and fluorescence. The actual value of the critical size depends on the strength of the interatomic or intermolecular forces. The weaker the forces, the weaker the overall interactions between the atoms in the particle. It is known from quantum mechanics that an atom or molecule can be characterized by a set of permitted electron energy levels. Those energy levels define physical and chemical properties of atoms and molecules. When two identical atoms are brought into proximity, they would experience both repulsing and attracting forces. An equilibrium distance might exist where the two forces are balanced. A new molecule containing two atoms will have a system of energy levels that is similar to that of the initial atoms, but each level will be split into two sublevels. The energy gap between the two closest sublevels in this molecule will now be smaller than the corresponding smallest energy gap in one atom. Each time a new atom is added, a new set of energy sublevels will be formed. The energy gap will be changing in value with the number of atoms used to build a nanoparticle, and because properties of the nanoparticle will depend on the energy gap, it will also depend on its size. Then millions of the same atoms form a bulk material; these energy sublevels are saturated and broadened into the energy bands that are insensitive to the changes in the number of atoms composing the solid body. Another component affecting the critical size of the nanoparticle is its surface-to-volume ratio. The smaller the size of the particle, the higher the proportion of the total number of atoms or molecules that are positioned at the surface. The surface atoms often have unsaturated or dangling bonds, leading to the high reactivity and catalytic ability of the nanoparticles. It also results in the restructuring and rearrangement of the crystal lattice near the surface. All of this affects the size-dependent properties of nanomaterials.

Nanoparticles can be made out of any material, including metals, ceramics, semiconductors, polymers, and biomolecules. They can possess a complex structure, which might contain a combination of different materials, or have a complex shape. Nanometer-sized objects that include nanoparticles fall in the realm of nanotechnology. Nanotechnology is developing in several directions: nanomaterials, nanodevices, and nanosystems. The nanomaterials/particles level is the most advanced currently, both in scientific knowledge and in commercial applications. Nanobiotechnology is a subfield of nanotechnology that deals with the applications of nanotechnology to biology. Understanding of biological processes on the nanoscale level is a strong driving force behind development of nanobiotechnology. Living organisms are built of cells that are typically more than $10\ \mu\text{m}$ across. However, the cell-forming components are much smaller and are in the submicron size domain. Even smaller are the proteins with a typical size of just 5 nm, which is comparable with the dimensions of the smallest manmade nanoparticles. This simple size comparison gives an idea of using nanoparticles as very small probes (1) that would allow us to spy at the cellular machinery without introducing too much interference. Semiconductor nanoparticles, also known as “quantum dots” (2), show a strong dependence of their physical properties on their size. Just a decade ago, quantum dots were studied because of their size-dependent physical and chemical properties. One of the properties of the semiconductor nanoparticles that are changing with size is the color of their fluorescence, and now they are used as photostable fluorescent probes. As nanoparticles are rapidly taken up by all kinds of cells, they are also used in drug delivery. In pharmacology, the term “nanoparticles” specifically means polymer nanoparticles or, sometimes, submicron particles that carry a drug load (3). This term has been used in drug delivery for more than three decades. At about the same time, magnetic particles with submicron dimensions were employed for the first time to assist with cell separation. However, colloidal gold, which can be alternatively called “a dispersion of gold nanoparticles,” has been used in medicine for many decades if not centuries. Colloidal gold tinctures were used by alchemists to treat many illnesses. Colloidal gold was used as a contrast agent by the first optical microscopists as early as the 1600s. In the 1950s, work was started on the use of radioactive colloidal gold as a treatment for cancer (4). When functionalized with antibodies, gold nanoparticles are used to stain cellular organelles or membranes to create markers for the electron microscopy (5). Consequent decoration of the gold markers with silver assists in further signal magnification.

Out of a plethora of size-dependent physical properties available to someone who is interested in the practical side of nanomaterials, optical and magnetic effects are the most used for biological applications. Hybrid bionanomaterials

Figure 1. Nanoparticles are a state of matter intermediate between the bulk (size-independent properties) and atomic or molecular (fixed properties) form of the same material with its physical and chemical properties (such as melting temperature, solubility, optical absorbance and fluorescence, magnetization, catalytic activity, and specific chemical reactivity) being dependent on the particle size. The critical size for the transition from the bulk to the nano-regime can vary from tenths to just a few nanometers. A 100 nm threshold is a convenient size to use for a generalized description of the expected bulk-nanoparticle transition.

can also be applied to build novel electronic, optoelectronics, and memory devices.

NANOPARTICLE FABRICATION

Two general ways are available to a manufacturer to produce nanoparticles (Fig. 2). The first way is to start with a bulk material and then break it into smaller pieces using mechanical, chemical, or another form of energy (top-down). An opposite approach is to synthesize the material from atomic or molecular species via physical condensation of atomized materials (energy released), or chemical reactions (exo- or endothermic), allowing the precursor particles to grow in size (bottom-up). Both approaches can be done in gas, liquid, or solid states, or under a vacuum. Both the top-down and the bottom-up processes can be happening during the formation of nanoparticles at the same time, for example, during mechano-chemical ball milling process.

The more detailed classification of the nanoparticle manufacturing techniques relies on the combination of the form of energy with the type of the controlled environment. Each technique has its advantages and disadvantages. Most manufacturers are interested in the ability to control particle size, particle shape, size distribution, particle composition, and degree of particle agglomeration. Absence of contaminants, processing residues or solvents, and sterility are often required in the case of biological and medical applications of nanomaterials. The scale-up of the production volume is also very important. Hence, the discussion of the nanoparticle production techniques is limited to some of those that are currently being pursued by the manufacturers.

Ball Milling

Ball milling is a process where large spheres of the milling media crush substantially smaller powder particles (6). Normally it is used to make fine powder blends or to reduce the degree of powder agglomeration. High-energy ball milling is a more energetic form capable of breaking ceramics into nanoparticles. It is used to create nano-structured composites, highly supersaturated solid solutions, and

amorphous phases. The drawbacks of this technique include high energy consumption and poor control over particle sizes. A variation of high-energy ball milling is called mechano-chemical processing. Chemical reactions are mechanically activated during milling, forming nanoparticles via a bottom-up process from suitable precursors. A solid diluent's phase is used to separate the nanoparticles. In the pharmaceutical industry, wet ball milling is often used to produce nano-formulations of the drugs that are poorly soluble in their bulk form but acquire a much improved solubility when turned into nanoparticles.

Electro-Explosion

This process is used to generate 100 nm metal nanoparticles in the form of dry powders. Michael Faraday first observed it in 1773. It involves providing a very high current over a very short time through thin metallic wires, in either an inert or a reactive gas, such that extraordinary temperatures of 20,000 to 30,000 K are achieved. The wire is turned into plasma, contained, and compressed by the

Figure 2. Two basic approaches to nanomaterials fabrication: top-down (shown here from left to the right) and bottom-up (from right to the left). Usually, energy in one of its forms (mechanical, thermal, etc.) is supplied to the bulk matter to create new surfaces. Chemical synthesis of nanomaterials from the atomic or molecular species can be either exothermic or endothermic. Condensation of atoms under vacuum results in cluster formation accompanied by the release of energy.

electromagnetic field. After that, the resistance of the wire becomes so high that the current terminates. The disappearing of the electromagnetic field makes the plasma expand very rapidly. The extremely fast cooling rate results in stabilization of otherwise meta-stable materials. The powders made by electro-explosion have greater purity and reactivity as compared with the ball-milled powders. This technique is used, for example, to produce high surface area nano-porous filtering media benefiting from the enhanced bactericidal properties of silver nanoparticles.

Laser Ablation

In laser ablation, pulsed light from an excimer laser is focused onto a solid target inside a vacuum chamber to supply thermal energy that would “boil off” a plume of energetic atoms of the target material. A substrate positioned to intercept the plume will receive a thin film deposit of the target material. This phenomenon was first observed with a ruby laser in the mid-1960s. Because this process then contaminated the films made with particles, little use was found for such “dirty” samples. The laser ablation method has the following advantages for the fabrication of nanomaterials: The fabrication parameters can be easily changed in a wide range; nanoparticles are naturally produced in the laser ablation plume so that the production rate is relatively high; and virtually all materials can be evaporated by laser ablation.

Colloidal Chemistry

Two general colloidal chemistry approaches are available to control the formation and growth of the nanoparticles. One is called an arrested precipitation; it depends on exhaustion of one of the reactants or on the introduction of the chemical that would block the reaction. Another method relies on a physical restriction of the volume available for the growth of the individual nanoparticles by using various templates (7).

Any material containing regular nanosized pores or voids can be used as a template to form nanoparticles. Examples of such templates include porous alumina, zeolites, di-block copolymers, dendrimers, proteins, and other molecules. The template does not have to be a 3D object. Artificial templates can be created on a plane surface or a gas-liquid interface by forming self-assembled monolayers. The template is usually removed by dissolving it in the solvent that is not affecting the formed nanoparticles. The main advantages of the colloidal chemistry techniques for the preparation of nanomaterials are low temperature of processing, versatility, and flexible rheology. They also offer unique opportunities for preparation of organic-inorganic hybrid materials. The most commonly used precursors for inorganic nanoparticles are oxides and alcoxides.

Aerosols

As an alternative to liquids, chemical reactions can be carried out in a gaseous media, resulting in the formation of nanoparticles aerosols (8). Aerosols can be defined as solid or liquid particles in a gas phase, where the particles can range from molecules up to 100 μm in size. Aerosol

generation is driven by the pressure differential created with the help of compressed gases, vacuum, mechanical oscillations, or electrostatic forces acting on liquid. Aerosols were used in industrial manufacturing long before the basic science and engineering of the aerosols were understood. For example, carbon black particles used in pigments and reinforced car tires are produced by hydrocarbon combustion; titania pigment for use in paints and plastics is made by oxidation of titanium tetrachloride; fumed silica and titania formed from respective tetrachlorides by flame pyrolysis; and optical fibers are manufactured by a similar process. Aerosols are also widely used as a drug delivery technique.

Solvent Drying

This technique is frequently used to generate particles of soluble materials (9). Starting materials, for example, a drug and a stabilizing polymer, are dissolved in water-immiscible organic solvent, which is used to prepare an oil-in-water microemulsion. Water can be evaporated by heating under reduced pressure, leaving behind drug-loaded nanoparticles. Both nanospheres (uniform distribution of components) and nanocapsules (polymer encapsulated core) can be created with this method. A monomer can be used instead of the polymer, if the micelle polymerization step is possible. Solvent drying can be achieved via spray-drying step, where a homogeneous solution is fed to an aerosol generator, which produces uniformly sized droplets containing equal amounts of dissolved material. Solvent evaporation from the droplets under the right conditions would result in the formation of nanoparticles with a narrow size distribution.

Electro-Spinning

An emerging technology for the manufacture of thin polymer fibers is based on the principle of spinning dilute polymer solutions in a high-voltage electric field.

Electro-spinning is a process by which a suspended drop of polymer is charged with thousands of volts. At a characteristic voltage, the droplet forms a Taylor cone (the most stable shape with an apex angle of about 57°), and a fine jet of polymer releases from the surface in response to the tensile forces generated by the interaction of an applied electric field with the electrical charge carried by the jet. This produces a bundle of polymer fibers. The jet can be directed to a grounded surface and collected as a continuous web of fibers ranging in size from a few micrometers to less than 100 nm.

Self-Assembly (10)

The appropriate molecular building blocks can act as parts of a jigsaw puzzle that join in a perfect order without obvious driving force present. Various types of chemical bonding can be used to self-assemble nanoparticles. For example, electrostatic interaction between the oppositely charged polymers can be used to build multilayered nanocapsules, the difference in hydrophobicity between the different molecules in the mixture can lead to a formation of a 3D assembly, and proteins can be selected to self-assemble

into virus like nanoparticles. Another example is a use of artificially created oligonucleotides that can be designed to assemble in a variety of shapes and forms.

Nanoparticle Surface Treatment (11)

“Bare” nanoparticles of the same material would rapidly agglomerate with each other, forming bulk material. Encapsulating nanoparticles after production helps to maintain particle size and particle size distribution by inhibiting particle growth that can be caused by evaporation/redeposition, dissolution/precipitation, or surface migration and/or flocculation/aggregation/agglomeration. Encapsulation quenches the particle’s reactivity and reduces degradation of either the particle or the matrix that surrounds it. The encapsulating coating may be functionalized to facilitate dispersion into organic or aqueous liquid systems. Surface treatment with functional groups enables direct interaction between nanoparticles and resins. Typical functional groups are as follows:

- Acrylate
- Epoxide
- Amine
- Vinyl
- Isocyanate

The stability of the collected nanoparticle powders against agglomeration, sintering, and compositional changes can be ensured by collecting the nanoparticles in liquid suspension. For semiconductor particles, stabilization of the liquid suspension has been demonstrated by the addition of polar solvent; surfactant molecules have been used to stabilize the liquid suspension of metallic nanoparticles. Alternatively, inert silica encapsulation of nanoparticles by gas-phase reaction and by oxidation in colloidal solution has been shown to be effective for metallic nanoparticles.

When nanosized powders are dispersed in water, they aggregate due to attractive van der Waals forces. By altering the dispersing conditions, repulsive forces can be introduced between the particles to eliminate these aggregates. There are two ways of stabilizing nanoparticles. First, by adjusting the pH of the system, the nanoparticle surface charge can be manipulated such that an electrical double layer is generated around the particle. Overlap of two double layers on different nanoparticles causes repulsion and hence stabilization. The magnitude of this repulsive force can be measured via the zeta potential. The second method involves the adsorption of polymers onto the nanoparticles, such that the particles are physically prevented from coming close enough for the van der Waals attractive force to dominate; this is termed steric stabilization. The combination of two mechanisms is called electrosteric stabilization; it occurs when polyelectrolytes are adsorbed on the nanoparticle surface.

APPLICATIONS (12)

The fact that nanoparticles exist in the same size domain as proteins makes nanomaterials suitable for biotagging and

Figure 3. Schematic representation of an example of a bio-functionalized nanoparticle containing a magnetic core coated with a fluorescent layer, which, in turn, is coated by a thin protecting layer (e.g., silica). Linker molecules are attached to the protective layer at one end and to various functional molecules at the other.

payload delivery. However, size is just one of many characteristics of nanoparticles that it is rarely sufficient if one is to use nanoparticles as biological tags. To interact with a biological target, a biological or molecular coating or layer acting as a bioinorganic interface should be attached to the nanoparticle. Examples of biological coatings may include antibodies, biopolymers like collagen, or monolayers of small molecules that make the nanoparticles biocompatible. In addition, as optical detection techniques are widespread in biological research, nanoparticles should either fluoresce or change their optical properties. The approaches used in constructing nano-biomaterials are schematically presented below (Fig. 3). Nanoparticle usually forms the core of nano-biomaterial. It can be used as a convenient surface for molecular assembly and may be composed of inorganic or polymeric materials. It can also be in the form of a nano-vesicle, surrounded by a membrane or a layer. The shape is more often spherical, but cylindrical, plate-like, and other shapes are possible. The size and size distribution might be important in some cases, for example, if penetration through a pore structure of a cellular membrane is required. The size and size distribution are becoming extremely critical when quantum-sized effects are used to control material properties. A tight control of the average particle size and a narrow distribution of sizes allow creation of very efficient fluorescent probes that emit narrow light in a very wide range of wavelengths. This helps with creating biomarkers with many well-distinguished colors. The core might have several layers and be multifunctional. For example, combining magnetic and luminescent layers, one can both detect and manipulate the particles. The core particle is often protected by several monolayers of inert material, for example, silica. Organic molecules that are adsorbed or chemisorbed on the surface of the particle are also used for this purpose. The same layer might act as a biocompatible material. However, more often, an additional layer of linker molecules is required to proceed with further functionalization. This linear linker molecule has reactive

groups at both ends. One group is aimed at attaching the linker to the nanoparticle surface, and the other is used to bind various moieties like biocompatibles (dextran), antibodies, and fluorophores, depending on the function required by the application.

Some current applications of nanomaterials to biology and medicine are listed as follows:

- **Biological tags or labels:** Mainly gold colloids are used for both electron and light microscopy; also, silver and silver-coated gold nanoparticles are used. A recent addition of semiconductor nanocrystals or quantum dots is finding increasing application as a substitute for the organic fluorophores. Greater photo-stability and the single-wavelength excitation option are among the quoted benefits. Badly designed quantum dots might disintegrate, releasing toxic components (e.g., cadmium or arsenic) that could be lethal at a cellular level. A use of porous silicon nanoparticles as fluorescent tags might be a safer option. Both quantum dots and colloidal gold were used recently for the detection of pathogens, proteins, and for the DNA sequencing. Colloidal gold and, more recently, quantum dots, have also been employed in phagokinetic studies.
- **Drug delivery:** Mainly use polymeric nanoparticles (13) because of their stability in biological fluids. Flexibility offered by a wide choice of polymers helps to control the rates of drug release and particle biodegradation. Polymeric nanoparticles can be used for all possible administration routes. Surface modifications allow creation of “stealth” as well as targeted drug carriers. Two major approaches are used in their preparation: from polymers (e.g., polyesters) or from monomers (e.g., alkylcyanoacrylate). Either solid nanospheres or liquid core nanocapsules can be produced. The fabrication technologies can be based on the solvent evaporation from oil-in-water microemulsions, created with help of surfactants, or by polymer precipitation caused by the addition of the nonsolvent. Another trend is to produce nanoparticles out of the poorly soluble drugs. Size reduction (nanosizing) (14) can significantly prolong drug bioavailability, increase its dissolution rate and maximum concentration, and dramatically shorten the onset of the drug action.
- **MRI contrast enhancement:** MRI detects the spatial distribution of the signals from water protons inside the body. These signals depend on the local amount of water and the proton relaxation times T1 and T2. The relaxation times can be affected by several factors; they can also be shortened by the presence of paramagnetic molecules or particles. The T1 shortening would result in the increased signal intensity, whereas the T2 shortening would lead to the opposite effect. These effects are nonlinear functions of the concentration of the contrasting agent.

Superparamagnetic iron oxide (SPIO), whose average particle size is 50 nm, with dextrane or siloxane coating, is used as a tissue-specific contrast agent

(Feridex, Endorem, GastroMARK, Lumirem, Resovist); ultra-small superparamagnetic oxide particles, 10 nm (Sinerem, Combidex), are used to distinguish between the metastatic and inflamed lymph nodes, and to identify arteriosclerosis plaque deposits. Intravenously injected SPIO would pass through the vascular endothelium into the interstitium. After that, the SPIO would be taken up by both healthy and inflamed lymph nodes. The uptake is followed by phagocytosis. Normal lymph nodes show a decrease in signal intensity on T2*- and T2-weighted MR images because of the effects of magnetic susceptibility and T2 shortening on the iron deposits that are a direct result of phagocytosis. However, metastatic lymph nodes are bad at phagocytosis, form no deposits, and do not show such reduction in the signal intensity. This effect can be used to distinguish between the healthy and the benign lymph nodes.

- **Separation and purification of biomolecules and cells:** Dynabeads are highly uniform in size and superparamagnetic; depending on the antibodies present on the surface, the beads can be applied to different tasks like separation of T-cells, detection of microbes and protozoa, HLA diagnostics for organ transplantation, and various *in vitro* diagnostics assays. They are also used for the isolation of DNA and proteins.
- **Tissue engineering:** Nanoparticles of hydroxyapatite are used to mimic the mineral particles occurring in the bone structure, whereas collagen is often replaced with a 3D porous scaffolding of a biodegradable polymer. This approach allows for the high mobility of the osteoblasts and, consequently, a uniform growth of the new bone. A similar strategy is used to promote the cellular growth on the surface of prosthetic implants.
- **Tumor destruction via heating (hyperthermia):** The nanoparticle approach is currently relying on the higher metabolic rates and enhanced blood supply to the tumors. As a result, the cancerous cells are likely to be enriched in a nanoparticulate matter, introduced in the blood circulation, or directly injected into the tumor. An external electromagnetic energy source is directed toward the tumor. The nanoparticles are designed to absorb the electromagnetic energy and convert it into localized heat, which would preferentially cause the apoptosis of the malignant cells. Localized heating might also result in the increased acidosis of the cancer cells. It is also been suggested that the high density of blood vessels in and around the growth stops them from expanding as efficiently as those in the healthy tissue, leading to a higher heat retention. The range of temperatures used is typically within 39 to 43 °C. Alternating magnetic fields can be used to heat up magnetic iron oxide nanoparticles concentrated inside the tumor tissue. More recently developed nanoshells rely on the illumination with a near-infrared laser. Nanoparticles can be designed to actively target the surface receptors on the malignant cells by coating the nanoparticles with the appropriate antibodies.

Recent Developments

Tissue Engineering. Natural bone surface often contains features that are about 100 nm across. If the surface of an artificial bone implant was left smooth, the body would try to reject it. So the smooth surface is likely to cause production of a fibrous tissue covering the surface of the implant. This layer reduces the bone-implant contact, which may result in loosening of the implant and further inflammation. It was demonstrated that by creating nanosized features on the surface of the hip or knee prosthesis, one could reduce the chances of rejection as well as stimulate the production of osteoblasts. The osteoblasts are the cells responsible for the growth of the bone matrix and are found on the advancing surface of the developing bone. The effect was demonstrated with polymeric, ceramic, and more recently, metal materials. More than 90% of the human bone cells from suspension adhered to the nanostructured metal surface, but only 50% did in the control sample. In the end, this finding would allow the design of a more durable and longer lasting hip or knee replacement and reduce the chances of the implant getting loose. Titanium is a well-known bone repairing material widely used in orthopedics and dentistry. It has a high fracture resistance, ductility, and weight-to-strength ratio. Unfortunately, it suffers from the lack of bioactivity, as it does not support cell adhesion and growth well. Apatite coatings are known to be bioactive and to bond to the bone. Hence, several techniques were used to produce an apatite coating on titanium. Those coatings suffer from thickness nonuniformity, poor adhesion, and low mechanical strength. In addition, a stable porous structure is required to support the nutrients' transport through the cell growth. It was shown that using a biomimetic approach — a slow growth of nanostructured apatite film from the simulated body fluid — resulted in the formation of a strongly adherent, uniform nanoporous layer. The layer was found to be built of 60 nm crystallites and possess a stable nanoporous structure and bioactivity. A real bone is a nanocomposite material, composed of hydroxyapatite crystallites in the organic matrix, which is mainly composed of collagen. Thanks to that, the bone is mechanically tough and plastic, so it can recover from mechanical damage. The actual nanoscale mechanism leading to this useful combination of properties is still debated. An artificial hybrid material was prepared from 15 to 18 nm ceramic nanoparticles and poly (methyl methacrylate) copolymer. Using the tribology approach, a viscoelastic behavior (healing) of the human teeth was demonstrated. An investigated hybrid material, deposited as a coating on the tooth surface, improved scratch resistance as well as possessed a healing behavior similar to that of the tooth.

Cancer Therapy. Photodynamic cancer therapy is based on the destruction of the cancer cells by laser-generated atomic oxygen, which is cytotoxic. A greater quantity of a special dye that is used to generate the atomic oxygen is taken in by the cancer cells when compared with a healthy tissue. Hence, only the cancer cells are destroyed and then exposed to a laser radiation. Unfortunately, the remaining dye molecules migrate to the skin and the eyes and make the patient very sensitive to the daylight exposure. This

effect can last for up to 6 weeks. To avoid this side effect, the hydrophobic version of the dye molecule was enclosed inside a porous nanoparticle. The dye stayed trapped inside the Ormosil nanoparticle and did not spread to the other parts of the body. At the same time, its oxygen-generating ability has not been affected and the pore size of about 1 nm freely allowed for the oxygen to diffuse out.

Another recently suggested approach is to use gold-coated nanoshells. A surface plasmon resonance effect causes an intense size-dependent absorbance of the near-infrared light by the gold shells. This wavelength of light falls into the optical transparency window of the biological tissue, which can be used to detect cancerous growth up to a certain depth. Compact, powerful, and relatively inexpensive semiconductor lasers are readily available to generate light at this wavelength. The nanoshells are injected into a blood stream and rapidly taken up by the cancerous cells, as they possess a higher metabolism rate. Laser light is absorbed by the gold shells and converted into a local heating, which only kills the cancer cells and spares the healthy tissue. Surface-modified carbon nanotubes can also be used for the same purpose as they would absorb light in the infrared region and convert it into heat.

Multicolor Optical Coding for Biological Assays. The ever increasing research in proteomics and genomic generates an escalating number of sequence data and requires development of high throughput screening technologies. Realistically, various array technologies that are currently used in parallel analysis are likely to reach saturation when several array elements exceed several millions. A three-dimensional approach, based on optical “bar coding” of polymer particles in solution, is limited only by the number of unique tags one can reliably produce and detect. Single quantum dots of compound semiconductors were successfully used as a replacement of organic dyes in various bio-tagging applications. This idea has been taken one step further by combining differently sized and, hence, having different fluorescent colors quantum dots, and combining them in polymeric microbeads. A precise control of quantum dot ratios has been achieved. The selection of nanoparticles used in those experiments had 6 different colors as well as 10 intensities. It is enough to encode over one million combinations. The uniformity and reproducibility of beads was high, allowing for bead identification accuracies of 99.99%.

Manipulation of Cells and Biomolecules. Fictionalized magnetic nanoparticles have found many applications, including cell separation and probing; these and other applications are discussed in a recent review. Most of the magnetic particles studied so far are spherical, which somewhat limits the possibilities to make these nanoparticles multifunctional. Alternative cylindrically shaped nanoparticles can be created by employing metal electrodeposition into a nanoporous alumina template. Depending on the properties of the template, the nanocylinder radius can be selected in the range of 5 to 500 nm while their length can be as big as 60 μm . By sequentially depositing various thicknesses of different metals, the

structure and the magnetic properties of individual cylinders can be tuned widely. As surface chemistry for functionalization of metal surfaces is well developed, different ligands can be selectively attached to different segments. For example, porphyrins with thiol or carboxyl linkers were simultaneously attached to the gold or nickel segments, respectively. Thus, it is possible to produce magnetic nanowires with spatially segregated fluorescent parts. In addition, because of the large aspect ratios, the residual magnetization of these nanowires can be high. Hence, the weaker magnetic field can be used to drive them. It has been shown that a self-assembly of magnetic nanowires in suspension can be controlled by weak external magnetic fields. This would potentially allow controlling cell assembly in different shapes and forms. Moreover, an external magnetic field can be combined with a lithographically defined magnetic pattern (“magnetic trapping”).

Protein Detection. Proteins are the important part of the cell’s language, machinery, and structure, and understanding their functionalities is extremely important for further progress in human well-being. Gold nanoparticles are widely used in immunohistochemistry to identify the protein–protein interaction. However, the multiple simultaneous detection capabilities of this technique are limited. Surface-enhanced Raman scattering spectroscopy is a well-established technique for detection and identification of single dye molecules. By combining both methods in a single nanoparticle probe, one can drastically improve the multiplexing capabilities of protein probes. The group of Prof. Mirkin has designed a sophisticated multifunctional probe that is built around a 13 nm gold nanoparticle. The nanoparticles are coated with hydrophilic oligonucleotides containing a Raman dye at one end and terminally capped with a small molecule recognition element (e.g., biotin). Moreover, this molecule is catalytically active and will be coated with silver in the solution of Ag(I) and hydroquinone. After the probe is attached to a small molecule or an antigen it is designed to detect, the substrate is exposed to silver and hydroquinone solution. Silver plating is happening close to the Raman dye, which allows for dye signature detection with a standard Raman microscope. Apart from being able to recognize small molecules, this probe can be modified to contain antibodies on the surface to recognize proteins. When tested in the protein array format against both small molecules and proteins, the probe has shown no cross-reactivity.

Commercial Exploration

Some companies involved in the development and commercialization of nanomaterials in biological and medical applications are listed below (Table 1). Most of the companies are small recent spinouts of various research institutions. Although not exhausting, this is a representative selection reflecting current industrial trends. Most companies are developing pharmaceutical applications, mainly for drug delivery. Several companies exploit quantum size effects in semiconductor nanocrystals for tagging biomolecules or use bioconjugated gold nanoparticles for labeling various cellular parts. Many companies are applying nano-

ceramic materials to tissue engineering and orthopedics. Most major and established pharmaceutical companies have internal research programs on drug delivery that are on formulations or dispersions containing components down to nanosizes. Colloidal silver is widely used in antimicrobial formulations and dressings. The high reactivity of titania nanoparticles, either on their own or then illuminated with UV light, is also used for bactericidal purposes in filters. Enhanced catalytic properties of surfaces of nano-ceramics or those of noble metals like platinum are used to destruct dangerous toxins and other hazardous organic materials.

Future Directions

As it stands, most commercial nanoparticle applications in medicine are geared toward drug delivery. In the biosciences, nanoparticles are replacing organic dyes in the applications that require high photo-stability as well as high multiplexing capabilities. There are some developments in directing and remotely controlling the functions of nanoprobe, for example, driving magnetic nanoparticles to the tumor and then making them either to release the drug load or just heating them to destroy the surrounding tissue. The major trend in further development of nanomaterials is to make them multifunctional and controllable by external signals or by local environment, thus essentially turning them into nanodevices.

HEALTH ISSUES (15)

It has been shown by several researchers that nanomaterials can enter the human body through several ports. Accidental or involuntary contact during production or use is most likely to happen via the lungs from where a rapid translocation through the blood stream is possible to other vital organs. On the cellular level, an ability to act as a gene vector has been demonstrated for nanoparticles. Carbon black nanoparticles have been implicated in interfering with cell signaling. There is work that demonstrates uses of DNA for the size separation of carbon nanotubes. The DNA strand just wraps around it if the tube diameter is right. Although excellent for separation purposes, it raises some concerns over the consequences of carbon nanotubes entering the human body.

Ports of Entry

Human skin, intestinal tract, and lungs are always in direct contact with the environment. Whereas skin acts as a barrier, lungs and intestinal tract also allow transport (passive and/or active) of various substances like water, nutrients, or oxygen. As a result, they are likely to be a first port of entry for the nanomaterials’ journey into the human body. Our knowledge in this field mainly comes from drug delivery (pharmaceutical research) and toxicology (xenobiotics) studies.

Human skin functions as a strict barrier, and no essential elements are taken up through the skin (except radiation necessary to buildup vitamin D). The lungs exchange oxygen and carbon dioxide with the environment, and some water escapes with warm exhaled air. The intestinal tract

Table 1. Examples of Companies Commercializing Nanomaterials for Bio- and Medical Applications

Company	Applications	Technology
Advectus Life Sciences Inc.	Drug delivery	Polymeric nanoparticles engineered to carry anti-tumor drug across the blood-brain barrier
Alnis Biosciences, Inc. Argonide	Bio-pharmaceutical Membrane filtration, implants	Biodegradable polymeric nanoparticles for drug delivery Nanoporous ceramic materials for endotoxin filtration, orthopedic and dental implants, DNA and protein separation
Biophan Technologies, Inc.	MRI shielding, nanomagnetic particles for guided drug delivery and release	Nanomagnetic/carbon composite materials to shield medical devices from RF fields
Capsulation NanoScience AG	Pharmaceutical coatings to improve solubility of drugs	Layer-by-layer poly-electrolyte coatings, 8–50 nm
Dynal Biotech (Invitrogen)	Cell/biomolecule separation	Superparamagnetic beads
Eiffel Technologies Evident Technologies	Drug delivery Luminescent biomarkers	Reducing size of the drug particles to 50–100 nm Semiconductor quantum dots with amine or carboxyl groups on the surface, emission from 350 to 2500 nm
NanoBio Corporation NanoCarrier Co., Ltd	Pharmaceutical Drug delivery	Antimicrobial nano-emulsions Micellar polymer nanoparticles for encapsulation of drugs, proteins, DNA
NanoPharm AG	Drug delivery	Polybutylcyanoacrylate nanoparticles are coated with drugs and then with surfactant, can go across the blood–brain barrier
Nanoprobes, Inc.	Gold nanoparticles for biological markers	Gold nanoparticles bioconjugates for TEM and/or fluorescent microscopy
Nanosphere, Inc.	Gold biomarkers	DNA barcode attached to each nanoprobe for identification purposes, PCR is used to amplify the signal; also catalytic silver deposition to amplify the signal using surface plasmon resonance
NanoMed Pharmaceutical, Inc. PSiVida Ltd	Drug delivery Tissue engineering, implants, drugs and gene delivery, biofiltration	Nanoparticles for drug delivery Exploiting material properties of nanostructured porous silicone
QuantumDot Corporation	Luminescent biomarkers	Bioconjugated semiconductor quantum dots

is in close contact with all of the materials taken up orally; here all nutrients (except gases) are exchanged between the body and the environment.

The histology of the environmental contact sides of these three organs is significantly different. The skin of an adult human is roughly 1.5 m²; in area and is at most places covered with a relatively thick first barrier (10 μm), which is built of strongly keratinized dead cells. This first barrier is difficult to pass for ionic compounds as well as for water-soluble molecules.

The lung consists of two different parts: airways (transporting the air in and out the lungs) and alveoli (gas exchange areas). Our two lungs contain about 2,300 km of airways and 300 million alveoli. The surface area of the lungs is 140 m² in adults, as big as a tennis court. The airways are a relatively robust barrier, an active epithelium protected with a viscous layer of mucus. In the gas exchange area, the barrier between the alveolar wall and the capillaries is very thin. The air in the lumen of the alveoli is just 0.5 μm away from the blood flow. The large surface area of the alveoli and the intense air–blood contact in this region makes the alveoli less well protected against environmental damage when compared with airways.

The intestinal tract is a more complex barrier and exchange side; it is the most important portal for macro-

molecules to enter the body. From the stomach, only small molecules can diffuse through the epithelium. The epithelium of the small and large intestines is in close contact with ingested material so that nutrients can be used. A mixture of disaccharides, peptides, fatty acids, and monoglycerides generated by digestion in the small intestine are further transformed and taken in. The area of the gastrointestinal tract (G_IT) is estimated as 200 m².

Lung. Most nanosized spherical solid materials will easily enter the lungs and reach the alveoli. These particles can be cleared from the lungs, as long as the clearance mechanisms are not affected by the particles or any other cause. Nanosized particles are more likely to hamper the clearance, resulting in a higher burden, possibly amplifying any possible chronic effects caused by these particles. It is also important to note that the specific particle surface area is probably a better indication for maximum tolerated exposure level than total mass. Inhaled nanofibers (diameter smaller than 100 nm) also can enter the alveoli. In addition, their clearing would depend on the length of the specific fiber. Recent publications on the pulmonary effects of carbon nanotubes confirm the intuitive fear that the nanosized fiber can induce a general nonspecific pulmonary response. Passage of solid material from the pulmonary

epithelium to the circulation seems to be restricted to nanoparticles. The issue of particle translocation still needs to be clarified: both the trans-epithelial transport in the alveoli and the transport via nerve cells. Thus, the role of factors governing particle translocation such as the way of exposure, dose, size, surface chemistry, and time course should be investigated. For instance, it would be also very important to know how and to what extent lung inflammation modulates the extrapulmonary translocation of particles. Solid inhaled particles are a risk for those who suffer from cardiovascular disease. Experimental data indicate that probably many inhaled particles can affect cardiovascular parameters, via pulmonary inflammation. Nanosized particles, after passage in the circulation, can also play a direct role in, e.g., thrombogenesis.

Intestinal Tract. Already in 1926, it was recognized by Kumagai that particles could translocate from the lumen of the intestinal tract via aggregations of intestinal lymphatic tissue [Peirel's Patches (PP)] containing M-cells (specialized phagocytic enterocytes). Particulate uptake happens not only via the M-cells in the PP and the isolated follicles of the gut-associated lymphoid tissue, but also via the normal intestinal enterocytes. There have been several excellent reviews on the subject of intestinal uptake of particles. Uptake of inert particles has been shown to occur trans-cellular through normal enterocytes and PP via M-cells and, to a lesser extent, across paracellular pathways. Initially it was assumed that the PP did not discriminate strongly in the type and size of the absorb particles. Later it has been shown that modified characteristics, such as particle size, the surface charge of particles, attachment of ligands, or coating with surfactants, offers possibilities of site-specific targeting to different regions of the GIT including the PP.

The kinetics of particle translocation in the intestine depends on diffusion and accessibility through mucus, initial contact with enterocyte or M-cell, cellular trafficking, and post-translocation events. Cationic nanometer-sized particles became entrapped in the negatively charged mucus, whereas negatively charged nanoparticles can diffuse across this layer. The smaller the particle diameter, the faster they could permeate the mucus to reach the colonic enterocytes. Once in the sub-mucosal tissue, particles can enter both lymphatic and capillaries. Particles entering the lymphatic are probably important in the induction of secretory immune responses, whereas those that enter the capillaries become systemic and can reach different organs. It has been suggested that the disruption of the epithelial barrier function by apoptosis of enterocytes is a possible trigger mechanism for mucosal inflammation. The patho-physiological role of M-cells is unclear; for example, it has been found that in Crohn's disease, M-cells are lost from the epithelium. Diseases other than of gut origin, for example, diabetes, also have marked effects on the ability of the GIT to translocate particles. In general, the intestinal uptake of particles is understood better and studied in more detail than pulmonary and skin uptake. Because of this advantage, it is maybe possible to predict the behavior of some particles in the intestines.

Skin. Skin is an important barrier, protecting against insult from the environment. The skin is structured in three layers: the epidermis, the dermis, and the subcutaneous layer. The outer layer of the epidermis, the stratum corneum (SC), covers the entire outside of the body. In the SC we find only dead cells, which are strongly keratinized. For most chemicals, the SC is the rate-limiting barrier to percutaneous absorption (penetration). The skin of most mammalian species is covered with hair.

At the sites where hair follicles grow, the barrier capacity of the skin differs slightly from the "normal" stratified squamous epidermis. Most studies concerning penetration of materials into the skin have focused on whether drugs penetrate through the skin using different formulations containing chemicals and/or particulate materials as a vehicle. The main types of particulate materials commonly used in contact with skin are liposomes, solid poorly soluble materials such as TiO₂, and polymer particulates and submicron emulsion particles such as solid lipid nanoparticles. TiO₂ particles are often used in sunscreens to absorb UV light and therefore to protect skin against sunburn or genetic damage. It has been reported by Lademann et al. that micrometer-sized particles of TiO₂ get through the human stratum corneum and even into some hair follicles, including their deeper parts. However, the authors did not interpret this observation as penetration into living layers of the skin. In a recent review, it was stated that "very small titanium dioxide particles (e.g. 5–20 nm) penetrate into the skin and can interact with the immune system." Unfortunately, this has not been discussed any further.

Penetration of nonmetallic solid materials such as biodegradable poly(D,L-lactic-co-glycolic acid (PLGA)) microparticles, 1 to 10 μm with a mean diameter of 4.61 ± 0.8 μm, were studied after application on to porcine skin. The number of microparticles in the skin decreased with the depth (measured from the airside toward the subcutaneous layer). At 120 μm depth (where viable dermis is present), a relative high number of particles was found; at 400 μm (dermis), some microparticles were still observed. At a depth of 500 μm, no microparticles were found. In the skin of persons, who had an impaired lymphatic drainage of the lower legs, soil microparticles, frequently 0.4–0.5 μm but as larger particles of 25 μm diameter, were found in the dermis of the foot in a patient with endemic elephantiasis. The particles are observed to be in the phagosomes of macrophages or in the cytoplasm of other cells. The failure to conduct lymph to the node produces a permanent deposit of silica in the dermal tissues (a parallel is drawn with similar deposits in the lung in pneumoconiosis). This indicates that soil particles penetrate through (damaged) skin, most probably in every person, and normally are removed via the lymphatic system.

Liposomes penetrate the skin in a size-dependent manner. Microsized, and even submicron sized, liposomes do not easily penetrate into the viable epidermis, whereas liposomes with an average diameter of 272 nm can reach into the viable epidermis and some are found in the dermis. Smaller sized liposomes of 116 and 71 nm were found in higher concentration in the dermis. Emzaloïd particles, a type of submicron emulsion particle such as liposomes and nonionic surfactant vesicles (niosomes), with a diameter of

50 nm to 1 μm , were detected in the epidermis in association with the cell membranes after application to human skin. The authors suggested that single molecules, which make up the particles, might penetrate the intercellular spaces and, at certain regions in the stratum corneum, can accumulate and reform into microspheres. In a subsequent experiment, it was shown that the used formulation allowed penetration of the spheres into melanoma cells, even to the nucleus.

From the limited literature on nanoparticles penetrating the skin, some conclusions can be drawn. First, penetration of the skin barrier is size dependent, and nanosized particles are more likely to enter more deeply into the skin than larger ones. Second, different types of particles are found in the deeper layers of the skin, and currently, it is impossible to predict the behavior of a particle in the skin. Third, materials, which can dissolve or leach from a particle (e.g., metals), or break into smaller parts (e.g., Emzalooid particles), can possibly penetrate into the skin.

Currently, there is no direct indication that particles, that had penetrated the skin also entered the systemic circulation. The observation that particles in the skin can be phagocytized by macrophages, Langerhan cells, or other cells is a possible road toward skin sensitization.

Summary of Health Risks

Particles in the nanosize range can certainly enter the human body via the lungs and the intestines; penetration via the skin is less evident. It is possible that some particles can penetrate deep into the dermis. The chances of penetration would depend on the size and surface properties of the particles and on the point of contact in the lung, intestines, or skin.

After penetration, the distribution of the particles in the body is a strong function of the surface characteristics of the particle. It seems that size can restrict the free movement of particles. The target organ-tissue or cell of a nanoparticle needs to be investigated, particularly in the case of potentially hazardous compounds. Before developing an *in vitro* test, it is essential to know the pharmacokinetic behavior of different types of nanoparticles; therefore, it would be important to compose a database of health risks associated with different nanoparticles.

Beside the study of the health effects of the nanomaterials, investigations should also take into consideration the presence of contaminants, such as metal catalysts present in nanotubes and their role in the observed health effects.

The increased risk of cardiopulmonary diseases requires specific measures to be taken for every newly produced or used nanoparticle. There is no universal "nanoparticle" to fit all cases; each nanomaterial should be treated individually when health risks are expected. The tests currently used to test the safety of materials should be applicable to identify hazardous nanoparticles.

NEONATAL MONITORING

MICHAEL R. NEUMAN
Michigan Technological
University
Houghton, Michigan

INTRODUCTION

The care of premature and newborn infants is quite different from other areas of clinical medicine. The infant represents a special patient with special problems not found in other patients. For this reason a subspecialty of pediatrics dealing with these patients has been established. Neonatology is concerned with newly born infants including those prematurely delivered and those delivered at term. The field generally covers infants through the first month of normal newborn life, and so for prematurely born infants this can be several additional months.

Neonatology includes special hospital care for infants who require it. In the case of the prematures, this involves specialized life-support systems, as well as special considerations for nutrition, thermal control, fluid and electrolyte therapy, pulmonary support, and elimination of products of metabolism. While the full-term infant generally only requires routine well-baby care, there are special cases that require intensive hospital care as well. These include treatment of infants of diabetic mothers, some infants delivered by cesarean section, infants with hemolytic diseases, infants who encounter respiratory distress, and other less common problems. Special hospital care is also necessary for infants requiring surgery. These infants are generally born with severe congenital anomalies that would be life threatening if not immediately repaired. These include anomalies of the gastrointestinal system, urinary tract, cardiovascular system, and nervous system. Pediatric surgery has developed to the point where many of these problems can be corrected, and the infant can grow and lead a normal life following the surgery.

The neonatal intensive care unit is a special nursery in major tertiary care hospitals that is devoted to the care of premature or other infants who require critical care. This unit is similar to its adult counterpart in that each patient is surrounded by equipment necessary for life support, diagnosis, and therapy. Often, as indicated in Fig. 1, the patient appears to be insignificant in the large array of equipment, but, of course, this is not the case. Nursing

Figure 1. Typical infant station in a neonatal intensive care unit showing infant warmer, infusion pumps, ventilator, transcutaneous oxygen instrument, cardiopulmonary monitor, bilirubin lights, and other miscellaneous apparatus.

functions in the neonatal intensive care unit are very important. The patient/nurse ratio is small, and the nursing staff must be familiar with the equipment as well as special procedures and precautions in caring for these special patients.

Electronic monitoring of the infant plays an important role in neonatal intensive care. Not only does it allow the clinical caregivers to follow vital signs, such as pulse rate, temperature, blood pressure, and respiration rate, but other critical variables in the care of these special patients can be followed as well. These include blood gas tensions, acid-base balance, bilirubin, and glucose concentrations. Monitoring is especially important in fluid therapy for it can provide precise data for fluid control of these very small patients. Electronic monitoring, however, goes beyond just monitoring the patient and its physiologic functions. A good neonatal intensive care unit also monitors the functioning of life-support systems. These include incubators for maintaining an appropriate thermal environment, ventilators for providing respiratory support, and phototherapy units for the control of bilirubin.

Although electronic monitoring devices for just about all of the areas mentioned in the previous paragraph are used in adult intensive care medicine, their application in neonatology often represents a unique aspect of the technology.

The infant should not be viewed as a miniature adult, but rather he/she is a unique physiologic entity. Although similar variables are measured to those measured in adults, they often must be measured in different ways. Frequently, sensors unique for infants must be applied because the sensors used for adults when interfaced to the infant might provide errors or change the variable being measured by their very presence. Size is an important aspect here. If one considers a sensor to be used on an infant and compares it to a sensor for the same variable on an adult, in most cases although the sensor for the infant is smaller than that for the adult, the ratio of sizes of the two sensors is quite different from the ratio of sizes of the different patients. Although sensors for use on infants are reduced in size, they are still quite large when compared to the size of the subject. This is especially true for premature infants and can result in the sensors actually interfering with the care of the patient.

There are also special problems related to the measurement of physiologic variables in infants resulting from the special physiology of newborns and especially premature newborns. One first must realize that a newborn has come to live in a new environment quite different from the uterus. In the case of premature infants, they are not ready for this major change in their lives, and special considerations need to be made to minimize the transitional trauma. In the case of the premature, some of the body systems are immature and not ready for life outside of the uterus. Two notable examples of this are the control of temperature and control of respiration. Both are obviously unnecessary in the uterus, but become crucial in extrauterine life. Instrumentation to assist these control systems or to detect when they are not functioning properly is essential in the care of many premature infants.

One also must realize in applying instrumentation systems for premature infants that the patient in many cases is much more fragile than an adult patient. Fluid and electrolyte balance has already been indicated as an important aspect of neonatal monitoring and control. When one considers some of the very small premature infants that are cared for in neonatal intensive care units today, this can be better appreciated. Infants between 500 and 1,000 g can be successfully cared for and nurtured until they are old enough and grow enough to go home with their parents. These very small babies, however, can easily run into problems if they receive either too much or too little fluid. Since feeding of these very small infants can be done by intravenous hyperalimentation, the possibility of a fluid overload is always present since it takes a certain amount of fluid to transport the nutritional requirements of the infant. Another example of the fragility of these very small patients is the simple problem of attaching devices to the infant's skin. In some infants, the skin is very sensitive and can easily become irritated by the attachment procedure or substance.

This article, looks more closely at electronic monitoring systems for neonatal intensive care and emphasize those aspects of these monitoring systems that differ from similar monitors for adult patients. The reader is encouraged to supplement information contained in the following paragraphs with other articles from this encyclopedia

dealing with the sensors and instrumentation for similar monitoring in adults.

CARDIAC MONITORING

Cardiac monitoring involves the continuous assessment of heart function by electronic measurement of the electrocardiogram and determination of heart rate and rhythm from it by means of electronic signal processing. As such, cardiac monitors for neonatal use are very similar to those for use with adults. There are, however, two major differences. The sensors used with both types of monitors are biopotential electrodes, and in the case of infants the interface between the electrodes and the patients has more stringent requirements than in the adult case. Second, cardiac monitors designed for use with infants frequently are incorporated into cardiorespiratory monitors that include instrumentation for determining breathing rate and apnea as well as cardiac function.

The primary use of cardiac monitors for infants is in determining heart rate. These electronic devices are designed to indicate conditions of bradycardia (low heart rate) and tachycardia (high heart rate) by determining the heart rate from the electrocardiogram. In the case of infants with heart diseases, cardiac monitors are used to detect various arrhythmias as well.

Cardiac monitors for use with infants are organized similarly to their adult counterparts (see MONITORING, HEMODYNAMIC). There are some minor differences due to the fact that infant heart rates are higher than those of adults, and the Q-S interval of the infant electrocardiogram is less than it is in the adult. Thus, heart rate alarm circuits need to be able to respond to higher rates in the infant case than in the adult case. For example, it is not at all unusual to set the bradycardia alarm level at a rate of 90 or 100 beats·min⁻¹ for an infant, which is well above the resting heart rate of a normal adult. Filtering circuits in the monitor for infants must be different from those of adult monitors for optimal noise reduction due to the different configuration of the neonatal electrocardiogram. Generally, bandpass filters used for isolating the QRS complex will have a higher center frequency than in the adult case.

Two types of cardiometer circuits can be used in cardiac monitors (1). The averaging cardiometer determines the mean number of heartbeats per predetermined interval to establish the heart rate. The mean R-R interval over a number, of heartbeats can also be used in average heart rate determination. In such systems the heart rate is calculated by averaging over from as few as three to as many as fifteen or more heartbeats. An instantaneous or beat-to-beat cardiometer determines the heart rate for each measured R-R interval. This type of cardiometer must be used when one is interested in beat-to-beat variability of the heart rate.

Biopotential electrodes for use with cardiac monitors for infants are usually scaled down versions of skin surface electrodes used for adult cardiac monitoring. As pointed out earlier, the scale factor does not correspond to the body size ratio between the neonate and an adult, and the smallest commercially available skin surface electrodes

for neonates only approaches about one-fourth the size of those used in adults. For this reason, electrodes used with neonatal cardiac monitors and their method of attachment can cover a large portion of the neonatal thorax. This is especially true with the small premature infant and can interfere with direct observation of chest wall movements, an important diagnostic method. In addition to size, shape and flexibility of the electrode are important for biopotential electrodes in neonates. Stiff, flat electrode surfaces will not conform well to the curved, compliant surface of the infant. This means that optimal electrical contact is not always possible and it, therefore, becomes more difficult to hold electrodes in place. This problem is further complicated by the fact that the neonatal skin can be sensitive to the electrode adhesive. It is not at all unusual to find skin irritation and ulceration as a result of placement of biopotential electrodes on the infant. Such skin lesions are usually the result of the adhesive and the electrode attachment system, although the electrode itself can in some cases be the problem as well.

Since electrodes are relatively large on the small infant, an additional problem develops. The materials used in many electrode systems are X-ray opaque; hence, it is necessary to remove the electrodes when X rays are taken so that shadows do not appear in the resulting radiograph. Some biopotential electrodes especially developed for neonates have minimized this problem by utilizing special electrode structures that are translucent or transparent to X rays (2). These electrodes are based upon thin films of metals, usually silver, deposited upon polymer films or strips or various fabric materials. These films are sufficiently thin to allow X rays to penetrate with little absorption, and the plastic or polymer substrate is also X-ray transparent. Such electrodes have the advantage of increased flexibility, which helps them to remain in place for longer periods of time. In intensive care units, however, it is a good idea to change electrodes every 48 h to minimize the risk of infection.

Electrode lead wires and patient cables present special problems for cardiac monitors used with infants. Lead wires should be flexible so as not to apply forces to the electrodes that could cause them to become loose, but this increased flexibility makes it easier for them to become ensnared with themselves and the infant. The potential for strangulation on older, active infants is always present. The connectors between the lead wires and the patient cable also present special problems. They must be capable of maintaining their connection with an active infant and provide a means of connection that will be unique for these components. The possibility of inadvertently connecting the lead wires, and hence the infant, to the power line must be eliminated (3).

RESPIRATORY MONITORING

Respiratory monitoring is the most frequently applied form of electronic monitoring in neonatology. In its most common application, it is used to identify periods of apnea and to set off an alarm when these periods exceed a predetermined limit. There are direct and indirect methods of

sensing alveolar ventilation and breathing effort. The direct methods are those in which the sensor is coupled to the airway and measures the movement or other properties of the air transported into and out of the lungs. In the indirect methods, the sensor looks at variables related to air movement, but not at the air movement itself. Indirect methods involve no contact with the airway or the air being moved into or away from the lungs. Usually, indirect methods are noninvasive and can be mounted on or near the body surface. Some of the most frequently applied methods are described in the following paragraphs.

Direct Methods

Various direct methods of sensing breathing effort and ventilation have been in use in the pulmonary physiology and pulmonary function laboratories for many years. These involve the measurement of volume, flow, and composition of inspired and expired gasses. Table 1 lists some of the principal methods that have been used for the direct measurement of respiration in infants and neonates. Most of these methods are not appropriate for clinical monitoring, since they involve direct connection to the infant airway through the use of a mask over the mouth and nose or an endotracheal canula. In other cases a sensor must be located at the nasal-oral area for signal detection. These methods are, however, useful in some cases for diagnostic studies carried out for periods from several hours to overnight in the hospital setting.

Many of the methods listed in Table 1 are described in detail in the article on pulmonary function testing, and therefore are not repeated here. Others, however, have special application to neonatal monitoring and will be mentioned.

Pneumotachography. Clinicians and researchers involved in neonatal and infant care agree for the most part that the best measurement of ventilation can be obtained using the pneumotachograph (4). Although this involves direct connection to the airway and can add some dead space due to the plumbing, it, with an appropriate electronic integrator, provides good volume and flow measurements that can be used as a standard against which other direct or indirect methods can be calibrated and evaluated. Identical instrumentation as used for adults can be applied in the infant case, but it must be recognized that dead space due to the instrumentation represents a more important problem with the infant than it does with the adult. Lower flows and volumes as well as faster respiration rates will be encountered with infants than with adults.

Table 1. Direct Methods of Sensing Breathing and Ventilation

Method	Primary Sensed Variable
Pneumotachograph	Flow volume
Anemometer	Flow velocity
Expired air temperature	Temperature
Air turbulence sounds	Sound
Spirometer	Volume

Capnography. Special carbon dioxide sensors have been developed for measuring air expired from the lungs, and these are used as the basis of a direct respiration monitor (5). Expired air has a higher percentage of carbon dioxide than inspired air, and this can be sensed by placing an open-ended tube at the nose or mouth so that it samples the air entering and leaving the airway. The sampled gas is transported along the tube to an instrument that contains a rapidly responding carbon dioxide sensor. This is generally a sensor that detects the increased absorption of infrared (IR) radiation by carbon dioxide-containing gas. Thus, when a sample of expired gas reaches the sensor, an increase in carbon dioxide content is indicated, while a decrease in carbon dioxide is seen in samples of air about to be inspired. There is a delay in response of this instrument due to the time it takes the gas to be transported through the tube to the sensor; thus, it is important to have rapid passage through this tube to minimize this delay. This can present some problems since the tube must be thin and flexible and, therefore, offers a relatively high resistance to the flow of gas. While it is generally not necessary to have a quantitative measure of carbon dioxide for respiration monitoring, the system can be refined to the point where it can measure the carbon dioxide content of the end tidal expired air, which is the gas that actually was in the alveoli (6).

Temperature Sensor. Similar sensing systems based upon temperature variations have also been used to monitor respiration (7). These generally can be divided into two types: one that measures temperature differences between inspired and expired air and one that measures the cooling of a heated probe as inspired or expired air is transported past it. In both cases, the temperature sensor of choice is a small, low mass, and therefore fast responding, thermistor. In the first mode of operation, the thermistor changes its resistance proportionally to the change in temperature of the air drawn over it. This can then be electronically detected and processed to determine respiration rate. It is also possible to heat the thermistor by an electrical current. Some of this heat will be dissipated convectively by the air passing over the sensor. As the flow of air over the thermistor increases, more heat will be drawn from the thermistor, and it will cool to a lower temperature. Changes in the thermistor's temperature can be determined by measuring its electrical resistance. Thus, an electrically heated thermistor will cool during both inspiration and expiration, and it will become warmer in the interval between these two phases when air is not passing over it. This type of anemometer gives a respiration pattern that appears to be twice the breathing rate, whereas the unheated thermistor gives a pattern that is the same as the breathing rate. An important consideration in using the nasal thermistor for ventilation measurement is its placement in the flowing air. For young infants, the sensor package can be taped to the nose or face so that the thermistor itself is near the center of one nostril. Another technique is to place a structure containing two thermistors under the nose so that each thermistor is under one nostril and expired air flows over both thermistors.

Nasal temperature sensors, such as thermistors, have been used for monitoring ventilation in research studies and for making physiologic recordings in the hospital and in the laboratory (8). Their advantage is that the electronic circuit for processing the signal is relatively simple and inexpensive compared with other techniques. The major problem of the method is the placement of the thermistor on the infant and maintaining it in place. Thermistors can also become covered with mucus or condensed water, which can greatly reduce their response time. Most investigators who use this technique prefer the temperature sensing rather than the flow-detecting mode. The devices can also be used with radiotelemetry systems to eliminate the wire between the thermistor on the subject's face and the remainder of the monitoring apparatus (9).

Although thermistors have a high sensitivity and can be realized in a form with very low mass, they are fragile when in this low mass form and are relatively expensive components. Low mass, high surface area resistance temperature sensors can also be fabricated using thin- and thick-film temperature sensitive resistors. (10) These can either be fabricated from metal films with relatively high temperature coefficients of resistance or more sensitive films of thermistor materials. Single use disposable sensors have been produced for use in infant and adult sleep studies as shown in Figure 2.

Sound Measurement. Air passing over the end of an open tube generates sound by producing local turbulence. A miniature microphone at the other end of the tube can detect this sound, and the level of sound detected is roughly proportional to the turbulence and, hence, the air flowing past the open end. Nasal air flow can thus be detected by placing the open end of the tube in the stream of inspired or expired air at the nose by taping the tube to the infant's face in much the same way as was done for the carbon dioxide sensor mentioned previously (11). As with the thermistor anemometer, this technique can detect changes for both inspired and expired air and will give a pattern that appears to indicate double the actual respiration rate. The method has been demonstrated to give efficacious monitoring results, but can suffer from sensitivity to extraneous sounds other than the air passing the open ended tube. This can lead to incorrect detection of breaths.

Indirect Sensors of Ventilation

There are a wide variety of indirect sensors of ventilation that can be applied to monitoring in infants. Table 2 lists some of the principal examples of these various types of sensors and sensing systems, and those with aspects unique to neonatal monitoring will be described in the following paragraphs. The main advantage of the indirect methods of sensing ventilation is that attachment to the subject is easier than for the direct measurements and less likely to interfere with breathing patterns. Of the methods described in Table 2 and this section, the transthoracic electrical impedance method is the one used in most presently available respiration-apnea monitors for both hospital and home use. This, therefore, will be described in greatest detail in a separate section.

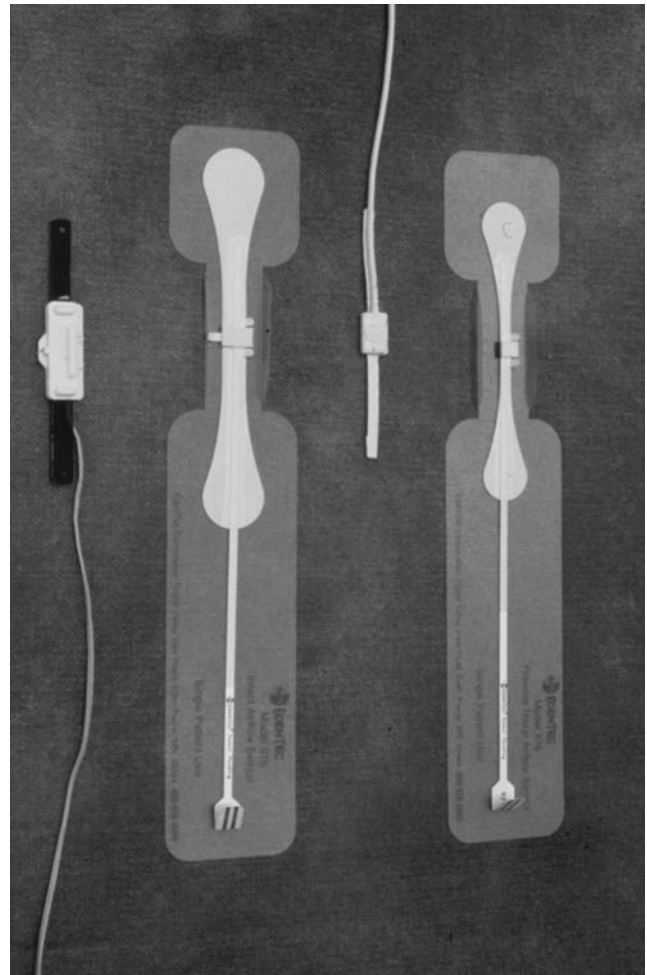

Figure 2. An example of commercially available thick-film nasal temperature sensors for measurement of breathing patterns. The small sensors on the illustration are conventional thermistor sensors.

The Whole-Body Plethysmograph. This method is used primarily in pulmonary function testing, and the reader is referred to the article on this subject for details on the method. Miniature whole-body plethysmographs have been designed for use with neonates and infants, but this

Table 2. Indirect Methods of Sensing Breathing and Ventilation

application is strictly for purposes of research or diagnostic studies. The technique is not appropriate for routine clinical monitoring.

Contacting Motion Sensors. Breathing effort involves the movement of different parts of the body for pulmonary ventilation to occur. Sensors can be placed upon and attached to an infant to measure this motion. These contacting motion sensors pick up movements of the chest and/or abdomen, and there are several different types of sensors that fall within this category. These are described in the following sections.

Strain Gage Displacement Sensors. Strain gages measure small displacements or strain in an electrical conductor by measuring changes in its electrical resistance. Most strain gages used for general measurements are made of thin metal foils or wires and are useful for measuring only very small displacements due to their very low mechanical compliance. A special type of strain gage consisting of a compliant, thin-walled, rubber capillary tube filled with mercury was developed by Whitney as a limb plethysmograph (12). This compliant device can be placed on the chest or abdomen of an infant such that breathing movements cause it to stretch and contract without offering significant mechanical constraint to the breathing efforts of the infant. By taping the ends of such a strain gage at different points on the chest or abdomen such that the gage is slightly stretched, the changes in electrical resistance of the gage can then be used to monitor infant breathing movements. Simple electronic resistance measurement circuitry can be used for processing the signal.

This technique is used primarily in research and in some rare cases for in-hospital monitoring and recording of infant respiration patterns. Its limitations are related to use of a toxic substance that could escape from the sensor and put the infant at risk. In addition, the mercury column frequently becomes interrupted after several days of use, thereby limiting the sensor's reliability for infant monitoring. Nevertheless, workers who use this sensor for monitoring purposes are enthusiastic about its reliability in picking up high quality respiration patterns.

Air-Filled Capsule or Vest. Breathing efforts of an infant can also be determined for chest or abdominal movements by a sensor consisting of an air-filled compliant tube, disk, or entire vest attached around an infant. The tube and disk can be taped to the infant's chest or abdomen in a fashion similar to the strain gage, and the structures will be stretched or compressed by the infant's breathing movements. This causes the pressure of the air within to increase or decrease as a result of volume changes, and this pressure variation can be measured by coupling the sensor to a sensitive pressure transducer through a fine-gage flexible tube. The advantage of this system is that the sensors on the infant are simple and inexpensive and thus can be considered disposable devices. Since only air is contained within the sensors, they are not toxic and are much more reliable than the mercury strain gages. They can be produced as inexpensive disposable sensors.

Displacement Magnetometers. The magnetic field from a permanent magnet or an electromagnet decreases as one gets farther from the magnet. By placing such a magnet on an infant's chest or abdomen with a detector located on the back of the subject or underneath the infant, differences in separation between the magnet and the detector can be sensed as the infant breathes (13). It is important that such a system be designed so that it will only respond to breathing movements and will be insensitive to other movements of the infant. Unfortunately, this is not always the case, and sensors of this type can respond to infant limb movement as well as movements between the infant and the pad upon which it is placed.

Inductance Respirometry. The inductance of a loop of wire is proportional to the area enclosed by that loop. If a wire is incorporated in a compliant belt in a zigzag fashion so that the wire does not interfere with the stretching of the belt, such a belt can be wrapped around the chest or abdomen of an infant to form a loop. As the infant inhales or exhales the area enclosed by this loop will change, and so the inductance of the loop will also change. These changes can be measured by appropriate electronic circuits and used to indicate breathing efforts. Investigators have shown that the use of such a loop around the chest and the abdomen of an adult can, when appropriately calibrated, measure tidal volume as well as respiratory effort (14). Although the system is simple in concept, realizing it in practice can involve complicated and therefore costly electronic circuitry (15). Often as the subject moves to a new position, the calibration constant relating inductance and volume will change thereby making the instrument less quantitative, yet still allowing it to be suitable for qualitative measurements. Variations in tidal volume measurements using this technology have been reported by Brooks et al. (16) Since the instrument is sensitive to inductance changes in the wire loop, anything in the vicinity of the wire that affects its inductance also will affect the measurement. Thus, the instrument can also be sensitive to moving electrical conductors or other magnetic materials in the vicinity of the infant.

Noncontacting Motion Sensors. Sensors of infant breathing effort and pulmonary ventilation that detect breathing movements of the infant without direct patient contact fit in this category. These sensors can consist of devices that are placed under the infant or can sense movement of the infant by means of a remotely located sensor. A clinician, in effect, is an indirect motion sensor when he or she determines infant breathing patterns by watching movements of the chest and abdomen. Devices in this category have a special appeal for monitoring systems that are used outside of the hospital, such as instruments for use in the home. With many of the noncontacting sensors, the infant-sensor interface can be created by individuals who do not have specialized training. For example, the motion sensing pad discussed in the next paragraph is attached to the infant by simply placing the infant on top of it in a bassinet or crib.

Motion Sensing Pad. Movements of neonates and infants can be sensed by a flexible pad that responds to

compression by producing an electrical signal when the infant is placed on top of the pad. There are two different forms of this sensor that can be used for motion detection. The first utilizes a piezoelectric polymer film, polyvinylidene fluoride, that has its surfaces metalized to form electrical contacts. Depending on the piezoelectric properties of the film, an electrical signal is produced between the metalized layers when the polymer is either compressed or flexed. In the former case, the polymer film and its metalized electrode need only to be packaged in an appropriate pad structure to be used, while in the latter case the package must be a little more complex with the polymer film positioned between two corrugated, flexible layers so that compression of the structure causes the piezoelectric polymer to be flexed (17). The second form of the pad uses an electret material to generate the electrical signal. The actual pad structure in this case is similar to that for the piezoelectric material.

The sensitive portion of the motion sensing pad structure is usually smaller than the overall size of the infant and is located under the infant's thoracic and/or lumbar regions. Infant breathing efforts result in periodic compression of the pad as the center of mass of the infant shifts cephalad and caudad with respiratory motion. This generates a periodic electrical signal related to the breathing effort.

The major limitation of the motion sensing pad is its sensitivity to movements other than those related to respiratory efforts of the infant. Other body movements can be picked up by the sensor, and the device can even respond to movements that are not associated with the infant at all, such as an adult walking near or bumping the bassinet or crib, a heavy truck, train, or subway passing nearby, or even earthquakes.

Radiation Reflection. Electromagnetic radiation in the microwave range (radar) or ultrasonic radiation (sonar) can be reflected from the surface of an infant. If this surface is moving, as, for example, would be the chest or abdominal wall during breathing efforts, the reflected radiation will be shifted in frequency according to the Doppler effect. In some cases the reflected signal's amplitude will be shifted as well as a result of this motion. These changes can be detected and used to sense breathing efforts without actually contacting the infant. The problem with these methods is that the movement of any surface that reflects the radiation will be detected. Body movements of the infant that are unrelated to respiratory movements can be detected and mistakenly identified as breathing effort, and even in some cases movement of objects in the vicinity of the infant, such as a sheet of paper shifting due to air currents, will also be detected as infant respiration. Thus, this type of monitor has the possibility of indicating apparent breathing activity during periods of apnea if moving objects other than the infant are within the range of the radiation sensor. This technique of noncontacting detection of breathing is not considered to be reliable enough for routine clinical use, and a commercial device based on this principle has been withdrawn from the market.

Variable Capacitance Displacement Sensor. A parallel plate capacitor can be fabricated so that an infant is

placed between the parallel conducting planes. For example, such a capacitor could be formed in an incubator by having the base upon which the mattress and infant are placed serving as one plate of the capacitor and having the second plate just inside the top of the incubator (18). To maintain good clinical practice, this second plate should consist of a transparent conductor, such as an indium tin oxide film, so that it does not interfere with a clinician's ability to observe the patient. Since a major component of the infant's tissue is water, and water has a relatively high dielectric constant compared to air, movements of the infant will produce changes in capacitance between plates that can be detected by an electronic circuit. Such changes can be the result of breathing movements by the infant, but they also can result from other infant movement or movement of some other materials in the vicinity of the conducting plates. Therefore, for this system to be effective, adequate electrical shielding of the capacitor is essential. Thus, this indirect motion sensor suffers from some of the same problems as other sensors in this classification: the lack of specificity for breathing movements.

Electromyography. Many different muscles are involved in breathing activity. The diaphragm is the principal muscle for pulmonary ventilation, but the accessory muscles of the chest wall including the intercostal muscles are also involved. Electromyographic activity of the diaphragm and intercostal muscles can be sensed from electrodes on the chest surface. By measuring these signals, one can determine if respiratory efforts are being made, although such measurements cannot be quantitative with regard to the extent of the effort or the volume of gas moved (19). Unfortunately, other muscles in the vicinity of the electrodes that are not involved in breathing also produce electromyographic signals. These signals can severely interfere with those associated with respiration, and this is especially true when the infant is moving. This represents a serious limitation of this method for clinical infant respiration monitoring.

Breath Sounds. Listening to chest sounds through a stethoscope is an important method of physical diagnosis for assessing breathing. The technique can be used for infant monitoring by placing a microphone over the chest or trachea at the base of the neck and processing the electrical signals from this sensor. In addition to the sounds associated with air transport and ventilation, the microphone will pick up other sounds in the body and the environment. Thus, for this type of monitoring to be efficacious, it must be done in a quiet environment. This puts a serious constraint on the practical use of this technique, and it has only been used in limited experimental protocols.

Intraesophageal Pressure. The pressure within the thorax decreases with inspiratory effort and increases with expiratory effort. These changes can be measured by placing a miniature pressure sensor in the thoracic portion of the esophagus or by placing a small balloon at this point and coupling the balloon to an external pressure

transducer through a small diameter flexible tube. While this method is invasive, it is not considered a direct method since there is no contact with the flowing air.

An important aspect of intraesophageal pressure measurement is that it represents a standard method that is accepted by physiologists as a measure of respiratory effort. Thus, by combining intraesophageal pressure measurement and the pneumotachograph, one is able to monitor both gas flow and breathing effort. Although both of these methods are generally too complicated for clinical monitoring, they can be used in conjunction with other monitoring methods described in this article as standards against which to assess the other devices.

Transthoracic Electrical Impedance. The electrical impedance across the chest undergoes small variations that are associated with respiratory effort. The measurement of these variations is the basis of the most frequently used infant respiration and apnea monitoring technique. The following section describes the basic principle of operation, the methods of signal processing, and sources of error for this technique.

RESPIRATION MONITORING BY TRANSTHORACIC ELECTRICAL IMPEDANCE

The chest contains many different materials ranging from bone to air. Each of these materials has its own electrical properties and of its own unique location in the thorax. One can roughly represent a cross section of the infant chest as shown in Fig. 3, where the major components consist of chest wall, lungs, heart, and major blood vessels. The various tissues contained in these structures range in electrical conductivity from blood, which is a relatively good conductor, to air, which is an insulator. Both of these materials in the thoracic cavity show a change in volume with time over the cardiac and breathing cycles. Blood varies in volume over the cardiac cycle due to changes in the amount of blood in the heart and the vascular compartments. Air undergoes wide volume changes in the lungs during normal breathing. Thus, the electrical impedance of

Figure 3. Cross-sectional view of the thorax of an infant showing the current distribution from electrodes placed on the chest wall and excited by a transthoracic impedance type of apnea monitor.

the lungs and heart will change as the volume of air and blood in each, respectively, changes. If we want to measure the impedance variation due to these volume changes, this can be done by placing electrodes on the surface of each structure. If it were practical to do this, we would see large changes in impedance as the volumes of the respective structures change. Unfortunately, it is not possible to place electrodes on the structures that are to be measured and so these large impedance differences are not seen in practice.

Electrodes must be placed upon the surface of the skin for practical electrical impedance measurements on infants. Most of the current passing between the electrodes will travel through the chest wall and will not pass through the heart and lungs because of the low resistivity of the tissues in the chest wall. Thus, the changes in impedance of the heart and lungs will only represent a small proportion of the impedance measured between the electrodes. Fig. 3 schematically illustrates the relative distribution of the current through the chest when electrodes are placed on the midclavicular lines at the fourth intercostal space. It is seen that most of the current is conducted along the chest wall, so the chest wall impedance will dominate any measurement.

The actual impedance measured by the monitor consists of more than just the impedance between the electrodes on the chest surface. Since an ac electrical signal is needed to measure the impedance, this signal will affect the measurement as well. Generally, a signal in the frequency range from 20–100 kHz is used. At these frequencies, impedances associated with the electrode, the interface between the electrode and the body, and the lead wires contribute to the measured value along with the actual transthoracic impedance. This is illustrated schematically in Fig. 4. The actual impedances for each block are dependent upon the excitation frequency and the actual structures used, but for most clinical applications the net impedance seen by the monitoring circuit is nominally 500 Ω. Of this, the variation associated with respiration is generally no > 2 Ω and frequently even less. The impedance

Figure 4. Block diagram of the various impedances seen at the terminals of a transthoracic electrical impedance apnea monitor looking along the lead wires to the patient.

Figure 5. An example of cardiogenic artifact on infant respiration signals from a transthoracic impedance type of monitor illustrating cardiogenic artifact during apnea.

variation associated with the beating heart can be of the same magnitude, although it is generally a little less. Thus, it is seen that a fundamental problem in the indirect measurement of respiration by the transthoracic impedance method is the relatively small changes in impedance associated with the measurement.

To further complicate the situation, each of the non-thoracic impedance components of the circuit illustrated in Fig. 4 can vary in electrical impedance by at least as much if not more than the variation due to respiration. The impedance between the electrode and the infant's skin is strongly dependent on the electrode-skin interface. As electrodes move with respect to the skin, this impedance can vary by amounts much $> 2 \Omega$. This is also strongly dependent on the type of electrode used and the method that electrically couples it to the skin.

Cardiogenic Artifact

The volume of the heart varies during the cardiac cycle, and so the contribution of the blood to the overall

transthoracic impedance will change from systole to diastole. To a lesser extent the vascular component of the chest wall and lungs will also change in blood volume during the cardiac cycle, and this will have some influence on the transthoracic impedance as well. Cardiogenic artifact is illustrated in Fig. 5, which shows a recording of transthoracic impedance from an infant during breathing and during a period of apnea. The cardiogenic artifact is best seen during the apnea, where it appears as a smaller impedance variation occurring at the heart rate. This can be seen by comparing the impedance waveform with a simultaneously recorded electrocardiogram. One notes that the cardiogenic artifact is also present during the breathing activity and appears as a modulation of the respiration waveform.

In the example in Fig. 5 the cardiogenic artifact is relatively small compared to the impedance changes due to breathing, and it is possible to visually differentiate between breathing and apnea by observing this recording. This is not always the case when recording transthoracic impedance as Fig. 6 illustrates. Here one observes periods of breathing and apnea with much stronger cardiogenic artifact. It is difficult to determine what impedance variations are due to breathing and what are due to cardiovascular sources. It is only possible to identify periods of respiration and artifact when the recording is compared with a simultaneous recording of respiration from a recording of abdominal wall movement using a strain gage as shown in Fig. 6. Note that in the case of the impedance signal in this figure, the cardiogenic artifact has two components during each cardiac cycle.

Figure 6. High amplitude cardiogenic artifact is shown on the transthoracic impedance tracing from this recording of multiple signals from a newborn infant. In this case, the transthoracic impedance changes correspond to the electrocardiogram shown on the third trace from the top. Simultaneous recordings from a nasal thermistor and an abdominal strain gage do not show these high frequency variations.

Signal Processing

The electrical signals from the electrical impedance sensor, or any of the other respiration sensors, must be processed to recognize breathing activity and to determine when apnea is present. Different sensors require processors of differing complexity because of different signal characteristics, but the general method of signal processing is the same no matter what sensor is used. The signal processing associated with the electrical impedance method of apnea monitoring will be described in the following paragraphs, since it is one of the most complex as well as most highly developed monitoring systems.

A block diagram of the generalized sections of a transthoracic electrical impedance type of apnea monitor is shown in Fig. 7. The basic functions of the system can be broken down into impedance measurement, breath detection, artifact rejection, apnea identification, and alarm functions. Each of these can be carried out with varying degrees of complexity, and sophisticated signal processing techniques can be used to get the most information out of a less than optimal signal.

A signal generator in the impedance measurement portion of the system produces the excitation signal that is applied to the electrodes. This can either be a sinusoidal or a square wave, and frequently will have a high source impedance so that it behaves as though it was generated by a constant current amplitude source. Passing this current through the lead wire–electrode–body system causes a voltage amplitude proportional to its impedance to appear at the monitor input. Variations in this voltage reflect the variation in impedance. It is therefore important that the current amplitude of the excitation signal remain constant during a measurement. Excitation signal frequency is chosen to be in the range of 20–100 kHz so that electrode–body interface impedances are relatively low, thereby producing less artifact. Detection of individual breaths from a complex breathing signal represents a major task for the respiration monitor. While the design of electronic circuits to carry out such a function on a regular, noise-free, nearly constant amplitude respiration signal such as seen in Fig. 8a presents no problem; very often the respiration waveform is much more complicated and not so easily interpreted, as illustrated in Fig. 8b. Cardiogenic artifact also helps to complicate the signal detection problem since in some cases it can masquerade as a breath. Some of the basic methods of identifying breaths are listed in the following paragraphs. Often individual monitors will use more than one of these in various unique signal processing algorithms.

Fixed Threshold Detection. A breath can be indicated every time the respiration signal crosses a predetermined fixed threshold level. It is important to carefully choose this level so that nearly all breaths cross the threshold, but

(a)

(b)

Figure 8. Typical infant respiration signals obtained from infant apnea monitors. (a) The top trace illustrates a relatively quiet signal that can be processed to determine respiration rate and apnea. (b) The bottom trace is a typical example of a noisy signal resulting from infant movement. In this case it would not be easy to determine respiration rate.

Figure 9. Three identical respiration signals in which different methods of detecting a breath are used. The arrows indicate when the apnea monitor would detect a breath for each method. (a) Fixed threshold detection, note missing breath when signal fails to cross a threshold. (b) Adaptive variable threshold detection, note that breaths can be missed with this method when the amplitude from one breath to the next is significantly different. (c) Peak detector, note that this method can result in double breath detection for signals with multiple peaks.

practically no noise or artifact does. Figure 9a illustrates the basic threshold breath indicator system in which a breath is indicated whenever the signal is greater than the threshold level.

Automatic Gain Control. The fixed threshold method of detection can be improved by preceding the threshold detector with an amplifier that has an automatic gain control. In this way the weaker signals are amplified more than the stronger ones so that all signals appearing at the fixed threshold detector circuit have roughly the same amplitude and will be detected. Although this method makes the fixed threshold detection scheme more reliable, there is also the possibility that noise or cardiogenic artifact will be amplified until it is strong enough to masquerade as a breath during periods of apnea thereby causing the monitor to fail to identify the apnea.

Adaptive Threshold Detection. A variable threshold level can be set by the monitor based upon a preprogrammed algorithm. One common example of this is to have the monitor determine the threshold level based upon the amplitude of the previous breath. This is illustrated in Fig. 9b, where the threshold is set at 80% of the peak amplitude of the previously detected breath. Since this threshold may still be too high if the previous breath had a large amplitude and subsequent breaths were of a relatively low amplitude, this threshold is not fixed, but rather it slowly decreases so that eventually a breath will be detected and the threshold level can be reset. The risk with this type of system is that the threshold will eventually get low enough to detect noise or cardiogenic artifact during an apnea resulting in a breath detected in error. Thus, the algorithm for this adaptive system must have minimum threshold levels that are still well above the noise or cardiogenic artifact level for it to work effectively.

Peak Detector. This circuit recognizes the maximum value of a signal over a short interval of time regardless of the overall amplitude of that signal. The way that a peak detector detects the breaths from a typical respiration waveform is illustrated in Fig. 9c. The basic peak detector can recognize more than one peak in a complex respiration wave. This can give errors if the monitor is used to determine respiration rate. Again, by adding complexity to the signal processing algorithm, this type of error can be greatly reduced.

Filtering. Frequency spectral analysis of infant respiration signals shows that most of the information is contained in the frequency band of 0–6 Hz, and in many cases the band is even narrower (20). Since artifactual signals can exist both within and outside of this frequency range, most apnea monitors filter the respiration signals so that only the frequencies containing information are processed. The type of filtering used depends on the particular monitor design, but any process of filtering can distort the waveforms and may itself introduce artifact. This is especially true when high pass filtering is used to remove the baseline. Thus, filtering can affect the performance of the breath detection method used in the instrument.

Although filtering is an important aspect of the breath detection circuitry, it can in some cases cause motion artifact to begin to look similar to a respiration signal and thus allow the detection circuit to recognize artifact as a breath. Often under the best conditions it is difficult to discriminate between artifact and true breathing signals, and the filtering only further complicates this problem. Nevertheless, without filtering breath detection would be much more difficult.

Pattern Recognition. Computer technology allows algorithms for recognizing various features of the respiration

waveform to be applied for breath detection in infant respiration monitors. Features, such as threshold crossing, peaks and valleys, slopes, amplitudes, width, and interval of a respiration wave can be readily detected. More sophisticated algorithms can be trained to recognize breaths that are similar in appearance to preprogrammed waveforms or based on the appearance of previous breaths for a particular patient. Another important aspect of computer recognition of patterns is that the computer can be programmed to ask various questions: Is the measured value physiologically possible? Does the waveform look more like artifact than information? Is the rate too fast? Does the signal correspond too closely to the cardiac cycle so that it might be cardiogenic artifact? Is there more than one peak per breath? All of these techniques of breath detection have advantages and disadvantages for infant monitoring. Each technique, however, imposes constraints on the signal that determine whether it will also detect artifact or miss some true breaths. Even the most sophisticated computer methods suffer from faults such as these and present limitations in breath detection.

Cardiogenic Artifact Rejection. Although cardiogenic artifact represents a major problem when breathing efforts are measured by the transthoracic electrical impedance method, this interference can be seen at times in the output of other indirect sensors of respiration as well. Usually, for these other sensors this artifact is small and does not pose any problem in breath or apnea recognition. Several methods have been used to reduce the problems associated with cardiogenic artifact in the transthoracic electrical impedance type of apnea monitor. Cardiogenic artifact occurs at the heart frequency and its harmonics, which can be different from the periodicity of the respiration signal. In infants the heart rate is usually higher than the respiration rate, although this is not always the case since infants can breath quite rapidly. If the respiration signal containing cardiogenic artifact is passed through a low pass filter having a cutoff frequency that is higher than the expected respiration rates but lower than the heart rates likely to be encountered, much of the cardiogenic artifact can be removed without seriously distorting the respiration signal. The problem with this approach is the selection of a cutoff frequency for the filter. It is generally not possible to find a frequency that is greater than the maximum respiration rate yet less than the minimum heart rate for small infants. Estimated values of such a frequency have to be changed according to the age of the infant, and since bradycardia can be associated with apnea, it is possible that the heart frequency will drop below the filter cutoff frequency during times of apnea, allowing cardiogenic artifact to get into the respiration channel just at the very time when it should be avoided.

The approach of using a filter, however, has merit if the above limitations can be taken into consideration in the design of the filtering system. Although there is no way that a filter can be useful when the heart rate is less than the respiration rate, the filter can help if its cutoff frequency is based upon the apparent respiration and heart rates of the infant. Such adaptive filtering techniques have been successfully used to minimize the effects of cardiogenic artifact.

Since most transthoracic electrical impedance apnea monitors also determine heart rate from the electrocardiogram, this cardiac signal can be used to help identify when a respiration signal consists primarily of cardiogenic artifact. The temporal relationship between the cardiogenic artifact and the electrocardiogram should be constant since both come from the same source. If the respiration signal consists only of cardiogenic artifact, as would be the case during a period of apnea, it is possible to identify the fixed temporal relationship between the signal and the electrocardiogram and therefore reject the signal from being accidentally detected as a breath. The only limitation with this technique is that in rare cases the infant can breath at the same rate as the heart is beating, and the monitor would indicate that an apnea had occurred when in fact it had not.

COMBINATION TRANSTHORACIC IMPEDANCE AND CARDIAC MONITORS

Most commercially available infant apnea monitors take advantage of the fact that the same sensor system, a set of biopotential electrodes, can be used for both transthoracic electrical impedance respiration monitoring and cardiac monitoring. Since the excitation signal for transthoracic impedance monitoring has a frequency of 20 kHz or greater and the highest frequency component of the infant electrocardiogram is < 200 Hz, the excitation signal can be applied to the same electrodes used for obtaining the electrocardiogram. By connecting a low pass filter between the electrodes and the heart rate monitor circuit, this excitation signal can be kept out of the cardiac monitor, and a bandpass filter in the respiration monitor centered at the excitation signal frequency will keep the electrocardiogram and biopotential motion artifact out of the transthoracic impedance monitor circuit.

The combination of respiration and heart rate monitoring in a single instrument helps to identify life-threatening events. If for some reason the respiration monitor fails to recognize prolonged apneas, bradycardia will often be associated with such episodes, and the heart rate monitor will recognize the reduced heart rate and set off an alarm.

MEASUREMENT OF BLOOD GASES

Blood gases refer to the oxygen and carbon dioxide transported by the blood. Acid-base balance is also included in discussions of blood gases since it is closely related to respiratory and metabolic status. Thus, measurements of blood gases are frequently combined with measurements of blood pH. There are invasive and noninvasive methods of measuring blood gases. Both can be used for hospital monitoring of critically ill infants. The principal methods that are used are described in this section.

Invasive Methods

Invasive blood-gas measurement techniques involve direct contact with the circulatory system so that blood samples can be drawn and measured in a laboratory analyzer or a

miniature sensor can be placed within the blood stream for continuous measurements. Some of these methods are described in the following paragraphs.

Intraarterial Catheter. The newly born infant has an advantage over other medical patients in that the vessels of the umbilical cord stump can accept a catheter for several hours after birth. Thus, it is possible to introduce a fine-gage, flexible, soft catheter into an umbilical artery of a cardiac or respiratory compromised infant and advance the tip into the aorta so that samples of central arterial blood can be obtained for analysis. Blood samples with a volume of only 50 μL can be analyzed for pH, P_{O_2} , and P_{CO_2} by means of specially designed miniaturized versions of standard analytical chemistry sensors of these variables. Such microblood analyzers are also used for analyzing fetal scalp blood samples. It is important in neonatal applications that only microblood analyzers be used since the total blood volume of very small infants is limited. Since an infant's blood gas status can be labile, it is often necessary to draw many blood samples during the clinical course of care, thus significant blood loss can occur unless very small samples are taken.

Microblood analyzers generally use the inverted glass electrode for pH measurement, a miniaturized Clark electrode for P_{O_2} measurement, and a miniaturized version of the Stowe-Severinghaus sensor for P_{CO_2} . The technology of microblood gas analyzers is well developed, and devices perform reliably in the intensive care situation. Instrumentation is frequently located within the neonatal intensive care unit itself, and respiratory therapists for collecting samples and carrying out the analyses as well as calibrating and maintaining the analyzers serve round the clock.

The major limitation of this sampling technique is that the sample only represents the blood gas status at the time it was taken. Thus, frequent samples must be taken during periods when variations can occur to track these variations, and even with microblood analyzers this can sometimes result in significant blood loss for very small infants. If the method for drawing the blood sample from the infant is stressful, such as a painful vascular puncture or heel stick, the blood gases of the sample will probably not reflect the quiescent status of the patient. As a matter of fact the very act of obtaining the blood sample may be of some risk to the infant since it can temporarily increase hypoxia (21).

The umbilical vessel cannulation is not without problems itself. In placing the catheters, one must be careful not to damage the lining of the vessels or perforate a vascular wall resulting in severe bleeding or hemorrhage. Catheters must be made of materials that do not promote thrombosis formation. When catheters are not used for drawing blood, they must be filled with a physiological solution containing an anticoagulant such as Heparin so that blood that diffuses into the tip of the catheter does not clot. Any thrombi formed on the catheter wall or within its lumen can break off and cause embolisms further downstream. For arterial catheters this can be in the blood supply to the lower periphery of the infant, and it is possible to see under perfused feet in infants having an umbilical artery catheter. Catheters in the umbilical vein or peripheral veins can also produce emboli. In this case the clots are

returned to the right side of the heart and can go on to produce pulmonary emboli.

Peripheral Blood Samples. Although it is frequently possible to introduce a catheter into an umbilical artery in a newly born infant, this is not always the case, or the need for blood gas monitoring may not arise until the infant is sufficiently old that the umbilical vasculature has permanently closed. In this case it is necessary to cannulate a peripheral artery to obtain frequent arterial blood samples. On very small infants this is no minor task since these vessels are very small and difficult to cannulate transcutaneously.

An alternative to drawing an arterial blood sample is to take a sample of capillary blood from the skin under conditions where the capillary blood flow has been significantly increased so that the capillary blood appears to be similar to peripheral arterial blood. This can be done, for example, in the heel by first warming an infant's lower leg and foot by wrapping it with warm, wet towels. A blood sample of sufficient size for a microblood analyzer can then be obtained by making a small skin incision with a lancet and collecting the blood sample in a capillary tube in a fashion similar to the technique for obtaining a fetal scalp blood sample (see FETAL MONITORING). Although this technique is not as reliable as sampling from an umbilical artery catheter, it can be used when only a single blood sample is desired and an umbilical catheter would be inappropriate or where it is not possible to place such a catheter. An important limitation of the technique is that the infant's heels can become quite bruised when frequent samples are required and suitable locations for additional samples might no longer be available. When frequent samples are required, it is generally better to attempt cannulation of a peripheral artery.

Internal Sensors. Blood gases can be continuously monitored from invasive sensors. Generally, these sensors are incorporated into umbilical artery catheters (22), but tissue measurements have also been demonstrated (23). The most frequently applied technique involves the incorporation of an amperometric oxygen sensor into a catheter system. This can be done either by incorporation of the sensor within the wall of the catheter, by using a double lumen catheter with the sensor in one lumen and the second lumen available for blood samples or infusion, or by using a conventional single lumen catheter with a sensor probe that can be introduced through the lumen so that the sensor projects beyond the distal tip of the catheter.

Oximetry, the measurement of hemoglobin oxygen saturation, can be carried out continuously by means of optical sensors coupled to intravascular catheters or probes. Optical fibers can be incorporated in the wall of a catheter or in an intraluminal probe and used to conduct light to the catheter's distal tip. The light illuminates the blood in the vicinity of the catheter tip, and an adjacent fiber or bundle of fibers collects the backscattered light and conducts it to a photo detector where its intensity is measured. By alternately illuminating the blood with light of two or more different wavelengths, one of which is close to

an isosbestic point, and measuring the backscattered light, it is possible to determine the hemoglobin oxygen saturation in the same way as done in laboratory instruments for *in vitro* samples.

Advantages and Disadvantages of Invasive Techniques.

The methods described in the previous sections represent direct measurements in that the sensor that is used is in direct contact with the body fluid, usually blood, being measured. This direct contact improves the possibility of accurate measurements. When the sensor is not located in the blood itself but is used to measure samples of blood drawn from the patient, instruments can be frequently calibrated using laboratory standards. Sensors that are used within blood or other tissues have the requirement that they must be small enough to fit in the tissue with minimal damage, either as a part of a catheter or some other probe. The miniaturization process must not compromise accuracy or reproducibility. In cases where micro-electronic technology can be used to miniaturize the structures, reproducibility can even be improved in the mass-produced miniature devices as compared to their piece-by-piece-produced larger counterparts. The continuous invasive sensors are also limited in where and when they can be applied. While the umbilical arteries are convenient conduits to the central arterial circulation, they are only patent for a few hours after birth in most newborn infants. Following this time it is very difficult to obtain arterial samples since other vessels must be used. The use of intravascular sensors, and those in tissue as well, also increases the risk of infection and mechanical damage. Care must be taken with intraarterial sensors to avoid serious hemorrhage due to system components becoming disconnected.

Noninvasive Methods

In noninvasive measurement of blood gases, there is no direct contact between the blood or other tissue being measured and the sensor. In this way there is usually less risk to the patient and the technique is easier to apply clinically. The major noninvasive methods used in neonatal monitoring are now described.

Transcutaneous Blood Gas Tension Measurement. One of the major advances in neonatal intensive care monitoring technology was the development of transcutaneous blood gas measurement instrumentation. This allowed the oxygen tension and later the carbon dioxide tension of infants at risk to be continuously monitored without invading the circulatory system (24). These methods make use of a heated sensor placed on the infant's skin that measures the partial pressures of oxygen or carbon dioxide of the blood circulating in the dermal capillary loops under the sensor. The heating of the skin to temperatures of 44 °C arterializes the capillary blood in a manner similar to that used for obtaining capillary blood samples with heel sticks. Although the heating of the blood increases the blood gas tensions in the capillary blood, oxygen consumption by the viable epidermis surrounding the capillaries and diffusional drops through the skin compensate for this increase

resulting in good correlations between the transcutaneously measured blood gas tensions and those determined from arterial blood samples in neonates. Sensors can be left in place on neonates for up to four hours, but for longer periods of time it is recommended to move the sensor to a new location to avoid tissue damage due to the elevated temperature. Multiple sensors have been developed in which the heating element is switched between several sensors in the same package periodically so that the overall sensor can be left in place for longer periods of time without producing damage (25).

Although transcutaneous instrumentation can give good correlations between transcutaneous and central arterial blood gas measurements in neonates, it would be misleading to suggest that the transcutaneous instrument is measuring the same thing as is measured from arterial blood samples. Indeed in infants with unimpaired circulatory status, the transcutaneous blood gases and those in the central circulation are similar; however, when there is cardiovascular compromise, heating of the sensor can no longer completely arterialize the capillary blood, and there are significant differences between the transcutaneous and central measurements. Thus, when one makes both transcutaneous and central measurements, differences can be used as a means of identifying shock-related conditions (26).

Transcutaneous Mass Spectrometry. Another noninvasive method for measuring blood gas tensions involves the use of a transcutaneous mass spectrometer (27). A sensor similar to the transcutaneous blood gas sensor in that it contains a heater to arterialize the capillary blood under it is made of a gas-permeable membrane in contact with the skin. This is connected to the mass spectrometer instrument through a fine-bore flexible tube through which an inert carrier gas is circulated to bring the gases that diffuse from the skin into the sensor to the instrument. (For details of this instrument see MASS SPECTROMETERS IN MEDICAL MONITORING). At the present time, mass spectrometry instruments are far more expensive than instruments for electrochemically determining the transcutaneous blood gas tensions. The advantage of the mass spectrometer, however, is that it can simultaneously measure more than a single blood gas component. It can also measure other gases in the blood stream, such as anesthetic agents or special tracers.

Pulse Oximetry. The use of optical techniques to determine the hemoglobin oxygen saturation in blood is well known and is the basis for routine clinical laboratory instrumentation along with the fiber optic catheter oximeter described in the previous section on internal sensors. Oximeters have also been developed for measuring the oxygen saturation transcutaneously. Initial devices measured the continuous steady-state reflection of light of different wavelengths from the surface of the skin. Pigmentation of the skin, unfortunately, limited this technique to qualitative measurements unless the instrument was specifically calibrated to a particular individual at a particular site. Upon examining the backscattered optical signal from the skin, one can notice a small pulsatile

component at the heart rate. This is due to the changing blood volume in the capillary beds reflecting the light, and it can be seen for transmitted light as well. By looking at this pulsatile component of the transmitted or reflected light, it is possible to measure only the effect of each fresh bolus of blood entering the capillary bed at systole. This allows the principle of oximetry to be adapted to the transcutaneous measurement of arterial blood hemoglobin oxygen saturation (28). This technique is used for continuously monitoring tissues that can be transilluminated, such as the hand, foot, fingers, toes, ears, and nasal septum. These pulse oximeters have the added advantage that in most applications it is not necessary to arterialize the capillary blood by heating; thus, sensors can be left in place for longer periods of time without risk of tissue injury.

Pulse oximeters have rapidly achieved a major role in neonatal and adult intensive care medicine. It is important to point out that oximetry differs from oxygen tension measurement in that it tells how much oxygen is carried by the hemoglobin. To know total oxygen transport one needs to know the amount of hemoglobin in the blood as well as the perfusion of the tissue in question. Thus, oximetry can with some additional data be quite useful in determining whether adequate amounts of oxygen are being supplied to vital tissues. There is one aspect of neonatal monitoring, however, where oximetry is of little assistance. The condition, known as retinopathy of prematurity, is found in premature infants and thought to be related to the newly formed capillaries in the retina, which are exposed to blood of elevated oxygen tension in infants who are receiving oxygen therapy. An important aspect of oxygen monitoring in premature infants is to determine if the arterial blood oxygen tension becomes elevated, so that the amount of oxygen that the infant breathes can be reduced to protect the eyes. If retinopathy of prematurity occurs as a result of elevated oxygen tensions, blindness can result. Thus, to truly protect the patient from this condition, one must measure oxygen tension not hemoglobin oxygen saturation.

Pulse oximeters in routine clinical use are primarily based on the transmission mode of operation, although backscatter oximeters have also been developed (29,30). The clinical instruments, therefore, are limited in terms of where they can be attached to the subject. Generally, these positions are found on the periphery and are, unfortunately, the first to experience diminished circulation under shock or preshock conditions. Another limitation of currently available pulse oximeters is their great sensitivity to motion artifact. Signal processing algorithms have been developed to reduce the effect of motion on the pulse oximetry signal and to detect motion artifact and prevent it from being indicated as data (31). Nevertheless, since the oxygen saturation values presented represent averages over several heartbeats, movement can result in an apparent decrease in oxygen saturation that in fact has not occurred.

TEMPERATURE MONITORING

An important aspect of treating premature infants is to the maintenance of their thermal environment. A premature

infant is not well adapted to extrauterine life, and its temperature control system is not fully developed since it normally would be in a temperature regulated environment in the uterus. Thus, an artificial environment must be provided to help the neonate control its body temperature. This environment is in the form of convective incubators and radiant warmers. Another reason for providing an elevated temperature environment for premature infants is that very often these infants suffer from problems of the respiratory system that limit the amount of oxygen that can be transported to the blood by the lungs. This oxygen is utilized in the metabolic processes of the infant, and among these are the generation of heat to maintain body temperature. By placing the infant in an environment at a temperature greater than normal room temperature, less energy needs to be expended for thermal regulation. A neutral thermal environment can be found where the temperature and relative humidity are such that the infant utilizes a minimum amount of energy to maintain its temperature, and oxygen and nutritional substrates that would normally go into heat generation can be utilized for metabolic processes related to growth and development. Thus, to maintain this environment, it is necessary to monitor both the temperature of the infant and that of the environment.

Temperature monitoring instrumentation in the nursery is relatively straightforward. The sensor is a thermistor that can be in one of two basic forms, an internal probe or a surface probe. The former consists of a semiflexible lead wire with a thermistor mounted at its distal tip. An electrically insulating polymer with good thermal conductivity covers the thermistor and is contiguous with the lead wire insulation. This probe can be placed rectally to give a neonatal core temperature measurement. The surface probe is a disk-shaped thermistor ~ 6 mm in diameter with lead wires coming out in a radial direction. The sensitive surface of the probe is metallic and is in intimate contact with the thermistor, while the other surface of the probe is covered with a thermally insulating polymer so that the thermistor is well coupled to the infant surface it contacts through the metal but poorly coupled to the environmental air. The surface temperature measured is not necessarily the same as core temperature and is strongly dependent on the infant's environment. Often the surface mounted probe is placed over the liver since this organ is highly perfused and is close to the skin surface in small infants. To aid and maintain a good thermal contact between the surface probe and the infant skin, the lead wires, especially near the probe, should be highly flexible so that the wires do not tend to force the thermistor to come loose from the skin as the infant moves. As was mentioned for surface mounted biopotential electrodes, the skin of premature infants is sensitive to many factors, and strong adhesive can produce severe irritation. Weaker adhesives, however, can allow the thermistor to come off, and the use of flexible lead wires greatly reduces this tendency.

The remainder of the instrumentation in temperature monitoring devices is straightforward. An electronic circuit senses the resistance of the thermistor and converts this to a display of its temperature. In some cases alarm circuits are incorporated in the monitors to indicate when the

Figure 10. A servo-temperature control system for incubator temperature directed toward maintaining infants at a preset temperature.

temperature lies outside of a preset range. Temperature instruments are used not only for indicating infant surface and core temperatures, but also for the control of incubator or radiant warmer temperature. Although convective incubators have internal control systems to maintain the air temperature at a preset point, the purpose of the incubator is not as an air temperature controller. Instead the incubator is used to maintain the infant's body temperature at a certain point and to minimize thermal losses from the infant. For this reason some incubators have servo systems that control incubator temperature based on infant temperature rather than air temperature. A block diagram of such a system is illustrated in Fig. 10. Here a thermistor is the sensor and is positioned on the infant's skin or internally. If a radiant warmer is used, it is important that any surface mounted thermistor is not in the radiant field and thus directly heated by the warmer. Frequently thermistors are covered with an insulating disk that has a highly reflective outer surface of aluminum foil so that no direct radiant energy from the heater falls on the thermistor. An electronic circuit determines the thermistor resistance, and hence, its temperature, which is assumed to be equivalent to the infant's temperature. This drives a control circuit that provides proportional control to the heating element of the convective or radiant source. In some cases integrating and differential control is added to the system for optimal response. Additional safety circuits are included in the system to prevent it from overheating or underheating, both of which are undesirable for the infant. The final block of the system is the heater itself. The control system must take into account the time response of this element so as to provide optimal control. An indicator is frequently included in the system to show infant temperature and heater status.

PRESSURE MEASUREMENT

The measurement of the pressure in fluids is important in many aspects of medical care. This is especially true in

neonatal monitoring, and instrumentation for the intermittent or continuous measurement of blood pressure is frequently used in the intensive care unit. There are also situations where the monitoring of intracranial pressure is important in the care of infants. Instrumentation for measuring these pressures is similar to other monitoring instrumentation described in this article in that measurements can be made by direct and indirect means. These are described in the following paragraphs.

Blood Pressure

The direct measurement of blood pressure consists of coupling the arterial or venous circulations to a pressure transducer that is connected to an electronic instrument for signal processing, display, and recording. The direct methods used are similar to those used in adult intensive care (see BLOOD PRESSURE MEASUREMENT). Generally, measurements are only made on the arterial circulation, and wherever possible an umbilical artery is used for access to this circulation. An umbilical artery catheter, such as described in the section on direct measurement of blood gases, is filled with a physiologic saline solution containing an anticoagulant. The proximal end of this catheter is connected to an external pressure sensor that is positioned in the incubator near the infant. This is usually a disposable semiconductor pressure sensor that is used only on a single infant and then discarded so that there is no risk of cross-contamination from one patient.

Indirect blood pressure monitoring in the neonate presents special problems not seen in the adult. It is generally not possible to measure an infant's blood pressure using a sphygmomanometer and the auscultation technique because Korotkoff sounds cannot be detected. Thus other, more complicated methods of indirectly measuring blood pressure must be used. If a sphygmomanometer cuff around a limb is still employed, it is important to use the correct size of cuff for the infant being studied. The width of the cuff should be from 45 to 70% of the limb circumference (32). Cuffs of several different sizes are, therefore, available for use with infants. These frequently are inexpensive disposable cuffs designed for use with a single infant.

Systolic and diastolic pressures can be sampled non-invasively using the oscillometric or the kinarteriography methods. Both techniques (see BLOOD PRESSURE MEASUREMENT) are based upon blood volume changes in the section of artery under or distal to the sphygmomanometer cuff. In the case of the oscillometric measurement, the actual volume changes are determined, while the kinarteriography method measures the radial velocity of pulsations in the arterial wall. In the former case pressure variations in the cuff itself are sensed, and signal processing allows mean arterial pressures as well as systolic and diastolic pressures to be determined.

The kinarteriographic technique utilizes an ultrasonic transducer under the cuff. Continuous wave ultrasound is beamed at the brachial artery, when the cuff is on an arm, and some ultrasonic energy is reflected from the arterial

wall. This is picked up by an adjacent ultrasonic transducer, and an electronic circuit determines the frequency differences between the transmitted and reflected waves. When the arterial wall is in motion, the reflected ultrasound is shifted in frequency thereby giving a frequency difference between the transmitted and reflected waves. Motion of the arterial wall is greatest when the cuff pressure is between systolic and diastolic pressures; and thus by measuring changes in the frequency shift of the reflected wave, it is possible to determine the systolic and diastolic pressures. Unlike the oscillometric technique, it is not possible to determine the mean arterial pressure with kinarteriography.

Monitoring of Intracranial Pressure

As was the case with blood pressure, intracranial pressure (the pressure of the cerebrospinal fluid and brain within the cranium) can be determined by direct and by indirect methods. The former involves the placement of a tube within the brain such that its distal tip communicates with the intraventricular fluid. The proximal end is connected to a low compliance pressure transducer. Although this technique is highly accurate, a significant risk of infection is associated with its application, and it is only used under extreme circumstances when no other technique is possible.

Noninvasive techniques of monitoring neonatal intracranial pressure are much safer than the direct technique but, unfortunately, are not as accurate. The newborn infant not only has special access available to the central circulation through the umbilical cord, but also has a means of accessing the intracranial contents through the anterior fontanel. This gap in the calvarium means that only soft tissue lies between the scalp surface and the dura mater. Thus, it is possible to assess intracranial pressure through this opening by various techniques.

A skillful clinician can palpate the anterior fontanel and determine to some extent whether the pressure is elevated or not (33). Another clinical method that can be used is to observe the curvature of the scalp over the fontanel as the position of the infant's head with respect to its chest is changed (34). The curvature should flatten when intracranial and atmospheric pressures are equivalent. These techniques are highly subjective and not suitable for neonatal patient monitoring; however, they can be the basis of sensors for more objective measurement.

Various forms of tonometric sensors have been developed for noninvasively measuring and monitoring intracranial pressure (35). These all consist of some sort of probe that is placed over the anterior fontanel in such a way that the

curvature is flattened and formed into a plane normal to the surface of the probe itself. Guard rings, calibrated springs, and other techniques have been used to achieve this appplanation. Ideally once this is achieved the pressure on either side of the membrane consisting of the soft tissue between the dura and the scalp surface should be equal. Thus, by sensing the pressure on the probe side, one can determine the pressure on the other side of the dura. Unfortunately, such a situation only holds in practice when the membrane is thin with respect to the size of its planar portion. In the case of the soft tissue between the dura and the scalp, the membrane thickness can often be close to the size of the planar portion because of the limitations imposed by the opening of the fontanel. Thus, the technique has some definite limitations. The method of attachment of the probe to the infant and the structure of the probe itself are critical to the efficacy of the resulting measurements.

Many investigators have considered different approaches to making an appropriate probe for transfontanel intracranial pressure measurement. These range from strain-gage-based force sensors with guard rings to transducers that attempt to achieve appplanation by means of a compliant membrane mounted upon a chamber in which air pressure can be varied. In the case of this latter technique, the position of the membrane is detected and a servo control system is used to adjust the pressure within the chamber so that the membrane presses the tissue of the fontanel into a flat surface. Such a device is shown schematically in Fig. 11. The position of the membrane is established optically by means of a shutter attached to the membrane such that it varies the amount of light passing from a fiber optic connected to a light source to one connected to a light detector. A servo system controlling the air pressure within the structure adjusts it so that the diaphragm, and hence the tissue of the fontanel, is flat. At this point, the pressure of the air within the sensor should theoretically equal that of the tissue within the fontanel, which in turn should give the intracranial pressure.

Elevated intracranial pressure in infants can be the result of volume occupying lesions, excessive secretion of fluids within the epidural space, the brain tissue itself, or fluid in the ventricles of the brain. A frequent form of lesion is bleeding or hemorrhage within one of these volumes, a condition that is far too often seen in premature infants. Another form of elevated intracranial pressure results from hydrocephalus, a condition in which intraventricular fluid volume and pressure become elevated. By continuous monitoring or serial sampling of intracranial pressure, it

Figure 11. A pressure sensor used for intracranial pressure measurements in the newborn based upon measuring membrane deflection by means of fiber optics.

is possible to provide better control of therapy for these problems.

Monitoring of Intracranial Hemorrhage

As pointed out in the previous section, one cause of elevated intracranial pressure in the newborn is intracranial hemorrhage. It is important to be able to detect when this occurs so that therapeutic measures can be immediately taken to minimize irreversible damage. Although no technique is suitable for continuous monitoring of infants at risk of intracranial hemorrhage, several techniques can be used for surveillance and periodic sampling especially of infants showing possible signs and symptoms of intracranial bleeding.

Devices for the noninvasive measurement of intracranial pressure have been described in the previous section. In addition to these, intracranial hemorrhage can be identified by measurement of transcephalic electrical impedance (36). In this case, it is the baseline value of the impedance that is important. For this reason, a tetrapolar method of measurement must be used to minimize the effects of electrode and lead wire impedances. An alternating current at an excitation frequency of 20–100 kHz is passed between a frontal and occipital electrode placed on the infant's head. A second pair of electrodes are located near the excitation electrodes, but far enough to avoid voltage drops due to the spreading current at the excitation electrodes. The signal is picked up by these electrodes and detected by an electronic circuit to give a voltage proportional to the baseline impedance value. Since the specific impedance of blood is ~ 2.5 times greater than the specific impedance of the cerebral spinal fluid, one should see an elevated transcephalic impedance when the ventricles are filled with blood rather than cerebral spinal fluid. Similarly, if the ventricles have grown in volume because of excess cerebral spinal fluid as in hydrocephalus, the transcephalic impedance should be lower than expected.

In practice, one can only look for changes in transcephalic impedance in infants and not at absolute baseline values because of differences in geometry from one subject to the next. Typically, the technique requires one or more measurements to be taken during the first 24 h of life on each infant and using these measurements to obtain baseline intraventricular, hemorrhage-free data for that particular infant. Subsequent measurements through the infant's hospital course are compared to these initial measurements, and deviations are noted. Significant elevations in impedance have been associated with the occurrence of intraventricular hemorrhage. Studies have been carried out to show that this impedance shift correlates with intraventricular hemorrhage as found using other diagnostic techniques or, in the case of infants who expire, at autopsy (36). The principal advantage of this method is its relative simplicity and ease of measurement on infants in the intensive care unit.

Ultrasonic determination of intraventricular hemorrhage involves making a B scan of the infant's head and locating the ventricular system (37,38). If the ventricles are filled with cerebral spinal fluid alone, the fluid in the ventricles does not reflect ultrasound, and the ventricles

appear clear on the image. If there is blood in the ventricular fluid, ultrasonic echoes are produced by the cellular components of the blood. This causes reflections to appear within the ventricle on the image and allows for a definite diagnosis of intracranial hemorrhage.

As with the transcephalic impedance method, the technique of making measurements on infants is straightforward and can be carried out in the neonatal intensive care unit. The equipment necessary for the measurement, however, is more costly than the impedance; but the results are far more specific to identifying intracranial hemorrhage, and thus this is the current method of choice.

An additional method that can be used for detecting bleeding within the ventricles is the use of computerized tomography (CT) scans (39). While this technique is highly efficacious from the standpoint of identifying intracranial bleeding, it is undesirable because it exposes the developing nervous system to significant amounts of X radiation. It also is necessary to transfer infants to the radiology department where the scanning equipment is located to make the measurement. For severely ill, premature infants, this transfer can significantly compromise their care.

MONITORING BILIRUBIN

Bilirubin is a product of the biochemical degradation of the heme moiety that occurs in the hemoglobin molecule as well as other proteins. It is normally found as a result of red blood cell turnover, but it can be elevated in some hemolytic diseases. This form of bilirubin, known as unconjugated bilirubin, enters the circulation and then the skin and other tissues. When it is present in the skin in sufficient concentration, it causes a yellow coloration known as jaundice. It also enters nervous tissue where, if it reaches sufficient concentration, it can cause irreversible damage.

Increased serum bilirubin can occur either as the result of increased production or decreased clearance by the liver. The former situation can occur in normal and premature infants and is referred to as physiologic jaundice of the newborn. It is usually more severe in prematurely born infants and generally peaks about the third day of neonatal life. There are several modes of therapy that can be used to reduce serum bilirubin once elevated values are detected. The simplest way to detect jaundice in the neonate is to observe the infant's skin and sclera for yellow coloration. Quantitative assessment can be carried out by drawing a blood sample and extracting the cellular components from the serum. The absorption of light at a wavelength of 450 nm in such a serum sample is proportional to its bilirubin concentration. Photometric instrumentation for doing this is readily available in the clinical laboratory and some intensive care units (38). The problem with this method is the need for obtaining a blood sample and the time necessary to transport the sample to the laboratory and analyze it in the photometer. A method for the rapid assessment of serum bilirubin in all infants would represent an improvement over these techniques. Fortunately, a relatively simple optical instrument has been developed for assessing serum bilirubin in infants (40). It is illustrated schematically in Fig. 12 and consists of a xenon flash tube

Figure 12. Schematic diagram of a transcutaneous bilirubin instrument.

light source and photometers with filters to measure the reflected light at 460 and 550 nm. A special feature of the instrument is a pressure switch on the portion of the probe that is pressed against the infant's forehead to make the measurement. This probe contains fiber optics that couple the xenon flash tube and the photometers to the skin surface. As the probe is pressed against the skin, the force squeezes the blood from the cutaneous capillaries. Once the force is great enough to sufficiently blanch the skin under the fiber optics so that the blood will not interfere with the measurement, a switch activates the flash tube and readings are taken from the photometers. An internal microprocessor analyzes the reflected light and compensates for any residual hemoglobin. It gives a number proportional to skin bilirubin on a digital display. The proportionality constant, however, differs for different types of neonatal skin; thus, proportionality constants have to be determined for infants of different age, race, and whether they have received phototherapy or not. This instrument involves a sampling technique and thus is only suitable for trend rather than continuous monitoring. Since changes in serum bilirubin are relatively slow, such a technique is entirely appropriate. The principal advantage of this instrument is that it can be readily applied to all infants in the nursery with little effort on the part of the clinical staff. Readings can be made quickly to identify those infants at risk of hyperbilirubinemia.

MONITORING LIFE SUPPORT SYSTEMS

Although one usually associates neonatal monitoring with the measurement of physiologic variables from the newborn or prematurely born infant, an aspect of neonatal monitoring that should not be overlooked is associated with monitoring the patient's environment. Various life support systems are important in neonatal intensive care, and electronic instrumentation for assessing and maintaining the function of these is also important. There should be alarm systems so that when the conditions of life support are inappropriate for neonatal care, care takers are alerted and the problem can be corrected before it causes any harm

to the patient. There are many examples of life support system monitoring in the neonatal intensive care unit, and some of the major ones will be described in the following paragraphs.

Maintaining an appropriate thermal environment for the neonate is an important aspect of neonatal intensive care. Incubators and radiant warmers need to have internal temperature instrumentation to ensure that the environment is appropriate for the infant and so that the clinicians providing care can be aware of environmental conditions. Convection incubators frequently have temperature sensors for measuring the environmental air temperature and indicating it on the control panel of the device. These temperature sensors are often a part of the thermal control system in the incubator itself, and as indicated earlier the infant's own temperature can be used as a control signal for some incubators. Built into this incubator temperature monitoring function is an alarm function that can indicate when the incubator temperature becomes too high or too low; potentially life threatening conditions.

It is sometimes necessary to intubate the trachea of a patient and to use a ventilator to control breathing. A gas with elevated oxygen content is often used to help provide additional oxygen to infants who require it. There are many points in a support system such as this where monitoring devices can be useful to assess and in some cases control the function of the device. Where gases of elevated oxygen tension are given, instrumentation to measure the partial pressure of oxygen within the gas to indicate the oxygen fraction of inspired gas is desirable. Various types of oxygen sensors are, therefore, placed in the air circuit to either continuously or intermittently measure and display this quantity. The temperature and humidity of the inspired air are also important, and appropriate sensors and instrumentation for these variables can be included as a part of the respiratory support system. Continuous positive airway pressure is a mode of therapy used in infants requiring ventilatory support. It is necessary to measure and control the positive pressure in such systems to minimize the risk of pneumothorax and to ensure that the desired levels are maintained.

The use of arterial and venous catheters in infants for blood pressure and blood gas monitoring as well as fluid therapy and hyperalimentation represents a safety risk to the infant. Arterial catheters and associated plumbing can become disconnected and cause serious losses of blood that if not quickly checked can result in severe injury or death to the patient. Gas bubbles inadvertently infused along with intravenous fluids can, if sufficiently large, compromise the circulation by producing gas embolisms. Fluid therapy in very small infants must be precisely controlled so that excessive or insufficient amounts of fluid are not provided to the infant. Electronic instrumentation for controlling all of these variables and producing an alarm when dangerous conditions are encountered have been developed (41). Some of these, such as intravenous infusion pumps, are routinely used in neonatal intensive care units. Safety devices for over- or underpressures can be built into the pumps, as can sensors, to indicate when the fluid source has been depleted so that additional fluid can be attached to the pump.

Phototherapy is a technique of illuminating the baby with blue light in the wavelength range of 420–500 nm to oxidize bilirubin to compounds that can be eliminated from the body. Phototherapy units consisting of a group of 20 W fluorescent lamps 30–40 cm above the infant must be used cautiously because there are risks associated with this radiation. Therefore, it is important to determine the amount of radiant energy received by the infant in the 420–500 nm band so that minimal exposure times sufficient to oxidize the bilirubin can be given. Instrumentation consisting of a small probe containing a photosensor that can be held just above the neonate has been developed for this purpose. It is not necessary for this instrumentation to be used to continuously monitor the phototherapy units, but frequent testing of the therapy devices helps not only to determine the appropriate exposure times, but also to indicate when the fluorescent lights become ineffective and need to be changed.

DIAGNOSTIC RECORDINGS

The role of infant monitoring is to determine when events requiring therapeutic intervention occur so that optimal care can be provided. Hard copy recordings from electronic monitoring devices can also be useful in diagnosis of illness and identification of infants who may benefit from electronic monitoring over a longer period of time. Two types of diagnostic recordings are currently used in neonatology: polysomnograms and oxycardiogram although both are still considered experimental and are not routinely used.

Polysomnography. Multiple channel, simultaneous, continuous recordings of biophysical variables related to the pulmonary and cardiovascular systems taken while the newborn or infant sleeps are known as polysomnograms (41–43). These recordings are often made overnight, and 8–12 h is a typical length. The actual variables that are monitored can vary from one study to the next as well as from one institution to the next. However, these usually include the electrocardiogram and/or heart rate. One or

more measures of respiratory activity, such as transthoracic electrical impedance or abdominal strain gage; measures of infant activity and movement; measures of infant sleep state, such as eye movements and usually a few leads of the electroencephalogram; and measures of infant blood gas status are also recorded. The number of channels of data in polysomnograms is at least 3 and often is 12 or more. Recordings are made using computer data acquisition systems.

The primary application of polysomnography has been as a tool for research evaluating infant sleep patterns and related physiologic phenomena during sleep. Some investigators feel that polysomnographic recordings are useful in evaluating infants considered to be at risk to sudden infant death syndrome, but at present there is no conclusive evidence that this technique has any value in such screening. There may, however, be specific individual cases where such evaluations may contribute to overall patient assessment.

Oxycardiogram. This technique is used for continuous computer monitoring of infants in the neonatal intensive care unit (44). Four or five physiologic variables are monitored and continuously recorded on a multichannel chart recorder (45). These are the electrocardiogram from which the beat-to-beat or instantaneous heart rate is determined; the respiration waveform or pattern as generally determined by transthoracic impedance monitoring; the respiration rate as determined from the respiration waveform; the oxygen status as determined from a pulse oximeter or transcutaneous blood gas sensors; and at times the relative local skin perfusion as determined by the thermal clearance method from the transcutaneous blood gas sensor.

The importance of the oxycardiogram is that it brings these variables together on a single record, where they can be presented in an organized and systematic fashion. This makes it possible to observe and recognize characteristic patterns between the variables that may be overlooked when all of these quantities are not monitored and recorded together. The oxycardiogram is able to look at variables related to various points along the oxygen transport pathway from the airway to the metabolizing tissue. Thus, it allows a more complete picture of infant cardiopulmonary function than could be obtained by monitoring just one or two of these variables. Typical oxycardiogram patterns have been classified and organized to assist clinicians in providing neonatal intensive care (46).

SUMMARY

Infant monitoring along with adult monitoring under critical care situations involves many individual types of sensors and instruments. Depending on the application, many different types of output data will be produced. In addition, many different conditions for alarms to alert the clinical personnel can occur for each of the different instruments in use. Needless to say that although this provides better assessment of the infant as well as quantitative and

in some cases hard copy data, it also requires that this data be integrated to provide manageable information. By combining data from several different pieces of instrumentation, more specific conditions for alarms can be defined and variables can be more easily compared with one another. This can then lead into trend analysis of the data, and the computer certainly represents an important overall controller, analyzer and recorder of these functions. As technology continues to become more complex, it is important not to lose track of the primary goal of this technology, namely, to provide better neonatal and infant care so that critically ill neonates can look forward to a full, healthy, and normal life.

INTRODUCTION

The electroencephalogram (EEG) is an electrical activity of the brain that is recorded by using electrodes appropriately placed on the scalp, then amplifying and displaying the electrical signal and its clinical relevant feature using a computer, or other suitable monitors. The EEG signal is a wave that varies in time. This wave contains frequency components that can be measured and analyzed. These frequency components have meaning and valuable properties. Table 1 shows the commonly defined waves or rhythms, their frequency, and their properties. Hans Berger, the discoverer of the EEG in humans, observed in 1924 all of the rhythms known today (except the 40 Hz “gamma” band). He described many of their basic properties. Since then, our definitions and understandings of the rhythms have been refined. However, there still remains some uncertainty, and controversy, in how to define and use these bands, for various purposes. Clinicians view the brainwaves for diagnostic purposes and seek to identify patterns that are associated with specific pathologies or conditions. Psychologists also study them in association with mental states, mental processing, and to test concepts of how the brain processes information (1–6).

The EEG is therefore a noninvasive marker for cortical activity. The EEG in humans and animals is used to monitor alertness; coma and brain death; locate area of damage following head injury, stroke, tumor, and so on; monitor cognitive engagement; control depth of anesthesia; investigate and locate seizure origin; test epilepsy drug effects; monitor human and animal brain development; test drugs for convulsive effects; investigate sleep disorder, monitor and track brain ischemia; and so on. Continuous EEG monitoring is a common routine in the intensive care unit (ICU). However, in digital processed EEG, we study the patterns that emerge during various behavioral, as well as introspective, states, and then see what they are defining in terms of a multidimensional representation of some state space. Research that is focused on understanding specific properties, such as attention, alertness, mental acuity, and so on; has uncovered combinations of rhythms, and other EEG properties, that are relevant to these studies. Generally, derived properties are found, that involve computer processing of the EEG, to produce quantification measurements that are useful for research, monitoring, and so on.

Since high speed computers and sophisticated and efficient digital signal processing methodologies have become available. These properties are significant and new features and properties have been extracted from the EEG signal. These features are combined in a system of multivariable representation to formulate various quantitative EEG (qEEG) measures. The features commonly employed are (7–21).

- Amplitude

In the following section, the EEG monitors are classified and the main devices of the monitor are described. This section presents two types of monitors. In the common specification of Optimized Monitor section, the general specifications of the optimized EEG monitor are provided.

CLASSIFICATION OF EEG MONITORS

What is an EEG Monitor?

The neurological monitor is simply a display that shows the ongoing neurological activity recorded as the electrical potential by appropriately placing electrodes on the scalp. The conventional monitor goes back to EEG machine, where the electrical activity of the brain could be detected and plotted on scaled paper. Today, the neurological monitors are based on advanced technologies. They are

Table 1. EEG Rhythms their Frequency Bands and Properties

Rhythm Name	Frequency Band, Hz	Properties
Delta	0.1–3	Distribution: generally broad or diffused, may be bilateral, widespread Subjective feeling states: deep, dreamless sleep, non-REM sleep, trance, unconscious Associated tasks and behaviors: lethargic, not moving, not attentive Physiological correlates: not moving, low level of arousal Effects of Training: can induce drowsiness, trance, deeply relaxed states
Beta	4–7	Distribution: usually regional, may involve many lobes, can be lateralized or diffuse; Subjective feeling states: intuitive, creative, recall, fantasy, imagery, creative, dream-like, switching thoughts, drowsy; oneness, knowing Associated tasks & behaviors: creative, intuitive; but may also be distracted, unfocused Physiological correlates: healing, integration of mind/body Effects of Training: if enhanced, can induce drifting, trance-like state if suppressed, can improve concentration, ability to focus attention
Alpha	8–12	Distribution: regional, usually involves entire lobe; strong occipital w/eyes closed Subjective feeling states: relaxed, not agitated, but not drowsy; tranquil, conscious Associated tasks and behaviors: meditation, no action Physiological correlates: relaxed, healing Effects of Training: can produce relaxation Sub band low alpha: 8–10: inner-awareness of self, mind/body integration, balance Sub band high alpha: 10–12: centering, healing, mind/body connection
Low Beta	12–15	Distribution: localized by side and by lobe (frontal, occipital, etc.) Subjective feeling states: relaxed yet focused, integrated Associated tasks & behaviors: low SMR can reflect “ADD”, lack of focused attention Physiological correlates: is inhibited by motion; restraining body may increase SMR Effects of Training: increasing SMR can produce relaxed focus, improved attentive abilities, may remediate Attention Disorders.
Mid-range Beta	15–18	Distribution: localized, over various areas. May be focused on one electrode. Subjective feeling states: thinking, aware of self and surroundings Associated tasks and behaviors: mental activity Physiological correlates: alert, active, but not agitated Effects of Training: can increase mental ability, focus, alertness, IQ
High Beta	15–18	Distribution: localized, may be very focused. Subjective feeling states: alertness, agitation Associated tasks and behaviors: mental activity, for example, math, planning, and so on. Physiological correlates: general activation of mind & body functions. Effects of Training: can induce alertness, but may also produce agitation, etc.
Gamma	40	Distribution: very localized Subjective feeling states: thinking; integrated thought Associated tasks and behaviors: high level information processing, “binding” Physiological correlates: associated with information-rich task processing Effects of Training: not known

computer based and display not only the raw EEG, but also various quantitative indexes representing processed EEG. The monitors are EEG processors that have the ability to perform data acquisition, automatic artifact removal, EEG mining and analysis, saving/reading EEG data, and displaying the quantitative EEG (qEEG) measures (indexes) that best describe neurological activity and that are clinically relevant to brain dysfunction.

Neurological Monitor Main Components

As shown in Fig. 1, a typical neurological monitor consists of a few main devices. These devices are connected together through a microcomputer, which supervises and controls the data flow from one device to another. It also receives and executes the user instructions. It implements the EEG methodology routine. The main devices of a typical monitor can be summarized as follows:

ELECTRODES AND ELECTRODE PLACEMENT

Electrodes represent the electrical link between the subject’s brain and the monitor. These electrodes are appropriately placed on the scalp for recording the electrical potential changes. Electrodes should not cause distortion to the electrical potential recorded on the scalp and should be made of materials that do not interact chemically with electrolytes on the scalp. The direct current (dc) resistance of each electrode should measure no more than a few ohms. The impedance of each electrode is measured after an electrode has been applied to the recording site to evaluate the contact between the electrode and the scalp. The impedance of each electrode should be measured routinely before every EEG recording and should be between 100 and 5,000 Ω (2).

The international 10–20 system of electrode placement provides for uniform coverage of the entire scalp. It uses

Figure 1. Block diagram of main components of a neurological monitor.

the distances between bony landmarks of the head to generate a system of lines, which run across the head and intersect at intervals of 10 or 20% of their total length. The use of the 10–20 system assures symmetrical, reproducible electrode placement and allows a more accurate comparison of EEG from the same patients, recorded in the same or different laboratories.

Patient Cable

The patient cable assembles the electrode terminals to the recording machine and monitoring instrument. It is preferable that the patient cable be of short length, which assures low impedance and causes no distortion of the electrical potential representing the neurological activity.

Data Acquisition System

It is composed of filters, amplifiers, analog-to-digital converters (ADC), and buffers. Bandpass filters of 0.5–100 Hz band are usually used to enhance the quality of the EEG signal. High gain amplifiers are required since the electrical potentials on the scalp are of microvolt. The input impedance of the amplifiers should be a large value while the output impedance should be a few ohms. The ADC converter digitizes the EEG data by sampling (converts the continuous-time EEG into discrete-time EEG) the data and assign a quantized number for each sample. Figure 2 shows a schematic diagram for the ADC converter while Fig. 3 shows the output–input characteristic of the uniform quantizer. Uniform quantization generates additive white noise to the EEG signal. Portable and wireless units of ADC have been used. The unit is connected to the monitor device through a standard wireless communication routine. This makes the monitor more comfortable and easier to be used.

Microcomputer

The microcomputer represents the master of the EEG monitor. It controls the data flow from one device to another. It reads the EEG data from the ADC buffers. It also hosts the software of the qEEG approaches and the artifact removal programs. Mathematical operations and analysis are carried out in the microcomputer. After processing the EEG data, the microcomputer sends the EEG signal and its qEEG measure (index) to the display. When the microprocessor is instructed to save the EEG session and its qEEG measure, it sends the data to the hard copy device.

Graphics Display

The graphics display displays the contentious EEG signals and online quantitative EEG (qEEG) measure. It helps the neurologists to follow and track in real-time fashion the changes in the brain activity and to monitor the brain development in the intensive care unit (ICU).

Hard Copy Output Device

This device is connected to the microcomputer and stores a version of the EEG data for future use. It could be a hard drive, computer CD, or a printer–plotter for plotting either version of the EEG or the qEEG measure to be investigated by neurologists and to be a part of the patient record.

User Input Device

Through this device, the user can communicate and interact with the monitor. Instructions and various parameters required for the EEG analysis are sent to the microcomputer through this device.

Figure 2. Schematic diagram of the ADC.

Figure 3. Input–output characteristic of the uniform quantization system.

TYPES OF EEG MONITORS

The EEG monitors can be classified into two main categories based on either their applications or the quantitative EEG index employed for processing and assessment of the brain electrical activity. Accordingly, the most popular monitors can be categorized as follows (7,22):

Application-Based Monitors

- Cerebral function monitor (CFM)
- Cortical injury monitor (CIM)
- Anesthesia monitor
- Narcotrend monitor
- Patient state analyzer (PSA) with frontal patient state index (PSI)
- BrainMaster 2E monitor portable bedside monitor

EEG Index-Based Monitors

- Amplitude integrated monitor
- Spectral index monitor
- Spectral-edge frequency monitor
- Bispectral index monitor
- Entropy and complexity based monitor

This section presents, a very brief description of both monitor types. This description gives the intuition for the neurological applications of the monitor and the EEG index employed.

Cortical Injury Monitor

The lack of blood and oxygen flow to the brain due to cardiac arrest causes brain ischemia, causing brain cells to die, and consequently affecting (changes) brain activity. It has been demonstrated by many studies that brain ischemia slows the brain electrical activity by suppressing the high frequency and enhances the background activity; the cortical injury monitor has been developed and used for the detection and tracking of brain ischemia. The advantage of the monitor comes from the fact that it provides a

quantitative measure extracted from the processed EEG signal for the severity of brain injury after cardiac arrest. It aids neurologists in providing better care for patients with cardiac arrest and provides them with therapeutic intervention, such as hypothermia. The monitor provides assessment of the brain function within the first 4 h after cardiac arrest.

Anesthesia Monitors

Patients receive general anesthesia during surgery. Anesthesia causes reduction of brain activity and concussions. The depth of anesthesia should be evaluated and tracked in real-time fashion to prevent perfect suppression of brain activity. The anesthesia monitor has been developed and used for the assessment of anesthesia and concussions. It provides a quantification measure or index for the depth of anesthesia. The monitor helps patients “rest easy” when they receive general anesthesia for surgery. Of the known anesthesia monitors, the bispectral (BIS) monitor, the narcotrend monitor, and the patient state analyzer (PSA4000) monitor are commonly employed. In the BIS monitor, a qEEG measure based on bispectrum is employed for tracking the depth of anesthesia. The PSA4000 is indicated for use in the operating room (OR), ICU, and clinical research laboratories. The monitor includes the patient state index (PSI), a proprietary computed EEG variable that is related to the effect of anesthetic agent. The narcotrend monitor provides a 6-letter classification from A (awake) to F (general anesthesia with increasing burst suppression). The narcotrend EEG monitor is similar to the BIS monitor positioned on the patient’s forehead. The EEG classification made by the narcotrend monitor are 6 letters: A (awake), B (sedate), C (light anesthesia), D (general anesthesia), E (general anesthesia with deep hypnosis), F (general anesthesia with increasing burst suppression) (23).

Cerebral Function Monitor

The cerebral function monitor (CFM) enables continuous monitoring of the cerebral electrical activity over long periods of time due to slow recording speeds. The cerebral electrical signals picked up by the electrodes attached to the scalp are registered in the form of a curve, which fluctuates to a greater or lesser extent depending on the recording speed. Examination of the height of the curve with respect to zero and its amplitude indicates the voltage of cerebral activity and yields information regarding polymorphism. Thus it is possible to monitor variations in cerebral activity over a prolonged period during anesthesia as well as during the revival phase with the monitor of cerebral function. The CFM is common practice in monitoring the cerebral function in intensive care. To bring the CFM into a polygraphy environment the hardware processing and paper write-out have to be implemented in software. The processor comprises a signal shaping filter, a semilogarithmic rectifier, a peak detector, and low pass filter. After taking the absolute value of the filtered EEG signal, the diode characteristic used to compress the signal into a semilogarithmic value was mimicked by adding a small offset to the absolute value before taking the

Figure 4. Color CFM of ~ 2.5 h, red is high density, blue low density, and black zero. Vertical scale from 0–5 μV linear, from 5–100 μV logarithmic. The median is given in black and the percentiles in white. As only 1 h of data was available to test the reproducibility of the process, we used a repeated playback mode for this picture. The low median episodes are neonatal State 1 (Quiet Sleep) with the beginning tracé-alternant (high peaks followed by low amplitude EEG) with half way diminishing peak heights, and a neonatal State 2 (REM Sleep) with symmetrical continuous EEG.

logarithm. The envelope of the resulting signal has been made by means of a leaky peak detector and a boxcar averager. Writing the resulting signal on a pixelized computer screen at a speed of 6 cm/h, say 200 pixels per hour gives 18 s per pixel. At a sample rate of 200 Hz, 3600 samples will be written to the same pixel column. Only a line connecting the highest and lowest value of the 18 s period will be seen. All information about local density of the signal between the high and low values will be lost. Therefore there is an amplitude histogram per pixel column and a color plot of this histogram is built. To give even more information, the median and the fifth and ninety-fifth percentile as bottom and peak estimates are shown. The CFM is shown to be useful for seizure detection, neonatal, care in the emergency room, and for the assessment of other brain disorders (18,19,21). The CFM trace may require a specialist for its interpretation. An EEG atlas provides a summary for the interpretation of the EEG based trace. Figure 4 shows an example for neonatal EEG monitoring. Studies have shown that when CFM is used in combination with a standard neurological examination, it enhances the clinician's ability to identify the presence of seizures or to monitor infants EEG and others.

Amplitude-Integrated EEG (aEEG) Monitor

Various brain activities may cause changes in normal EEGs. These changes might be in the amplitude, power, frequency, BIS, entropy or complexity. In fact, since EEG has become available, visual investigation of EEG has been used to assess the neurological function. It is evident that continuous EEG is a sensitive, but nonspecific measure of brain function and its use in cerebrovascular disease is limited. Visual interpretation of EEG is not an easy target and needs well-trained expertise, which is not available all the times in the ICU. Besides, information that can be extracted by visual investigation is limited. The EEG amplitude shown in Fig. 5 by the aEEG monitor is the first feature, which has received the attention of neurologists and researchers. It is obvious that there is no clear difference between the aEEG associated with the normal and ischemic injury EEGs. The cerebral function monitor (CFM) uses the aEEG extracted from one channel. The aEEG can show bursts and suppression of the EEG. The

Figure 5. Amplitude-integrated EEG for normal EEG (top) and injury-related EEG of grade CPC 5. It is obvious that no significant differences between the two cases, which implies that amplitude may not be used for injury identification.

CFM is well used for seizure detection and neonatal monitoring (18,19,21). However, the EEG amplitude shows low capability. To clarify this disadvantage, let us ask the question: Does isoelectrical EEG mean brain death or even coma? There has been a study seeking the answer of this question (24). In this study, from 15 patients with clinical diagnosis as brain death, EEG was isoelectricity in eight patients while the remaining seven showed persistence of electrical activity. Comatose patients may also show the presence of electrical activity in the alpha band (8–13 Hz). Such diagnosis is referred to as alpha coma. This implies that both investigation and monitoring of EEG amplitude may not be a reliable confirmatory test of brain function and coma. The amplitude assessment of the EEG may then mislead the neurologist's decision.

Spectrogram-Based Monitor

A number of studies have focused their attention to the prognostication of frequency contents and the power spectrum of EEG (6,20,25,26). The normal EEG of adults often show three spectral peaks in delta, theta, and alpha, as demonstrated in Fig. 5 (top). The most common observation, in ischemic injury, for example, has been slowing background frequencies by increasing the power of delta rhythm and decreasing the powers of theta and alpha rhythms. Numerous approaches have been employed the frequency contents for developing a diagnostic tool or index. Monitoring the real-time spectrum has also been employed. While this approach gives an indication for ischemic injury, it requires a well-trained specialist. In animal studies, the spectral distance between a baseline (i.e., normal) EEG and the underlying injury-related one was employed as a metric for injury evaluation and

Figure 6. The EEG fragment with isolated 15 Hz spindles, which are clearly visible in the spectrogram. The spectrogram also shows that the spindles are alternated by short periods of 9 Hz activity.

monitoring. However, the spectral distance has the disadvantage of using the whole frequency contents. This is because using the whole frequency contents of the EEG signal increases the likelihood of artifacts-corrupted spectral contents. Time–frequency analysis is a signal analysis technique that provides an image of the frequency contents of a signal as a function of time. Several methods (or time–frequency distributions) can be used, one of which is the spectrogram. The spectrogram is the power spectrum of the investigated signal seen through a time window that slides along the time axis. Figure 6 shows a segment of sleep EEG signal (top) and its spectrogram. It is obvious that the spectrogram shows a sleep spindle at 15 Hz. The spectrogram shows the times where the spindle is activated. The time–frequency analysis can then be a helpful tool to facilitate the EEG interpretation, as is shown in the examples below.

Normalized Separation-Based Monitor

As mentioned, ischemic injury manifests itself in the EEG by slowing the background activity and reducing the high frequency. Such injury-related changes can be used for the separation of normal EEG from injury-related one. Based on this frequency information, a normalized separation was adopted as an qEEG measure. The normalized separation is a spectral-based qEEG measure for assessment of severity of brain injury. It uses the most relevant spectral information related to the normal EEG signal. The normal EEG has a power spectral density showing three fundamental spectral peaks as shown in Fig. 7 (top). It has been demonstrated that employing these three peaks is enough to yield a satisfactory quantitative measure. Moreover, looking selectively at the principal features of the EEG spectrum reduces the sensitivity of the measure to noise and artifacts. This is primarily because a full spectrum-based measure is likely to be susceptible to spectral components related to noise and artifacts. Therefore, the normalized separation employs the principal features of the spectrum and ignores the minor features, which are more sensitive to noise and artifacts. In comparison with amplitude-based measures, such as the aEEG, the aEEG is not a quantitative measure and represents a continuous EEG. This finding implies that well-trained specialist are needed for the interpretation of the aEEG trace. The

Figure 7. Power spectral density of EEG computed using the AR method applied to 4 s window and averaged >10 windows. (Top) Normal EEG signal and (bottom) abnormal. It is obvious that with abnormal EEG the background frequency gets slower and the high frequencies diminish.

amplitude is also susceptible to noise and artifacts that mislead the interpretation. In comparison with the higher order spectra-based measures, the normalized separation is enough since most information and features of the EEG are described by the power spectrum. A recent study and clinical investigation supports this claim. The EEG is commonly modeled as a stochastic process and for this reason phase is not important. The phase is the only feature retained in higher order spectra. Figure 8 shows three EEG signals and their corresponding normalized separations. The first EEG is very close to normal and provides a normalized separation of 0.2. In the second EEG spectrum, the third peak is diminished and the normalized

Figure 8. Normalized separation for three EEG cases. The left one is normal EEG where three spectral peaks are shown, the middle one is mildly injury-related, and the right one is a severely injury-related EEG. It is obvious that the spectral-based normalization makes significant separation between these three categories.

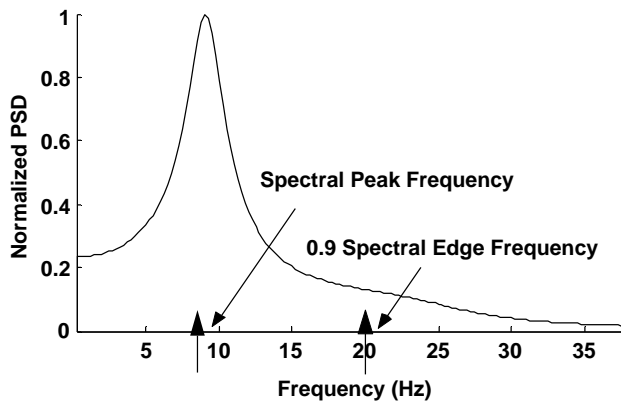

Figure 9. Normalized power spectral density (PSD) showing the spectral peak frequency (SPF) and the 90% spectral edge frequency.

separation is 0.55. In the third EEG spectrum, both second and third spectral peaks are diminished causing the EEG to be separated from the normal EEG by 0.98. The normalized separation ranges from 0 to 1, where the zero value represents and quantifies the normal EEG, while the one value corresponding to the severe abnormal EEG.

Spectral Edge Frequency Monitor

Computers make computation and search for spectral edge frequency of the EEG signal applicable for assessing and monitoring the cortical activity and brain dysfunction. The median frequency and the frequency edges providing 90–95% of the power have been reported to be useful (27,28). The spectral mean and peak frequencies have also been employed (29,30). The success of computing the time-varying spectral edge frequencies depends on the best estimation of the time-varying power spectrum. The fast-Fourier transform (FFT) is a commonly used approach for computing the real-time power spectrum. However, the FFT-based power spectrum provides poor frequency resolution since the resolution is proportional to the reciprocal of the analysis window. The model-based power spectrum estimate, such as the time-varying autoregressive, provides high resolution and low variance estimate of the power spectrum (Fig. 9).

Bispectral Index Monitor

In addition to spectrum, BIS also describes the frequency contents of the EEG. The power spectrum is often used for

describing the frequency contents of the EEG modeled as a sum of noncoupled harmonics (17,31–33). In such situations, BIS are identically zero. However, if the focus is on the frequency contents of coupled harmonic (quadratic phase coupling harmonics), BIS is often used. Bispectrum is one of the first successful applications of electroencephalography, which measures the effects of anesthetics on the brain. The BIS index is a number between 0 and 100. It produces a number between 0 and 100 (100 represents the fully awake state, and zero no cortical activity). The BIS correlates with depth of sedation and anesthesia, and can predict the likelihood of response to commands and recall. The BIS values correlate with end-tidal volatile agent concentrations, and with blood and effect-site propofol concentrations. It is not very good at predicting movement in response to painful stimuli. However, there has been a recent study, which shows that BIS information is not necessary and power spectrum is satisfactory to describe an EEG signal. Another fact is that BIS is very sensitive to spike artifacts. The BIS index is a quantitative EEG index developed and employed for measuring the depth of anesthesia. It is based on third-order statistics of the EEG signal, specifically BIS density, and is commercially used for monitoring anesthetic patients. The index quantitatively measures the time-varying BIS changes in the EEG signal acquired from the subject before and during anesthesia. The BIS index will be zero when both the baseline and the underlying signal are either identical or Gaussians. This measure has been demonstrated to be effective for depth of anesthesia measurements. However, in some applications (classification of brain injury due to hypoxic/asphyxic cardiac arrest) the principal information and features of the EEG signal lie in second-order statistics, that is the power spectrum, and only minor information and features are associated with higher order statistics. Therefore, indexes based on higher order statistics may not be best suited to classify brain injury due to hypoxia/asphyxia (33). Besides, that higher order statistics are very sensitive to sparse-like artifacts, which deteriorates the index (34). Therefore, employing higher order statistics-based indexes require an efficient artifact removal approach for preprocessing the EEG signal. Below, a simulated example of BIS is presented. In this example, the BIS density is shown to present information on the coupling harmonics. Let $x(n)$ be a time-series consisting of three sinusoidal components whose frequencies are 64, 128, and 192 Hz. It is obvious that harmonic coupling between the first two sinusoids exists. Fig. 10a

Figure 10. Bispectral density (a) and bicoherence (b) of a simulated sinusoidal signal. Bispectral density shows two lines at the coupling frequencies $(f_1, f_2) = (64, 64)$ and $(f_1, f_2) = (64, 128)$. Bicoherence shows two lines of unity value at the coupling frequencies.

Figure 11. Contour plot of the bicoherence of $x(n)$.

and b shows the mesh plots of the BIS and the two-dimensional bicoherence. Figure 11 shows the contour plot of the bicoherence. It is obvious that the BIS density shows two spectral lines at the frequencies $(f_1, f_2) = (64, 64)$ and $(f_1, f_2) = (64, 128)$. The bicoherence is unity (perfect coupling) at these frequencies.

Entropy- and Complexity-Based Monitor

Since the brain processes information, the brain's total electrical activity probably corresponds to information processing in the brain. This assumption was used to study the entropy or self-information in the EEGs of anesthetic patients, postcardiac arrest, in sleep research, and seizure. Entropy as a measure quantifies the disorder of the EEG signal. It represents the complexity and nonlinearity inherent in the EEG signal. It has been shown that normal control subjects provide larger entropy values than those showing ischemic injury postcardiac arrest. The entropy starts to increase with the recovery of brain function. That is, entropy is a relevant indication of the brain order-disorder following cardiac arrest. The subject under anesthesia provides low entropy, while the awake subject shows high entropy since their brain is full of thinking and activity. Numerous approaches for the calculation of entropy have been used, such as Shannon entropy, approximate entropy, Tasllis entropy, and wavelet entropy.

Complexity based on chaotic, state space and correlation dimension has also been employed for assessment and monitoring of brain function (11–13,22,35–41).

COMMON SPECIFICATIONS OF OPTIMIZED MONITOR

The EEG monitor specifications are the hardware and software properties that make the monitor capable of easily and significantly performing assessment and classification of cortical activity. The monitor should satisfy minimum requirements. Common specifications of EEG monitors may include the following: compact design that is rugged and lightweight; automatic classification of EEG; off- and on-line qEEG index; optimized recognition and removal of artifacts; easy operation via friendly touch screen;

continues testing of the electrodes to ensure a constant high quality of the EEG signal; variable electrode position; interface to external monitors and documentation systems; wireless communication between various sensors attached to the human; provides a secure way to transmit and store measured data; high-speed data processing; large amount of memory; on-board Ethernet connection.

CONCLUSION

This article presented a descriptive review for commonly known and employed neurological monitors. The typical neurological monitor consists of a few main devices and the software for running these devices. A brief review of the device specifications and their roles have been given. The monitors are classified into two main categories based on their applications and the indexes acquired from the digital EEG signal and employed for monitoring and assessment of cortical dysfunctions. Intuitions of the EEG monitors, with no mathematical details, have been presented. The article concludes by describing the most common specifications for the optimized monitor.

NEUTRON ACTIVATION ANALYSIS

XIAOLIN HOU
Risø National Laboratory
Roskilde, Denmark

INTRODUCTION

Neutron activation analysis (NAA) as an elemental analytical method has been used for a long time to determine trace elements in biomedical research and clinical analysis (1,2). The main problems associated with the determination of trace elements in biomedical research and clinical analysis are the very low concentrations of some elements, and the limited amount of sample materials available. It is necessary that the analytical method be sensitive and free of blank contribution.

As a nuclear analytical technique, NAA is based on the excitation of the atomic nucleus of an isotope of the element with neutrons, and the emission of specific radiation, such as gamma rays, from the excited nucleus by decay. Therefore, only trace elements present in the sample during neutron activation will be excited and are able to be measured in this way. The possible contamination of sample during subsequent handling will not influence the result. Thus a comprehensive radiochemical separation of a particular element from interfering elements can be carried out to significantly improve the detection limit, which will not introduce any blank for the measured element. If no pretreatment of sample is completed, almost no blank value will be introduced in the analytical procedure. Therefore, the method can be free of blank contribution. Neutron activation analysis is very sensitive for many trace elements, while many matrix elements such as carbon, hydrogen, oxygen, and nitrogen are less activated by neutrons and produce almost no activity after neutron activation. Therefore, NAA is suitable for the analysis of biomedical

samples due to little or no interference from matrix elements. The interference from activated minor elements such as chlorine, sodium, bromine, and potassium may be eliminated by a few days decay of sample due to the short lifetimes of radioactive nuclides of these elements. It is normally used for *in vitro* analysis, but also can be used for *in vivo* analysis of the whole or part of living bodies. This consists of mostly major and minor elements, such as Ca, Cl, K, N, Na, and P, but also some trace elements, such as iodine in thyroid, Si, Cd, Hg in lung and kidney. The contrast with conventional NAA, isotopic and accelerator neutron sources and small reactor are used and prompt gamma rays are measured (3). However, the problem of radiation to living body limits its application. This article will not describe this problem in detail and is an updated version of the previous article published in the first edition of this encyclopedia (4).

THEORY

Neutron activation is a reaction of the nucleus of an element with neutrons to produce a radioactive species, so-called radionuclide. Neutrons used in NAA can be produced by a nuclear reactor, a radioisotope, and an accelerator, in which the nuclear reactor is the most common neutron source used for NAA due to its high neutron flux and suitable neutron energy. Neutrons can exhibit a wide range of energy, which range from thermal neutrons with an average energy of 0.025 eV in a thermal nuclear reactor to fast neutrons of 14 MeV in an accelerator neutron generator. By bombarding an element with neutrons, a neutron is absorbed by the target nucleus to produce a highly energetic state of the resulting nucleus containing an additional neutron. Some excess energy is immediately lost, usually by emission of a gamma ray, a proton, or an alpha particle. In a sample exposed to neutrons, the type of nuclear reactions depends on the energy of the neutrons and on the elements present. The main reaction occurring with thermal neutrons is the (n, γ) reaction. In this case, the highly energetic level of the produced nucleus is de-excited by emission of a gamma ray, while (n, p) and (n, α) reactions are induced by fast neutrons reaction. In conventional NAA, the element is determined by measurement of the radionuclides formed by de-excitation of the produced nucleus. However, the element can be determined also by the measurement of the gamma rays emitted during the de-excitation of the produced nucleus, which is so-called prompt gamma activation analysis due to the very fast de-excitation process (1 ps). In this article, only conventional NAA is discussed. The probability of a particular reaction is expressed by the activation cross-section, σ , with a unit of barn (10^{-28} m²). An isotope of an element has its specific activation cross-section. The cross-section of a particular nucleus depends on the energy of the neutron. The (n, γ) reaction normally has a higher activation cross-section than (n, p) and (n, α) reactions. The rate of formation of the radionuclide in the neutron activation is expressed as

$$\frac{dN^*}{dt} = \sigma\phi N \quad (1)$$

N is the number of the target nuclei in the atom, so $N = (m/M)N_A\theta$. Here, m is the mass of the target element (in g); M is the atomic mass; N_A is Avogadro's number; and θ is the isotope abundance of the target nuclide, N^* is the number of the activated nuclide at time t ; ϕ is the neutron flux density (in neutron $\text{m}^{-2}\cdot\text{s}^{-1}$), which is used to express the neutron number pass through a unit area in a unit time, which can be considered also as a product of velocity of a neutron and its concentration.

If the nuclide formed is radioactive, it will decay with time and the decay rate of the radionuclide will be

$$\frac{dN^*}{dt} = -\lambda N^* \quad (2)$$

Here λ is the decay constant of activated nuclide, $\lambda = \ln 2/T_{1/2}$ and $T_{1/2}$ is the half-life of activated nuclide. So, the production rate of an activated nuclide is expressed as:

$$\frac{dN^*}{dt} = (\sigma\phi N) - (\lambda N^*) \quad (3)$$

The activity or disintegration rate (A_0) at the end of irradiation time t_i is then:

$$A_0 = \lambda N^* = \sigma\phi N(1 - e^{-\lambda t_i}) \quad (4)$$

The saturation activity of the activated nuclides (Am), that is, the activity when the production of activity is equal to the decay of the activity, can be calculated as:

$$\text{Am} = \sigma\phi N = \frac{m}{M}N_A\theta\sigma\phi \quad (5)$$

If considering the decay of activated radionuclides during the decay (t_d) and counting (t_c), the measured activity of radionuclides is calculated by

$$A = \sigma\phi N(1 - e^{-\lambda t_i})e^{-\lambda t_d}(1 - e^{-\lambda t_c})/\lambda \quad (6)$$

The actual number of events recorded by a detector for a particular radionuclide is only a fraction f of the number of decays calculated from Eq. 6, because not every decay can emit a characteristic gamma ray, and once a gamma ray is emitted they may not reach the detector. Considering these findings, the simplest and most accurate way to determine an element by NAA is to irradiate and measure a comparator standard with an exact known content of the element together with the sample. In this case, the ratio of the element content in sample m_s to that in comparator standard m_c is equal to the ratio of their activities, $A_s/A_c = m_s/m_c$. Therefore, the content of target element in the sample can be calculated by

$$m_s = \frac{A_s}{A_c}m_c \quad (7)$$

In addition, from such a single comparator, it is also possible to calculate the sensitivity of other elements by means of the k -factor (5). This factor is an experimentally determined ratio of saturation specific activities expressed in counts:

$$k = \frac{f\theta\sigma}{f^*\theta^*\sigma^*} \frac{M^*}{M} \quad (8)$$

Here, the asterisk refers to the element of a single comparator. The factor f is a combination of the emission probability of η and detection efficiency ε . If the relative efficiency function of the detector is known, calibration may be based on k_0 values (5):

$$k = k_0 \frac{\varepsilon}{\varepsilon^*} \quad (9)$$

where

$$k_0 = \frac{\eta\theta\sigma}{\eta^*\theta^*\sigma^*} \frac{M^*}{M} \quad (10)$$

These k_0 values are fundamental constants and may be found in tabulation; methods for taking into account the influence on k_0 values of difference in neutron flux spectrum have been developed.

The analytical sensitivity of NAA for various elements can be predicted from Eq. 6, combined with the emission probability of gamma rays of the radionuclide and the counting efficiency of the characteristic energy of the radionuclide. The calculated interference free detection limits of NAA for various elements are listed in Table 1. Note that this data is only applied to radionuclides completely free from all other radionuclides, that is after a complete radiochemical separation. In actual analysis, the activity from other activated elements will interfere with the detection of the target element by increasing the baseline counts under its peaks, so the detection limit will be poorer than that estimated in Table 1. However, in a sample with known composition, practical detection limits may be predicted in advance (6).

Since NAA is based on the excitation of the atomic nucleus of an isotope instead of the surrounding electrons, no information on the chemical state of the element can be obtained. In addition, the de-excitation of the produced nucleus by the emission of high energy gamma rays or other particles gives the formed radionuclide a nuclear recoil energy of several tens of electron volts. This is more than sufficient to break a chemical bond, and the formed radionuclide may no longer be found in its original chemical state. It is therefore not possible to directly use NAA for chemical speciation of an element. However, a NAA

Table 1. Interference Free Detection Limit for Elements by NAA Based on Irradiation for 5 h at a Neutron Flux Density of $10^{13} \text{ n/cm}^2\cdot\text{s}^{-1}$ and Typical Counting Conditions^a

detection coupled with a preseparation of chemical species of elements, so-called molecular activation analysis, can be applied for the chemical speciation of elements for biomedical studies (7). Used in this way, NAA is no longer without a blank problem.

EQUIPMENT AND METHODOLOGY

Optimal utilization of the special qualities of NAA requires an appropriate methodology, which is adapted to the analysis of various biomedical samples for different elements and their species. Figure 1 shows a scheme of NAA, which divides NAA into several steps, some of which are indispensable, while others are supplementary for specific purposes.

Sampling

Sampling is the first step for any analysis, and is the most important step in any meaningful investigation (8,9). There is increasing awareness that the quality of an analytical result may often be influenced more by sample collection than by final measurements. One of the main considerations during sampling should be devoted toward the representativity of the analyzed sample to the object under study. Other considerations should be the avoidance of any contamination during sampling and finding suitable storage of the sample until analysis to prevent the losses of the elements of interest and to avoid contamination. The selection and collection of a representative sample may need to consider two aspects: the type of sample and the size of the selected sample (8). Frequently, valuable data can be obtained from the analysis of readily accessible *in vivo* samples, such as blood and urine. In some cases, the analysis of tissue sample may provide more useful information. A considerable effort has been spent on the analysis of hair and nail (9). They have an advantage of being easily available, however, it may be less representative for most of the elements, and a multitude of factors may affect the observed results. The contamination during

the sampling mainly comes from the tools and the container used for samples and the sampling environment. With the exception of excreta, all biomedical materials have to be removed from the organism by means of tools for piercing, cutting, or shearing. The best materials for tools from the point of view of eliminating contamination are polyethylene, Teflon, or other plastic materials, or stainless steel, if Cr, Ni, Co, and Fe are not being considered, but pure titanium is a good material due to its hardness for cutting. For the container, polyethylene, Teflon, and synthetic quartz are the best materials to avoid contamination and absorption of trace elements on the wall of the container. The problems of sampling and sample handling have been given more attention in the studies of medical trace elements. A number of sampling protocols were recommended. A detailed discussion of this issue can be found in many articles and books (2,8,9).

Preseparation

Since NAA cannot be directly used for chemical speciation, various chemical species of trace elements have to be separated before irradiation. In recent years, many methods have been developed for the chemical speciation of various trace elements, such as Se, I, Cr, Hg, As, Al, Fe, Zn, Cu, and rare earth elements in biomedical samples (7,10–15). All of these methods are based on preseparation using various chemical and biochemical separation techniques, such as ion exchange, gel chromatography, high-performance liquid chromatography (HPLC), supercritical fluid, electrophoretic, and fractionation techniques. The chemical speciation in biomedical trace elements studies normally includes the following aspects: subcellular distribution of trace elements in various tissues; chemical valence states of trace elements in liquid samples such as urine, blood, and cytosol of tissue homogenate; specific combination of trace elements with various proteins, polypeptides, enzymes, hormones, and small molecular compounds. The separated chemical species of trace elements is then quantitatively determined by NAA. Since the sample is not destroyed and no chemical reagents are used, NAA itself is actually a contamination-free analytical technique. However, in preseparation the utilization of chemical reagents and many types of equipment can cause a high risk of contamination. An enriched stable isotope trace technique was therefore used to overcome this problem (15), which is based on the fact that NAA is actually an analytical technique for isotopes instead of elements. In this case, the contaminations during the separation can be identified and eliminated because of the different isotopic components of the trace elements in the samples with those contaminants from the chemical reagents and other sources.

Due to the very low concentration of most trace elements in biomedical samples, preseparation of elements of interest from main interfering elements and preconcentration is sometimes useful for the improvement of the detection limit of the elements of interest. The simplest preconcentration should be lyophilization and ashing of the samples, which can be directly carried out in an irradiation container, such as a quartz ampoule and aluminum foil to eliminate problems associated with sample transfer. The

techniques used for pre-separation of the elements of interest are similar as those for radiochemical separation described below. Special attention should be given to avoid contamination and addition of extra interfering elements, such as Cl and Na.

Sample Preparation

Before neutron irradiation, the sample must be transferred to an irradiation container for transport to and from the irradiation position. These containers should not contaminate the sample, nor should they add significantly to the total amount of radioactivity produced during activation. Suitable materials are low density polyethylene for moderate irradiation and high pure aluminum and synthetic quartz for prolonged irradiation. For short-term irradiation, the sample can be wrapped in a thin polyethylene film and inserted in a polyethylene irradiation capsule. After irradiation, the sample with the polyethylene foil is directly measured, since there is no significant contribution of trace elements and radioactivity from the polyethylene film and difficulties on removal of sample from the irradiated film. In the determination of some elements, such as Se, F, B, and Li (16,17), the irradiated samples have to be measured very quickly (<10 s) due to the very short half-lives of the formed radionuclides (0.8 s for ^8Li , 17.5 s for $^{77\text{m}}\text{Se}$, 11.0 s for ^{20}F). In this case, the sample with the polyethylene capsule has to be directly transferred to the detector for measurement. For long-term irradiation of sample in a reactor, it is normally required that the sample be dried to avoid any problem of explosion of the container due to the high pressure produced in the container by the radiolysis of water in the samples. In addition, the removal of water from the sample will improve the determination of elements of interest, because an increased amount of sample can be irradiated and the counting geometry can be improved. Lyophilization techniques are normally used for the removal of water, although evaporation by heating can be used. In addition, dry ashing is sometimes used to further improve the determination of elements, but we should watch for loss of elements of interest during this process. The dried sample is normally wrapped in high purity aluminum foil, which is then inserted into an aluminum container for irradiation, since only a short-lived radioisotope of aluminum, ^{28}Al (2.24 min), is formed in the neutron irradiation of Al. This radioisotope quickly disappears by decaying, so it does not interfere with the determination of trace elements that form long-lived radionuclides. For some elements, such as mercury and arsenic, a synthetic quartz ampoule was used because they volatilize during irradiation and have very low impurities in quartz materials and are less radioactive from activated SiO_2 . To minimize losses and contamination, biomedical samples are often sampled in a high purity quartz ampoule. They are then directly lyophilized and ashed in the quartz ampoule. After irradiation, they can be measured in the same ampoule.

Irradiation

Different neutron sources are available for the activation analysis of samples. Isotopic neutron sources, such as Ra–Be and Am–Be sources that rely on the (α , n) reaction and

^{252}Cf source that is based on spontaneous fission, yield neutron spectra with a limited range of neutron energies. Accelerators can also be used to produce a particular energy of neutrons, such as 14 MeV neutrons produced by (D,T) reaction and 2.5 MeV neutrons by (D,D) reaction. A miniature, sealed-tube neutron generator with a yield of 10^8 – 10^{11} neutron/s has been used widely as a neutron source for NAA (18,19). However, due to low neutron flux produced in these two kinds of neutron sources, they are very seldom used for the NAA of biomedical samples.

Nuclear reactors are much more suitable for NAA of biomedical materials, because they provide much higher neutron flux density (10^{11} – 10^{14} n/cm 2 .s) with correspondingly higher sensitivities for trace elements. In addition, neutrons in the reactor can be well moderated to thermal energies, which is very suitable for NAA because of the high thermal neutron activation cross-sections of trace elements and less interference from fast neutron reactions. For some elements such as iodine, arsenic, and selenium, which are preferably determined by epithermal NAA, an epithermal neutron irradiation channel was set up in some reactors by shielding thermal neutrons with cadmium (20). Almost all research reactors installed pneumatic transfer systems for easy and automatic transfer of samples to and from the irradiation position. Some of them can also quickly transfer the irradiated sample to the counting position above the detector for the determination of elements by counting short-lived radionuclides. The detection limit and analytical precision of NAA can be improved by repeated irradiation and counting of samples, the so-called cyclic NAA. This is particularly useful for the elements determined by short-lived radionuclides (such as Se, F, I, etc.). Cyclic NAA systems were therefore installed in some reactors (17). As a nuclear facility, many nuclear reactors are located in large research centers, normally outside of the city; it makes them less accessible and consequently makes NAA inconvenient for most researchers and medical doctors. In the 1980s, a miniature neutron source reactor (MNSR) was developed especially for NAA in China. Due to its intrinsic safety in design, this reactor can be installed in hospitals and research institutes in a big city. With a combination of its small size and low price, it makes NAA possible as a clinically analytical tool easily and conveniently accessible for many researchers and medical doctors. Ten such reactors were installed in universities and institutes in China, Pakistan, Iran, Syria, Ghana, and Niagara (20,21). A few similar reactors (SLOWPOKE reactor) were developed and installed in Canada.

Measurement

Trace elements are determined by measurement of the activity of the radionuclides formed after neutron irradiation, which can be carried out by counting the number of events taking place in the detector. The choice of the detector used for NAA depends on the type of decay and energies of the radiation emitted by the radionuclides formed. Some radionuclides produced by neutron activation of uranium and thorium decay by emission of neutrons, which are counted by means of a neutron detector filled with BF_3 or ^3He gas. Meanwhile, the radionuclides of

boron and lithium, which decay by emitting very high energy β particles, may be counted by a Cherenkov detector (16). All these analyses require that the detector be installed at the reactor site because of the short half-lives of these radionuclides, and are consequently not commonly used for biomedical materials.

The most common radionuclides measured by NAA decay by emission of characteristic gamma rays. The most widely used detector is a gamma semiconductor detector, of high purity germanium (HpGe). This detector has high energy resolution; it may separate the gamma rays with energy difference of only 2–3 keV. According to the energies of the radionuclides of interest, different types of germanium detectors can be used. Planar germanium detector and HpGe detector with a thin window are used for the measurement of low energy gamma rays down to 10–20 keV. These detectors have the best energy resolution. In addition, a silicon (lithium) detector can be used for the measurement of low energy gamma rays and X rays. A normal coaxial HpGe detector is used for most radionuclides with energies of gamma rays >60 keV, and well-type HpGe detectors can be used for improvement of the counting efficiency if a very low level of radioactivity needs to be measured. In this kind of detector, the sample sits in the middle of the germanium crystal and almost 4π geometry can be obtained. However, only a small sample can be measured in this detector due to the limited well size of the detector. In connection with appropriate electronic equipment, such as high voltage supply, preamplifier and main amplifier, and a pulse height analyzer with 4,096 or 8,192 channels, it is possible to determine simultaneously many different radionuclides if only their gamma-ray energies differ by 2–3 keV. Additional discrimination is achieved between radionuclides with different half-lives by counting the sample at different decay times.

The measurement of gamma rays is based on the interactions of gamma rays with matter, such as the photoelectric effect, Compton scattering, and pair production. In the photoelectric effect, the gamma ray ejects a shell electron from a germanium atom and produces a vacancy; the ejected electron has a kinetic energy equal to the energy of the gamma ray less the binding energy of the electron. It may interact with other electrons, thus causing secondary ionization, and produce more vacancies in the shell of the germanium atoms. The number of produced photoelectrons and corresponding vacancies is determined by the energy of the gamma ray. In this way, the gamma-ray energy is converted to an electric signal in the detector, which is then amplified by preamplifier and main amplifier, the output from the main amplifier is a peak of nearly Gaussian shape with an amplitude proportional to the gamma-ray energy that enters the detector. This electric signal is finally registered by a multichannel analyzer (MCA) as a count, the number of the channel in the MCA corresponds to the gamma-ray energy and the counts in a channel correspond to the numbers of the gamma rays with the same energy. The peak of the gamma spectrum registered in the MCA is normally also a Gaussian distribution. The width of the peak, or the energy resolution, is an important parameter of the detector. Except for the photoelectric effect, pair production process results in a

gamma ray with energy less than 0.511 and 1.02 MeV of the original one. Compton scattering results in a continuum of energy being transferred, which increases the baseline counts of the gamma peaks, and therefore worsens the detection limit of the radionuclide of interest. Most gamma emitting radionuclides also emit beta particles. The interaction of the beta particle with the detector results in a continuum of energy under the gamma spectrum. A beta absorber can be used to reduce the interference of the beta particles. The utilization of anti-Compton techniques will reduce Compton interference; a recently developed multiparameter coincidence spectrum technique significantly improved the detection limit of the trace elements of interest (22).

Radiochemical Separation

NAA for very low level of elements is limited by the presence of other elements in the sample. Some minor elements in the biomedical samples such as Na, Cl, Br, and P contribute to high radioactivity of the irradiated sample, and the signals of the radionuclides produced from many trace elements of interest are overlapped by an increased Compton continuum under the gamma peaks. In order to measure the trace elements of interest and improve the detection limit and analytical accuracy of many trace elements, it is required that these interfering elements be eliminated before counting. Since the irradiated sample is radioactive, this procedure is called radiochemical or post-irradiation separation. Radiochemical separation is normally carried out by the following steps: addition of carrier, decomposition of irradiated sample, chemical separation, and preparation of separated samples for counting. Detailed development and the present progress of RNAA were reviewed by several authors (22–24). Since the activated elements are radioactive, this procedure does not create any blank problem, but may easily result in losses of trace elements to be determined. In order to minimize these losses, a suitable amount of carrier element is always added to the sample before radiochemical separation. Since the amount of carrier element is much higher than the same element from the original sample, it can then be used to monitor the chemical recovery of the elements determined during the radiochemical separation. In many cases, some carriers of interfering elements are also added to improve the removal of these interferences, the so-called holdback carrier. A complete equilibrium between an inactive carrier and radioactive element is necessary to be sure that both undergo the same physical and chemical procedure, and the same chemical recoveries during the radiochemical separation, which is normally carried out by a comprehensive oxidation–reduction cycle.

Both dry ashing and wet digestion are used to decompose the biomedical samples. Dry ashing at 400–700 °C is more suitable for large samples; then the ashed sample can be easily dissolved by diluted acid. However, a considerable loss of several elements may occur during ashing due to volatilization, which can be partly eliminated by ashing in a closed system or by using low temperature ashing at 200–250 °C under vacuum. Iransova and Kucera (25) recently showed alkali fusion at high temperature (800–850 °C) is

very effective and rapid for decomposition of the biomedical sample and reduction of the losses of many trace elements. Based on the volatilization of some elements, a combustion method was used to directly separate these elements from the matrix and interfering elements. A particular example is the radiochemical NAA of iodine (26). Acid digestion is a more popular method for decomposition of biomedical samples. This method is normally carried out by boiling a sample in concentrated HNO_3 with HClO_4 or H_2SO_4 . Sometimes H_2O_2 is added to completely decompose the organic components of the sample. Heating in an open system can also result in losses of some volatile elements such as iodine and mercury; utilization of refluxing can significantly improve the recovery of these elements. Recently, a microwave assisted digestion system was also introduced for the decomposition of sample. The main advantages of this method are rapid digestion and less loss of trace elements due to a closed digestion system. Usually, it is used for small sample analysis.

The main activities of irradiated biomedical material are produced from ^{38}Cl , ^{82}Br , ^{24}Na , and ^{32}P . A complete separation of an element from all other radionuclides is rarely necessary. The removal of main radionuclides and several group separations are very useful for improvement of the determination of most trace elements with adequate accuracy and precision (23,24). Precipitation, ion exchange, and extraction are the most commonly used methods for radiochemical separations. Both ^{38}Cl and ^{82}Br can be removed by anion exchange absorption, precipitation as AgCl and AgBr , and evaporation as HCl and Br_2 . A simple and effective separation of ^{24}Na can be carried out by absorption on a hydrated antimony pentoxide (HAP) column (27). Various procedures have also been developed for the group separation (23,24,27). However, the separation of a single element sometimes may be necessary due to their very low level in biomedical materials, such as iodine, vanadium, silicon, uranium, selenium, and mercury (26,28,29). For efficient measurement, the separated sample has to be prepared in small amounts for counting on the detector. This process is normally completed by precipitation to convert the separated elements to a solid form or by evaporation to remove most of the water.

Chemical Recovery

In comprehensive radiochemical separation, the addition of carrier cannot entirely prevent losses of the elements of interest, even in a simple separation procedure. For accurate results, a correction for losses should therefore always be made, which can be carried out by measurement of the chemical recovery of the determined element in the radiochemical separation.

Chemical recovery can be measured by carrier and radiotracer. Before decomposition, carriers are added to the irradiated material in macroamount compared to the element originally present in the sample. When the carriers behave as the probed element in the sample, their chemical recoveries should be the same. Thus the chemical recovery of the carrier element is taken as the recovery of the determined element. The carrier element can be easily measured by classic analytical methods, such as gravime-

try, calorimetry, and titration method, especially when a single carrier is added and separated, and the contribution from other elements is negligible. When more than one carrier is added and multielements are separated and determined, a reactivation method could be used for determination of the carrier content in the separated sample. After the measurement, the separated sample containing the activated elements and the carriers is reactivated by irradiation with neutrons, and the amount of carrier is determined by NAA. As the amount of the radionuclide originated from the sample is negligible compared to the added carrier, and the amount of added carrier is known, the chemical recovery can be calculated. Radiotracer is a more direct method for monitoring chemical recovery. In this case, radioisotopes are added to the sample with carrier before the radiochemical separation. These radiotracers are not the same as those produced by neutron activation, and can be measured simultaneously by a gamma detector due to the different energies of gamma rays. Since the radiotracer is another indicator of the same element as the radionuclide produced from the element of interest, the chemical recovery of the radiotracer is the same as the indicator. For example, ^{125}I was used as a radiotracer for monitoring the chemical recovery of iodine in RNAA (29), and ^{57}Co for cobalt.

If the radiochemical separation is carried out in a well-controlled manner, a constant chemical recovery can be assumed, and the recovery correction may be carried out without measurement of chemical recovery for every individual sample. But first the constant chemical recovery has to be determined by processing an unirradiated sample to which is added irradiated carriers or other radiotracers using the same chemical separation procedure. In order to evaluate the precision of the correction, at least 10 determinations should be made.

Analysis of Gamma Spectrum and NAA Calculation

The data acquired by a germanium detector are registered in the MCA, and may be transferred directly or via an analyzer buffer to a computer for processing. At present, MCA can even be made as an interface card, which can be directly inserted to a personal computer. Then the computer can control the gamma detector and the gamma spectra can be acquired and analyzed by computer software. Data acquisition software is chiefly concerned with the handling of the MCA system and its components; the programs will connect the hardware of the spectrometry system with the storage memory for the data. Critical physical parameters such as starting time, duration, and dead-time of the acquisition are recorded together with the spectral data. The acquisition software can also take care of controlling sample changers and automatic sample transfer systems for cyclic NAA. The acquired spectrum can be stored separately or summarized.

Many γ -spectrum analysis programs have been developed to analyze gamma spectra, which can search for γ peaks, calculate their energies, and their peak areas. The special software for NAA can even identify nuclides by the energy of γ peaks and decay time, calculate the radioactivity of a radionuclide, and finally calculate the concentrations

of the trace elements in the sample. The energy of a gamma peak can be identified by calibration of the counting system by measurement of some known gamma-ray sources. By comparison with a database of gamma-energy and half-life of radionuclides, the identification of the nuclides can be carried out. The calculation of the peak area is the most critical step in the NAA calculation. Many techniques have been developed to calculate the peak area and to subtract the baseline under the peak, such as Gaussian shape and experimental peak shape fitting. When the peak area and the efficiency of the detector are measured, the activity of the nuclide can be calculated easily by correcting for decay and counting time. If the comparator method is used, the contents of elements of interest can then be calculated using Eq. 7 after the measurement of a comparator element standard. In NAA, overlapping peaks may sometimes occur, when the energy difference between peaks is not large enough, a significant error may result from incorrect separation of peaks and baseline subtraction. However, with proper execution of NAA and correction of results for possible separation losses, NAA is capable of providing unbiased results with known precision for a multitude of trace elements in biomedical materials.

Evaluation and Quality Assurance

NAA has been demonstrated to be reliable and under statistical control due to the absence of unknown sources of variability. This means that it is possible to predict the standard deviation of analytical results so well that the observed and expected variation among replicate data are in agreement. The special qualities of NAA make the method one of the best for the certification of reference materials in the biomedical field. Hardly any certification of trace elements is carried out without considering this method. Its high sensitivity for many elements and the absence of blank values make NAA the preferred method for analysis at an ultratrace level of concentration in many types of biomedical samples. The insensitivity to contamination has proven particularly valuable for the establishment of a normal concentration of a number of elements in human samples. Results by NAA serve as a reference for testing or verifying the reliability of other methods.

The common sources of uncertainty in NAA come from irradiation, counting, spectra acquisition and analysis, blank and interference of nuclear reactions and gamma rays. The uncertainty of irradiation is contributed from the variation of neutron flux during irradiation and inhomogeneous distribution of neutron flux in the irradiation container. The instability of neutron flux may significantly influence the analytical results of elements determined by measuring short-lived radioisotopes, because the sample and standard are not irradiated simultaneously. This problem is normally overcome by on-line monitoring of the neutron flux, and most research reactors, especially a small reactor such as MNSR, installed such a system. In most cases, the uncertainty from this source is low (<0.5%). The neutron flux gradient is sometimes very significant in a big irradiation container, so that a flux monitor foil of Fe, Co, or Au alloy may be used to monitor the different positions to

make a neutron flux correction. Uncertainty in counting mainly results from the variation of counting geometry. The uncertainty due to counting geometry can be controlled reliably by well efficiency calibration of the detector for various source shapes; software is available for appropriate calculation. The matrix effects can suppress gamma rays, especially low energy gamma rays, by self-absorption; this effect can be calibrated by measurement of a standard with a similar matrix with sample. Many natural matrix certified reference materials (CRM) have been prepared for this purpose and are commercial available (30).

Uncertainty in the spectra acquisition may come from dead time and pile-up losses of signals. A quick varying and high counting rate often occur in the NAA of biomedical materials due to high concentrations of Cl and Na which may cause a high and varying dead time during the counting. Dead time is normally measured by the gamma spectra system, and live time is used for activity calculation. But when the dead time is quickly changed during counting, the activity may be underestimated by this method. This problem can be solved by using a loss-free counting method, which estimates the number of counts lost during a dead time interval and adds this number to the channel of the just processed pulse, thus presenting a loss-corrected spectrum. The pile-up losses are corrected by electronic or computational mean built in the counting system. Uncertainty in the spectra analysis results mainly from the evaluation of peak area and subtraction of baseline, especially for the analysis of multipeaks. A large attempt has been made to develop effective software to improve the analysis of the gamma spectra.

The blank problem can usually be ignored in NAA. But a blank correction will be necessary, when pre-separation and sample preparation are used before irradiation. A given radionuclide can often be produced in more than one way. If the indicator nuclide used in NAA is produced from an element other than the element determined, then nuclear reaction interference occurs, such interference is mainly produced by (n,p) or (n, α) reactions with fast neutrons and elements with an atomic number 1 or 2 above the element to be determined. A typical example of such interference is the formation of ^{28}Al from Al, P, and Si by reactions: $^{27}\text{Al}(n, \gamma)^{28}\text{Al}$, $^{28}\text{Si}(n, p)^{28}\text{Al}$, and $^{31}\text{P}(n, \alpha)^{28}\text{Al}$. In biomedical materials, the concentrations of Al and Si are very low, but P is high in many kinds of samples. The contribution of P to the activity of ^{28}Al may be very significant, especially when the fraction of fast neutron in the irradiation position is high, it will seriously interfere with the determination of aluminum. This interference can be significantly reduced by using a thermal neutron irradiation channel, where the ratio of thermal/fast neutron flux is very high; in many research reactors, such a thermal neutron channel is available. Since there are no suitable thermal neutron activation products of P and Si, they are determined by using these two fast neutron reactions in NAA, so the interference from Al to P is also very significant due to a much higher cross-section of thermal neutron activation than fast neutrons. The correction can be carried out by the irradiation of the sample with and without thermal neutron shielding. The activity of ^{28}Al in a sample irradiated under thermal neutron shielding (such as in a Cd or B

container) mainly contributes from fast neutron reaction, while under conditions without shielding from both thermal and fast neutron reactions.

Double and triple neutron activation reactions can also result in an interference, for example, the interference from $^{197}\text{Au}(2n, \gamma)^{199}\text{Au}$ to the determination of Pt by $^{199}\text{Pt}(n, \gamma)^{199}\text{Pt}(\beta^-)^{199}\text{Au}$ reaction, and from $^{127}\text{I}(3n, \gamma)^{130}\text{I}$ to the determination of ^{129}I by $^{129}\text{I}(n, \gamma)^{130}\text{I}$ reaction (29). But, interference from triple reactions is normally negligible due to their very low probability.

A special type of nuclear reaction interference is caused by the presence of uranium, which yields a large number of radionuclides as a result of fission. The greatest correction is required in the determination of molybdenum and some rare earth elements (REs), but the concentrations of uranium in biomedical materials are usually too low to present any problem.

Gamma-ray spectral interference means that two radionuclides emit gamma rays with the same or nearly the same energy. For example, ^{51}Ti and ^{51}Cr used for NAA of Ti and Cr emitting a single 320.08-keV gamma ray, ^{75}Se and ^{75}Ge used for Se and Ge emitting 264.66 keV gamma ray. For these nuclides, a separation via decay is possible practically due to their different half-lives. However, the interference for the determination of Hg via the 279.19 keV line of ^{203}Hg (46.6 days), which overlapped by the 279.54 keV line of ^{75}Se (119.77 days), cannot be eliminated by decay because their half-lives are not significantly different. This problem can be resolved by measurement of ^{75}Se by other gamma lines and correcting the contribution of ^{75}Se to the peak of 279.54 keV.

As an effective method for analytical quality control, certified reference materials (CRMs) with a matrix similar to the samples, which have appropriate combinations of elements to be determined and with concentration bracketing the range of interest, are normally analyzed to evaluate the analytical accuracy and precision. A large number of CRMs have been prepared by many countries and international organizations (30), which are not only for analytical quality control of NAA, but actually all other analytical methods.

Uncertainty from the sampling procedure and inhomogeneity of the sample should also be considered as a probable contribution to the total uncertainty of the analytical data, although it is not directly related to the NAA method itself. Especially at very low concentration, the trace elements distribution in samples is normally inhomogeneous and a selection of a representative sample is very important for analytical quality. In recent years, the NAA of large samples has been given much attention (31). In this case, a whole sample is analyzed and the uncertainty resulting from the inhomogeneity of elements in the sample can be overcome.

Applications

As an analytical technique for determination of trace elements, the NAA has been widely used in various aspects of biomedical studies and analysis related to trace elements, such as an investigation of the normal trace element level in the human body, trace element related endemic disorder

and inheritable diseases, environmental exposure of toxic and nonessential trace elements and their effect on human health, and investigation of trace element nutrition status.

The distribution and normal level of trace elements in blood, urine, and human tissue are basic data for the studies on biomedical trace elements. Some activities have been organized by the International Atomic Energy Agency (IAEA) for establishing the normal level of trace elements in "reference man" with different dietary habits and in different geographic areas. This information was completed by analyzing various normal human tissues collected from different countries in which most of the data was supplied by NAA (32,33). In addition, many NAA were also carried out to analyze a large number of blood, urine, hair, and nail samples for normal trace element level determinations. In combination with the analysis of diets and environmental samples, some trace element related endemic disorders have been investigated, such as Keshan disease found in China, which is related to the deficient intake of selenium, and normally also associated with the deficiency of iodine. Some disorders caused by excessive intake of arsenic from ground water and mercury from contaminated fish and foods have also been investigated by NAA in China and many other countries. Trace element nutrition status by analysis of the trace element level in blood, hair, and diets has also been investigated by NAA in many countries. The results were used as a basis for improved recommendations of safe and adequate, daily average intake of these elements.

Some inheritable diseases have been attributed to the metabolism problem of trace elements, such as Menkes' syndrome, Wilson's disease, and Acrodermatitis enteropathica. Determination of specific trace elements in a small amount of living tissue can be used to diagnose disease and to evaluate the treatment. The ability to analyze very small samples by NAA creates a possibility of following temporal changes in trace element concentrations in a living subject. Menkes' disease was found to be a recessive X-linked disturbance of copper metabolism, resulting in accumulation of copper in several extra-hepatic tissues, including the placenta, by NAA of various human tissues of patients and normal persons (2). The method is being used to diagnose Menkes' disease and identification of female carriers by NAA of the placental tissues (2,34). Wilson's disease was also confirmed to be a copper metabolic defective disease; determination of copper in liver biopsy by NAA was used as a control and verification method for estimation of the adequate treatment of this disease.

A high environmental exposure may cause the increase of some nonessential trace elements in the human body, which may create a potential effect for human health. In recent years, rare earth elements found wide application in industry and agriculture, rare earth trace element fertilizer has widely been used in China for increasing the yield of various agricultural products. It also increases the exposure of humans to these trace elements. Neutron activation analysis was used to investigate the uptake of these elements in the human body via the food chain, their distribution in human tissues, and their combination with different components of tissue, especially brain tissue (7,13).

Since hair and nails are easily obtained compared to blood and tissue samples, they serve as a useful indicator of trace element levels in the body. Neutron activation analysis is very suitable for the analysis of hair and nails, because no decomposition of sample is necessary, therefore they are often used for the analysis of these materials for investigation of the nutrition status of trace elements, the environmental exposure level of toxic elements, and the diagnosis of various diseases related to trace elements (9).

A series international conference entitled Nuclear Analytical Methods in the Life Sciences was held since 1967, and the three most recent conferences in this series were held in 1993, 1998, and 2002. The main achievements in this field can be found in the Proceedings of these conferences (35,36) and other relevant conferences (37,38).

NEUTRON BEAM THERAPY

RICHARD L. MAUGHAN
 Hospital of the University of
 Pennsylvania

INTRODUCTION: THE ORIGINS OF FAST NEUTRON THERAPY

The year 1932 was a remarkable one at the Cavendish Laboratory of the University of Cambridge. It represented a pinnacle of achievement for Lord Ernest Rutherford and his collaborators in the nuclear physics laboratories. The results of three experiments performed in this single year resulted in Nobel Prizes in physics for four of the university faculty. Two of these experiments were of great significance for the production of neutrons. Of course, the most significant was the discovery of the neutron itself by James Chadwick in February, 1932 (1). Chadwick needed a source of neutrons to perform this experiment. At that time, the only sources of energetic heavy particles were naturally occurring isotopes that emitted alpha particles. Chadwick's neutron source was comprised of a polonium source (^{210}Po), which emits a 5.3 MeV alpha particle and a block of beryllium housed in a vacuum chamber. The nuclear reaction

produces a flux of neutrons with energies of several million electronvolts (MeV). To detect these neutrons, Chadwick used an ionization chamber with a thin entrance window. Pulses could be observed on an oscillograph as the source was brought closer to the ionization chamber. The chamber was air filled and the increasing count rate was interpreted as being due to recoil nitrogen nuclei in the chamber. When a sheet of paraffin wax was placed in between the source

and the ionization chamber a further increase in the source count rate was observed and interpreted as resulting from recoil protons from n–p elastic scattering. Further measurements confirmed that the particles producing the recoil protons were neutral particles of the same mass as the proton. With this simple and elegant apparatus Chadwick discovered the neutral nuclear particle, the existence of which Rutherford had postulated in 1919.

Sources of this type give very low neutron fluxes and are not suitable for neutron radiation therapy or radiobiology. It was another of the Nobel Prize winning discoveries of 1932 at Cavendish Laboratory that offered the means for producing intense sources of neutrons. This was the discovery of artificial transmutation of nuclei by John Cockroft and Ernest Walton in April 1932. In this experiment, Cockroft and Walton used their specially designed high-voltage apparatus (now commonly known as a Cockroft–Walton accelerator) to produce protons of energy 700 keV. When these protons interacted with a lithium target, the resulting mass eight compound nuclei disintegrated into two alpha particles with the release of ~17 MeV of energy

The alpha particles were detected as scintillations on a zinc sulfide screen and, in order to observe these events, Cockroft or Walton had to sit in a small darkened enclosure at the end of the accelerator tube (2).

Although this first artificial splitting of the atom did not involve the production of neutrons, it was not long before another Rutherford's research team, Mark Oliphant, was to apply the new technology to an experiment to demonstrate the fusion of deuterium nuclei. In this reaction, the products are helium 3 and a neutron

The reaction has a positive Q value of 3.27 MeV and a deuteron beam of 400-keV energy produces neutrons with energies up to ~3.5 MeV.

This experiment was performed in 1934 and almost immediately L.H. Gray, yet another of Rutherford's ex-students, working as one of the first British medical physicists at Mount Vernon Hospital in Northwood, England, realized the potential of this reaction as a source of neutrons for radiobiology research. The ability of neutrons to produce ionizing radiation in the form of heavy recoil particles had been realized soon after their discovery and that these particles might be able to produce biological damage similar to that produced by the recoil electrons associated with X ray beams and radium sources had also been recognized. Neutrons are heavy particles and can transfer relatively large amounts of energy to their secondary recoil particles in comparison to the recoil electrons produced when X rays interact with matter. The neutrons are, therefore, capable of high linear energy transfer (LET) to the recoil particles associated with them and for this reason are known as high LET particles. Gray and others observed that the very great difference between the distribution of ions along the track of a recoiling nucleus and a fast electron made it probable that the biological action of neutrons would show interesting differences from that of

the other radiations. It was hoped that a study of these differences would throw light on the mode of action of radiations on biological material. There was also the possibility that eventually neutrons might prove a more potent means of treating cancer (3).

Gray obtained funding to build a 400 keV Cockroft–Walton accelerator in which he used the deuterium–deuterium reaction to produce a neutron beam for radiobiology research (3). The capital cost of the unit was \$2400 with maintenance costs of \$320/annum for 1937 and 1938. The unit was housed in a wooden shed.

Concurrently, progress was being made in accelerator technology in the United States by another renowned physicist, Ernest O. Lawrence. Lawrence's invention of the cyclotron earned him the 1939 Nobel Prize for physics and provided a means for producing ion beams with energies of several tens of million electronvolts, far in excess of the energies obtained by Cockroft and Walton with their accelerator. Ernest Lawrence's brother, John, was a physician and the two brothers soon realized the potential medical benefits of applying neutron beams produced by accelerated protons or deuterons. In 1938, funding was obtained from the National Cancer Institute (NCI) for the construction of a 60 in. medical cyclotron; this was the first NCI research grant. This cyclotron was used to produce a neutron therapy beam using a 16 MeV deuterium beam incident on a thick beryllium target. With the use of this beam, Dr. Robert Stone performed the first clinical trials of fast neutrons.

Hence, by 1938 accelerated beams of particles were being used to produce high intensity neutron beams for radiobiology and/or external beam radiation therapy research in both the United States and the United Kingdom.

RADIOBIOLOGICAL RATIONALE FOR FAST NEUTRON THERAPY

The first clinical trials of neutron therapy were performed at the University of California in Berkeley, and were interrupted by the Second World War, when the Berkeley cyclotron was utilized for nuclear physics research associated with the Manhattan Project. Patients with advanced inoperable head and neck tumors were treated with neutron therapy using the same number of treatment sessions, or fractions, as was normally used for conventional X-ray therapy. Although remarkable tumor regression was seen in a few cases, this was at the cost of excessive damage to the surrounding irradiated normal tissues. In 1947, Stone concluded that “neutron therapy as administered by us has resulted in bad late sequelae in proportion to the few good results that it should not be continued”, (4). The trials had been undertaken to test the hypothesis that neutron radiation may be superior to X-ray radiation in curing human cancers. However, at the time little was known about the radiobiological effects of neutron irradiation in comparison to conventional X-ray irradiation. It was not until later, when some basic radiobiological research on the effects of neutron irradiation on mammalian cells had been completed, that the reasons for the failure of this original clinical trial could be understood. Further neutron radio-

biology research enabled a firm rationale for neutron therapy to be established.

When mammalian cells are irradiated *in vitro* by ionizing radiation (X rays or neutrons) cells are killed in proportion to the radiation dose delivered. A plot of the cell kill as a function of the radiation dose, or survival curve, is markedly different in shape depending on whether the cells are irradiated by X rays or fast neutrons. This finding is illustrated in Fig. 1, taken from the work of McNally et al. (5). On a log-linear plot at high doses the response appears linear (i.e., exponential), but at low doses there is a “shoulder” on the survival curve. This shoulder is more pronounced for X ray irradiations than for neutron irradiations. Another point to notice is that for a given radiation dose the cell-kill by fast neutrons is greater than for X rays. The relative biological effectiveness (RBE) of neutrons relative to X rays is defined as the ratio the dose of X rays required to produce a given level of cell-kill compared to the dose of fast neutrons required to give the same cell kill. Because of the different shapes and sizes of the shoulders on the neutron and X ray cell survival curves it can be seen from Fig. 1 that the RBE at a surviving

Figure 1. Survival curve for WHFIB mouse tumor cells irradiated with fast neutrons and X rays. Reproduced with permission from McNally, et al. *Rad. Res.* 1982;89:234.

Figure 2. Survival curves for V79 and WHFIB cells, irradiated in air and hypoxia. Squares, X rays; circles neutrons; open symbols, air; solid symbols hypoxia. Reproduced with permission from McNally, et al. *Rad. Res.* 1982;89:232.

fraction of 10^{-2} (i.e., a relatively high dose) is ~ 3.8 , while for a surviving fraction of 3×10^{-1} (i.e., a lower dose) the RBE increases to ~ 5 . John Lawrence measured the RBE in nonhuman biological systems, prior to commencing the Berkeley fast neutron therapy trials with Robert Stone, using large single doses of radiation to produce an observable biological effect. Based on an RBE measured at high single doses, they calculated the required total neutron dose from a knowledge of the total X ray doses delivered to cancer patients at that time. Unfortunately, radiation therapy doses are delivered as a large number of small doses and at these smaller doses the RBE is much larger, hence, the fast neutron dose delivered to patients in the original fast neutron trial was overestimated by a considerable margin. This of course resulted in good tumor control compared to conventional X rays, but also produced an unacceptable level of normal tissue damage. It was not until 1971 that Sheline et al. (6) explained this phenomenon.

In the meantime, L.H. Gray working at Hammersmith Hospital had described a logical rationale for fast neutron therapy. In 1954, in a landmark paper in radiation therapy, Thomlinson and Gray described how, in a poorly vasculated tumor, areas of reduced oxygenation, or hypoxia, can exist as the distance from blood vessels increases (7). If oxygenation drops low enough, the cells become necrotic and die. Gray showed, using diffusion kinetics, that an oxygen concentration gradient can exist within a tumor and that in certain areas of the tumor there may be severely hypoxic, yet viable cells. How this phenomenon can be exploited to advantage in fast neutron therapy is illustrated in Fig. 2. In this figure, cell survival curves for cells irradiated by both X rays and fast neutrons in an oxygen (oxic) and a nitrogen (anoxic) environment are

plotted. The anoxic cells are more resistant to radiation than the oxic cells and as tumors are poorly oxygenated and contain anoxic cells this could well result in an inability to deliver sufficient radiation to kill all the tumor cells, leading to tumor recurrence. Normal tissues are well oxygenated and, therefore, are more easily damaged. Hence, it is possible that the doses to the normal tissues surrounding the tumor may reach their acceptable tolerance level before sufficient dose has been delivered to the hypoxic tumor cells to eradicate them. Figure 2 shows that the differential cell killing for oxic and anoxic cells is much greater for X rays than for fast neutrons. Thus for a given level of normal tissue, cell kill or damage neutrons should be more effective at killing hypoxic cells in the tumor than conventional X-ray therapy. It was this hypothesis that led to the restarting of fast neutron clinical trials at Hammersmith Hospital in London in 1970. The encouraging results obtained at Hammersmith Hospital rekindled interest in fast neutron therapy and by 1980 there were close to 20 centers treating patients.

The clinical results showed that fast neutron therapy appeared to be particularly effective in the treatment of slow growing tumors such as adenocarcinoma of the prostate and bladder. In the meantime, radiobiology research had revealed another important difference between X rays and fast neutrons related to the variation of the radiation sensitivity of mammalian cells at different phases of the mammalian cell cycle. Mammalian cells exhibit well-defined stages in their cycle first described by Howard and Pelc (8). Figure 3 shows a schematic representation of the phases of the cell cycle. Cells spend most of their time in a quiescent phase known as G1 (gap 1), after the G1 phase they move into a phase during which duplicate DNA is synthesized, the S phase. Following DNA synthesis there

Figure 3. Schematic representation of the phases of the cell cycle.

is another gap phase, G2, which precedes cell division or mitosis (the M phase). The S, G2, and M phase have a similar duration for all mammalian cells, being typically 8, 4, and 1 h, respectively. It is the G1 phase that varies for rapidly and slow growing cells, being as short as 1 h for fast growing cells and as long as 200 h for slow growing cells. The variation in the radiosensitivity of cells irradiated with conventional X rays at different phases of the cell cycle can be considerable (9). The late G1 phase is a relatively radioresistant phase and in cells with a long G1 there is also a period of radioresistance during early G1. As a result, slow growing cells, which spend a larger proportion of the cell cycle in G1 phase than rapidly proliferating cells, would be expected to be more resistant to radiation than the fast growing cells. Withers et al. (10) have shown that the variation of cell sensitivity during the cell cycle is less for fast neutron irradiation than for conventional X-ray radiation. This is a potential advantage for fast neutron therapy, since it means that neutrons are relatively more effective in killing cells in the radioresistant phases of the cell cycle. This would explain the observed efficacy of neutrons in the treatment of slow growing tumors. Another observation, which confirms the efficacy of fast neutrons in treating slow growing tumors, was made by Battermann et al. (11), who showed that the relative biological effectiveness of fast neutrons increases with tumor doubling time.

Thus by the early 1980s it had been established that fast neutron therapy could be justified on radiobiological rationale related to both tumor hypoxia and volume doubling time.

REVIEW OF CLINICAL RESULTS

After the original unsuccessful clinical trials at Berkeley, fast neutron therapy was restarted in 1970 by Dr. Mary Catterall, at Hammersmith Hospital in London. Although Dr. Catterall's studies were not controlled clinical trials they did demonstrate the potential efficacy of fast neutron therapy in the treatment of advanced or recurrent tumors. The success of these studies led to the establishment of many fast neutron therapy centers around the world and to the instigation of a number of clinical studies of those tumors thought to be the most promising candidates for

neutron therapy. These tumors included advanced inoperable tumors of the salivary glands; squamous carcinoma of the head and neck; adenocarcinoma of the prostate, rectum, bladder, and soft-tissue; osteo- and chondro-sarcomas. The results of these studies demonstrated that fast neutron therapy was particularly promising for the treatment of salivary gland tumors, prostate tumors, and bone tumors. The results for squamous carcinoma of the head and neck, however, were ambiguous. Prompted by these results, the NCI in the United States decided to fund four purpose-built hospital-based neutron therapy facilities to contribute to a definitive series of controlled clinical trials performed at these and other approved centers.

The NCI trials were undertaken in two phases starting with dose searching studies, designated as phase II trials, followed by efficacy studies (phase III trials). The patient accrual into these trials is shown in Table 1. The phase II trials established the general treatment protocol for the phase III studies, that is, a dose of 20.4 Gy would be delivered in 12 fractions over 4 weeks and after 13.6 Gy abdominal and pelvic treatment fields would be reduced in size.

Of the seven phase III trials undertaken, only three were successfully completed; the head and neck, lung, and prostate trials. The salivary gland trial was terminated early; the investigators thought it unethical to continue with randomization because of the excellent results obtained with neutron therapy (12). The remaining three trials were closed because of poor patient accrual. The only other trial to yield a positive result was the prostate trial (13). This trial also highlighted the importance of shaping the beam to conform to the tumor outline. The three centers contributing patients to this trial had facilities with different beam collimation systems of varying degrees of sophistication. The occurrence of normal tissue complications in the bladder and rectum was closely related to the

Table 1. Patient Accrual for NCI-NTCWG Clinical Trials Using the New Generation of Neutron Therapy Facilities in the United States (1984-1991)

<i>Total accrual</i>	<i>1174</i>

sophistication of the beam collimator. The University of Washington, which utilized a sophisticated multileaf collimator for beam shaping, had the least number of treatment related complications, while the M.D. Anderson Hospital in Houston, which used an insert-based collimation with limited shaping capability, had the greatest number of normal tissue complications (13).

An earlier NCI funded Phase III trial for advanced adenocarcinoma of the prostate had shown that a mixed-beam treatment regimen of 60% photons combined with 40% neutrons was superior to conventional photon only therapy (14). With this in mind, Forman et al. (15) undertook a series of in-house neutron therapy trials at Wayne State University using mixed-beam therapy (50% photons and 50% neutrons) for early and some late stage patients. This trial also utilized a sophisticated beam shaping system, a multirod collimator. These trials demonstrated that mixed-beam therapy is as effective as any other state-of-the-art radiation therapy techniques (Intensity Modulated Radiation Therapy or IMRT, proton therapy, brachytherapy) in the treatment of early stage prostate cancer, and that it is probably superior for the treatment of late stage disease (15).

Full reviews of neutron therapy in the treatment of cancer can be found in the work of Wambersie et al. (16) and in a recent International Atomic Energy Agency (IAEA) publication (17). The IAEA report concludes that fast neutrons are superior to photons in the treatment of salivary gland tumors (locally extended, well differentiated), paranasal sinuses (adenocarcinoma, adenoid cystic carcinomas, and possibly other histologies), some tumors of the head and neck (locally extended, metastatic adenopathies), soft tissue sarcomas, osteosarcomas, chondrosarcomas (especially slowly growing/well differentiated), prostatic adenocarcinomas (locally extended), and melanomas (inoperable and recurrent). The IAEA report also identifies tumors for which conflicting or incomplete results have been reported and for which additional studies are necessary, these include inoperable pancreatic tumors, bladder carcinoma, recurrent and inoperable adenocarcinoma of the rectum, tumors of the esophagus, locally advanced tumors of the uterine cervix, and brain tumors for treatment with a neutron boost irradiation before or after X-ray therapy.

NEUTRON SOURCES FOR RADIATION THERAPY

Characteristics of Neutron Sources for Medical Use

In order to be useful for medical applications, fast neutron therapy facilities must meet a set of minimum requirements. As described above, in the early years of the 1970s many neutron therapy centers were set up to carry out clinical trials. Most of these centers made use of existing physics research accelerators (cyclotrons or proton linacs), which were adapted for clinical use. The trials produced results, which were often ambiguous and much of this ambiguity was ascribed to the inadequacies of the equipment. When the NCI in the United States decided to fund a number of therapy facilities, the basic specifications for these accelerators were defined to ensure that the equip-

Table 2. Summary of Some of the Key Requirements for a Hospital-Based Neutron Therapy Facility as Defined by the NCI^a

Neutron beams having build-up and depth-dose characteristics equivalent to 4 MV X rays, penumbra not less sharp than ⁶⁰ Co gamma-ray beams, and dose rates not less than 20 cGy/min.
Preferably an isocentric beam delivery system and as a minimum one horizontal and/or vertical beam delivery port.
Access to the neutron beam therapy facility for a minimum of 8 h/day, 4 days/week, 45 weeks/year for patient treatment and 16 h/week additional for physics and biology.
Methodology for providing a variety of square, rectangular, and irregularly shaped fields ranging in size from 5 × 5 cm ² to 20 × 20 cm ² .
Capability to shape treatment fields using a variety of wedges and blocks so that any treatment field normally used for conventional X ray therapy can be reproduced on the neutron beam.

^aSee Ref. (18).

ment would be adequate to allow meaningful clinical trials to be completed (18); the key requirements are summarized in Table 2. All the facilities funded by the NCI were hospital-based and had rotational isocentric capability, that is, the neutron beam could be rotated around the patient in the treatment position.

Several of these requirements depend critically on the neutron source. In particular, the attenuation (depth-dose) characteristics of the beam, the neutron dose rate (treatment time), and the reliability of the device may be dependent on the neutron source and the means of neutron production.

In order to fully characterize a neutron source it is necessary to have a detailed knowledge of a number of physical characteristics of the neutron beam. Most importantly, the physical data must be sufficient to allow for the accurate calculation of the physical dose delivered both to the tumor site and the surrounding normal tissues in the patient. In addition, physical data may also be necessary to adequately interpret the biological effects that are observed with high linear energy transfer (LET) beams. Table 3 lists the type of data, which are necessary to fully characterize the neutron source. These data are also necessary to fully assess the relative merits, usefulness, and

Table 3. Physical Data Necessary to Characterize Neutron Sources for Radiation Therapy

Total neutron yield or dose or kerma rate.
Neutron spectrum (i.e., Neutron yield as a function of neutron energy).
Neutron yield as a function of angle relative to the forward direction of the beam.
Neutron dose as a function of depth in a water phantom (i.e, depth-dose data).
Relative neutron dose as a function of the lateral position (i.e, dose profiles).
The microdosimetric properties of the beam (i.e., the LET distribution of the secondary particles).
Neutron interaction data (cross-sections or kerma) for the interaction of the neutron beam with the constituent nuclei of tissue (C, N, O, H, Ca).

suitability of the various different neutron sources for radiation therapy applications. Much of the data in Table 3 are interconnected. In theory, a detailed knowledge of the neutron spectrum as a function of angle should be sufficient to calculate the other data provided there are comprehensive data on the nuclear cross-sections for the interaction of the neutrons with all the various biological target nuclei involved across the energy range of interest. Although, these data do exist for fast neutron beams they are not comprehensive and performing the necessary calculations with Monte Carlo codes remains a formidable and time consuming task. For this reason, until now it has proved simpler and more efficient to rely on various types of direct measurements to collect the necessary data; this situation may change in the future.

Basic Source Data

Neutron Yield. Neutron yields may be measured using a suitable detector that counts the number of particles arriving at the detector with no regard to the energy of the particle. Such detectors must usually be calibrated in order to determine their absolute efficiency. An excellent account of neutron detectors can be found in the work of Knoll (19). Neutron yields are generally expressed in terms of neutrons per steradian per microcoulomb of incident beam charge ($\mu\text{C}^{-1}\cdot\text{sr}^{-1}$).

Neutron Spectra. Neutron spectra are measured using a variety of neutron detectors (19,20). For a spectral measurement, the detector must exhibit an energy response in which the magnitude of the detector signal is proportional to the energy of the incident neutrons. Such detectors must also be calibrated so that correction can be made for their counting efficiency.

In a spectrum measurement, the neutron yield is measured as a function of energy ($\mu\text{C}^{-1}\cdot\text{MeV}^{-1}\cdot\text{sr}^{-1}$). The total neutron yield at a particular angle can be calculated from a spectral measurement by integrating over the neutron energy.

Neutron Dose. Neutron dose is most easily and accurately measured using the methods of mixed-field dosimetry (21). A tissue equivalent plastic ionization chamber is used to measure the total neutron plus gamma-ray dose and a Geiger-Muller (GM) tube is used as a neutron insensitive detector. From the two measurements, the neutron and gamma-ray dose can be determined separately. This does not mean that spectral and kerma data are not important. Indeed, the calculation of dose from an ionization chamber reading involves the use of factors, which rely on the exact nature of the neutron spectrum (e.g., kerma ratios and the energy to produce an ion pair). These factors are readily available in the literature in ICRU Report No. 46 (22). In practice, it is sufficient to measure the total dose only, since the percentage of gamma-ray dose is relatively small and its biological effectiveness is ~ 3 times less than an identical neutron dose.

Microdosimetric Measurements. Microdosimetric data are most commonly measured using a Rossi type A-150

tissue equivalent plastic proportional counter in which the sensitive volume of the counter is filled with a tissue equivalent proportional counter gas at reduced pressure (23). Typically, the internal diameter of these counters is 12.7 mm, and when filled to a pressure of 8.8 kPa with propane-based tissue equivalent gas, the counter simulates a sphere of solid tissue of diameter 2 μm . The counter detects the energy deposited in the gas as recoil particles traverse the gas volume after a neutron interaction has occurred in the plastic wall of the counter. From a knowledge of the counter geometry, it is possible to calculate the energy deposited per unit path length ($\text{keV}/\mu\text{m}$) (24). The microdosimetric spectrum is usually plotted as a single event spectrum in which the event size (y), in units of $\text{keV}/\mu\text{m}$, is plotted on a log scale as the ordinate and the differential dose distribution in event size (y) per unit logarithmic interval, $y\cdot d(y)$, is plotted on a linear scale as the abscissa. A typical microdosimetric spectrum plotted in this form is shown in Fig. 4. In this representation, the area under the curve represents the total dose. The various peaks in the curve can be interpreted as due to the different components of the dose, gamma-rays, recoil protons, alpha particles, and recoil heavy ions. Hence, such plots can be used to distinguish between neutron beams produced by different sources. A detailed account of microdosimetric methods can be found in ICRU Report No. 36 (24).

Beam Characteristics. From a practical radiation therapy physics point of view, the most useful data is that which allows you to calculate the neutron radiation dose distribution within the patient. A detailed knowledge of the neutron fluence and energy is not necessary to make these calculations. In radiation therapy measurements of absorbed dose in a water tank, $\sim 60 \times 60 \times 60 \text{ cm}^3$ are made using a small volume (typically 0.3 cm^3) ionization chamber; the tank is known as a "water phantom". Neutron dose at a point in the phantom must be determined at a known depth, field size, and source-to-surface distance

Figure 4. A typical microdosimetric event size spectrum measured with a tissue equivalent plastic Rossi proportional counter. The portions of the spectrum attributable to recoil electrons from gamma-ray interactions and recoil protons, alphas, and heavy ion recoils (C^{12} , N^{14} , and O^{16}) from neutron interactions are identified. (see the section: Neutron Dose). Measurements are also made along the radiation beam central axis to determine the attenuation of the beam. The parameter Z_{50} is a measure of the beam penetration as defined by the depth in a water phantom at which the neutron dose is reduced to 50% of its maximum value for a $10 \times 10 \text{ cm}^2$ field. The Z_{50} value varies as a function of the energy and type of particle used in the primary beam. As the incident particle energy increases the mean neutron energy increases and the Z_{50} increases; this can be seen from the data in Table 4. This 50% depth-dose point also varies with the dimensions of the irradiation field (normally known as the field size). Some form of collimator is required to set the field size, this may be an attenuating block with a predefined rectangular opening, a pair of attenuating jaws, which provide a variable rectangular opening, or a multileaf collimator, which can define rectangular fields or more complex shapes. Generally, square fields are used for beam data measurements and the field size is defined at the center of the treatment volume (isocenter). The Z_{50} variation with field size arises because the dose at a point depends not only on attenuation of the primary beam in the water phantom, but also on the scattered component of the beam, which is field size dependent. To fully characterize a therapeutic beam it

is, therefore, necessary to measure depth dose curves at a variety of field sizes; Fig. 5 illustrates this phenomenon.

Another beam parameter, which varies with the primary beam particle and energy is the beam build-up. When

an indirectly ionizing radiation beam (neutrons or X rays) passes from air into a solid water medium, the secondary particle fluence in the surface layers is much less than at depth, because in the shallower layers the secondary particles are those that originated in the air and passed into the solid. Since air is much less dense than the solid, there are relatively few secondary particles in the surface layer. As the neutron beam penetrates the solid medium, more and more secondary particles are set in motion in the solid medium, until an equilibrium situation is reached at a depth that is about equal to the average range of the secondary particles in the solid. The energy deposition (dose) reaches a maximum at this depth (known as the depth of maximum dose, d_{\max}) and is attenuated beyond this point as shown in Fig. 5. This build-up region of the curve cannot be measured using the instrumentation used to measure the attenuation data in Fig. 5. A specialized thin pill box shaped ionization chamber (known as an extrapolation ionization chamber) is required for these measurements. The build-up region has considerable clinical significance, when treating tumors at depths $>d_{\max}$, since the dose in the surface layers of the skin is reduced relative to the tumor dose and, hence, the skin can be spared from excessive radiation damage. Table 5 shows how the surface dose (dose at zero depth), expressed as a percentage of the dose at d_{\max} , and d_{\max} vary as a function of the neutron producing nuclear reaction and the incident particle energy.

Beam profiles are also measured in the water phantom by scanning the ionization chamber in a direction perpendicular to the radiation beam central axis. A typical beam profile is shown in Fig. 6. As can be seen from this figure, the exact shape of the profiles depends on the depth in the phantom and the radiation field size. The most important feature of the profiles is the sharpness of the beam edges; This parameter degrades with both increase in field size and depth due to increased scattering of the neutrons. The exact sharpness of this penumbra region depends on many factors including, the source size, scattering from the collimator system and beam monitoring components in the beam path, the collimator geometry (i.e., whether the edges of the collimator jaws or leaves are divergent), and finally on neutron scattering in the patient (or phantom). Generally, phantom scatter is the predominating factor.

Depth-dose and profile data are inputted to the computer programs used for calculating the dose distribution in patients. These programs use a variety of different mathematical algorithms to calculate the dose distributions in the patient.

NEUTRON PRODUCTION

Fast Neutron Therapy Beams

Over the past 65 years, there have been at least 34 centers that have been involved in fast neutron radiation therapy. Table 4 lists these centers and indicates which nuclear reaction has been used to produce the neutron beam. In column 2, the lower case letter indicates the accelerated particle, the number in parenthesis is the energy in mega-electronvolts of this projectile and the final letter(s) represents the target nucleus. Of the facilities, 12 have used the deuteron stripping reaction with a beryllium target, 14 the proton inelastic scattering reaction on a beryllium target, 7 the deuteron-tritium fusion reaction and only 1, the deuteron-deuteron fusion reaction. The relative

merits of these various modes of neutron production will be discussed.

The d-Be Reaction

In practice, the deuteron stripping reaction on beryllium is the most prolific neutron producing reaction since a solid beryllium target capable of stopping the full energy of the beam can easily be constructed. There are basic physical reasons for the deuteron stripping reaction on beryllium being more prolific in producing neutrons than the inelastic scattering of protons from a beryllium target. The deuteron is a loosely bound structure of a neutron and a proton in which the two particles spend most of their time at greater distances from each other than the range of the forces between them. Hence, when an energetic deuteron approaches a beryllium target nucleus it is possible for the proton to be absorbed into the target nucleus, breaking free from the neutron that carries on following its original path at its original velocity (i.e., with half the kinetic energy of the original deuteron). The excited ^{10}B nucleus formed may also decay by neutron emission. When a proton beam interacts with a beryllium target the proton is absorbed into the target nucleus to form a compound nucleus, ^{10}B , in an excited state, which may decay by emitting a neutron. Hence, the stripping reaction is a much more prolific source of neutrons, since many neutrons originate from the break-up of the deuteron. In addition, the stripping reaction is very forward-peaked in the laboratory, while the (p,n) reaction on beryllium produces a more isotropic distribution, since it involves the formation of a compound nucleus. The theoretical aspects of the production of intense neutron beams using the deuteron stripping reaction with beryllium targets has been discussed by August et al. (26). Experimental neutron yield data and spectral data on the characteristics of neutrons from beryllium targets bombarded with protons and deuterons with energies of 16, 33, and 50 MeV are available in the work of Meulders et al. (27). The above experiments measure the total neutron fluence at 0° or the differential fluence as a function of neutron energy at various angles relative to the forward direction. In order to estimate the usefulness of a given reaction as a neutron source for radiation therapy, it is necessary to know the neutron dose rate produced in practice by a given attainable beam current. Such information can be calculated from neutron spectrum data using neutron kerma factors for water or body tissue (22).

Another vitally important parameter is the penetration of the neutron beam in tissue. Although in principle it is possible to calculate this information from the spectral and kerma data, in practice there are insufficient data and the calculations are difficult. Therefore, ionization chamber measurements are often more convenient for measuring both the dose rate and penetration of neutron beams. There is extensive data on neutron dose rates and depth dose characteristics of neutron beams across a wide range of energies for the deuteron stripping reaction on beryllium. Smathers et al. (28) reviewed the available dose rate data in the incident deuteron energy range of 11–50 MeV and concluded that the tissue kerma measured free-in-air at a target-to-detector distance of 1.25 m and for a $5 \times 5 \text{ cm}^2$

field size could be fitted by an equation of the form

$$\ln K = \ln a + b \ln E \quad (1)$$

In this equation, E is the energy of the incident beam in million electronvolts, K is the tissue kerma in units of $\text{cGy min}^{-1} \cdot \mu\text{A}^{-1}$ and a and b are constants with numerical values of 1.356×10^{-4} and 2.97, respectively.

Later, Wootton (29) reviewing ionization chamber dose rate data for the d-Be reaction quoted the following expression for the dose rate at 1.25 m

$$D \cdot Q^{-1} = 2.49 \times 10^{-2} E_d^{2.95} \quad (2)$$

where $D \cdot Q^{-1}$ (in Gy/C) is the absorbed dose to tissue free-in-air at a 1.25 m target to detector distance per unit charge of deuteron beam, and E_d is the incident deuteron energy in million electronvolts. If Eq. 1 is rewritten in this form and normalized to the same units it becomes

$$D \cdot Q^{-1} = 2.26 \times 10^{-2} E_d^{2.95} \quad (3)$$

At $E_d = 50$ and 10 MeV, these equations agree to within 2 and 5%, respectively. Of course, such equations can only be used to give a rough estimate of the neutron dose output of a neutron therapy device, since the exact output depends on the details of the target, flattening filter, collimator, and dose monitor design.

The spectral data of Lone et al. (30) gives information on the fluence averaged energy of the neutron beam (E_n), they derived the following expression:

$$E_n = 0.4 E_d - 0.3 \quad (4)$$

relating the mean neutron energy to the incident deuteron energy (E_d) in million electronvolts.

Data on the penetration of neutron beams, produced by the d-Be reaction, have been published by Shaw and Kacperek (31). In Fig. 7, the values of Z_{50} from Table 4 for the d-Be reaction is plotted as a function of incident deuteron energy. A power law fit to the curve yields the

Figure 7. The neutron beam 50% depth-dose value (Z_{50}) for neutrons produced by the d-Be reaction plotted as a function of the incident deuteron energy (E_d). The solid line is a power law fit to the data (Eq. 5). The data are for a $10 \times 10 \text{ cm}^2$ field at a range of source-surface distances (SSD) between 91 and 183 cm.

following equation

$$Z_{50} = 2.90 E_d^{0.39} \quad (5)$$

The exact value of Z_{50} depends on the target structure and the beam filtering effects of the flattening filter and the dose monitor devices.

The clinical relevance of microdosimetric data in neutron therapy planning has been discussed by Pihet et al. (32). The microdosimetric dose distribution shown in Fig. 4 can be analyzed in several ways, the most useful single parameter, which can be used to describe the distribution is the dose mean lineal energy corrected for saturation

$$y_1^* = \int y_{\text{sat}} \cdot d_1(y) \cdot dy \quad (6)$$

This parameter was defined in the dual radiation action theory of Kellerer and Rossi (33). The function y_{sat} is a response function that accounts for the saturation effect that is observed in mammalian cell systems (34); as the LET of the beam is increased the observed RBE decreases due to the overkill effect (35). In Fig. 8, the y_1^* values for a variety of different therapy beams are plotted as a function of the mean neutron energy, as defined in Eqs. (4) and (8). The closed circles represent the data for the d-Be reaction.

The p-Be Reaction

From Table 4, it can be seen that most of the early neutron therapy centers (i.e., those operating at lower energies) utilized the deuteron stripping reaction or the fusion reaction as the source of neutrons (see Section: The d-T Reaction). Interest in the p-Be reaction increased when the importance of constructing neutron sources with rotational isocentric capability (i.e., capable of rotating around the patient with the tumor center on the axis of rotation) and with penetration equivalent to 4 MV photon beams was realized (Table 2). Good penetrability requires deuteron or proton beams with energies of 40–50 MeV or greater, and isocentricity requires bending magnet systems capable of

bending these beams 180° (a 45° bend followed by a 135° bend). Conventional cyclotrons capable of producing 50 MeV deuterons were too large and expensive as were the magnet systems for bending these beams. Proton cyclotrons of 50 or 60 MeV offered a much less expensive alternative in the late 1970s, when the decision to install a new generation of hospital-based neutron therapy facilities was being made by the NCI in the United States. The problems of switching from the deuteron stripping to the p-Be reaction were soon recognized: the energy spectrum from the reaction of protons on a beryllium target has a significant low-energy tail, which reduces the average neutron beam energy and spoils the penetration. Also the neutron output is much less, therefore, higher beam currents are required with an increase in the problems associated with target cooling and target activation. The penetration problem can be overcome by using nonstopping targets (i.e., beryllium targets in which the incident proton beam does not lose all its energy) in conjunction with polyethylene filters, which filter out the low energy component of the beam. These techniques have been discussed in detail for proton beams with energies between 30 and 60 MeV by Bewley et al. (36) and for a 41 MeV proton beam by Smathers et al. (37). The absorbed dose rate ($D \cdot Q^{-1}$) to tissue at 1.25 m from the target is given by Wootton (29) as

$$D \cdot Q^{-1} = 2.44 \times 10^{-2} E_p^{2.37} \quad (7)$$

where $D \cdot Q^{-1}$ is in units of Gy/C and E_p is the incident proton energy in million electronvolts.

For the p + Be reaction with a stopping target, the average neutron energy for neutrons with energies >2 MeV (E_n) measured at 0° to the incident beam is given by

$$E_n = 0.47 E_p - 2.2 \quad (8)$$

where E_p is the incident proton energy (29).

In Fig. 9, the value of Z_{50} from Table 4 for the p-Be reaction is plotted as a function of incident proton energy, the solid curve is a power law fit to the data that gives the

Figure 8. The microdosimetric parameter mean lineal energy corrected for saturation (y_1^*) plotted as a function of the mean energy of the neutron beam for various neutron producing reactions: d-Be, open circles (E_n from Eq. 4); p-Be, open circles (E_n from Eq. 8), and d-T reaction, open triangle ($E_n = 14.1$ MeV).

Figure 9. The neutron beam 50% depth-dose value (Z_{50}) for neutrons produced by the p-Be reaction plotted as a function of the incident proton energy (E_p). The solid line is a power law fit to the data (Eq. 9). The data are for a 10×10 cm² field for range of SSD between 125 and 190 cm.

following equation:

$$Z_{50} = 2.06 E_p^{0.50} \quad (9)$$

The greater spread in the data points, when compared with the similar data plotted in Fig. 7, is a result of the greater variety in the target design (i.e., target thickness and filtration conditions) used at the different facilities.

The microdosimetric data for the p-Be reaction is represented by the open circular data points in Fig. 8. The dose mean lineal energy corrected for saturation correlates with the mean neutron energy for both the p-Be and the d-Be produced neutron beams.

The d-D Reaction

This reaction was used in the neutron radiation therapy facility at the University of Chicago, where a deuteron beam of energy 8.3 MeV was incident on a thick cryogenic deuterium gas target designed by Kuchnir et al. (38). Two reactions predominate when a deuterium target is bombarded with deuterons:

and,

Hence, there are two distinct groups of neutrons produced, the higher energy group resulting from the first of these two reactions. The neutron energy spectrum for bombardment of a thick stopping target exhibits two maxima corresponding to the two groups. The relative magnitude of the two peaks depends on the incident deuteron energy. At an incident deuteron energy of 6.8 MeV the higher energy peak due to the $D(d,n){}^3\text{He}$ reaction predominates, but for an incident energy of 11.1 MeV, the two peaks are comparable (39). Waterman et al. (39) calculated the neutron spectra at 6.8, 8.9, and 11.1 MeV from a knowledge of the mass stopping power of deuterons in deuterium and from the cross-sections of the two reactions as given by Schraube et al. (40).

The dosimetric properties of the d-D neutron beam are summarized in the work of Kuchnir et al. (38). Figure 10 shows the variation in absorbed tissue dose rate ($\text{Gy}/\mu\text{C}$) as a function of the incident deuteron energy for a thick deuterium gas target. The measurements were made at a SSD of 126 cm with a $11.1 \times 11.1 \text{ cm}^2$ field size. The data can be fitted by a power law expression.

$$D \cdot Q^{-1} = 2.41 \times 10^{-2} E_d^{3.28} \quad (10)$$

where $D \cdot Q^{-1}$ (Gy/C) is the absorbed dose to tissue measured free-in-air per coulomb (C) of incident beam current, and E_d is the incident deuteron beam energy. Measurements have been made by Weaver et al. (41) at an incident deuteron energy of 21 MeV, but with a transmission gas target. For a target filled to a pressure of 3.33 MPa (33 atm), equivalent to an energy loss of ~ 3.5 MeV, the measured dose was $2.25 \times 10^{-4} \text{ Gy}/\mu\text{C}$ for a $10 \times 10\text{-cm}$ field at 1.25 m SSD.

In practice, the University of Chicago neutron therapy facility produced a maximum dose rate of 0.12 Gy/min at an

Figure 10. Absorbed dose at the depth of maximum dose as a function of incident deuteron energy for the d-D reaction. The data are from Kuchnir et al. (38). The solid curve is a power law fit to the data (Eq. 10). Measurements were made in a $11.1 \times 11.1 \text{ cm}^2$ field at an SSD of 126 cm.

SSD of 91 cm, for a $10 \times 10 \text{ cm}$ field size. The penetration of the University of Chicago d-D beams in terms Z_{50} is 9.8 cm (Table 4). An interesting feature of the d-D reaction is that as the incident deuteron energy is increased the mean neutron energy produced remains practically constant. This finding is evident in the depth-dose data of Kuchnir et al. (38), where changing the incident deuteron energy has no significant effect on the value of Z_{50} . Even at 21 MeV with a transmission target the Z_{50} remains constant at ~ 10 cm. Thus, the inherent poor penetration of neutron beams produced by the d-D reaction, combined with the difficulties of producing a cryogenic deuterium gas target discouraged the use of this reaction as a neutron source for radiation therapy.

The d-T Reaction

For many years, this reaction was seen as the ideal reaction for producing a relatively inexpensive source of neutrons for radiation therapy. The large positive Q -value for the reaction

results in monoenergetic neutrons of energy ~ 14 MeV. In principle, a relatively modest deuteron energy of 250–500 keV should be sufficient to produce an intense source of 14-MeV neutrons if sufficient beam current can be obtained. The original intention was to produce the source and target assembly in the form of a sealed tube, which could be easily replaced in the treatment head and would have a lifetime of 1000 h or more. Such a unit would have been similar in this respect to the 250-kVp X-ray units that were in widespread use before the advent of ${}^{60}\text{Co}$ units and high-energy electron linacs in conventional photon radiation therapy. Initially, the main problem with these devices was that associated with producing a target in the sealed tube configuration that would provide sufficient neutron dose rate. However, many different systems were used in attempts to produce a practical d-T generator and these have been reviewed in detail in ICRU Report No. 45 (21).

Of the five types of commercially available d-T generators, which were used in clinical trials to treat significant numbers of patients, four were of a type that employed some form of sealed tube in which a mixed deuterium-tritium beam was accelerated to an energy of 200–250 keV and used to bombard a tritiated rare earth target (titanium, erbium, or scandium). The characteristics of these four machines are given in Table 4. The Haefely device produced the highest dose rate with the longest average tube life of ~300 h and was installed in Heidelberg and Münster. The operation of the Philips and Elliot tubes are described by Broerse et al. (42). A Philips machine was installed in Amsterdam and the Elliot devices were used in Glasgow and Manchester. An account of the construction of the Haefely machine is given by Schmidt and Rheinhold (43) while a detailed appraisal of its clinical operation can be found in the work of Höver et al. (44). The University of Pennsylvania D-T generator was built by the Cyclotron Corporation (Berkeley, CA).

The fifth commercial unit, installed in Hamburg, was produced as a collaboration between AEG in Germany and Radiation Dynamics Inc. (RCI) in the United States. The machine used a pure deuterium beam accelerated to 500-keV incident on a replaceable rotating tritiated titanium target (45). The source and target design were improved by incorporating an analyzed deuterium beam (to remove molecular D_2^+ beam components) and a larger target (46). With these improvements a dose rate of 0.12–0.13 Gy/min was achieved.

PRACTICAL FAST NEUTRON THERAPY FACILITIES

In fast neutron radiation therapy the need for state-of-the-art neutron facilities, which allow neutron treatments to be delivered with precision and sophistication equivalent to that used in modern conventional X-ray therapy, is well recognized. Modern trends in X-ray therapy are toward conformal therapy with multiple static fields, multileaf collimators, three-dimensional (3D) treatment planning and most recently (IMRT). All these tools must be available for neutron radiation therapy if effective randomized phase III clinical trials are to be completed to compare the two modalities.

An important aspect of this problem is beam penetration. The problem with neutron beams is that it is not possible to increase the mean energy of the neutrons to a point at which the neutron beams have percentage depth-dose characteristics that are equivalent to modern high energy (15–25 MV) photon beams, since as the neutron beam energy increases, the average LET of the beam decreases. If the average LET is decreased too far, the radiobiological advantage of the neutron beam will be significantly diluted (e.g., RBE tends to decrease and neutron beam advantages associated with hypoxia decrease, the radiosensitivity variation within the cell cycle tends to that of low LET radiations). Hence, there is a trade-off between beam penetration and LET effect. This trade-off can be seen in Fig. 8, which illustrates how the effective LET (γ_1^*) of the neutron beam decreases as the mean neutron energy (E_n) increases.

The requirement that neutron beams should be at least equivalent to 4 MV photon beams (Table 2) arises in part from this trade-off. Of the 34 facilities listed in this Table 4, only 10 satisfied this penetration requirement. Of the 6 operational facilities 4 satisfy the requirement and the most penetrating beams at the Ithemba Laboratory in South Africa and Fermi Laboratory in the United States, produced by the p(66)Be reaction, are equivalent to an 8-MV photon beam. If all the requirements of Table 1 are considered and in addition a multileaf or multirod collimator for producing irregularly shaped fields is made mandatory, then only three of the operational facilities meet all the requirements. These are at the University of Washington in Seattle, the Ithemba Laboratory in South Africa and at Harper Hospital, Wayne State University in Detroit. The fact that the neutron beams are less penetrating than the 15–25 MV photon beams that are commonly used for treating deep-seated tumors may not be a problem. In a treatment planning comparison of 3D conformal neutron and photon radiotherapy for locally advanced adenocarcinoma of the prostate, Forman et al. (47) showed that the dose-volume histograms for gross tumor, rectal, and bladder volumes treated with neutrons and photon beams are not significantly different. Wootton (29) suggested that neutron beams with a Z_{50} of >15 cm are required, and that for the d-Be reaction to be useful in this case, an incident deuteron energy of 61 MeV would be required. Forman's data, however, indicate that a Z_{50} of 13.6 cm is adequate for producing acceptable dose distributions for the treatment of pelvic tumors.

In the late 1970s, economic considerations led to the choice of the p-Be reaction as the neutron source for a new generation of hospital-based high-energy proton cyclotrons for clinical trials in the United States, because deuteron producing conventional cyclotrons and the associated bending magnet system required to produce rotational beams were too costly. These machines were installed at the MD Anderson (MDA) Hospital in Houston, at the University of California Los Angeles, and at the University of Washington in Seattle (Table 4). Since this time the development of a compact superconducting deuteron cyclotron for neutron radiation therapy by Henry Blosser and his associates at the National Superconducting Cyclotron Laboratory at Michigan State University has had a significant impact on the technology of neutron therapy. This superconducting facility (25,48) has many innovative features. The accelerator weighs ~25 Mg (25 tons), ~10 times less than a conventional 50 MeV deuteron cyclotron. The unit has an internal beryllium target and is mounted between two large rings (4.3 m outer diameter) in order to provide for 360° rotation around the treatment couch. A 25 Mg counterweight mounted on the rings acts as a primary beam stop, which reduces the required thickness of the shielding walls. The total rotating mass is ~60 Mg (60 tons). Figure 11 is a schematic of the cyclotron and gantry. Figure 12 shows a section through the median plane of the cyclotron indicating its' main components. The unit does not require a separate bending magnet system to produce an isocentric beam and it can be installed in a single shielded room. With no beam extraction or elaborate bending magnet system, the operation is

Figure 11. A schematic of the superconducting cyclotron mounted on the rotating gantry at the Wayne State University Facility. Reproduced with permission from Maughan et al., Med. Phys. 1994;21:781.

Figure 13. A photograph of the multirod collimator. One-half of the polystyrene foam form used to push the rod array into the desired shape is visible on the left. Reproduced with permission from Maughan et al., Med. Phys. 1994;21:781.

considerably simplified. The unit also incorporates a unique multirod collimator for producing irregularly shaped fields (49), which conform accurately to the tumor volume (Fig. 13). This facility has been in routine clinical use since March of 1992, and up to the end of 2002, ~1800 patients have been treated. Close to 10,000 individual treatment fields have been routinely treated in a single year making this the busiest and most efficient neutron therapy facility in the world.

DISCUSSION AND CONCLUSIONS

Neutron therapy has been demonstrated to be superior to conventional therapy in the treatment of salivary gland tumors, some tumors of the paranasal sinuses and other head and neck sites, soft tissue sarcomas, chondrosarcomas, osteosarcomas, advanced adenocarcinoma of the prostate, and inoperable and recurrent melanoma (17). For a range of other sites, further investigation is necessary to establish the efficacy of neutron therapy; these sites include pancreas, bladder, rectum, esophagus, uterine cervix, and brain.

However, in spite of these successes, neutron therapy appears to be in decline with only six centers actively treating patients (three in the United States and one each in Germany, France, and South Africa). The emphasis on precision radiation therapy has resulted in the development of intensity modulated radiation therapy techniques in conventional X ray therapy. These techniques allow for highly conformal dose delivery, maximizing the dose to the tumor volume and minimizing the dose to the surrounding normal tissues. There is also a considerable increase in the number of proton beam therapy centers, using the unique energy deposition patterns associated with proton beams to achieve even greater conformality than is achievable with IMRT.

In Europe and Asia, there is interest in developing ¹²C ion beams for radiation therapy. These developments are spurred by the superior results achieved with neutron therapy in the cases outlined above. Heavy ion beams,

Figure 12. such as ^{12}C beams, are high LET beams, which combine the biological advantages of neutrons with the dose distribution advantages of protons. Such beams are extremely expensive to produce. The application of intensity modulated radiation therapy techniques in neutron therapy (IMNT) could improve the conformality of neutron therapy. Compact superconducting cyclotrons with computer controlled multileaf collimators, which allow IMNT to be delivered, could be an attractive and less expensive alternative to ^{12}C therapy.

The superconducting technology could be applied to designing a compact 60–70 MeV gantry mounted proton cyclotron to provide a beam with better depth dose characteristics than the existing Wayne State University cyclotron. The possibility of building a compact conventional 50 MeV proton cyclotron in a similar configuration to the superconducting deuteron cyclotron has been suggested (Jongen, unpublished data). A computer controlled MLC is at present under construction at Wayne State University with the intention of using it to implement IMNT (50). Such advances in neutron therapy technology are important if it is to achieve its full potential and remain competitive with the other radiation therapy modalities (i.e., conventional X rays and electrons, protons, and heavy ions).

In the >80 years since its discovery in Cambridge by James Chadwick, the neutron has found an important place in radiation therapy research, and much has been done to improve the means of neutron production and delivery.

NONIONIZING RADIATION, BIOLOGICAL EFFECTS OF

ANDREW WOOD
Swinburne University of
Technology
Melbourne, Australia

INTRODUCTION

Non-ionizing radiation (NIR) refers to that portion of the electromagnetic (EM) spectrum in which the characteristic wavelength is greater than around 180 nm. Radiation of shorter wavelength than this has sufficient quantum energy (given by hc/λ , with h = Planck's constant, c = wavespeed in vacuo, and λ = wavelength) to remove outer electrons from neutral atoms to cause the atom to become ionized, hence, the term "ionizing radiation." NIR consequently does not have the same intrinsic potential for atomic and molecular alteration or the health effects consequent to this. For this reason, damage to DNA and other biomolecules due specifically to the removal of electrons is difficult to envisage. The main groupings of NIR, with increasing wavelength (and decreasing frequency) are ultraviolet (UVR), visible, infrared (IR), radio frequency (RF), and extremely low frequency (ELF). The RF spectrum can be further divided as shown in Table 1 to include microwaves (MW), millimeter waves (MMW), terahertz radiation (THzR), as well as the conventional divisions for broadcast communications. Although not part of the EM spectrum, UVR is normally considered to be part of NIR, as are static (0 Hz) electric, and magnetic fields. The application of the term "radiation" to the ELF portion is also of little consequence, because the wavelength is several thousand kilometers at 50/60-Hz power frequencies.

NON-IONIZING RADIATION PROTECTION

Guidelines on NIR radiation protection are developed by the International Commission on NIR Protection (ICNIRP). In North America, other bodies have developed standards, such as the IEEE International Committee on Electromagnetic Safety and the American National Standards Institute (ANSI), or guidelines, such as the American Conference of Government Industrial Hygienists (ACGIH). Some jurisdictions have chosen to incorporate these (or related) guidelines into legislation.

The mechanism of interaction of NIR with living tissue varies with the groupings just mentioned. These are summarized below, along with effective protection measures against overexposure.

UVR

UVR exposure from the sun outweighs that from all other sources except for a small group of persons in exceptional circumstances. Solar UVR over-exposure is a worldwide problem, leading to increased skin cancer, and by World Health Organization estimates, up to 3 million people are made blind through cataracts. Burning of the skin is a direct indicator of overexposure, at least in the short term. Solar radiation and other UVR sources can initiate photochemical reactions, such as the breakdown of atmospheric oxygen to form oxygen-free radicals and ozone. UVR also has a role in vitamin D control and production. Of greater relevance to adverse health effects, biomolecules (such as DNA components and proteins) can undergo resonant UVR absorption to give rise to dimers (where two similar molecules join to form a single unit). For example, adjacent thymine bases in DNA can fuse to cause an abnormal form. The cell repair mechanisms can sometimes fail to detect this, leading to mutations. The initial response of the skin to UVR within hours of exposure is reddening (erythema or sunburn) due to increased blood flow and edematous changes. The role of photochemical reactions in erythema is unclear. In addition, the immune response can also be suppressed by UVR, increasing risk of infection. On the other hand, the socially attractive tanning of the skin is caused by UVR-induced increase in melanin pigmentation. Chronic exposure leads to skin aging and increased risk of skin cancer. Non-melanoma skin cancers (NMSC) include basal cell carcinoma (BCC: 80%) and squamous cell carcinoma (SCC). The risk of NMSC varies with annual solar UVR dose to the power of between 2 and 3. Melanoma, which has a poor prognosis due to its ability to metastasize, is related to the amount of sun exposure or sunburn during childhood. Chronic eye exposure leads to

increased cataract risk. Certain pharmaceutical and other agents lead to photosensitization, in which absorption of longer wavelength UVR can lead to resonant absorption usually associated with shorter wavelengths. The UVR range is usually divided into UV A, B, and C, as indicated in Table 1. The rationale for this is that (1) biological photoreactions are less important above 315–320 nm, and (2) there is virtually no terrestrial solar radiation below 280–290 nm. The boundaries between the ranges are somewhat imprecise. UVA has less capability to cause erythema (by a factor of around 1000) than UV B, but because UVA radiation is the predominant form of solar radiation, it contributes around one sixth of erythemal dose. A minimum erythemal dose (MED) is the UVR exposure (in joule per centimeter squared), which gives rise to just noticeable reddening in the skin of previously unexposed persons. Overexposure is defined as that which leads to erythema within 3 hours or less in a normal population. MEDs have been determined experimentally for narrow bandwidths in the range 180–400 nm, giving a minimum of $30 \text{ J}\cdot\text{m}^{-2}$ at 270 nm. A set of values S_λ , which denote the relative effectiveness of UVR to cause erythema at a specific wavelength λ , are then derived. For example, because at 180 nm, $2500 \text{ J}\cdot\text{m}^{-2}$ is required for the occurrence of erythema compared with $30 \text{ J}\cdot\text{m}^{-2}$ at 270 nm, S_{180} is $30/2500$ or 0.012. As exposures are usually to a range of wavelengths (and mainly in the UVA range), a weighted sum for each wavelength component according to its capacity to cause erythema can be obtained. The standard erythemal dose (SED) is then defined such that 1 SED is $100 \text{ J}\cdot\text{m}^{-2}$. This measure is independent of skin type, because MED measurements relate to fair-skinned subjects. Most commonly, overexposure is a result of being outdoors without skin protection, but it can also result from artificial sun-tanning

Table 1. The Non-ionizing Radiation Spectrum

Name of Range	Frequency Range	Wavelength Range	Common Sources
Ultraviolet	UVC 1.07–3 PHz ^a	100–280 nm	Germicidal lamps, Arc welding
	UVB 0.95–1.07 PHz	280–315 nm	Solar radiation, Arc welding
	UVA 750–950 THz ^b	315–400 nm	Solar radiation, Solarium
Visible	430–750 THz	400–770 nm	Solar radiation, indoor and outdoor illumination
Infrared ^c	Near IR (IR A) 214–430 THz	0.7–1.4 μm	Furnaces
	Mid IR (IR B) 100–214 THz	1.4–3 μm	Night photography
	Far IR (IR C) 0.3–100 THz	3 μm –1 mm	Infrared spectroscopy
Terahertz			
Microwave (including millimeter wave)	Extremely High Freq 30–300 GHz	1 mm–1 cm	Satellite, radar, and remote sensing
	Super High Freq 3–30 GHz	1–10 cm	Speed radar guns, Communications
Radio frequency	Ultra High Freq 1–3 GHz	10–30 cm	Mobile telephony
	Ultra High Freq 0.3–1 GHz	30 cm–1 m	Mobile telephony
	Very High Freq 30–300 MHz	1–10 m	TV, FM Radio Broadcasting
	High Freq 3–30 MHz	10–100 m	Electro-welding equipment
	Medium Freq 0.3–3 MHz	100 m–1 km	AM Radio
Extremely low frequency	Low Freq 30–300 kHz	1–10 km	Long-wave radio
	Very Low Freq 3–30 kHz	10–100 km	Navigation and time signals
	< 3 kHz	> 100 km	Electrical power, Electrotherapy
Static	0 Hz		Geomagnetic field, Magnetic Resonance Imaging systems

^aPHz = peta-Hertz, or 10^{15} Hz

^bTHz = tera-Hertz, or 10^{12} Hz

^cThe boundaries between near-, mid-, and far-IR are imprecise, as is the terahertz range indicated.

(in a solarium), proximity to tungsten halogen lamps (without filtering glass covers), proximity to UVR light-boxes in scientific and industrial applications, and certain forms of flame welding, with the main possibility of eye damage in these latter sources. Cases of erythema from fluorescent tubes have been reported in extreme cases of photosensitization. The main forms of protection are wearing appropriate clothing, sunblocks (such as zinc oxide cream), sunscreens (based on photo-absorbers, such as para-amino-benzoic acid and cinnamates), and effective sunglasses. Staying out of the sun where this can be avoided is a good behavioral approach for exposure minimization. The “sun protection factor” (SPF) is effectively the ratio of time of exposure before erythema occurs in protected skin to the corresponding time in unprotected skin. A ratio of at least 30 is recommended for effective protection in recreational and occupational exposure to solar radiation. It is important to ensure that sunglasses have sufficient UVR absorption to protect against cataract. Various forms of clothing protect against UVR exposure to differing degrees, ranging from wet open-weave cotton, which offers an ultraviolet protection factor or UPF (which is analogous to SPF) of only around 3–6, to elastane (Lycra) with UPF values of around 100 (99% absorption). It should be noted that these protection factors are computed as the ratio of effective dose (ED) with and without protection (ED/ED_m). The ED is the sum of solar spectral radiance components weighted according to erythema effectiveness. Here $ED = \sum E_\lambda S_\lambda \Delta\lambda$, where E_λ is the solar spectral irradiance in watt per centimeter squared per nanometer, S_λ is the relative effectiveness of UVR at wavelength λ causing erythema (as mentioned), and $\Delta\lambda$ is a small bandwidth in nanometers. The units of ED are watt per centimeter squared. ED_m is similar, but it contains a factor T_λ to denote the fractional transmission of the test sunscreen (cream, fabric) at a particular wavelength (i.e., $ED_m = \sum E_\lambda S_\lambda T_\lambda \Delta\lambda$). The Global UV Index (UVI) is a dimensionless quantity in which the ED is summed over the range 250–400 nm and multiplied by $40 \text{ m}^2\text{W}^{-1}$. In Darwin, Australia, this ranges from 0 to 3 in the early morning and evening to 14 or more at noon on a clear day. At this UVI, erythema will result in fair skin after 6 minutes. See <http://www.icnirp.de/documents/solaruvi.pdf> for further information.

It is estimated that significant reductions in the incidence of both malignant and benign forms of skin cancer could be achieved by the enforcement of protective measures, particularly in occupational settings involving fair-skinned people in outdoor work in tropical or subtropical regions. Occupational exposures in Australia have recently been measured (1), and UVR safety has been reviewed in several publications (see Reference (2), for example). Indicative exposure limits are given in Table 2. It should be emphasized that for brevity many details are omitted from this table. For full details of limits pertaining to a particular geographical region, local radiation protection authorities should be consulted. The ICNIRP guidelines are readily accessible via downloads from <http://www.icnirp.de>. These represent reviewed publications originally appearing in *Health Physics*.

Visible Radiation

This is the region of NIR to which the retinal pigments of the eye are sensitive, so understandably, eye injury is the main concern in overexposure. There are two forms of hazard: photochemical and thermal. In addition, if the eye lens has been surgically removed (aphakia), there is an enhanced risk of damage. Photochemical damage becomes more likely with shorter wavelengths and is sometimes referred to as the “blue light hazard.” The type of photochemical reaction is bleaching of the visual pigments, leading to temporary loss of vision. Thermal injury can result in permanent impairment of vision, especially if the foveal region, used for fine focus, is involved. Thresholds for these forms of injury have been determined in the wavelength range 400–1400 nm (thus including near infrared, see below) and an assessment of whether these are exceeded, for a particular source takes into consideration the spectral characteristics of the source. For exposures shorter than a few hours, the total radiance should be below $10^6 \text{ W}\cdot\text{m}^{-2}\cdot\text{sr}^{-1}$, where sr refers to a unit solid angle tended by the source. Lasers represent the sources most likely to cause injury, and because these emit a small number of discrete wavelengths, this assessment can be straightforward. Eye injury is minimized by the blink reflex, but laser wavelengths outside the visible range are less easy to control, because their paths are difficult to track, especially from incidental reflections. Lasers are classified according to the luminous power, their visibility, and their effective aperture, as described further in a separate entry on **LASERS**. High-power lasers are used in machining, welding, and engraving of a variety of materials, including plastics, metals, and fabrics. They also provide the source of beams in communications and photonics research laboratories. During normal operation, a combination of administrative and engineering controls provide adequate protection for workers. On the other hand, high-power lasers used in “light show” entertainment have sometimes given rise to unintentional beams directed at members of the public. The unrestricted distribution of laser pointers, with a capacity of causing eye damage, has also been a concern in several jurisdictions. Apart from laser sources, welding flames represent the next most common form of visible light hazard (“welder’s flash”). Hazard can be minimized by the use of appropriate goggles. Recently, high-powered light-emitting diode (LED) sources have been evaluated by the ICNIRP for their potential for visible light hazard, particularly those emitting blue light. Although injury is unlikely, the power density of these devices continues to increase as technology develops.

IR

The major sources of IR radiation that are of concern are furnaces and some high-powered non-visible laser devices (femtosecond lasers). Here there is an increased possibility of local thermal injury, but because there is poor penetration of the lens of the eye, the possibility of retinal damage is reduced compared with the visible range. The IR range is divided into three ranges as shown in Table 1. Above 1–2 μm , water is a strong absorber of IR. Whereas guidelines for optical radiation extend up to 1.4 μm (near

Table 2. Approximate Exposure Limits for NIR: Exact Limits Vary Between Countries and In Some Cases Between Different Contexts of Exposure

Name of Range	Indication of Level Above Which Intervention Is Recommended	Biohazard Forming Basis of Protection	References to <i>Health Physics</i> Publications
Ultraviolet	U-shaped over wavelength range: 180 nm–2.5 kJ·m ⁻² ; 270 nm–30 J·m ⁻² (minimum); 400 nm–1 MJ·m ⁻²	Skin reddening due to burn (erythema), also prevention of cataract	Vol 71, p 978 (1996) Vol 84, pp 119–127 (2004)
Visible	Depends on viewing position and spectral content of source	Retinal thermal or photochemical damage	Vol 73, pp 539–554 (1997)
Lasers (includes above and below)	Depends on wavelength, exposure duration, and size of aperture. For long exposures (> 100 s), limits are of the order of 1 W·m ⁻²	Retinal (esp. foveal) damage: photochemical or thermal Also skin.	Vol 71, pp 804–819 (1996) Vol. 79, pp 431–440 (2000)
Infrared	100 W·m ⁻² for long exposure* Not well defined	Thermal injury to lens and cornea	Vol 73, pp 539–554 (1997)
Terahertz			
Microwave (including millimeter wave)	6–300 GHz: 50 W·m ⁻² (time averaged) 50 kW·m ⁻² peak ^a	Rise in tissue temperature sufficient to cause protein denaturation	Vol. 74, pp 494–522 (1998)
Radio frequency	10 mJ·kg ⁻¹ within 50 μs interval ^a 0.1–6,000 MHz: 0.4 W·kg ⁻¹ for whole-body exposure; 10 W·kg ⁻¹ for 10 g mass (head and torso) ^a . 3–10,000 kHz: f/100 (f in Hertz) mA·m ⁻² in head and torso ^a	Microwave hearing Rise in tissue temperature sufficient to cause protein denaturation Shocks or burns due to induced current or contact current	As above As above As above
Extremely low frequency	Tissue induced field: 18 mV·m ⁻¹ for f, 20 Hz; 18(f/20) mV·m ⁻¹ for f between 20 & 800 Hz (IEEE) ^b , 10 mA·m ⁻² for range 4–1,000 Hz (ICNIRP)	Magnetophosphenes, micro-shock	As above
Static	0.2 T time weighted average ^a , 2 T ceiling, 5 T limbs	Magnetophosphenes associated with movement	Vol 66, pp 100–106 (1994)

^a These basic restrictions are for occupational exposures: Divide by 5 to get general public limits.

^b These basic restrictions are for “controlled environment” (i.e., occupational) exposures: Divide by 3 to get general public limits.

infrared), there is some disagreement on the appropriate levels beyond that. Levels of incident radiation above 100 W·m⁻² are considered as posing an unacceptable thermal hazard. Those at risk of overexposure include foundry workers and welders. Recently, advances have extended telecommunications frequencies into the “terahertz gap,” the region between 0.3 and 3 THz, which has been unexploited by technological applications. The health effects are currently unknown, but they are expected to be similar to those of the contiguous frequency ranges. However, there is a current discontinuity between IR and RF standards or guidelines for a 1 mm wavelength (0.3 THz).

RF

Common sources of high-power RF emissions include welding equipment and induction heaters used in industrial drying processes. Radio, TV, and telecommunications transmitters can involve high broadcast powers (400 kW or more for commercial TV stations). There are two types of potential hazard: thermal injury in the range 100 kHz–300 GHz and neural stimulation due to induced

currents or contact with metallic surfaces at frequencies below 10 MHz. At 300 GHz, the effective wavelength in tissue is less than 1 mm, so very little will penetrate below the skin. On the other hand, at 80 MHz, the wavelength is comparable with the long axis of the human body, so absorption is enhanced. Protective measures in terms of incident RF power density (W/cm²) are thus strictest in the range 10–400 MHz. The basic restriction above 100 kHz is on the rate of energy absorption by tissue (specific absorption rate, or SAR, in W/g of tissue). SAR is related to the RF electric field induced in tissue (E_i V·m⁻¹) such that

$$\text{SAR} = \sigma E_i / \rho$$

where σ is local conductivity in S/m and ρ is tissue density in kg/cm³. In unperfused insulated tissue, SAR is related to the rate of rise of temperature dT/dt via

$$\text{SAR} = k \cdot dT/dt$$

where k is the specific heat of tissue, 3480 J·kg⁻¹·K⁻¹ approximately.

This basic restriction is limited to values for whole-body or localized exposures such that normal thermoregulation would not be compromised, with a 10-fold safety margin. Although there is some variation between standards in place throughout the world, many countries employ a distinction between occupationally exposed persons ("aware users") and the general public, for whom an extra five-fold level of protection is provided. The ICNIRP value for whole-body SAR for the general public is $0.08 \text{ W}\cdot\text{kg}^{-1}$, with higher values of $2 \text{ W}\cdot\text{kg}^{-1}$ in the head and trunk and $4 \text{ W}\cdot\text{kg}^{-1}$ in the limbs, averaged over 10 g of tissue. The power density of incident plane-wave radiation (in watt per centimeter squared), which would give rise to these levels of SAR (for far-field exposures), has been computed by mathematical modeling and animal studies in a conservative manner, such that if these reference levels are complied with, the basic restrictions will be met. As, for free space, the power density S is related to the electric and magnetic field values (E and H , respectively) by $S = E^2/377 = H^2 \cdot 0.377$, compliance testing can be accomplished by measuring E -field values alone. Reference levels at particular frequencies can be found by reference to the ICNIRP guideline as indicated in Table 2.

Induced current density restrictions are imposed at 10 MHz and below. Above this frequency, it is considered that the fields vary too quickly to produce neural stimulation. Again, there is a safety factor of 10 between occupational levels and the level at which mild stimulatory effects can be noted in 1% of the population. This ranges from $100 \text{ A}\cdot\text{m}^{-2}$ at 10 MHz to $10 \text{ mA}\cdot\text{m}^{-2}$ at 4 Hz–1 kHz, in the ICNIRP guidelines. This will be discussed further in the ELF section.

At frequencies between 0.2 and 6 GHz, a phenomenon of "microwave hearing," due to thermoelastic expansion of brain tissue in response to pulsed radiation, occurs. Additional restrictions are in place in the ICNIRP guidelines to prevent this from occurring.

Overexposure to RF radiation, leading to serious burns, is usually due to the failure of control measures, such as guards on RF seam welding apparatus or work on RF antennas mistakenly thought to be nonoperational.

The safety of communications equipment, including mobile telephony handsets and base stations, is a major community concern. There is little substantive evidence of harm from long-term exposure at so-called "non-thermal" levels, but because there are many young users of handsets, many countries have endorsed a precautionary approach, encouraging use only for necessity. The scientific evidence for the possibility of "non-thermal" effects has been reviewed in the United Kingdom by the Independent Expert Group on Mobile Phones (IEGMP) (3) and by other bodies. The IEGMP concluded that although "the balance of evidence to date suggests that (low levels of RF radiation) do not cause adverse health effects" that "gaps in knowledge are sufficient to justify a precautionary approach." Some national standards (for example, Australia and New Zealand) incorporate a "precautionary" clause; that is, exposures incidental to service delivery should be minimized (but taking other relevant factors into consideration). The limiting of mobile phone use by children was recommended by the IEGMP (3), but the Health Council of

the Netherlands sees no convincing scientific argument to support this (4).

ELF and Static

The range of frequencies (0–3 kHz) includes power transmission and distribution systems (50/60 Hz) as well as transportation systems (0, 16.7, 50, and 60 Hz), surveillance systems, and screen-based visual display units. Here the main potential hazard from exposure to fields (rather than direct contact with conductors) seems to be from inappropriate neural stimulation due to induced current (as in the case of RF, above). Consequently, treating ELF as a special case may seem out of place, but because the ELF range is precisely that of biogenic currents due the operation of nerves and muscles, its separate treatment is justified. The susceptibility of cells to the influence of exogenous currents is related to the time constants for the operation of cell membrane channels, which are typically of the order of milliseconds. At lower frequencies, cell membranes tend to adapt to imposed electrical changes, so restrictions need to be strictest in the range 10–1000 Hz. In humans, the retina of the eye represents a complex network of interacting nerve-cells, giving rise to sensations of pinpoints of light when stimulated by external electric and magnetic fields (EMFs). As this gives a guide to the levels at which stimulatory effects could become an annoyance, or could possibly be interpreted as a stressor, a basic restriction for occupational exposure of $10 \text{ mA}\cdot\text{m}^{-2}$ (which corresponds to an induced field of around $100 \text{ mV}\cdot\text{m}^{-1}$) has been adopted by the ICNIRP for the range 4–1000 Hz. This restriction rises above and below this range. In particular, at 0 Hz (static fields), levels are restricted to $40 \text{ mA}\cdot\text{m}^{-2}$. Levels for the general public are less by a factor of 5. Reference levels for magnetic fields are derived from these basic restrictions by considering the body to be simple geometric objects, but more advanced modeling yields similar results. For sinusoidally varying fields, the reference magnetic fields can be derived from basic restrictions via the formulas

$$B = E/(\pi fr) \quad \text{or} \quad B = J/(\sigma\pi fr)$$

where E refers to the basic restriction in terms of induced tissue electric field (in volt per meter), J is the basic restriction in induced current density (A/cm^2), f is the frequency in Hertz, σ is the tissue conductivity (S/m), and r is the radial distance from the center of symmetry (in the same direction as the external magnetic field B).

Electric field reference levels are derived more from considerations of avoiding "microshocks," which may occur, for example, if an arm with finger extended is raised in an intense electric field. Details of these reference levels can be found (for the ICNIRP limits) at <http://www.icnirp.de>. As it is possible to exceed the electric field reference levels in electrical switchyard work, special precautions need to be taken. Exceeding magnetic field reference levels is rare. Some government and other organizations have advocated a much more prudent approach to limiting exposure, particularly to the general public. This comes from some dozen or so well-conducted

epidemiological studies linking exposure of children to a time-weighted average magnetic field of $0.4 \mu\text{T}$ or more, to an approximate doubling of leukemia incidence. The possibility of low-level health effects of ELF has been the topic of research for nearly three decades. As there is no agreed mechanism for how elevated leukemia rates could be brought about, nor is there adequate evidence from long-term animal studies, there is doubt that magnetic fields are the causative agent. Nevertheless, time-varying ELF magnetic fields (but not electric fields, nor static fields) have been categorized by the International Agency for Research in Cancer (IARC) as a "possible carcinogen" (category 2B) (5). Essentially, the U.S.-government funded EMF-RAPID (Electric and Magnetic Field Research and Public Information Dissemination) program, whose Working Group reported in 1998 (6), came to a similar conclusion. The final report of the NIEHS Director (7), on the other hand, concluded that "the scientific evidence suggesting that ELF-EMF pose any health risk is weak" but also acknowledged that "exposure cannot be recognized as entirely safe because of weak scientific evidence that exposure may pose a leukemia hazard." The report also advocated "educating both the public and regulated community on means aimed at reducing exposures." There is intense debate on how a policy of prudence should actually be interpreted, because approximately 1% of homes would be in the "over $0.4 \mu\text{T}$ " category (8,9) (this percentage varies widely between and even within countries). Several moderate cost engineering measures can be employed to reduce field levels from transmission lines, and electric power companies often employ these in new installations.

PERCEIVED ELECTRO-SENSITIVITY

Several persons claim debilitating symptoms associated with proximity to electrical installations or appliances or in association with the use of mobile (cell) phones. Despite several well-conducted, independent, "provocation studies," in which sufferers have been subjected to energized and not energized sources in random order, no association between exposure status and occurrence of symptoms has been established. A recent Dutch study of psychological sequelae of mobile phone use implied that the overall baseline responses in a group of "electro-sensitives" differed from a similarly sized group of "normals," but that the changes associated with mobile phone use were similar in both groups.

ULTRASOUND

Few processes and devices outside of clinical medicine involve the possibility of human exposure to ultrasound if normal protective guarding measures are in place. Airborne ultrasound is used in surveying instruments and in a variety of drilling, mixing, and emulsification industrial processes. Ultrasonic descalers are used in dentistry and to clean jewelry. Reports of injury are rare. For industrial applications, the frequency range of 20–100 kHz is covered by ICNIRP limits and is based on the pressure amplitude of

the ultrasound in air (these are of the order of 110 dB, referenced to 2×10^{-5} Pa). In clinical applications, ultrasonic energy is usually delivered across the skin via coupling gel and is in the frequency range 1–25 MHz. Diagnostic ultrasound is designed to prevent tissue temperature rising above 41°C for sustained periods (10,11). Effectively, beam intensities are capped at $1000 \text{ W}\cdot\text{m}^{-2}$ (spatial peak, temporal average), except for short periods of insonation. Higher intensities are possible if the energy density is below $500 \text{ kJ}\cdot\text{m}^{-2}$. This gives a large margin below established hazardous effects. Therapeutic ultrasound exposure is usually limited by patients reporting excessive heat, but use on patients with limited sensation is of concern. Intensities of $10 \text{ kW}\cdot\text{m}^{-2}$ are common in therapeutic applications. Tissue damage occurs above $10 \text{ MW}\cdot\text{m}^{-2}$.

SERIOUS INJURY FROM NIR

From above, it would appear that NIR is fairly innocuous. It should be stressed, however, that high-power devices, if inappropriately used or modified, can cause serious injury. UVC is routinely used as in germicidal devices, and the micro-cavitation produced by intense ultrasound beams is used to disrupt tissue. Laser skin burns occasionally occur in research laboratories. Severe injury and fatalities have resulted from surgical uses of lasers in which gas embolisms have become ignited within body cavities. Early unshielded microwave ovens were associated with severe kidney damage. Cases of severe burns are still too common in small businesses using RF heat sealers, often due to the removal of guards. Serious burns result from an accidental or ill-advised approach to broadcast antennas and other communications equipment (12). In addition to burns, severe chronic neurological deficits can also result from overexposure to RF currents (13).

ACHIEVING ADEQUATE PROTECTION AGAINST NIR

Opinion is divided about the need to control NIR exposure by legislation. Communications equipment manufacturers have to comply with rigid requirements related to health guidelines and standards, and many countries have the power to prosecute in instances where equipment is tampered with or altered such that the guidelines would be exceeded. Codes of practice often have provisions for marking "no go" areas where levels could be exceeded, with appropriate signage. In terms of the potential for preventing debilitating illness or early death, the link between solar UVR and skin cancer and cataract represents the area where intervention is most warranted. It is estimated that adequate sun protection could perhaps save tens of lives per million of population per annum with over \$5M pa per million in savings in health costs. The costs of ensuring employers of outdoor workers and the workers themselves complying with measures of UVR exposure reduction are hard to estimate, but they are likely to be high. Whereas compliance with a limit of $30 \text{ J}\cdot\text{m}^{-2}$ equivalent (or MED) is achievable in relation to artificial sources, this level can be exceeded in less than an hour's exposure to intense solar

radiation around noon in low latitudes. Employers can be required to educate their workforce to use appropriate measures to reduce the risk of becoming sunburnt, but it is virtually impossible to eliminate this from actually occurring. It would seem unreasonable to require employers to be responsible for an overexposure to a familiar and essential source of energy to which we have all been exposed since the dawn of time.

As several forms of NIR carry with them an uncertainty of possible harm in the long term, several national radiation protection authorities have espoused the "Precautionary Principle." This entails taking measures to reduce exposure, even where exposures are well within levels set by scientific evaluation of the available research. It is recognized that reducing exposure might itself introduce new hazards or increase other hazards (such as being unable to use a cell-phone in an emergency because of extra power restrictions), so an evaluation of the need to be "Precautionary" with respect to NIR should be in the wider context of overall risk management. In general, the introduction of arbitrary extra margins of safety, in order to appease public outcry, is not warranted.

USES OF NIR IN MEDICAL DIAGNOSIS AND THERAPY

UVR

The UVR-induced photochemical reactions form the basis of an effective treatment of the disease psoriasis, which is marked by widespread red itchy scales on the skin. This is caused by an accelerated cell cycle and DNA synthesis in skin cells. The drug psoralen is preferentially taken up by these dividing cells, which on subsequent exposure to UVA radiation, leads to binding with DNA and subsequent inhibition of synthesis and cell division. A normal course of treatment consists of 25 monthly visits to a clinic, with 8-methoxypsoralen taken orally, followed 2 h later by a UVR exposure of 10–100 kJ·m⁻² per visit. This is usually delivered via a bank of 48 or so high-intensity fluorescent tubes.

A second use of UVR in biological and clinical analysis and research is in the identification of biomarkers through fluorescence. One technique involves placing electrophoretic gels over a UVR lightbox to localize the fluorescent regions. As mentioned, the possibility of overexposure in those who perform multiple observations is a matter of concern.

Lasers

The high intensity of laser radiation, particularly if it is pulsed, provides a means of tissue ablation, carbonization, coagulation, and desiccation. High-intensity short pulses produce photomechanical disruptions of tissue. At longer pulse lengths (~ 1 s), thermal and photochemical processes become more important. Excimer (= excited dimer) laser radiation has proved to be useful in the surgical treatment of defects in vision. This technique, radial keratotomy or keratectomy, reshapes the corneal surface to alter the effective focal length of the eye and thus do away with the need for spectacles or contact lenses. Laser ablation is also useful in the treatment of ocular melanoma, Barratt's

esophagus, removal of "port wine" stains on the skin, and (using an optical fiber delivery system in a cardiac catheter) the removal of atheromatous plaque in coronary arteries. A second property of intense laser light, that of photo-activation, is exploited in a range of treatments known as photodynamic therapy (PDT). In this, several compounds are known to be preferentially taken up by tumor tissue but also have the property of resonant absorption of light to produce free radicals, such as singlet oxygen and oxygen radical, which ultimately lead to endothelial cell membrane damage, blood supply shutdown, and hence necrosis of tumor tissue. These photosensitizing compounds are injected, or in some cases taken by mouth. Intense laser light (of 600–770 nm wavelength) is then directed at the tumor to produce this photo-activation. Energy thresholds are of the order of 1 MJ·m⁻². Although used mainly on superficial tumors (depth less than 6 mm), optical fiber delivery into deeper tissue (such as the breast) has also been trialled. As the tumor tissue becomes fluorescent on uptake of these compounds, diagnostic techniques (photodynamic diagnosis or PDD) are based on a similar principle. Suitable compounds are related to hemoglobin (hematoporphyrin derivative or HpD), rhodamine, amino levulinic acid, bacteriochlorins, and phthalocyanines. The herb St John's Wort also yields hypericin that have similar properties. The ability to use scanning optics in association with optical fibers has provided ways of making microscopic endoscopy possible.

Incoherent sources of blue light are used in the treatment of neonatal jaundice (hyperbilirubinemia). Bilirubin is decomposed during the exposure of the neonate to fluorescent tubes (filtered to remove wavelengths shorter than 380 nm).

IR

Infrared reflectivity from the skin and from layers immediately below the skin varies with skin temperature. Thermography has been used to identify regions of enhanced or reduced peripheral blood flow, occurring, for example, in mammary tumors. The high false-positive rate has inhibited its use in mass screening for this disease. On the other hand, breast imaging using time-of-flight IR transmission methods shows promise. Blood oxygen saturation is easily measured noninvasively via the ratio of reflectances at two wavelengths, 650 and 805 nm (the wavelengths showing greatest and least sensitivity to the degree of saturation, respectively). This forms the basis of the pulse oximeter, which clips on the finger and gives an indication of pulse rate in addition to oxygen saturation. Laser Doppler blood flow meters give an indication of capillary blood flow via the autocorrelation of reflected light signals. Wavelengths of 780 nm are selected because of the good depth of penetration of skin.

IR spectroscopy has a wide range of industrial and research applications, because of specific molecular stretching, bending, and rotational modes of energy absorption.

Terahertz

Several medical applications have been proposed for terahertz radiation, arising out of differential reflection from

cancerous/normal skin and from its relatively good transmission through bones and teeth. Its use in biosensing is also being investigated.

RF

The tissue heating and consequent protein denaturation has been used in catheter-tip devices for ablating accessory conduction pathways in the atria of the heart, giving rise to arrhythmias. The use of focused RF in cancer hyperthermia treatment has been used in conjunction with conventional radiotherapy to improve the hit rate of the latter, most likely due to the increased available oxygen via thermally induced blood flow increase. Increased blood perfusion is also thought to underlie the use of RF diathermy in physiotherapy, although this has now been almost entirely replaced by therapeutic ultrasonic diathermy (see below). RF exposures are part of magnetic resonance imaging (MRI), where some care has to be taken to avoid "hot spots" during investigation. SARs can exceed $2 \text{ W}\cdot\text{kg}^{-1}$ at frequencies in the region of 100 MHz. If we can extend the term "radiation" to include the direct application of RF currents, then electrical impedance tomography (EIT) should be included. In this technique, current of approximately 50 kHz is applied via a ring of electrodes to the torso or head, essentially to identify differential conductivity values in different organs and thus track shifts in fluid content, post-trauma, for example.

ELF

In clinical diagnosis, nerve conduction and muscular function studies are performed by examining responses to electrical stimulation (by single pulses or trains of pulses of the order of a few milliseconds in duration) of particular groups of nerve fibers. Electrical stimulation of specific regions of the body are also reported to give rise to beneficial effects. For example, or transcutaneous electrical nerve stimulation (TENS) is of some efficacy in controlling pain by raising the threshold for pain perception. Interferential therapy, which consists of a combined exposure of regions of the skin to low currents at two narrowly separated frequencies (for example, 4 kHz and 3.7 kHz) are claimed to be useful for a range of muscular and joint pain conditions and for circulatory disorders, but the mode of interaction is unclear. The currents are of the order of 50 mA, and the tissue is reportedly performing a demodulation of the 4 kHz carrier to produce a TENS-like deep current of a few hundred Hertz. Similarly, pulsed magnetic fields (PEMFs) are claimed to be effective in speeding healing in bone fractures, despite the small magnitude of induced currents. On the other hand, electroconvulsive therapy (ECT), in which pulses of current of several milliamperes are passed through the head, cause general nerve activation. This therapy is of proven value in cases of severe depression, but the origin of this benefit is an enigma. Transcranial magnetic stimulation (TMS) can be used both in diagnosis by eliciting specific responses and in therapeutic mode, in a manner analogous to ECT. However, the therapeutic efficacy of TMS still awaits clarification.

Static

The application of permanent magnets to painful joints is claimed to have beneficial effects, but the evidence for efficacy is equivocal. It has been suggested that the Lorentz-type forces on flowing electrolytes (such as blood) produce electric fields and currents. However, at typical blood flow velocities of $0.1 \text{ m}\cdot\text{s}^{-1}$, a 1 mT magnet will only induce $0.1 \text{ mV}\cdot\text{m}^{-1}$, which is well below levels shown in Table 2.

Ultrasound

The use of ultrasound in the range 1–25 MHz in diagnosis originates from the wavelength (and, hence, resolution) being of the order of a few millimeters. Acoustic mismatch between tissue layers gives radar-type echoes that form the basis of 2D and 3D imaging. The Doppler shift due to flowing fluid forms the basis of its use in blood flow measurements. Differential absorption provides a means for tissue characterization. In therapeutic ultrasound, the warmth is produced by adiabatic expansion and contraction within the tissue, to a depth of several centimeters. At higher intensities, cavitation and mechanical movement of organelles can occur.

NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

WLAD T. SOBOL
University of Alabama
Birmingham, Alabama

INTRODUCTION

When two independent groups of physicists (Bloch, Hansen, and Packard at Stanford and Purcell, Torrey, and Pound at MIT) discovered the phenomenon of nuclear magnetic resonance (NMR) in bulk matter in late 1945, they already knew what they were looking for. Earlier experiments by Rabi on molecular beams, and the attempts of Gorter to detect resonant absorption in solid LiF, seeded the idea of NMR in bulk matter. Fascinating stories describing the trials and tribulations of the early developments of NMR concepts have been told by several authors, but Becker et al. (1) deserve a special citation for the completeness of coverage.

For his achievements, Rabi was awarded a Nobel Prize in 1944, while Bloch and Purcell jointly received theirs in 1952. What was the importance of the Bloch and Purcell discoveries to warrant a Nobel Prize despite an abundance of prior work offering numerous clues? It was not the issue of special properties of elementary particles, such as a spin or magnetic moment: This was first demonstrated by the Stern–Gerlach experiment. It was not the issue of the particle interactions with magnetic field: This was first illustrated by the Zeeman effect. It was not even

the magnetic resonance phenomenon itself: This was first demonstrated by Rabi. It was the discovery of a tool that offered a robust, nondestructive way to study the dynamics of interactions in bulk matter at the atomic and molecular level that forms the core of Bloch and Purcell’s monumental achievements. However, despite the initial excitement at the time of their discovery, no one could have predicted just how extensive and fruitful the applications of NMR would turn out to be.

What is the NMR? The answer depends on who you ask. For Bloch’s group at Stanford, the essence of magnetic resonance was a flip in the orientation of magnetic moments. Bloch conceptual view of the behavior of the nuclear magnetic moments associated with nuclear spins was, in essence, a semiclassical one. When a sample substance containing nuclear spins was kept outside a magnetic field, the magnetic moments of individual spins were randomly oriented in space, undergoing thermal fluctuations (Brownian motion). The moment the sample was placed in a strong, static magnetic field, quantum rules governing the behavior of the spins imposed new order in space: the magnetic moments started precessing around the axis of the main magnetic field. For spin $\frac{1}{2}$ particles (e.g., protons), only two orientations w.r.t. static magnetic field were allowed; thus some spins precessed while oriented somewhat along the direction of the external field, while other spun around while orienting themselves somewhat opposite to the direction of that field. To Bloch, a resonance occurred when externally applied radio frequency (RF) field whose frequency matched the precessional frequency of the magnetic moments, forced a reorientation of precessing spins from parallel to antiparallel (or vice versa). They called this effect a nuclear induction.

As far as the Purcell’s group was concerned, NMR was a purely quantum mechanical phenomenon. When a diamagnetic solid containing nuclei of spin I is placed in a static magnetic field, the interactions of nuclear magnetic moments with the external magnetic field cause the energy levels of the spin to split (the anomalous Zeeman effect). When an external RF field is applied, producing quanta of energy that match the energy difference between the Zeeman levels, the spin system would absorb the energy and force spin transitions between lower and upper energy states. Thus, they described the phenomenon as resonance absorption.

It can be proven that these two concepts of NMR phenomenon are scientifically equivalent. However, the two views are psychologically very different, and have been creating a considerable chasm in the accumulated body of knowledge. Some aspects of NMR applications are intuitively easier to understand using Bloch’s semiclassical vector model, while other naturally yield themselves to the quantum picture of spin transitions among energy states. The details of this dichotomy and its impact on the field of NMR applications are fascinating by themselves and have been extensively discussed by Ridgen (2).

At the time of the NMR discovery, nobody had any inkling that this phenomenon might have any applications in medicine. To understand how NMR made such a big impact in the medical field, one has to examine how the NMR and its applications evolved in time. Nuclear mag-

netic resonance was discovered by physicists. Thus it is not surprising that the initial focus of the studies that followed was on purely physical problems, such as the structure of materials and dynamics of molecular motions in bulk matter. During a period of frenzied activities that followed the original reports of the discovery, it was very quickly understood that interactions among nuclear spins, as well as the modification of their behavior by the molecular environment, manifest themselves in two different ways. On the one hand, the Zeeman energy levels could shift due to variations in the values of local magnetic field at different sites of nuclear spins within the sample. This causes the resonant absorption curve to acquire a fine structure. Such studies of NMR lineshapes provide valuable insights into the structure and dynamics of molecular interactions, especially in crystals. This branch of NMR research is customarily referred to as radiospectroscopy.

On the other hand, when a sample is placed in the external magnetic field, the polarization of spin orientations causes the sample to become magnetized. When the sample is left alone for some time, an equilibrium magnetization develops. This equilibrium magnetization, \mathbf{M}_0 , is proportional to the strength and aligned in the direction of the external static magnetic field, \mathbf{B}_0 . An application of RF field disturbs the equilibrium and generally produces a magnetization vector, \mathbf{M} , that is no longer aligned with \mathbf{B}_0 . When the RF field is switched off, the magnetization returns over time to its equilibrium state; this process is called a relaxation. The process of restoring the longitudinal component of the equilibrium magnetization requires that the spins exchange energy with their environment; thus, it is commonly referred to as spin–lattice or longitudinal relaxation. The characteristic time that quantifies the rate of recovery of the longitudinal component of magnetization toward its equilibrium value, \mathbf{M}_0 , is called the spin–lattice relaxation time and denoted T_1 or, in medical applications, TI . At equilibrium, the transverse magnetization component is zero. Thus, any nonzero transverse component of nonequilibrium magnetization must decay back to zero over time. This process tends to be dominated by interactions among spins and is thus called a spin–spin or transverse relaxation. The characteristic time that quantifies the rate of decay of the transverse component of magnetization is called the spin–spin relaxation time and denoted T_2 or, in medical applications, $T2$. Both T_1 and T_2 strongly depend on the nature of the molecular environment within which the spins are immersed, thus offering a robust probe of molecular dynamics and structure in a variety of materials (solid, liquid, and gaseous) over a range of conditions (temperature, phase transitions, chemical reactions, translational and rotational diffusion, etc.). Studies of relaxation times are referred to simply as NMR relaxation studies, and sometimes as relaxometry.

In solids, dipole–dipole interactions among spins are dominant, which for proton NMR (^1H NMR) studies results in fairly wide lineshapes (with a width of several kHz) with very little fine structure. In most liquids, however, the substantially faster molecular reorientations average the dipole–dipole interactions, effectively suppressing them to

produce a vanishing net effect on the NMR absorption curves that become much narrower (typically of the order of Hz). This feature has led to a discovery of chemical shift phenomenon.

The most dramatic demonstration of the chemical shift was the observation made in 1951 by Arnold et al. (3) who showed separate spectral NMR lines from nonequivalent protons in a sample containing a simple organic substance, ethanol. This gave birth to high-resolution NMR spectroscopy or HR NMR, a powerful tool that assists chemists in nondestructive analysis of organic compounds. This *in vitro* technique underwent massive developments over the years and almost overshadowed the NMR applications in physics. An exhaustive overview of HR NMR applications has been published by Shoolery (4). Today, HR NMR spectroscopy plays a major role in studies of biological materials *in vitro* and in drug development research. This research, although not directly used in clinical care, nevertheless is having a major impact on the development of medical arts. A comprehensive review of biological applications of NMR spectroscopy has been provided by Cohen et al. (5).

Standard NMR studies are performed *in vitro*: The sample is placed in the bore of a laboratory magnet, and the signal is collected from the entire volume of the sample. Samples are relatively small: The typical NMR tube vial is ~ 5 mm outside diameter (OD) and holds ~ 0.5 mL of sample material. Nuclear magnetic resonance magnets have relatively small active volumes [typical bore size of modern NMR cryomagnets is ~ 70 mm inside diameter (ID)], but very high magnetic field homogeneity, routinely $> 10^{-9} \mathbf{B}_0$.

In the early 1970s, a revolutionary concept emerged from the pioneering work of Lauterbur in the United States and Mansfield, Andrew, and Hinshaw in the United Kingdom. They discovered that by using judiciously designed magnetic field gradients it was possible to retrieve an NMR signal from a small localized volume (called a voxel) within a much larger sample (e.g., a human body). This started a new field of NMR applications, called magnetic resonance imaging (MRI) that greatly enhanced the practice of diagnostic medicine (see the section **Magnetic Resonance Imaging**).

One of the frustrating limitations of MRI applications was the ambiguity of lesion characterization. The development of MRI focused on the noninvasive visualization of soft tissues within the living human body; as a result, the technical and engineering trade-offs made in the process of improving the quality of images have essentially rendered the method nonquantitative. In essence, MRI proved to be extremely sensitive in the detection of various lesions within the patient's body, but not very robust in providing information needed to fully identify the characteristics of the tissue within the lesion. Thus, in addition to basic NMR tissue characteristics (proton density, T_1 , and T_2), the interpreters of medical MR images came to rely on morphology of lesions (size, shape, and location) to draw conclusions about lesion pathology. In this context, the concept of localized NMR spectroscopy experiments, where MRI techniques are used to locate the lesion and localize the volume of interest, while NMR spectroscopic techniques are used to acquire NMR spectra of the tissue within a lesion, becomes intuitively

evident. However, while the concept may appear naturally obvious, implementations have proven to be extremely difficult. Despite first successful experiments in acquiring localized phosphorus ^{31}P NMR *in vivo* spectra from a human forearm, performed in 1980 by a group led by Chance, the true clinical applications of localized NMR spectroscopy have only recently begun to appear. While first attempts focused on ^{31}P NMR spectroscopy using surface coils to localize the signals within the human body, current clinical applications almost exclusively utilize ^1H NMR spectra to gain additional, clinically relevant information about the lesion of interest. The methodology used in this approach is referred to as magnetic resonance spectroscopy (MRS), magnetic resonance spectroscopic imaging (MRSI), or chemical shift imaging (CSI). Techniques of this particular application of the NMR phenomena in medical practice will be the subject of further discussion here. While the interest in exploring clinical applications of MRS of nuclei other than protons (e.g., ^{31}P , ^{13}C , ^{19}F , and ^{23}Na) still remains, a vast majority of current clinical applications uses ^1H MRS and thus only this particular nucleus will be considered in further discourse. Readers interested in other nuclei are encouraged to explore literature listed in the **Reading List** section.

THEORY

In this section, the quantum mechanical approach of formalism is used, since this formalism is most naturally suited to explain the various features of NMR spectra. To begin with, consider an ensemble of noninteracting protons, free in space where a strong, perfectly uniform magnetic field \mathbf{B}_0 is present. Because all spins are considered identical, the Hamiltonian of the system includes a single spin and all quantum mechanical expectation values are calculated over the entire assembly of spins. Under those conditions, the Hamiltonian (\mathcal{H}) describes the Zeeman interaction of the nuclear magnetic moment μ with the external magnetic field and has a form

$$\mathcal{H} = -\boldsymbol{\mu} \times \mathbf{B}_0 = -g\hbar B_0 I_z \quad (1)$$

where γ is the gyromagnetic ratio, \hbar is the Planck's constant, and I_z is the z component of the nuclear spin operator \mathbf{I} , which for protons has an eigenvalue value of $1/2$. Because I_z has only two eigenvalues, $\pm 1/2$, the system's ground energy level is split into two sublevels, with the energy gap proportional to B_0 , as shown in Fig. 1. Now assume that spins are allowed to weakly interact with their molecular environment, which are collectively described as the *lattice* (regardless of the actual state of the sample; e.g., in liquids the lattice refers to thermal diffusion, both rotational and translational, of the atoms or molecules that host the spins). When the system is left undisturbed over time, it will reach a thermal equilibrium, where the spin populations at the higher and lower energy levels are described by a Boltzmann distribution, as shown in Fig. 2. The resultant sample equilibrium magnetization is equal to

$$M_z^{\text{eq}} = M_0 = \frac{g^2 \hbar^2 N B_0}{4kT} \quad (2)$$

Figure 1. The Zeeman splitting of the ground-state energy levels for the spin $1/2$ system as a function of the external magnetic field strength, B_0 .

where T is the absolute temperature of the sample, N is a number of spins in the sample, and k is the Boltzmann constant. At normal conditions, this equilibrium magnetization is too small to be detectable, but when a resonance phenomenon is exploited by applying a short burst of RF energy at resonance frequency ω_0 (called an RF pulse), the magnetization can be flipped onto a transverse plane, perpendicular to the direction of \mathbf{B}_0 . This transverse magnetization will precess at the resonant frequency of the spins and thus will generate an oscillating magnetic field flux in the receiver coils of the NMR apparatus, which will be detected as a time-varying voltage at the coils terminals. This signal is called a free induction decay (FID) and its time evolution contains information about the values of resonant frequency of the spins, ω_0 , the spin-spin relaxation time, T_2 , and the distribution of local static magnetic fields at the locations of the spins, T_2^* . The local static magnetic fields, experienced by spins at different locations in the sample, may vary from spin site to spin site, chiefly due to the inhomogeneity of the main magnetic field B_0 . In addition, in heterogeneous samples, commonly encountered in *in vivo* experiments, local susceptibility variations may contribute to T_2^* effects. For a variety of reasons, the chief one being the ease of

Figure 2. An illustration of Boltzmann distribution of spin populations for an ensemble of identical spins $1/2$, weakly interacting with the lattice, at thermal equilibrium.

Figure 3. Real and imaginary components of an FID signal.

interpretation, the FID signal is always recorded in the reference frame that rotates at the frequency ω close to ω_0 , (called “the rotating frame”). From the engineering point of view, recording the signal in the reference frame, rotating at the frequency ω , is equivalent to frequency demodulation of the signal by frequency ω .

The recorded FID has two components: one, called real, or in-phase, is proportional to the value of transverse spin magnetization component aligned along the y' axis of the rotating frame (the $[x', y', z]$ notation is used to denote rotating frame, as opposed to the stationary, laboratory frame $[x, y, z]$). The other FID component is proportional to the value of transverse spin magnetization projected along the x' axis and is referred to as imaginary, or out-of-phase signal (see Fig. 3). To a human being, the FID signals can be difficult to interpret; thus an additional postprocessing step is routinely employed to facilitate data analysis. A Fourier transform (FT) is applied to the FID data and the signal components having different frequencies are retrieved, producing an NMR spectrum (see Fig. 4).

The chemical shift, mentioned earlier, is responsible for a plethora of spectral lines (peaks) seen in a typical NMR spectrum. Consider a simple organic molecule that contains hydrogen localized at three nonequivalent molecular sites. Chemists call molecular sites equivalent if the structure of chemical bonds around the site creates an identical distribution of electron density at all proton locations. When the sites are nonequivalent, different distributions of electron cloud around the protons will have a different shielding effect on the value of the local magnetic field, experienced by individual protons. The strength of electron shielding effect is proportional to the value of B_0 and is accounted for in the Hamiltonian by using a shielding constant, σ .

$$\mathcal{H} = -g\hbar \sum_{i=1}^3 \hat{\alpha} (1 - s_i) B_0 I_{zi} \quad (3)$$

In this example, a molecule with only three nonequivalent

Figure 4. A method of generating an NMR spectrum from the FID signals.

proton sites has been considered; in general, the summation index in Eq. (3) must cover all nonequivalent sites, however, many may be present. It is evident from Eq. (3) that individual protons located at different sites will have slightly different resonant frequencies, which will give rise to separate resonant peaks located at different frequencies in the observed NMR spectrum, as shown in Fig. 4. This accounts for a fine structure of NMR spectra that consists of multiple lines at different frequencies, identifying all nonequivalent molecular sites in the sample studied.

The interaction of the nuclear spin with the electron cloud surrounding it has a feedback effect, resulting in a slight distortion of the cloud; the degree of this alteration is different depending on whether the spin is up or down w.r.t. the magnetic field B_0 . This distortion has a ripple effect on surrounding nonequivalent spins, and consequently they become coupled together via their interactions with the electron cloud; this phenomenon is called a spin–spin coupling or J coupling, and is accounted for by adding another term to the spin Hamiltonian:

$$\mathcal{H} = -\sum_{i=1}^n \hat{\alpha} \frac{e}{e} g\hbar (1 - s_i) B_0 I_{zi} + \sum_{j < i} \hat{\alpha} J_{ij} I_i \times I_j \frac{\hat{u}}{\hat{u}} \quad (4)$$

where J_{ij} , known as a spin–spin coupling constant, describes the strength of this effect for each pair of nonequivalent protons. The presence of spin–spin coupling leads to a hyperfine structure of the NMR spectra, splitting peaks into multiplet structures, as shown in Fig. 5 that contains two fragments of an NMR spectrum of lactic acid. The structure of each multiplet can be explained using simple arrow diagrams, visible next to NMR lines. The signal at 1.31 ppm is generated by 3 equiv protons located in the CH_3 group that are linked to the proton spin in the CH group via J coupling. The spin of the proton in the CH group can have only two orientations: up or down, as indicated by arrows

Figure 5. A fragment of experimental spectrum (lactic acid at 500 MHz) showing resonances from a CH_3 group (at 1.31 parts per million, ppm) and a CH group (at 4.10 ppm), respectively. The splitting of CH_3 resonance into a doublet and the CH resonance into a quadruplet is caused by the J coupling. The structure of each multiplet can be derived using simple rule of grouping spins according to their orientations, as shown by groups of arrows.

that follow the bracket next to the CH_3 label. Thus, the signal from CH_3 protons is expected to split into a doublet with relative signal intensities 1:1, as indeed is seen in the recorded spectrum. Similarly, the signal at 4.10 ppm is generated by a single proton in the CH group that is linked via J coupling to 3 equiv protons in the CH_3 group. The spins within this group of three protons can assume eight different configurations, depending on their orientation w.r.t. to the magnetic field B_0 . Some of those orientations are equivalent (i.e., they have the same energy) and thus can be lumped together, as shown by groups of arrows that follow the bracket next to the CH label. Simple counting leads to a prediction that the signal from the CH proton should split into a quadruplet with relative signal intensities 1:3:3:1. Again, this is clearly visible in the recorded spectrum.

As illustrated in Fig. 6, these simple considerations show that each peak in the spectrum can be fully characterized by specifying its position w.r.t. an established reference peak (chemical shift), amplitude, intensity (intensity, or the area under the peak, is proportional to the concentration of spins contributing to the given peak), linewidth (provides information $\sim T_2^*$ and magnetic field homogeneity), and multiplet structure (singlet, doublet, triplet, etc., carries information about J coupling). Thus, the NMR spectra, like the one in Fig. 4 showing an experimental spectrum of vegetable (maize) oil, contain a wealth of information about the structure and conformation of molecules found within the sample.

Strictly speaking, the linewidths of the peaks in the NMR spectrum are determined by the values of T_2^* and thus are sensitive to the homogeneity of the main magnetic field and other factors contributing to the distribution of local static magnetic fields seen by the spins. Wider distributions of local fields, lead to shorter T_2^* values and broader corresponding peaks in the NMR spectrum. Broad peaks make spectra harder to interpret due to overlap between peaks located close to each other. This feature puts a premium on shimming skills of the NMR spectrometer operator (shimming includes methods to improve the homogeneity of the static magnetic field). For *in vivo* studies, the shimming tasks are made even more difficult by tissue heterogeneity that causes local variations in the magnetic field (referred to as susceptibility effects within the MRS community).

There is a peculiar feature in the way the NMR spectra are recorded that routinely confounds the NMR newbies. For historical reasons, the NMR spectra are plotted as if the spectrometer frequency was kept constant and the magnetic field B_0 was varied (swept) over a range of values to record all the characteristic peaks (see Fig. 7a). In this approach, the horizontal axis of the plot represents the values of the external magnetic field necessary to reach a resonant condition for a given group of spins. However, all modern NMR spectrometers use an acquisition method in which the magnetic field B_0 is kept constant and differences in resonant frequencies of various nuclei (due to their

Figure 6. A schematic representation illustrating various characteristic parameters used to describe elements of an NMR spectrum.

diverse chemical shifts) are recorded instead. It is fundamental to understand that if the horizontal axis of an NMR spectrum was meant to represent the resonant frequencies of nuclei with different chemical shift, all residing in the same external magnetic field B_0 , then the lines to the right would represent signals with *lower* frequencies, which at best is counterintuitive. This paradox is resolved when one looks at the relationship between magnetic field and NMR resonance frequency for nuclei located at sites with varying electron shielding. This relationship is derived from Eq. (3), leading to the well-known Larmor equation:

$$w = g(1 - s)B_0 \quad (5)$$

This equation is plotted in Fig. 7b for three sites with different values of the chemical shielding constant σ . As σ increases, the slope of the line decreases. Thus, if the RF frequency is kept constant and the magnetic field is swept to reach subsequent resonant conditions, the weakly shielded nuclei will resonate at lower field, and as the strength of the shielding effect increases, the external

magnetic field must be increased to compensate for the increased shielding. It must be reiterated that the term magnetic field used in this context refers to the *external* magnetic field B_0 , produced by the spectrometer's magnet, and not to the value of the local magnetic field that the spin is actually experiencing. Therefore, the signals from heavily shielded nuclei will appear at the high end of the spectrum, as illustrated by the horizontal line in Fig. 7b. On the other hand, if the external magnetic field B_0 is kept constant and the frequency content of the FID signal is looked at, it will be noticed that nuclei at heavily shielded sites resonate at lower frequency, which reflects the decrease of the *local* magnetic field due to the shielding effects. Therefore, the signals from heavily shielded nuclei will appear at the low end of the spectrum, as illustrated by the vertical line in Fig. 7b. Historically, magnetic field sweeping was used in the early days of NMR spectroscopy and a sizeable volume of reference spectra were all plotted using the fixed-frequency convention. This standard was retained after pulsed NMR technology replaced the earlier continuous wave NMR spectroscopy, despite the fact that the fixed-field approach would have been far more natural.

The size of the chemical shift varies linearly with the strength of the magnetic field B_0 , which makes comparison of spectra acquired with NMR spectrometers working at different field strengths a chore. To simplify matters, chemists introduced a concept of relative chemical shift, which is defined as follows: It is realized that the term ω in Eq. 5 represents a resonant frequency of a group of equivalent spins in their local magnetic field, B_L . Thus, Eq. (5) can be used to define a variable τ as

$$\tau = s \times 10^6 = \frac{B_L - B_0}{B_0} \times 10^6 \quad (6)$$

The value of τ is dimensionless and expresses the value of the shielding constant σ in ppm. It is interpreted as a change in the local magnetic field *relative* to the strength of the main magnetic field produced by the spectrometer's magnet. As seen from Eq. (6), the τ scale is directly proportional to σ , that is, heavily shielded nuclei will have a large value of τ (see Fig. 7a). This also makes the τ scale collinear with the B_0 axis, which is inconvenient in modern NMR spectroscopy, which puts a heavy preference on spin resonant frequencies. To address this awkward feature, chemists use a more practical chemical shift scale, called δ , that is defined as

$$d = 10 - \tau \quad (7)$$

This scale is a measure of the change in local resonant frequency relative to the base frequency of the NMR spectrometer, ω_0 . The factor 10 in the above relationship arises from the fact that a vast majority of observed proton chemical shifts lie in the range of 10 ppm; by convention, tetramethylsilane (TMS), which exhibits one of the strongest shielding effects, has been assigned a value of $\delta = 0$. This was done after careful practical consideration: all 12 protons in TMS occupy equivalent positions, and thus an NMR spectrum of TMS consists of a strong, single line. The referencing procedure has evoked a considerable amount of

Figure 7. An apparent paradox in the interpretation of the abscissa calibration for an NMR spectrum: (a) the same spectrum can have a value of magnetic field B assigned to the abscissa so that the values of B increase when moving to the right, or have the value of frequency ω assigned to the same abscissa, but increasing when moving to the left. (b) The diagram on the right provides an explanation of this effect (see the main text for details).

debate over the years and currently the International Union of Pure and Applied Chemistry (IUPAC) specifies that shields are to be reported on a scale increasing to high frequencies, using the equation

$$d = \frac{\omega_x - \omega_{\text{ref}}}{\omega_{\text{ref}}} \times 10^6 \quad (8)$$

where ω_x and ω_{ref} are the frequencies of the reported and reference signals, respectively.

Since TMS easily dissolves in most solvents used in NMR spectroscopy, is very inert, and is quite volatile, it is a very convenient reference compound. In practice, a small amount of TMS can be added to the sample, which will produce a well-defined reference peak in the measured spectrum (see Fig. 5). After the experiment is completed, TMS is simply allowed to evaporate, thus reconstituting the original composition of the sample.

In MRS applications, the δ scale is used exclusively to identify the positions of the peaks within the spectra. For example, the water peak is known to have $\delta = 4.75$ ppm; therefore, if an MRS spectrum is acquired on a machine with the main magnetic field of 1.5 T and the base RF frequency of 63.86 MHz, the water line will be shifted by $4.75 \times 63.86 = 303$ Hz toward the higher frequency from the reference TMS peak. It also means that the protons in water experience weaker shielding effects than protons in the TMS. Finally, if the spectrum is plotted according to the accepted conventions, the water line appears to the left of the reference peak. Unfortunately, TMS cannot be used as an internal reference in MRS applications (it cannot be administered to humans). Thus in practice, the signal from NAA is used as a reference and has an assigned value of $\delta = 2.01$ ppm, which is the chemical shift of the acetyl group within the NAA NMR spectrum, acquired *in vitro*.

EQUIPMENT AND EXPERIMENTS

In medical applications, standard MRI equipment is used to perform MRS acquisitions. Thus, in contrast to standard *in vitro* NMR experiments, *in vivo* MRS studies are performed at lower magnetic field strength, using larger RF coils, and with limited shimming effectiveness due to magnetic susceptibility variations in tissue. As a result, the MRS spectra inherently have lower signal-to-noise characteristics than routine *in vitro* spectra; this is further aggravated by the fact that in MRS signal averages are accumulated using fewer scans due to examination time constraints. This creates a new set of challenges related to the fact that when the MRI equipment is used to perform MRS, it is utilized outside its design specifications that focus on the imaging applications of MR technology. Fortunately, many hardware performance characteristics that are absolutely crucial to the successful acquisition of spectroscopy data, such as magnetic field uniformity and stability, or coherence and stability of the collected NMR signals, are appreciated in MRI as well. Thus, steady improvements in MRI technology are contributing to the emergence of clinical applications of MRS. Since this article focuses on MR spectroscopy, the following considerations will describe features of data acquisition schemes that are unique to MRS applications, and disregard those aspects of hardware and pulse sequences design that form the core of the MRI technology (see the section on **Magnetic Resonance Imaging**).

The first challenge of MRS is volume localization. Obviously, an NMR spectrum from the entire patient's body, while rich in features, would be of very little clinical utility. Over the years, many localization techniques have been proposed, but in current clinical practice only two

methods are routinely used. The first one collects NMR spectra from a single localized volume and is thus referred to as single voxel MRS, or simply MRS. The other allows collection of spectra from multiple voxels arranged within a single acquisition slab. It is often referred to as multi voxel MRS, MRS imaging (MRSI), or chemical shift imaging (CSI). With this method, more advanced visualization techniques can be used, such as generation of specific metabolite concentration maps over larger regions of interest (ROI).

Single voxel (SV) MRS is simpler to implement. The volume of interest (VOI, or voxel) is selected using one of the two alternative data acquisition pulse sequences. The first one uses a phenomenon known as a stimulated echo to produce a signal used to generate the spectroscopic FID that is then transformed into the NMR spectrum. To produce a stimulated echo, three RF pulses are used, each rotating (flipping) the magnetization by 90° . The theory of this process is too complex to be discussed in detail here; an interested reader is referred to the original paper by Hahn (6) or to more specific texts on NMR theory, such as those listed in the **Reading List** section. The application of the stimulated echo method for *in vivo* MRS was first proposed by Frahm et al. (7) who coined an acronym STEAM (Stimulated Echo Acquisition Mode) to describe it. A simplified diagram of the stimulated echo MRS acquisition pulse sequence is shown in Fig. 8. The three RF pulses are shown on the first line of the diagram, the echo signal from the localized voxel can be seen on the bottom line of the diagram. How does this sequence allow the selection of a specific VOI as a source of collected signal? The key to successful VOI localization is to use a slice-selective RF excitation. This technology is taken straight from mainstream MRI, and thus the reader is referred to MRI-specific information for further details (see the section **Magnetic Resonance Imaging** or MRI monographs listed in the

Reading List). Briefly, the slice selection technique relies on the use of band-limited RF pulses (notice the unusual modulation envelope of RF pulses shown in Fig. 8) applied in the presence of tightly controlled magnetic field gradients (MFG), shown as pulses labeled G_x , G_y , and G_z in Fig. 8. When a band-limited RF pulse is played in the presence of an MFG, only the spins in a narrow range of positions, located within a thin layer of the studied object (a slice) will achieve the resonance conditions and respond accordingly; all the spins outside the slice will be out of resonance and remain unaffected. Thus, the spin magnetization within the selected slice will be flipped by the RF, and magnetization outside the slice will remain unaffected. An analysis of this process shows that the slice orientation is perpendicular to the direction of the MFG, slice thickness is controlled by the amplitude of the MFG pulse, and location (offset from the magnet's isocenter) is determined by the shift in carrier frequency of the RF pulse. Thus, the first pulse in Fig. 8 will excite spins in a slice that is perpendicular to the z axis of the magnet (G_z was used), the two remaining pulses will excite spins in slices perpendicular to the x and y directions, respectively. Since the condition required to produce a stimulated echo is that the spins be subject to all three pulses, only the matter located at the intersection of the three perpendicular slices fulfills the criterion, and thus only the spins located within this volume will generate the stimulated echo signals. The dimensions of the VOI selected in such a way are determined by the thickness of individual slices, and the location of the VOI is determined by the position of individual slices, as illustrated in Fig. 9.

The other single voxel MRS protocol uses a spin echo sequence to achieve volume selection. To produce the localized signal, three RF pulses are used, as before. However, while the first RF pulse still rotates the magnetization by 90° , the remaining two RF pulses flip the magnetization by

Figure 8. A simplified diagram of a basic STEAM MRS sequence. Time increases to the right, the time interval covered by this diagram is typically ~ 100 ms. On the first line the RF pulses are shown; the next three lines show the timing of the pulses generated by the three orthogonal magnetic field gradient assemblies (one per Cartesian axis in space); the last line, labeled signal, shows the timing of the resulting stimulated echo NMR signal.

Figure 9. The principle of VOI selection in STEAM protocol (see text for details).

180° each. As a result, two spin echoes are produced, as shown on the bottom line of Fig. 10. The first echo contains a signal from a single column of tissue that lies at the intersection of the slices planes generated by the first and second RF pulses, while the second echo produces a signal from a single localized VOI within this column. As with the stimulated echo, the theory of this process is too complex to be discussed here; an interested reader is referred to the original paper by Hahn (6) or to more specific texts on NMR theory, such as those listed in the *Reading List* section.

The application of dual echo spin echo method to *in vivo* MRS has been proposed by Bottomley (8) who coined an acronym **P**oint **R**esolved **S**pectroscopy (PRESS) to describe it. A simplified diagram of the PRESS acquisition pulse sequence is shown in Fig. 10. The three RF pulses are shown on the first line of the diagram; but only the second echo signal seen on the bottom line of the diagram comes from the localized voxel region.

What are the advantages and weaknesses of each volume localization method? First, in both methods an echo is used to carry the spectroscopy data. Since echoes are produced by transverse magnetization, the echo amplitudes are affected by T_2 relaxation and the time delay, TE , that separates the center of the echo from the center of the first RF pulse that was used to create the transverse components of magnetization. The longer the TE , the stronger the echo amplitude attenuation due to T_2 effects will be. Since the amplitude of the echo signal determines the amplitude of the spectral line associated with it, the SV MRS spectra will have lines whose amplitudes will depend on the selected TE in the acquisition sequence. For the STEAM protocol, it is possible to use relatively short TE values; mostly because the magnetization contributing to the stimulated echo signal is oriented along the z axis during the period of time between the second and third RF pulses, and thus it is not subject to T_2 decay (in fact, it will grow a little due to T_1 relaxation recovery). Therefore, the time interval between the second and the third RF pulse is not counted toward TE . Furthermore, 90° RF pulse have shorter duration than 180° ones, offering an additional opportunity to reduce TE . Consequently, in routine clinical applications the STEAM protocols use much shorter TE values (~ 30 ms) than PRESS protocols (routine TE values used are ~ 140 ms). Therefore, when using the

Figure 10. A simplified diagram of a basic PRESS MRS sequence. Notice similarities in VOI selection algorithm within both STEAM and PRESS protocols.

STEAM protocol one is rewarded with a spectrum whose line intensities are closer to the true metabolite concentrations in the studied tissue. However, theoretical calculations show that the signal intensity of a stimulated echo is expected to be 50% less than that of a spin echo generated under identical timing conditions (i.e., TE). This is an inherent drawback of the STEAM protocol, since the spectra tend to be noticeably noisier than those produced using PRESS.

PRESS, by design, uses two spin echoes to generate a signal from localized VOI. This limits the minimum TE possible for the second echo to ~ 80 ms or so, depending on the MR scanner hardware. Since the magnetization never leaves the transverse plane (except during RF pulses), the T_2 effects are quite strong. As a result, metabolites with shorter T_2 will decay down to the noise levels and vanish from the final spectrum, which has an ambivalent impact on clinical interpretations, simplifying the spectrum on one hand while removing potentially valuable information on the other. This effect can be further amplified by signal intensity oscillations with varying TE , caused by J coupling. For further details on this topic the reader is referred to the specific texts on MRS theory and applications, listed in the **Reading List** section.

One word of caution is called for now. The numbers quoted here reflect capabilities of MR hardware that represent a snapshot in time. As hardware improves, these parameters rapidly become obsolete.

There are other, finer arguments supporting possible preferences toward either method (STEAM or PRESS). These include such issues as suppression of parasitic signals arising from outer-volume excitation (residual signals coming from outside the VOI), sensitivity to baseline distortion of the spectra due to the use of solvent suppression, accuracy of VOI borders defined by each method, and so on. Thus, in current clinical practice there are strong propo-

nents of both STEAM and PRESS techniques, although lately PRESS seems to be gaining popularity because of simpler technical implementation issues, such as magnetic field homogeneity correction (shimming), or compensation of effects caused by eddy currents induced in the magnet cryostat by magnetic field gradient and RF pulses.

While SV MRS is relatively straightforward, and thus preferred by novices in the practice of clinical MRS, most routine applications today demand spectroscopic data collected from multiple locations within the organ studied. Therefore, a solution that would allow collection of MR spectra from multiple locations at the same time has a natural appeal to physicians. To achieve such a task is no small matter, and many schemes have been proposed before a method that today is considered most practical in daily use has been found. The method was first proposed by Brown et al. (9). Their method is both conceptually simple and revolutionary. It utilizes a method that encodes both space–(localization) and time–dependent (NMR spectra) information using mechanisms that manipulate the phases of signals emitted by individual spins at different locations. The acquisition sequence is schematically shown in Fig. 11, which illustrates the two-dimensional (2D) CSI principle using a PRESS pulse sequence. Of course, this approach is equally applicable to STEAM method as well. An astute reader will immediately recognize that the spatial encoding part of the protocol is virtually identical to dual phase encoding techniques used in 3D MRI acquisitions. At this point, readers less familiar with advanced MRI techniques probably would want to read more about this method elsewhere (see **Magnetic Resonance Imaging** or MRI monographs listed in the **Reading List**). The enlightenment occurs when one realizes that with this scheme the acquired signal is not frequency encoded at all. Therefore, after 2D FT processing in the two orthogonal spatial directions, one ends up with a collection

Figure 11. A simplified diagram of a basic 2D CSI MRS sequence. The dotted gradient lobes represent phase encoding gradients responsible for multivoxel localization.

of FIDs that are free from any residual phase errors due to spatial encoding, but nevertheless represent NMR signals from localized VOIs, anchored contiguously on a planar grid. The size and orientation of the grid is determined by the spatial encoding part of the protocol; thus, localization is conveniently decoupled from NMR frequency beats caused by the chemical shifts of studied metabolites.

If this method is so simple, why do people still want to acquire SV spectra? First, the method is quite challenging to implement successfully in practice, despite the seeming simplicity of the conceptual diagram shown in Fig. 11. Both spatial and temporal components affect the phase of collected NMR signals, and keeping them separated requires a great deal of MR sequence design wizardry and the use of advanced MR hardware. Due to peculiarities of the FT algorithm, even slight phase errors (of the order of 1°) are capable of producing noticeable artifacts in the final spectra. Second, the VOI localization scheme is ill suited to a natural way of evaluating lesions spectroscopically; most clinicians like to see a spectrum from the lesion compared to a reference spectrum from a site that is morphologically equivalent, but otherwise appears normal. In the human brain, where most spectroscopic procedures are performed today, this means that the reference spectrum is acquired contralaterally to the lesion location. Such an approach represents a drawback in CSI acquisitions where VOIs are localized contiguously, and typically a few wasted voxels must be sacrificed to ensure the desired anatomic coverage of the exam. Finally, the dual-phase encoding scheme requires that each pulsed view (a single execution of the pulse sequence code with set values of both phase encoding gradients) is repeated many times to collect enough data to localize voxels correctly. As many views must be acquired as there are voxels in the grid, which causes the required number of views to grow very fast. For example, even for a modest number of locations, say 8×8 , 64 views must be generated. This leads to acquisition times that appear long by today's imaging standards (typical MRSI acquisition requires 3–8 min).

It is difficult to fully exploit the richness and diversity of technical aspects of localization techniques used in *in vivo* MRS; extended reviews, such as papers by Kwock (10), den Hollander et al. (11), or Decorps and Bourgeois (12), can be used as springboards for further studies.

The second major challenge of *in vivo* ^1H MRS arises from the fact that the majority of tissue matter is simply water, which for humans can vary from 28% in the bones to 99% in CSF, with an average of ~ 75 –80% in soft tissues (e.g., brain matter, muscle, lung, or liver). Thus, if a proton spectrum from just about any soft tissue (except adipose) is recorded, the result would look like the one presented in Fig. 12a, where an experimental spectrum from a muscle tissue of a young (and lean) rat, collected *ex vivo* on a 300 MHz NMR spectrometer, is shown. At a first glance, the result is boring: Only a single, strong peak from water is visible. Closer inspection, however, uncovers some additional details: First of all, the background of the spectrum is not totally flat, but composed of a broad peak, much wider than the normal range of chemical shifts expected in HR ^1H NMR spectra. This is illustrated in Fig. 12b, where the background of the spectrum in Fig. 12a has been

enhanced by amplifying the background and cutting off most of the strong, narrow water peak. The broad spectrum is produced by protons in macromolecular components of the tissue: the proteins, DNA, RNA, and thousands of other compounds responsible for function and control of cellular activities. The spectrum broadening is caused by the residual dipolar interactions that were not fully averaged out because large molecules move more slowly than the small ones. *Note:* This component of the NMR signal is normally not visible in MRI and MRS applications; since the line is so broad, the relaxation time T_2 of this component is quite short (on the order of hundreds of μs), thus by the time the MR signals are collected at TE that are in the range of milliseconds, this signal has decayed out. One can see some small blips on the surface of the broad line in the Fig. 12b: Those are signals from tissue biochemical compounds whose molecules are either small enough, or have specific chemical groups that are free to move relatively fast due to conformational arrangements. These clusters of protons have T_2 s long enough to produce narrow lines, and their chemical environment is varied enough to produce a range of chemical shifts. In short, those little blimps form an NMR spectral signature of the tissue studied. As such, they are the target of MRS. To enhance their appearance, various solvent suppression techniques are used. In solvent suppression, the goal is to suppress the strong (but usually uninteresting signal) from solvent (in case of tissue, water), thus reserving most of the dynamic range of signal recorder for small peaks whose amplitudes are close to the background of a tissue spectrum. This point is illustrated in Fig. 12c, which shows a spectrum from the same sample as the other spectra in this figure, but acquired using a water suppression technique. Now, the metabolite peaks stand out nicely against the background, in addition to some residual signal from water peak (it is practically impossible to achieve 100% peak suppression).

The most common implementation of water suppression in MRS *in vivo* studies uses a method known as CHES: **C**hemical **S**hift **S**elective suppression, first proposed by Haase and colleagues at the annual meeting of the Society of Magnetic Resonance in Medicine in 1984. It consists of a selective 90° pulse followed by a dephasing gradient (homogeneity spoiling gradient, or homospoil). The bandwidth of the RF pulse is quite narrow, close to the width of the water line, and the carrier RF frequency offset is set to the water signal center frequency. When such a pulse is applied, only the water protons will be at resonance and they will flip by 90° , leaving magnetizations of all other protons unchanged. The resultant FID from the water signal is quickly dispersed by using the homospoil gradient. When the CHES segment is followed by a regular spectroscopy acquisition sequence (STEAM or PRESS), the first RF pulse of those spectroscopic sequences will tip all the magnetizations from metabolites, but will not create any transverse magnetization from water. The reason is that at the time the spectroscopic acquisition routine starts, the longitudinal magnetization for water protons is zero, as prepared by the CHES routine. The description of technical details of various solvent suppression methods can be found in the paper by van Zijl and Moonen (13). The side effect of solvent suppression is a baseline distortion of the resulting spectrum;

Figure 12. An example of NMR spectra obtained from the same sample (a lean muscle from a young rat's leg) collected *in vitro*: (a) standard spectrum obtained using a single RF pulse and performing an FT on the resulting FID; (b) the same spectrum scaled to reveal a wide, broad line generated by protons within macromolecules, notice small humps on top of this broad line: these are signals from small mobile macromolecules; (c) the high-resolution spectrum of the same sample, obtained using a spin-echo method and applying water suppression, both water and macromolecular peaks are suppressed, revealing small narrow lines that are subject to clinical MRS evaluations.

this distortion can be particularly severe in the vicinity of the original water peak, (i.e., at 4.75 ppm). To avoid difficulties associated with baseline correction, the MRS spectra in routine clinical applications are limited to the chemical shift range from 0 to ~ 4.5 ppm.

In this short description of clinical MRS, the discussion had to be limited to its main features. There are many interesting details that may be of interest to a practitioner in the field, but had to be omitted here because

of space constraints; the reader is encouraged to consult comprehensive reviews, such as the work of Kreis (14), to further explore these topics.

APPLICATIONS

Now that there is a tool, it is necessary to find out what can be done with it. The clinical applications of MRS consist of

three steps: first, an MR spectrum is acquired from the VOI; second, specific metabolite peaks are identified within the spectrum; and third, clinical information is derived from the data, mostly by assessing relative intensities of various peaks. The first step has been covered, so let us now look at step two. The easiest way to implement the spectral analysis is to create a database of reference spectra and perform either spectrum fitting or assign individual peaks by comparing the experimental data to the reference spectra. This is easier said than done; the reliable peak assignment in NMR spectra acquired *in vivo* has been one of the major roadblocks in the acceptance of MR spectroscopy in clinical practice.

Currently, the majority of clinical MRS studies are performed in the human brain. Over the past several years, a database of brain metabolites detectable by proton MRS *in vivo* has been built and verified. This process is far from finished, as metabolites with lower and lower concentrations in the brain tissue are identified by MRS and their clinical efficacy is explored. A list of components routinely investigated in current clinical practice is shown in Table 1. Even a short glance at this list immediately reveals the first major canon of the MRS method: more than a cursory knowledge of organic and biochemistry is required to fully comprehend the information available. An appreciation of the true extent of this statement can be quickly gained by taking a closer look at the first molecule listed in that table: *N*-acetylaspartate, or NAA. This compound belongs to a class of *N*-alkanoamines; the italic letter *N* represents the so-called locant, or a location of the secondary group attached to the primary molecule. In this case, *N* is a locant for a group that is attached to a nitrogen atom located within the primary molecule. The primary molecule in this case is an *L*-aspartic acid, which is a dicarboxylic amino acid. Dicarboxylic means that the molecule contains two carboxylic (COOH) groups. As an amino acid, *L*-aspartic acid belongs to the group of the so-called nonessential amino acids, which means that under normal physiological conditions sufficient amounts of it are synthesized in the body to meet the demand and no dietary ingestion is needed to maintain the normal function of the body. The *N*-acetyl prefix identifies a molecule as a secondary amine; in such compounds the largest chain of carbon compounds takes the root name (aspartic acid), and the other chain (the acetyl group, CH₃CO-, formed by removal of the OH group from the acetic acid CH₃COOH) becomes a substituent, whose location in the chain (the *N*-locant) identifies it as attached to the nitrogen atom. But what about the *L* prefix in the *L*-aspartic acid mentioned above? It has to do with a spatial symmetry of the molecule's configuration. The second carbon in the aspartic chain has four bonds (two links to other carbon atoms, one link to the nitrogen atom, and the final link to a proton). These four bonds are arranged in space to form a tetrahedron with the four atoms just mentioned located at its apexes. Such a configuration is called a chiral center, to indicate a location where symmetry of atom arrangement needs to be documented. There are two ways to distribute four different atoms among four corners of a tetrahedron, one is called levorotatory (and abbreviated by a prefix *L*-), and the other is called dextrorotatory (and abbreviated by a prefix *D*-). It

turns out that the chirality of the molecular configuration has a major significance in biological applications: Since successful mating of different molecules requires that their bonding sites match, only one chiral moiety is biologically active. In our case, *L*-aspartic acid is biologically active; the *D*-aspartic acid is not. Last, but not least, the reader has probably noticed that the name of the molecule is listed as *N*-acetylaspartate, while we keep talking about aspartic acid. . . well, when an acid is dissolved in water, it undergoes dissociation into anions and cations; the molecule of aspartic acid in the water solution loses two protons from the carboxylic groups COOH (the locations of the cleavages are indicated by asterisks in the structural formulas shown in Table 1), and becomes a negatively charged anion. To reflect this effect, and suffix -ate is used. Thus, the name *N*-acetylaspartate describes an anion form of a secondary amine, whose primary chain is a levorotatory chiral form of aspartic group, with a secondary acetyl group attached to the nitrogen atom. The NAA is so esoteric a molecule that most standard biochemistry books do not mention it at all; its chief claim to prominence comes from the fact that it is detectable by MRS. A recent review of NAA metabolism has been recently published by Barlow (15).

The example discussed above emphasizes that much can be learned just from a name of a biological compound. To gain more literacy in the art of decoding the chemical nomenclature of biologically active compounds, the reader is encouraged to consult the appropriate resources, of which the Introduction to Subject index of CAS (16) is one of the best.

As mentioned earlier, routine clinical MRS studies focus on proton spectra spanning the range from 0 to ~ 4.5 ppm; the NMR properties of compounds listed in Table 1 are presented in Table 2, which identifies each molecular group according to carbon labeling used in structural formulas shown in Table 1. For each molecular group, the chemical shift of the main NMR peak is listed, along with the spectral multiplet structure characterizing this line. A simulated theoretical spectrum shows all lines in the range from 0 to 5 ppm, to give the reader an idea where the molecular signature peaks are located in the spectra acquired *in vivo*. Finally, information is provided whether, for a particular line, the signal acquired in standard MRS *in vivo* studies is strong enough to emerge above the noise levels and become identifiable. This information is further supplemented with comments indicating whether a particular line is expected to be visible on spectra acquired with short or long *TE* values. It is evident that the information provided in Table 2 is absolutely critical to successful interpretation of clinical MRS results; unfortunately, space limitations prevent us from further dwelling into details of spectral characteristics of clinically important metabolites. This information can also be difficult to locate in the literature since most of the data still reside in original research papers; fortunately, a recent review by Govindaraju et al. (17) offers an excellent starting point.

An examination of data shown in Table 2 quickly leads to a realization that only a limited number of metabolite signature lines can be successfully used in the

Table 1. Basic Properties of Metabolites Most Commonly Detected in MRS Spectra of the Human Brain

Metabolite	Full Name	Acronym	Formula	CAS ^a Number	Structure	Molecular Weight	Normal Concentration Range in brain, mmol
<i>N</i> -Acetylaspartate	<i>N</i> -Acetyl-L-aspartic acid; amino acid	NAA	C ₆ H ₉ NO ₅	[997-55-7]		175.14	8–17
Creatine	(1-Methylguanidino) acetic acid; non-protein amino acid	Cr	C ₄ H ₉ N ₃ O ₂	[57-00-1]		131.14	5–11
Glutamate	L-Glutamic acid; amino acid	Glu	C ₅ H ₉ NO ₄	[56-86-0]		147.13	6–13
Glutamine	L-Glutamic acid-5-amide; amino acid	Gln	C ₅ H ₁₀ N ₂ O ₃	[56-85-9]		146.15	3–6
<i>myo</i> -Inositol	1,2,3,5/4,6-Hexahydroxycyclohexane	m-Ins	C ₆ H ₁₂ O ₆	[87-89-8]		180.2	4–8
Phosphocreatine	Creatine phosphate	PCr	C ₄ H ₁₀ N ₃ O ₅ P	[67-07-2]		211.11	3–6
Choline	Choline hydroxide, Choline base, 2-Hydroxy- <i>N,N,N</i> -trimethylathanaminium	Cho	C ₅ H ₁₄ NO	[62-49-7]		104.20	0.9–2.5
Glucose	D-Glucose, dextrose anhydrous, corn sugar, grape sugar	Glc	C ₆ H ₁₂ O ₆	[50-99-7]		180.15	1.0
Lactate	L-Lactic acid, 2-hydroxypropanoic acid	Lac	C ₃ H ₆ O	[79-33-4]		90.07	0.4
Alanine	L-Alanine, 2-amino-propanoic acid	Ala	C ₃ H ₇ NO ₂	[65-41-1]		89.09	0.2–1.4

^aCAS = Chemical Abstracts Service Registry Number of the neat, nondissociated compound. In structural formulas, an asterisk * indicates a site where, upon dissociation, a proton is released; apostrophe indicates a site where, upon dissociation, a proton is attached. Metabolite names refer to dissociated (ionic) forms of the substances since this is the form they are present in the *in vivo* environment.

Table 2. The NMR Properties of Metabolites Most Commonly Detected in MRS Spectra of the Human Brain

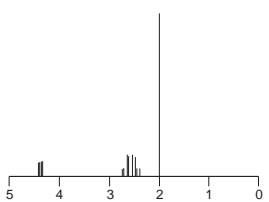

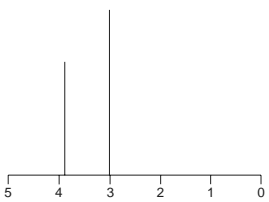

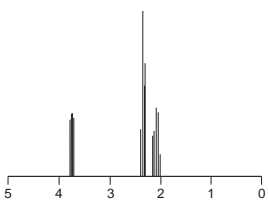

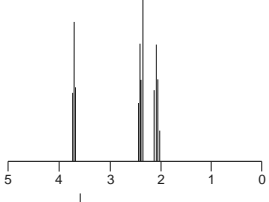

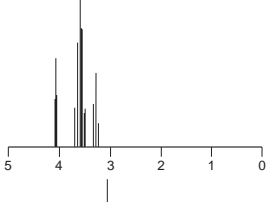

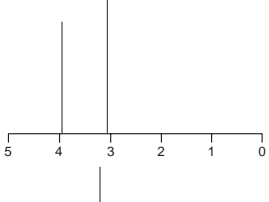

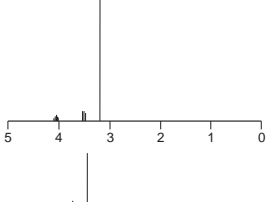

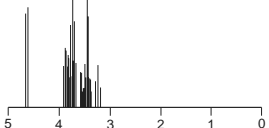

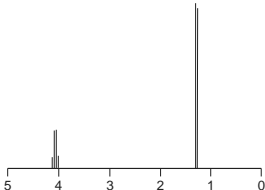

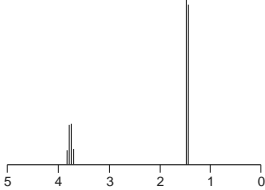

Metabolite	Acronym	Molecular Group	Chemical Shift δ ppm ^a	Multiplet Structure ^b	Visibility <i>in vivo</i> ^c	Theoretical Spectrum –Range (0,5) ppm
N-Acetylaspartate	NAA	• CH ₃ Acetyl	2.00	s	Yes	
		• CH ₂ Aspartate	2.49	dd	No	
		• CH ₂ Aspartate	2.67	dd	No	
		• CH Aspartate	4.38	dd	No	
Creatine	Cr	N-CH ₃	3.03	s	Yes	
		• CH ₂	3.91	s	Yes	
Glutamate	Glu	• CH ₂	2.07	m	Yes, on short TE	
		• CH ₂	2.34	m	Yes, on short TE	
		• CH	3.74	dd	No	
Glutamine	Gln	• CH ₂	2.12	m	Yes	
		• CH ₂	2.44	m	Yes	
		• CH	3.75	t	No	
Myo-inositol	m-Ins	• CH	3.27	t	No	
		• CH, • CH	3.52	dd	Yes, on short TE	
		• CH, • CH	3.61	t	Yes, on short TE	
		• CH	4.05	t	No

		• CH ₂	3.93	s	Yes	
Choline	Cho	N-(CH ₃) ₃	3.18	s	Yes	
		• CH ₂	3.50	m	No	
		• CH ₂	4.05	m	No	
Glucose	Glc	β -• CH	4.63	d	Not visible in normal brain due to low concentration	
		All other CH	3.23–3.88	m		

Table 2. (Continued)

Metabolite	Acronym	Molecular Group	Chemical Shift δ ppm	Multiplet Structure	Visibility <i>in vivo</i>	Theoretical Spectrum –Range (0,5) ppm
Lactate	Lac	• CH ₃	1.31	d	Not visible in normal brain due to low concentration	
		• CH	4.10	q		
Alanine	Ala	• CH ₃	1.47	d	Not visible in normal brain due to low concentration	
		• CH	3.77	q		

^aThe bold type indicates a dominant line in the spectrum.

^bs = singlet, d = doublet, dd = doublet of doublets, t = triplet, q = quadruplet, m = multiplet.

^cReference to short TE indicates that those signals have short T2s and thus will be suppressed in acquisitions with long TE.

interpretation of clinical proton MRS spectra. In normal volunteers, five major markers can routinely be detected and evaluated:

The *N*-acetylaspartate peak at 2.0 ppm, commonly referred to as NAA.

The combination of creatine (Cr) and phosphocreatine (PCr); reported together as two lines positioned ~ 3.0 and 3.9 ppm, respectively. Mostly referred to as Cr, but some people use a label tCr (for total creatine). The peak at 3.0 ppm is often identified as Cr, and the peak at 3.9 ppm as Cr2,

The combination of glutamine (Gln) and glutamate (Glu) at 2.2–2.4 ppm; since the peaks from those two compounds strongly overlap and are typically unresolvable, they are routinely reported together and referred to as Glx.

The choline peak at 3.25 ppm, referred to as Cho; The primary contributions to this peak are from bound forms of choline: phosphorylcholine (PC) and glycerophosphorylcholine (GPC), with only minor signal from free choline.

The *myo*-inositol group at 3.6 ppm is visible only in spectra acquired with short TE (due to *J* coupling effects that suppress the intensity of lines forming this signal at long TEs). *Myo*-inositol name poses evidently a challenge to acronym creators, since it can be found labeled as m-Ins, MI, mI, and In.

In addition, the following markers are routinely evaluated in a variety of diseases:

Lactate (Lac), often visible as a doublet at 1.3 ppm.

Mobile lipids (Lip) whose methyl (CH₃) groups are visible at 0.9 ppm and methylene (CH₂) groups provide signal at 1.3 ppm.

In special cases other metabolites may become visible, and we list here two examples:

Alanine (Ala) with a signature peak at 1.5 ppm.

Glucose (Glc), mostly showing as a broad peak ~ 3.5 ppm; note that the theoretical spectrum shown in Table 2 is a superposition of α - and β -anomers that occur in 1:2 ratio, respectively, in equilibrium *in vivo* conditions.

Examples of typical MRS spectra obtained from healthy subjects are shown in Fig. 13. The first thing to notice is that the signal noise ratio in those spectra is poor, so indeed, only the strongest lines from metabolites listed in Table 2 have a chance to become visible.

In the context of this discussion, the following questions have been discussed: What is MRS, how to perform it, who is interested in those studies, and why? If an actual clinical MRS examination were being performed, at this stage of MRS study we would have localized the lesion, collected an *in vivo* MR spectrum from the tissue within this lesion, identified the signature metabolite peaks, and analyzed their relative intensities. Now would have come the time to ponder what the results mean and what is their clinical significance. It is not an easy task, since the last analytic step listed above produces results that must be compared to “normal” baseline references. These reference data are obtained by performing statistical analysis of multiple results obtained from healthy people: a challenging task given biological diversity of normal subjects. Thus, MRS results are reported using such imprecise terms as unchanged, elevated, or suppressed. Sometimes, when clinicians want to be particularly precise, they will report ratios, such as the NAA/Cr ratio, which essentially renormalizes all observed signal intensities by assigning an arbitrary intensity of one unit to the Cr peak. In other words, this approach uses the Cr peak as an internal reference. As mentioned in Table 3, the rationale for such

Figure 13. Examples of typical MRS spectra obtained *in vivo* for a normal volunteer: (a) STEAM SV protocol with $TE = 30$ ms and TR of 2000 ms, magnitude mode; (b) PRESS SV protocol with $TE = 144$ ms and TR = 1500 ms, magnitude mode; (c) PRESS 2D CSI with $TE = 135$ ms, TR = 1000 ms, 16×16 voxel locations, real mode; (d) Image reference showing a location of selected VOI associated with the spectrum shown in (c) The VOI is generated by combining voxel locations. All data acquired within a single study, lasting ~ 15 min; spectra (a) and (b) were acquired at the same location using the same VOI size, no signal averaging was used (NEX = 8).

an approach is that the levels of Cr tend to be relatively stable under normal physiologic conditions. Such findings are purely phenomenological and their value is established over time by practicing evidence-based medicine, that is by performing statistical analysis of a large number of findings and looking for correlations between MRS results and the patient's clinical status. The drawback of such an approach is that in the early stages of new methodology, there is no established consensus regarding data interpretation, thus one is forced to read a large number of published clinical reports and develop one's

own approach to the inclusion of MRS findings into the clinical decision making process. A short summary of the current understanding of clinical findings related to MRS results is provided in Table 3. However, since these findings are still subject to frequent updates, it would have been pointless to try to provide in-depth coverage of these issues here, knowing full well that the data are likely to be obsolete by the time this publication appears in print. Instead, the reader is strongly encouraged to survey the current literature for reviews of clinical MRS topics; some excellent, previously published papers can serve as a

Table 3. Clinical Properties of Metabolites Most Commonly Detected in MRS Spectra of the Human Brain

Metabolite	Full Name	Acronym	Function	Pathological Variation
<i>N</i> -Acetylaspartate	<i>N</i> -Acetyl-L-aspartic acid; amino acid	NAA	Plays osmoregulatory function in the intercompartmental system, thought to be responsible for the removal of intracellular water, against the water gradient, from myelinated neurons	Decrease in NAA levels is indicative of reversible axonal injury or neuronal loss. In adults it has been associated with neoplasia, multiple sclerosis, hypoxia, ischemia, stroke, trauma, epilepsy, encephalitis, and neurodegenerative syndromes
Creatine	(1-Methylguanidino)acetic acid	Cr	Synthesized in the liver, it is exported to muscle and brain where it is phosphorylated into phosphocreatine and used as an energy store	Levels of creatine and phosphocreatine are tightly controlled under physiologic conditions, and thus this peak has been suggested as an internal reference for metabolite amplitude or area ratios. Increased levels of Cr and PCr have been observed, however, in hyperosmolar states, as well as in trauma. They also increase with aging
Glutamate	L-Glutamic acid; amino acid	Glu	Most abundant amino acid found in the human brain, acts as an excitatory neurotransmitter	Plays a role in detoxification of ammonia in the hyper ammonemic states
Glutamine	L-Glutamic acid-5-amide; amino acid	Gln	Plays a role in glutamate regulation; astrocytes metabolize glutamate to glutamine, thus preventing excitotoxicity	Elevated levels of glutamate and glutamine have been observed in hepatic encephalopathy, Reyes syndrome, meningiomas, and rare inherited enzyme deficiency. Reduced levels have been associated with Alzheimer's disease
<i>myo</i> -Inositol	1,2,3,5/4,6-Hexahydroxycyclohexane	<i>m</i> -Ins	A component of membrane phospholipids, functions as a cerebral osmolyte. It is also thought to play an essential role in cell growth	Concentration fluctuates more than that of any other major metabolite in the brain. Increased levels of <i>myo</i> -inositol have been observed in neonates, Alzheimer's disease, diabetes, and hypersomolar states. <i>myo</i> -Inositol levels are decreased in hepatic encephalopathy, hypoxia, stroke, and some neoplasms
Phosphocreatine	Creatine phosphate	PCr	A major energy storage in the body	See notes for creatine.
Choline	Choline hydroxide, Choline base, 2-Hydroxy- <i>N,N,N</i> -trimethylathanaminium	Cho	Choline is important for normal cellular membrane composition and repair, normal brain function and normal cardiovascular function	Increased levels of choline have been detected in normal infants, and aging adults. They were also associated with neoplasia, gliosis, demyelinating disease, inflammation or infection, trauma, diabetes, chronic hypoxia, and AIDS. Decreased levels of choline have been found in hepatic encephalopathy, stroke, and dementias, including Alzheimer's disease
Glucose	D-Glucose	GLc	A major energy carrier throughout the body.	Increased levels notes in diabetes mellitus, parental feeding, hypoxic encephalopathy
Lactate	L-Lactic acid, 2-hydroxypropanoic acid	Lac	Lactate is a signature byproduct of carbohydrate catabolism and thus when normal cellular oxidative respiration mechanisms are active, its levels in the brain tissues are very low	Visible in a variety of diseases. Increased levels of lactate were observed in some tumors, during the first 24 h after infarction, in hypoxia, anoxia, near-drowning, and hypoventilation
Alanine	L-Alanine, 2-Aminopropanoic acid	ALa	Alanine is a nonessential amino acid of uncertain function in the brain	The alanine peak is difficult to detect since it is easily overshadowed by lactate. Alanine levels might be elevated in meningiomas
Lipids	Fatty acids, glycerides, glycolipids, lipoproteins	Lip	Normally the lipid signals are not visible in the MRS spectra of the brain, but might appear due to fat contamination (voxel bleed)	Mobile protons from lipids (0.9 ppm for CH ₃ and 1.3 ppm for CH ₂) are not normally visible in brain spectra, but can appear in diseased conditions. Lipid signals are suppressed at long <i>TE</i> s. Elevated lipid levels are observed in cellular necrosis, high-grade astrocytoma, and lymphoma

starting point (18–21). The last paper on this list, by Smith and Stewart (21), also offers excellent overview of spectroscopy studies in organs other than the brain.

It is impossible, in one short article, to offer a fully comprehensive coverage of such an advanced and rapidly

evolving discipline as clinical magnetic resonance spectroscopy. The author can only hope that this brief overview offers sufficient information and enough reference pointers to let the readers start exploring this new and exciting field on their own.

Reading List

Bernstein MA, King KF, Zhou XJ. *Handbook of MRI Pulse Sequences*. Burlington (MA): Elsevier Academic Press; 2004. This is a “geek’s delight”. A detailed, step-by-step presentation and discussion of problems and solutions encountered in routine MRI practice today. A must-read for anyone seriously interested in learning MRI beyond the popular level.

deGraaf R. *In Vivo NMR Spectroscopy: Principles and Techniques*. Chichester (UK): John Wiley & Sons Inc.; 1999. This book covers both theoretical and practical aspects of MRS and is widely considered to be one of the best textbooks available on the subject. The book is particularly well suited for people involved in MR research outside a clinical medical environment, since it focuses on physics and engineering aspects of the methodology. Students, beware: it is very expensive (\$350 for 530 pages), so it is best to seek it out at the library.

Ernst RR, Bodenhausen G, Wokaun A. *Principles of NMR in One and Two Dimensions*. Oxford (UK): Clarendon Press; 1987. Fundamental monograph on modern theory of NMR spectroscopy. Very comprehensive coverage, but definitely not for beginners.

Fukushima E, Roeder SBW. *Experimental Pulse NMR: A Nuts and Bolts Approach*. Reading (MA): Addison-Wesley; 1982. The best introduction to practical NMR. The book is out of print, but libraries still carry it and it is relatively easy to purchase second-hand, since it has been hugely popular among graduate students starting up in the NMR field at a graduate level.

Goldman M. *Quantum Description of High Resolution NMR in Liquids*. Oxford (UK): Clarendon Press; 1988. Very methodical and thorough coverage of HR NMR Spectroscopy in liquids, but sometimes unconventional formalism requires an extra effort on the part of the reader to really understand all aspects of discussed subject matter.

Grant DM, Harris RK, editors. *Encyclopedia of NMR*. Chichester (UK): John Wiley & Sons Inc.; 1996. This is a monumental piece of work (eight volumes and one update volume thus far) that rightly deserves the title of the most comprehensive review of the field to date.

Martin ML, Martin GJ, Delpuech J-J. *Practical NMR Spectroscopy*. London (UK): Heyden & Son, Ltd.; 1980. This book is out of print, but copies are available at libraries. It is one of the best “hands-on”, practical texts on HR NMR spectroscopy. Covers practical hints on hardware, experiment setup, sample preparation, various techniques of spectral editing, and so on.

Slichter CP. *Principles of Magnetic Resonance*. Berlin: Springer-Verlag; 1990. Considered by many as the “the Bible” of MR theory. It is an advanced textbook that is meant to provide the beginner a necessary background to get started in the field of MR.

Young IR, editor. *Methods in Biomedical MRI and Spectroscopy*. Chichester (UK): John Wiley & Sons Inc.; 2000. This two-volume set contains most entries that have been originally included in the *Encyclopedia of NMR*, but they have been expanded and updated by the original contributors.

NUCLEAR MEDICINE INSTRUMENTATION

LAWRENCE E. WILLIAMS
City of Hope
Duarte, California

INTRODUCTION

Nuclear medicine exists as a clinical specialty due to two basic reasons involving signal detection. Of primary importance is the high sensitivity of tissue measurements. In principle, a single labeled molecule or nanostructure may be detected upon the decay of its attached radiolabel. A second reason is the possibility of using radiolabeled

materials of interest to study the physiology of animals and eventually patients. While imaging is the primary application of nuclear techniques, targeting implies an associated therapeutic strategy. All three traditional forms of radioactive emission, alpha (α), beta (β^- and β^+), and gamma radiation (γ) are available to the investigator. Negative betas are identical to the electrons found external to the atomic nucleus and are the antiparticle to β^+ (positron). Penetration distances in soft tissue for α and β rays range from μm and up to several millimeters, respectively, and so limit imaging use to organ samples or perhaps very small intact animals. Both of these particles are, however, employed in radiation therapy.

It is the photon emitter that is most valuable as an imaging label since it can be used *In vivo* on relatively large animals and patients. One exception to this general rule is the application of positron emitters (β^+) in imaging. Notice that a β^+ annihilates with a local atomic electron to form two or three photons of high energy. Thus, the positron emitter is effectively giving off quanta of a detectable type although up to several millimeters away from the site of the original decay. Because of momentum conservation, emission of two annihilation photons is essentially back-to-back; that is, at 180° separation, so as to define a line in space. This fact allows positron emitters to be an almost ideal label for 3D imaging.

Labeling Strategies

Radioactive labels may be used, in principle, to locate and quantitatively measure pharmaceuticals within excised samples, intact animals, and patients. Several strategies of labeling are possible. The radioactive tag may be used directly in the atomic form, such as ^{123}I as a test species replacing the stable isotope ^{127}I for evaluation of the patient's thyroid physiology. A secondary method is to replace a stable atom in a biological molecule by a radioactive isotopic form as ^{14}C in lieu of stable ^{12}C in a sugar. Finally, as is most common, the label is simply attached by chemical means to a molecule or engineered structure of interest. One can tag an antibody with radioactive ^{131}I or use ^{111}In inside a 50 nm phospholipid vesicle to track their respective movements inside the body of a patient. Because of protein engineering and nanotechnology, such radiolabeled manmade structures are of growing importance. Table 1 gives an outline of the three types of labeling and examples of associated clinical studies.

Applications of nuclear tagging can literally go far beyond clinical assays. When the 1976 Viking landers came down on the surface of Mars, a test for living organisms was performed using various ^{14}C labeled nutrients. An assay

was then performed on a scoop of Martian soil mixed with the radiotracers using a radiation detector sampling emitted gases. It was thought that ^{14}C -methane would prove metabolism (i.e., life). While a weak positive signal was detected in the reaction chamber, these results have yet to be verified by other test procedures. Methane has, however, been found as an atmospheric gas by more recent exploratory spacecraft.

Limitations of Radioactive Labels

In the last two types (II and III) of labeling, radionuclides can become separated from the molecule or structure of interest. This disassociation may occur during preparation and/or delivery of the pharmaceutical or later *In vivo*. Responsible processes include reversible binding of the radionuclide, enzymatic action, or even competition with stable isotopes of the same element. Nuclear medicine specialists must recognize such limitations in any resultant analyses: a subtlety often overlooked in a report or document.

A second important logical issue associated with nuclear imaging is tissue identification and anatomic localization. Nuclear imaging physicians are very analogous to astronomers in that entities may be observable, but indeterminate as to type or location. Relatively strong (hot) sources appearing against a weak background in a nuclear image may be coming from a number of tissues. The physician may not, in fact, be able to identify what structure or organ is being observed. Hybrid imaging devices combining nuclear and anatomic imagers such as computed tomography, (CT) are being implemented to correct for this ambiguity and are discussed below.

Lack of specific radiopharmaceuticals has been the greatest limitation to the growth of nuclear medicine. Many tracer agents owe their discovery to accidental events or the presence of a traditional metabolic marker for a given tissue type. Yet, these historical entities may target to several different organs *In vivo* and thus lead to ambiguous images. More recently, molecular engineering, computer modeling and the generation of specific antibodies to tissue and tumor antigens have improved production of novel and highly specific agents. The most specific of these entities is the monoclonal antibody binding to a particular sequence of amino acids in the target antigen's structure.

Therapy Applications

Detection and imaging via tracers are not the only clinical tasks performed in nuclear medicine. Of increasing importance is the provision of radiation therapy when there is preexisting imaging evidence of radiopharmaceutical

Table 1. Methods and Examples of the Three Types of Nuclear Medicine Labeling

Method	Label Example	Clinical Study	Detector Device
I. Substitution of radioactive atom for common stable atom	^{123}I for ^{127}I (stable)	Thyroid uptake	Single probe or gamma camera
II. Insertion of radioactive atom in a molecule	^{14}C for ^{12}C in glucose	Glucose metabolism	Liquid Scintillator (LS) detecting exhalation of $^{14}\text{CO}_2$
III. Attachment of radioisotope to a structure	^{111}In attached to an liposome	Planar or SPECT image of cancer patient	Gamma camera

targeting to the lesion(s) in question. The oldest such treatment is the use of ^{131}I as a therapy agent for thyroid cancers including both follicular and papillary types. Here, the radionuclide emits imaging photons and moderate energy beta radiation so that localization can be demonstrated simultaneously with the treatment phase of the study. In some applications, the therapy ligand is intentionally a pure beta emitter so as to limit radiation exposure to the medical staff and patient's family. In this case, no gamma photons are available to the imaging devices. The therapist must use the coadministration of a surrogate tracer to track the position of the pure beta therapy agent. An example is the use of ^{111}In -antibodies to cancer antigens to track the eventual location of the same antibody labeled with the pure beta emitter ^{90}Y .

RADIONUCLIDE PRODUCTION

Reactor Production of Radionuclides

Production of radionuclides that are useful in nuclear medicine relies on several different methodologies. The most common nuclear medicine radiolabel, $^{99\text{m}}\text{Tc}$, is produced as a decay product of its parent ^{99}Mo . Production of ^{99}Mo is generally done via nuclear fission occurring inside a nuclear reactor. Radioactive ^{99}Mo is taken into the radio-pharmacy where it is attached to an alumina (Al_2O_3) column. By washing physiological saline through this generator device, the user may elute the technetium that is chemically dissimilar from the ^{99}Mo , and so comes free of the column. Possible breakthrough or leakage of Mo is measured upon each so-called "milking" procedure to assure the pharmacist that the eluted material is indeed technetium. While other generator systems are available, obtaining specific radionuclides generally requires provision of the appropriate reaction using a suitable accelerator.

Cyclotron Production of Radionuclides

A more general way to produce radioactive species of a given type is via a designated nuclear reaction. For example, while many isotopes of iodine can be found in fission reactor residues, their chemical identity makes separation a difficult problem. For that reason, ^{123}I has been obtained with the nuclear transmutation:

More than one reaction can occur given the same initial conditions. In the above case, production of ^{124}I is possible when only one neutron is generated by the bombarding proton in an isotopically pure ^{124}Te target. This contamination is intrinsically present in any ^{123}I product resulting from the bombardment. Since ^{124}I has a 100 h half-life that is much longer than that of ^{123}I (13 h), the relative amount of this impurity increases with time and may become difficult to correct for in resultant gamma camera images.

While a variety of particle accelerators may be used, the most common device to produce a given radionuclide by a specific reaction is the industrial or clinical cyclotron. This is a circular accelerator invented by Lawrence and

Livingston in which large electromagnets hold the proton (or other charged particle) beam in a circular orbit of increasing radius as its energy is enhanced twice per cycle with radio frequency (rf) radiation. Circulation of the beam is permitted over extended acceleration times as the volume between the magnetic poles is kept in a relative high vacuum condition.

Straight-line machines, such as tandem Van de Graaff units and linear accelerators (linacs), in which the beam moves in a geometric line from low energy ion source to the reaction site, have some disadvantages compared to a cyclotron design. In linear devices, length is generally proportional to the desired energy so as to make the machine difficult to house: particularly in a clinical setting. The clinical cyclotron is small enough to fit within a medium-sized room as shown in Fig. 1. Second, the high voltage needed to accelerate the proton or other ion may be difficult to maintain over the length of the straight-line device. Electric breakdowns not only interrupt accelerator operation, they may also damage the internal electrodes.

In order that the appropriate nuclear reaction is possible, the proton beam must strike an isotopically purified target. This may occur within the cyclotron or in a separate chamber external to the accelerator. The latter method is preferred as it permits easier access to the resultant product and rapid switching of one target with another as the reactions are varied. External target locations also reduce the radiation level inside the accelerator. In the ^{123}I example shown above, the target is a foil of highly purified Te metal; this is an isotope that is $\sim 5\%$ abundant in natural tellurium.

Unlike linear machines, beam extraction into the target chamber can be problematic for a cyclotron since the ion being accelerated is moving in a stable circular orbit. Traditionally, extraction was done using an electrode. A more effective way to extract protons from the vacuum chamber is to initially attach two electrons to each proton to form an H^- ion. This molecular species is accelerated until it reaches the correct reaction energy and a corresponding outer orbit. At this point, the circulating negative hydrogen ion is allowed to hit a so-called stripper foil that removes both electrons and converts the ion back to an ordinary proton (H^+). The proton is not geometrically stable at that radius and field and is magnetically led out of the cyclotron's vacuum chamber and into the target chamber for the desired reaction.

In addition to longer lived radionuclides, such as ^{123}I , ^{67}Ga , and ^{201}Tl , cyclotrons are conventionally used to manufacture short-lived radionuclides for positron emission tomography (PET) imaging. The latter include ^{11}C (20 min half-life), ^{13}N (10 min), and ^{15}O (2 min). Commercially, the most common product is ^{18}F (110 min) for use in fluorodeoxyglucose (FDG) as described below. Because of the several minute half-lives of the first three of these labels, it is necessary that the cyclotron is available on-site within the nuclear pharmacy. With ^{18}F production, the accelerator may be more remote; perhaps as far as an hour's drive from the clinical site so that fluorine decay does not appreciably reduce the delivered activity.

SYSTEMATICS OF RADIATION DETECTION

Detection Methods for Ionizing Radiation

Ionizing radiation is detected using electrons liberated within a sensitive volume of a detector material. All three classical states of matter, gas, liquid, and solid have been used as an ionization medium. Table 2 lists examples of each state and the devices associated with it. Most materials have ionization energies on the order of 30 eV per electron-ion pair. In solid-state semiconductors, such as Si or Ge, electron-hole pairs can be formed using ~3 eV. This lower value means that semiconductors can provide many more (~10×) ionization events for a given photon or electron energy. Such an increased number of events in

turn yields improved statistical certainty that the particle has activated the counter. High thermal noise levels and elevated costs of large arrays of semiconductors have limited their use clinically.

Spectrometry

Signals of various sizes can arise in the detection process. Radionuclide counting depends on selection of the appropriate signal in a milieu of background radiation and other sample decays. For example, the technologist may have to count several beta emitters simultaneously or to detect a given gamma ray energy among many other emissions. Figure 2 shows a gamma spectrum from ¹³⁷Cs; both

Table 2. Detector Materials used to Measure Ionizing Radiation

State of Matter	Material	Energy per Ionization, eV	Device	Application
Gas	Argon	32	Dose calibrator	Photon activity assay
	Air	32	Ion chamber	Exposure level measurement
Liquid	Scintillation fluid (toluene)	30	Liquid counter	Beta assay in biological samples
Solid	NaI (Tl)	30	Gamma camera or probe	Photon counting
	Si (Li)	3	Solid-state probe	Photon and beta counting
	LiF (Tl)	30	TLD (Thermoluminescent dosimeter)	Radiation safety

Figure 2. Energy spectrum of ^{137}Cs as measured by a NaI(Tl) probe.

Compton scattering and photoelectric effect (PE) are observed in this probe made of NaI (Tl).

In the PE, all of the photon energy is given over to an electron-ion pair in the absorbing material. Compton scatter may go on inside the patient prior to the photon coming into any detection system. In such cases, the direction and energy of the quantum may be changed so that an unwanted source may contribute to the counting process. Photon energy analysis is used to guard against such events in imaging; if the energy is seen to be reduced from that of the expected value, an electronic discriminator circuit rejects the ionization event. This pulse height analysis (PHA) is common to all nuclear detector systems and is described for imaging devices below.

ONE-DIMENSIONAL NUCLEAR MEDICINE DETECTORS

Well Counters

The most primitive instrument for photon detection is the counter or probe. In this case, a NaI(Tl) crystal is generally used to form a single large scintillation detector. In the scintillation process, the ionization event within the crystal is converted to visible light with a decay time on the order of 2 μs or less. Note that NaI is hygroscopic so that isolation of the crystal from the atmosphere is required. A reflective cap of Al is generally used as part of this hermetic seal. Resultant scintillation light is amplified by photomultiplier (PM) tubes to yield an electric signal proportional to the total amount of visible light. Well counters have the crystal in a hollow (cup) shape with the sample within the cup to maximize geometric sensitivity. Shielding is provided by an external layer of lead so as to reduce background counts. This is particularly important in a laboratory or clinical context. A mobile combination of well counter and probe system is shown in Fig. 3. Applications include sample assay using a standard source to give absolute values to the amount of detected activity. Counting experiments may involve patient tissue specimens obtained from the surgeon or animal organs obtained during measurement of biodistributions. Radiation protection is an additional application, whereby surface swab samples are counted to see if contamination is removable and possibly being spread around a lab or clinical area.

A second type of well counter, using high pressure Argon gas as the detector, is the dose calibrator. This device is

Figure 3. Well counter and probe mounted on a mobile chassis.

used in all nuclear pharmacies and clinics to measure the amount of radioactivity (mCi or MBq) in the syringe prior to administration via injection into a patient's vein. A curie is defined as 3.7×10^{10} decays per second and a becquerel is one decay per second. Standards are used to calibrate the device at the relevant energy of the radiopharmaceutical. Since the walls of the counter stop alpha and beta radiation, a dose calibrator generally may be used only for the photon component of the decay radiation. One exception is the assay of very high energy beta emitters, such as ^{90}Y or ^{32}P . In these cases, the betas give off a continuous spectrum of X rays of appreciable energy while they are decelerated before coming to rest. Such brake radiation (bremsstrahlung in German) may be detected quantitatively to calculate the amount of high energy beta emitter present in the syringe. Lower energy beta emitters, however, present difficulty in quantitative assays and generally require a different strategy for detection.

Liquid scintillation (LS) counters are a third form of well counter. Here, the beta emitter is dissolved into a liquid hydrocarbon that has been doped so as to produce scintillations suitable for PM detection. These devices have wide application in the quantitative assay of low energy beta emitters used for *In vitro* biological research. Radionuclides of interest include ^3H ($E_{\text{beta max}} = 18 \text{ keV}$), ^{14}C (155 keV) and ^{35}S (167 keV). Energies cited refer to the kinetic energy of the betas. These labels are generally used in type II labeling as shown in Table 1. Multiple samples are sequentially measured for a fixed counting interval by lowering the tube containing mixed scintillator and radioactive material into a darkened space viewed by one and probably two PM tubes. The sample is dissolved in a liquid (usually toluene), which is activated with small amounts of fluors, such as PPO (2,5-diphenyloxazole) and POPOP (4-bis-2,5-phenyloxazolyl) benzene as solutes so as to provide visible light upon being struck by the electrons released during decay. Standards are included in the experimental

Figure 4. Operating principle of the clinical probe. Note that the observed field of view increases with distance from the opening of the collimator.

run to give absolute values for the activity. Efficiencies may approach 90% or more for moderately energetic betas. Reduction (quenching) of the light output due to solvent impurities and biological molecules within the sample can significantly affect the results and are accounted for by using standards.

The addition of fluors may not be needed to count very high energy beta particles. If the beta speed exceeds that of light in the solvent ($E_{\beta, \text{max}} > 0.26 \text{ MeV}$ in water), a photon shock wave is produced in the medium. Termed Cerenkov radiation, the emitted light is analogous to that of the acoustic wave or sonic boom produced by an aircraft exceeding the speed of sound. An observer may use Cerenkov light, which includes a continuum of visible and ultraviolet (uv) photons, to directly quantitate beta activity in the sample.

Probes

Clinical probes contain a planar crystal, usually a right circular cylinder, placed at the end of a long, shielded tube called a collimator. The central field of view is typically on the order of a circle 10 cm in diameter. The collimator is another right circular cylinder so that the total field observed increases with distance from the opening. Since the patient has a relative small thickness, on the order of 30 cm or less, this expanding view is not detrimental to the resultant clinical counting experiments. Such static NaI (Tl) devices are routinely used in measurements of thyroid uptake of radioactive ^{123}I as described above. Figure 4 contains a cross-section through a typical probe. With a single probe giving a result of activity for a relatively small, fixed field of view, it is necessary that sets of several probes be employed for measurement in an extended or spatially variable organ.

Conformal arrays have been used to yield information on regional cerebral blood flow (rCBF) in patients. Sets of 10 or more detectors have been arranged around the patient's skull so as to measure regional accumulation of perfusion tracers, such as ^{133}Xe in the brain. Because of the low gamma energy (81 keV) of ^{133}Xe , a given probe essentially views only physically adjacent tissues in rCBF counting. Such arrays led to the discovery that regional brain-blood flow varied with the mental task that the patient was performing during the time of observation. In this application, it is necessary that the intervening scalp blood flow be subtracted from the time-activity curves for each region. Tomographic methods such as PET do not suffer from this

limitation. The PET flow measurements have confirmed the probe rCBF results and generalized them to other aspects of brain blood flow and metabolism during conscious and subconscious thought processes.

A more recent probe application is the detection and uptake measurement of so-called sentinel lymph nodes in melanoma, breast, and other cancer patients. These sites are defined as the first draining node associated with the lesion. They are located following a near-primary injection of a $^{99\text{m}}\text{Tc}$ -labeled cluster of sulfur colloid particles. Particle sizes up to $1 \times 10^3 \text{ nm}$ may be used. Of necessity for spatial resolution, the hand-held probe has a greatly reduced field of view, on the order of a few millimeters, and may be driven by battery power for convenience in the operating room (OR). Because of size limitations at incision sites, such probes may be of the solid-state type, whereby the ionizing event is converted to an electronic signal directly without the necessity of PM tube signal amplification. At present, CdTe and CsI(Tl) detectors have been incorporated into clinical probe systems. In the latter case, a photodiode is used in lieu of a PM tube to provide miniaturization of the device. An example of a surgical probe is shown in Fig. 5. For use in the OR, the device is usually gas sterilized, and then placed into a plastic sleeve before being put into an operating field.

Similar probe applications can involve radiolabeled antibody proteins used to locate small metastatic lesions in cancer patient after removal of their primary tumor. This has been termed radioimmune-guided surgery (RIGS). By measuring the gamma activity per gram of excised tissue, the radiation oncologist may estimate the radiation dose achievable with that patient's disease if radioimmunotherapy (RIT) were eventually utilized. In the case of RIT, a beta label is attached to the antibody in lieu of the gamma label used in localization if the radionuclide label does not emit both types of ionizing radiation. Probe-guided biopsy allows direct treatment planning for the RIT procedure that may follow.

Probes are also available for positron detection in the OR. This measurement assures the surgeon that the resection has taken out all of the suspect tissue that has been previously located using a FDG imaging study and a PET scanner. Because of the presence of both annihilation 511 keV photons and positrons, some correction mechanism is necessary for these instruments. A dedicated microprocessor attached to the detector system will provide this information if the probe has separate sensitive elements for positrons plus photons and for photons alone so that a subtraction may be done in real time.

TWO-DIMENSIONAL DETECTORS

Rectilinear Scanners

Because of the limited field of view of single probes, it was once considered clinically relevant for such devices to be mounted on a motor-driver chassis so as to pass in raster fashion over an entire organ. The trajectory of the probe in this context is the same as a gardener mowing the lawn. A simple thyroid probe in this application would prove problematic since it is focused at infinity; that is, observes all

Figure 5. Operating room probe. Miniaturization is dictated by the need to minimize the incision site at the sentinel lymph node. With robotic developments, even smaller designs will be necessary.

tissues from one side of the patient through to the opposite side. It can be used on the thyroid since no other organ taking up radioiodine usually lies within the neck region. In order to generally restrict the depth of the field of view, focused (converging) collimation was developed for raster-driven rectilinear scanner systems so that only emitters at a fixed distance were detected with relatively high efficiency. Dynamic studies, whereby activity was imaged during its physiological motion within the body, were difficult with this device unless the kinetics were significantly slower than the total raster scan time. Today the rectilinear scanner is a historical artifact that is no longer used in the clinic because of the development of the gamma camera. A camera allows both static and dynamic imaging over a reasonably large field (50 cm) without requiring movement of the detector assembly.

Gamma Cameras

H. Anger, in the late 1950s, avoided most of the scanner problems by inventing a gamma camera. As in the probe example, a right circular cylinder of NaI(Tl) was used to detect the photon. However, instead of a single PM tube, a hexagonal array of such tubes was employed to determine (triangulate) location of a given scintillation within the detector's lateral (x, y) dimensions. This fundamental principle is illustrated in Fig. 6. In order to spread the light somewhat more uniformly over the PM cathode, a light pipe (diffuser) is generally interposed between scintillation crystal and photomultiplier array. Localization was originally done with an analogue computer measuring the relative signal strength from each of a set of PM tubes. A second type of processing occurs with the sum of the PM signals. An energy window is set so that only photons having

energy within a prespecified range are recorded as true events. The window is sufficiently wide, for example, $\pm 10\%$, that most signals arising from PE absorption of a monoenergetic gamma are recorded, but other photons, such as those scattered in the patient, are rejected. If the radionuclide emits several different photons, separate energy windows are set to count each energy level. The sum of all counts within all windows is then taken as the clinical result.

The original camera had cylindrical geometry arising from the single-crystal shape. Modern cameras generally have rectangular NaI(Tl) detectors made by combining annealed crystals of relatively large size allowing the

Figure 6. Principle of the Anger gamma camera. If no collimation is included (as shown) there is ambiguity of decay position.

entire width of the patient to appear in one field of view. The ensemble of crystal, multiple PM tubes, and associated computer electronics is referred to as the camera head. It is usually in the form of a rectangular solid and is mounted on a gantry allowing rotation and translation with respect to the patient bed. In the latter case, the motion is one dimensional (1D).

In the absence of directional information, a photon coming from anywhere within the entire hemisphere above the detector may impact the same position on the camera face. To remove the ambiguity, it is necessary that a collimator be provided between the detector crystal and the radioactive object(s). A collimator projects the activity distribution onto the crystal face. Essentially, this is a shadow or projection of the radioactivity distribution. Four standard types of collimators are shown in Fig. 7. The most common of these in clinical use is the parallel-hole type that is focused at infinity; that is, only passes parallel photons (rays) coming from the tissue of interest. Notice that the image and object size are equal in this case (magnification, $M, = 1$). This is essentially the same geometry used in the thyroid probe. Divergent collimators minify ($M < 1$) and convergent collimators magnify ($M > 1$) radioactive objects being imaged. The terms divergent and convergent refer to the point of view of the camera crystal. Convergent collimation is focused at a point in space; this is the same type of system used in the rectilinear scanner described above. However, in the camera case, the

focal point is on the other side of the patient where this is no activity. Pinhole collimation may lead to either magnification or minification depending on the location of the object relative to the pinhole aperture.

Efficiencies of all collimators are relatively poor with pinholes becoming the worst at extended distances from the camera face. Typical values are on the order of 1×10^{-4} for commonly used parallel-hole types. Thus, if an experimenter deals with a very flat (essentially 2D) source, such as a thin radioactive tissue sample, it is better to simply remove all collimation and use the intrinsic localizing capability of the bare crystal and attached PM system. A transparent plastic sheet should be placed between source and camera face to minimize possible contamination.

Every collimator is designed to be effective at a given photon energy. Lead septae in the device are effectively four to five half-value layers for the quantum of interest. A half-value layer is that thickness of material that reduces the intensity of gamma radiation by a factor of 2. Thus, using a collimator designed for high energy photons in the case of a relatively low energy emitter will lead to both lower efficiency as well as poorer image quality. For radionuclides emitting several different photons, the collimation must be appropriate for the highest gamma ray energy being measured. If this is not done, a hazy background of events due to these photons passing through the collimator walls will obscure the image.

Figure 7. Four standard types of collimators used on the gamma camera.

Spatial resolution of gamma camera systems is on the order of 1 cm near the collimator surface, but generally becomes worse with increasing source depth inside the patient. When the count rate becomes extremely elevated, however, the localizing algorithms of such devices can be confused by multiple simultaneous scintillations with resulting imaging artifacts and reduced resolution. Most clinical protocols recognize this limitation by keeping the count rate at or below 5×10^4 counts per second (cps).

Because absolute measurement of resolution as well as object (organ) size is important, it is useful to image point sources of radiation for testing each camera-collimator system. This test object may be a set of small (1 mm) radiation sources of the imaged radionuclide having a known spacing. Resolution and object size in any resultant film or digital image can be defined directly using such devices. Variation with depth (patient thickness) and distance from the collimator may also be evaluated.

Digital Processor Applications Within the Camera Head

Anger's patented design originally relied on an analog computer to position the scintillation flash within the lateral dimensions of the NaI(Tl) crystal. Each scintillation event was weighted by location and signal amplitude of the several recording PM tubes. One of the original problems of the design has been the non-uniformity of response due to intrinsic and temporal variation in PM tube and other analog circuit components. In modern camera heads, digital processors are used to position the scintillation flash as well as perform spectroscopic analyses in real time on the detected events. Such dedicated processors inside the camera head observing individual PM tubes can greatly improve the uniformity so that the central field of view (CFOV) can have uniformities approaching 2%. Uniformity is particularly important for 3D imaging involving rotation of the camera head as described below. Values for each head are measured regularly with a flat source of radioactivity of an appropriate energy for most of the clinical imaging. Cobalt-57 is the radionuclide of choice for this procedure since it is close in emission energy (120 keV) to the common radiolabel ^{99m}Tc (140 keV) and has an extended half life of 270 d.

Note that communication formats are now available for information transfer between cameras and external computers. The digital imaging and communications in medicine (DICOM) standard is the international format for this transfer of information. This information may be used to produce comparisons of nuclear and other images to improve the diagnostic process.

Types of Acquisition from Gamma Cameras

One very important choice made by an operator prior to any camera study is the method of photon event recording in any external computer or work station memory. It is most common to acquire each scintillation as an event or count at coordinates (x, y) . With total time of acquisition fixed at some realistic (patient-derived) limit, these events are added at their spatial positions to form a single digital image. This method of data recording is called frame mode. It is, by far, the most common type of camera data acquisition.

It may be that the timing of the tracer movement is either very rapid or uncertain for the patient-study. In that case, one may *a priori* choose list mode acquisition whereby each event is recorded as a triplet: (x, y, t) with computer clock time (t) included. After all events are list mode recorded, the operator or clinician may reconstruct the study in any sequence of time frames that is desired. For example, the first minute may be assigned to image 1, the second minute to image 2, and minutes 3–10 to image 3. Each of these images would appear to the reader as if they were taken in frame mode over that interval. Such an allotment may be revised subsequently as clinical questions arise. Large memory sizes are clearly useful if list mode imaging is to be pursued. Modern cameras often do not offer the possibility of list mode acquisitions, but instead rely on use of high speed frame-mode data recording.

A special type of frame mode acquisition is the gated study. Here, data are acquired in synchrony with a repeated physiological signal, usually the patient ECG. The *R*-wave-to-*R*-wave interval is predivided into a number (n) of equally spaced segments. Data obtained during time segment 1 of the cardiac cycle are placed into image 1, from time segment 2 into image 2, and so on. The result is a closed loop of n images that shows the beating heart when the gating signal is derived from the electrocardiogram (ECG).

External computer processing of camera data has been used to generate an additional type of output referred to as a functional image. For example, the clinician may wish to measure the rate of physiological clearance of a radiotracer from individual pixels within a time sequence of organ images. Using the external computer to calculate regional rate constants and to store this array, the resultant functional image displays the relative magnitudes of the computed kinetic values. Using an arbitrary scale, faster clearing regions are shown as brighter pixels. By looking at the functional image, regions of slower clearance can be readily identified and followed post subsequent therapies such as microsurgery for stroke patients.

Gamma Camera Types

Mobile Cameras. Battery-powered Anger cameras may be mounted on motor-driven chassis for use at the bedside or other remote areas. In such cases, the head is generally smaller than a static camera, on the order of 25 cm in diameter, and the energy range limited to 140 keV (^{99m}Tc) due to shielding weight concerns. Movement up ramps and using elevators would be restricted otherwise. Mobile units are most often utilized in planar heart work and have been involved in the testing of patients under escalating stress such as on a treadmill in cardiology. Patient evaluations in the OR or ICU are other applications of the device. Aside from breast imaging using ^{99m}Tc -sestamibi, use of mobile gamma cameras has been limited, however, because of two specific reasons listed below.

Tomographic imaging is generally not possible with the mobile camera due to the difficulty of rotating the device in a rigorous orbit about the patient. In addition, use of high energy gamma labels is not possible for the minimally

shielded detector head. Because of the importance of 3D imaging of the heart (see below), clinical usage has dictated that the more optimal study results if the patient is brought to the nuclear medicine clinic in order that optimal tomographic images be obtained.

Static Single-Head Cameras. The most common camera type, the static single head, is usually a large rectangular device with a NaI(Tl) crystal having a thickness of ~6–9 mm. Larger thicknesses up to 25 mm may be useful for higher energy gammas, but loss of spatial resolution occurs as the PM location of the scintillation becomes more indeterminate. Lateral crystal dimensions are approximately 35 × 50 cm, although actual external size of the head would be significantly larger due to the necessity of having lead shielding surrounding the detector. This shielding must go both around the detector crystal as well as behind it to prevent radiation coming into the sensitive NaI(Tl) from the direction opposite the patient. Such protection is of importance in a busy clinical situation where more than one study is being conducted simultaneously in a relatively small space. Large rectangular camera heads permit simultaneous imaging over the entire width of a typical patient and allow whole body imaging with a single pass of the detector from the head to the feet. This is essentially an updating of the rectilinear scanner concept although here it is a 1D motion (*z*).

Images from Single-Head Cameras. Two standard imaging formats are employed with the gamma camera. Regional images, or vignettes, are taken of the organs of interest in the clinical study. A patient complaining of pain in the knee will be placed adjacent to the camera to permit various views of that joint following administration of a

bone-seeking radiotracer, such as ^{99m}Tc-MDP. In addition, a whole-body image may be acquired to check for overall symmetry of tracer uptake. An example of the latter is given in Fig. 8. Here, the camera head is driven from the head to the foot of the patient and a series of frame images acquired over a span of 20–30 min. A computer attached to the camera allows these separate images to be seamlessly united to form the whole-body format.

Anger's camera concept has had one of its greatest impacts in cardiac dynamic imaging, whereby the sequential heart images are stored in a repetitive sequence that is correlated to the ECG signal obtained from the patient as described above. Figure 9 includes a continuous loop of 16 images of the left ventricle during a cardiac cycle using a labeled red cell tracer based on ^{99m}Tc. By setting a computer-generated region of interest (ROI) over the ventricle, one can measure the relative amount ejected; that is, the left ventricular ejection fraction (LVEF). Note that absolute amount of the tracer is not needed in the study since it is only a fractional ejection fraction that is of interest to the cardiologist. Irregular heart beats and/or patient motion during the 10–20 min of data taking can make such studies difficult to process.

Other dynamic studies are popular and clinically important. These include the renogram whereby the uptake and clearance of a filtered agent, such as ^{99m}Tc-DTPA is measured over a 1 h period. Both kidneys are followed and characteristic times of tracer accumulation and excretion are estimated by the radiologist: often using external computer software. A partial listing of typical studies involving gamma camera image data is included in Table 3.

Multiple-Head Cameras. It is becoming common to use more than one gamma detector head within a single

Figure 8. Whole-body image of a bone scan patient using translation of the gamma camera from head to foot. A sample of 20 mCi of ^{99m}Tc-MDP was used as the radiotracer for this image taken at 4 h postinjection.

Figure 9. A multiple gated (MUGA) study of the left ventricle. The 16 images acquired over a heartbeat are uniformly assigned in time to the R wave-to-R wave cardiac interval. An ejection fraction of 69% was calculated.

supporting gantry (cf. Fig. 10). Speed of data acquisition, in either 2D or 3D mode, is the most important reason for this augmentation. By using two heads in a 2D study, the patient may be imaged from opposing sides simultaneously. Thus, if the organ of interest or tumor site were closer to the back of the patient, one could obtain information from the posterior head that would be useful even if the anterior head showed no discernible uptake sites. Alternatively, anterior and lateral views of an organ system may be obtained simultaneously and serially in a dynamic study of gastric emptying, for example. A second, and very important, application of multiple head camera systems is in more efficient 3D imaging.

THREE-DIMENSIONAL DETECTORS

There are two quite distinct methods to provide 3D imaging in nuclear medicine. If one uses ordinary (nonpositron) gamma-emitters, the strategy is referred to as single-photon emission computer tomography or SPECT.

SPECT Imaging

Here, the detector head or, more likely the set of two or three heads, is rotated around the patient over an extended arc. This orbit may be a full 360° arc or may be less due to body habitus or tissue location. One uses the rectangular Anger

Table 3. Representative Gamma Camera Imaging Studies Done in Nuclear Medicine

Study	Agent	Label	Device	Results
Renogram	DTPA and MAG3	^{99m}Tc	Camera	Kinetic values
MUGA	Red cells	^{99m}Tc	Camera with EKG gating	Ejection fraction of LV
Myocardium	Sestamibi	^{99m}Tc	Camera	Bulls eye image of LV
Bone scan	MDP	^{99m}Tc	Camera	Fracture location. Tumor location
Lung scan	Aggregated albumin	^{99m}Tc	Camera	Regions of reduced perfusion
Lung scan	Aerosolized albumin	^{99m}Tc	Camera	Regions of reduced ventilation
Lung scan	Xenon gas	^{133}Xe	Camera	Regions of reduced ventilation
Thyroid imaging	Iodine	^{123}I	Camera	Uniformity of uptake in gland

Figure 10. Dual-headed gamma camera. Both detector heads are mounted on the same gantry to allow translation (for whole body) and rotation (for SPECT) of the system. An open geometry permits use of gurneys with this system.

head as described above with the parallel-hole collimation in place. With injected activities on the order of 100–300 MBq, data acquisitions require on the order of 20 min. Patient immobility is necessary. Data may be taken in a shoot-and-step mode at fixed angular intervals or they may be acquired continuously during the rotation. Storage of such vast amounts of information requires a dedicated computer system recording the counts at each spatial position on the head (x,y) and at each angle (θ) during the rotation.

Several reconstruction algorithms are available to the technologist to generate the requisite tomographic images of the patient. Corrections for attenuation and Compton scatter must also be applied for the generation of these images. While pseudo-3D images may appear on the computer monitor as an output of the reconstruction, the radiologist will review and file to the picture archival and communication system (PACS) system the transaxial, sagittal, and coronal projections of the activity. It is important to realize that numerical values usually shown in these various projection images are not absolute, but only relative quantities. Quantitative SPECT, in which the numerical pixel value is equal (or at least proportional) to the activity in Bq, requires, in addition to the above corrections, that a set of standard sources of the same radionuclide be imaged along with the patient. Such calibrations can be done simultaneously with the clinical study, but are usually performed as a separate procedure. Figure 11 shows the three projection sets (axial, sagittal and coronal) in the case of a patient having a ^{99m}Tc sestamibi myocardial scan of the left ventricle.

PET Systems

Back-to-back photon emission (511 keV each) characteristic of positron decay of a labeling radionuclide has led to the

development of PET. While paired Anger camera heads have been used as the detectors, it is much more efficient to use a ring of solid-state scintillation detectors arrayed around the patient. Bismuth germinate (BGO) has been the standard material, but LSO (lutetium orthosilicate) is becoming more popular due to its higher light output and shorter pulse length at 511 keV. In the standard situation, each detector block is broken into separate light emitting substructures that act as individual scintillation detectors. By having a few phototubes observing a separate block of such elements, the number of PMs may be reduced using Anger's gamma camera principle. Whole body PET scanners may have $> 10^4$ individual scintillators arrayed in an open circle or set of rings around the patient bed. Multiple rings are conventional so that several axial sections may be acquired simultaneously over a distances of 10–15 cm. Note that no detector rotation is inherently required since the solid-state system completely encircles the patient. If needed, the bed will be driven along the axis of the detector rings in order to perform extended imaging of the subject. The most common study utilizes FDG with ^{18}F as the radiolabel and covers the patient from head to groin. Sites within the body that metabolize glucose are imaged thereby. Brain and possible tumor areas are important applications of PET glucose imaging. Ambiguity with infection sites is a limitation to this protocol; this is particularly the case in the immune-compromised patient.

Because the two emitted photons are coincident in time and define a line in space, the positron detection process does not, in principle, require collimation (Fig. 12). Using contiguous rings of detectors is the most common system design; if the rings act alone or together as a single detector system defines the two types of imaging that are performed on a PET system. Internal (patient) photon attenuation is taken into account in the reconstruction of the PET image set. This is done using a transmission source of positron emitter, usually ^{68}Ge , to evaluate the patient thickness for the various ray directions at each bed position. Typically, the attenuation correction occurs during the scanning procedure with a short time interval given over to use of the source at each bed location.

Two-Dimensional PET Imaging

A clinical PET scanner is shown in Fig. 13. In 2D PET, every ring of detectors is isolated by tungsten collimation from all but single adjacent rings. Thus, each circle of solid-state scintillators is used in isolation to generate a single axial slice through the patient. This approach yields the highest resolution available in positron tomography with systems having spatial resolutions on the order of 5 mm. Reduction in the amount of scatter radiation is also obtained in 2D images. A FDG image is given in Fig. 14. While described as 2D, the result is actually tomographic and gives the usual projections in the three planes intersecting the patient's body. In these planes, the precise estimate of resolution depends on the positron's kinetic energy. One must combine, in quadrature, the positron range in soft tissue with inherent ring resolution to predict the overall spatial distance ambiguity. Higher energy positron emitters will have correspondingly poorer spatial

Figure 11. The SPECT image set for a gated myocardial study. In each pair of rows, the upper set of images gives the stress result, the lower set the resting result. The patient received 30 mCi of ^{99m}Tc -sestamibi for the study.

resolution due to the greater range of the positron prior to decay.

Other criteria for the selection of a positron label may be applied; for example, the half-life of the radionuclide. If that lifetime is very short, manufacturing and targeting may take so many physical half-lives that imaging is not possible. Additionally, one should consider the relative probability of β^+ emission in the decay scheme. This likelihood may be reduced because of competition with electron capture from the K shell of the radionuclide. Additionally, there is the possibility that other photons may be emitted along with the positrons so as to cause a background effect in the PET scanner. For example, ^{124}I , along with annihilation radiation at 511 keV, also emits ordinary gamma rays with energy in excess of 2 MeV. Such high energy photons readily penetrate collimators to reduce contrast in the images and make quantitation of the absolute radioiodine activity difficult.

Three-Dimensional PET Imaging

When the collimation between PET scanner rings is removed, each circle of detectors can have coincidences with itself as well as with all other detector rings. This mode of operation is referred to as 3D imaging. Spatial resolution is somewhat worse than that of the collimated (2D) case and may be 1 cm or more. However, the added

sensitivity may be very important: particularly if whole body images are to be obtained in a patient with possible multiple sites of interest such as a referral from medical oncology. Sequential PET images of the whole body may be used to evaluate chemotherapy or other interventions. A quantitative method is available for such comparisons.

One feature of PET imaging merits emphasis. In the quality assurance of the positron scanner, the operator will routinely obtain transmission images through a phantom of known size using 511 keV photons from an external source. With this information and calibration using a known activity source, the user may reconstruct radioactivity distributions in the patient with absolute units. Thus, the concentration of positron emitter at a given image voxel can be estimated. Called the specific uptake value (SUV), this parameter is essentially $\%ID \cdot g^{-1}$, where ID refers to the injected activity or dose (MBq). The resultant SUV value is a function of time. Two direct consequences result. First, the clinician can make comparisons between organ sites both now and with regard to earlier studies on that patient or relative to normal individuals. Results of therapy may be directly evaluated thereby. The SUV values may even be used to make diagnostic assessments, such as the likelihood of malignancy at the voxel level. In addition, the radiation dose to the entire organ and even to local volumes within the tissue may be directly made with the SUV parameter. This

Figure 12. Principle of a PET scanner. Note that the direction of the annihilation radiation defines a line in space. 2D and 3D configurations are accomplished with and without collimation, respectively.

is in contrast to gamma camera planar data whereby the results may be quantified only with associated calculations that depend upon acquiring a set of images from at least two sides of the patient.

HYBRID IMAGING INSTRUMENTS

Nuclear image information, of either gamma camera or PET type, is limited in that regions of elevated (or reduced) activity are not necessarily identifiable as to anatomic location or even organ type. A patient may exhibit a hot

Figure 14. A PET image of a breast cancer patient following injection of 10 mCi of FDG. A MIPS projection is shown with areas of elevated FDG appearing as dark foci. Note accumulation in regional lymph nodes near the breast primary.

spot in a planar gamma camera view that could correspond to uptake in a lobe of a normal organ, such as the liver or perhaps to an adjacent metastatic site. Similar arguments may be made with SPECT or PET images. Clinical decisions and surgical options are difficult to determine in this ambiguous context. Radiologists viewing nuclear medicine images are forced to cloak their patient assessments in correspondingly vague spatial terms.

Lack of anatomic correlation has been one of the most difficult issues in the history of nuclear imaging. Physiological data determined with nuclear techniques are considered complementary to anatomical information separately obtained by other imaging modalities such as

Figure 13. A clinical PET scanner.

CT or magnetic resonance imaging (MRI). The radiologist or referring clinician will frequently have to conceptually fuse disparate data sets to help identify the specific organ or tissue where a nuclear tracer uptake zone occurs. Using DICOM and PACS technologies, one may also attempt to digitally overlay nuclear and anatomic images. In this case, however, magnification, rotation, and translation of one image relative to the other must be accounted for with appropriate software and adjustable parameters. Using commercial programs, CT and MRI digital images may be fused to nuclear imaging results using least-squares techniques and an external workstation.

In order to remove this conceptual and computational bottleneck, recent developments in nuclear medicine have included manufacture of hybrid physiologic/anatomic imagers. In this strategy, both devices share a common patient bed so that two types of images are spatially registered and, although successive, nonetheless obtained within a few minutes of each other. Note that the PM tubes of a typical gamma camera or PET system are sensitive to magnetic field effects at the level of the earth's value; that is, at ~ 0.5 G. Yet clinical MRI scanners operate in the range of 1.5–3.0 T (1.5×10^4 to 3.0×10^4 G) so that hybrids of MRI and nuclear devices would be problematic. Thus, essentially all of the hybrid systems have involved combinations of nuclear and CT imagers.

SPECT/CT Hybrid Imagers

A logical approach to the issue of radionuclide localization is to have two scanners, one nuclear and one based on X-ray attenuation, located on attached gantries. This pair of devices shares the same patient couch. Because the distances of bed movement can be known within 1 mm or less, the user can identify an uptake volume in the nuclear SPECT image with a geometrically corresponding part of the anatomy as seen via CT scan. Additionally, attenuation corrections may be made more effectively using the CT data to improve SPECT sectional images. Some difficulties remain: (1) the breathing motion of the patient, and (2) possible changes in posture from one sequence to the other during the double imaging procedure. Complementary nature of the two images makes the interpretation of either somewhat clearer.

PET-CT Hybrid Imagers

Analogous to the gamma camera, a PET detector ring imager can be mounted adjacent to a CT scanner to provide registration of images from two modalities. As in the case of SPECT-CT devices, disparities in the speed of the two data acquisitions leads to some remaining ambiguity involving organs that move with respiration such as liver or lungs. While it is possible to hold one's breath for a CT scan, the PET whole body nuclear imaging time remains on the order of 20–30 min to preclude such possibilities for the emission segment of the study. A set of hybrid images and their superimposition are given in Fig. 15.

Radiation therapy treatment planning has been one of the primary beneficiaries of hybrid imaging devices. It may be that some mass lesions visible via CT or other anatomic imagers are necrotic or at least not active meta-

bolically. This result can most clearly be seen in the fused image so that the more physiologically active sites may be treated with higher external beam doses. Likewise, with appropriate resolution, the radiation oncologist may elect to treat part of a lesion that has heterogeneous tracer uptake in an effort to spare contiguous normal (albeit sensitive) sites, such as in the lung, spinal cord, or brain. Those segmental regions of a tumor mass that are metabolically active may be targeted with external beam therapy using a number of linear accelerator strategies including conformal therapy, intensity modulated radiation therapy (IMRT) and tomotherapy using a rotating radiation source.

ANIMAL IMAGING DEVICES

As indicated previously, the growth of nuclear medicine is limited by availability of specific radiopharmaceuticals. Historically, useful agents were often discovered (sometimes by accident) and were almost never invented. This strategy is inefficient and modern molecular biologists and pharmacists attempt to directly engineer improved tracers for a given clinical objective; that is, imaging or therapy of a particular tissue or tumor type. A specific molecule or cellular organelle is generally the target in these efforts. Molecular imaging has become an alternative name for nuclear medicine. After initial protein or nanostructure development is completed, the next task is the determination of the relative usefulness of the prototype in an animal study. Usually, this work involves mouse or rat radiotracer biodistributions involving sacrifice of 5–10 animals at each of a number of serial times. If multiple time points and comparison of various similar radiotracers are involved, numbers of mice may approach thousands for the development of a single radiopharmaceutical.

It is more analogous to clinical procedure if serial images of the same animal are obtained during the course of the research study. Far fewer animals are required and the data are more homogenous internally. Imaging with standardized nuclear technology is generally unsatisfactory due to poor spatial resolution associated with typical gamma cameras (1 cm) or PET scanners (0.5 cm). Early investigators had utilized a suitably small pinhole collimator and gamma camera combination on mouse and rat imaging studies. By collimator magnification, the image can be made large enough that the internal structures can be resolved. As noted previously, magnification and sensitivity depend on distance from the pinhole so that quantitative interpretation of these images was difficult. Sensitivity of pinhole imaging was likewise low so that relatively large amounts of activity were required for the study. It is more effective if a dedicated, high efficiency, animal-size imaging device is designed for the experimental species. Such instruments have been developed for planar and SPECT gamma camera as well as PET imager systems.

Animal Gamma Cameras

Imaging a 10 cm mouse is best done with a gamma camera having approximately that sized crystal. Rather than employing a hexagonal array of multiple, miniaturized PM tubes to locate the scintillation, an animal camera

Figure 15. The CT–PET hybrid image showing respective CT, PET, and combined images. Clarity of location follows from the last of these results.

relies on the use of a single spatially sensitive PM tube. This device sends both x and y coordinates and the energy of the scintillation to a dedicated computer. Otherwise, the murine camera is operated essentially identically to the full-size version. Parallel-hole collimation is most common, although pinholes may be used to form highly magnified images of murine organs, such as the liver, kidneys, or even the thyroid. Figure 16 illustrates the last of these targets for a mouse receiving a tracer injection of ^{125}I to enable imaging of the murine thyroid. SPECT imaging is also possible; it is accomplished by rotating a rigorously constrained mouse or other small animal within the field of view of the camera. The usual projections, coronal, sagittal and transaxial are then available.

Animal PET Imagers

Miniature PET scanners have become of importance to the development of new radiopharmaceuticals. Here, a ring of BGO or LSO crystals is installed in a continuous cylinder extending over the entire length of the mouse. Spatial resolution is on the order of 2 mm or less over the 12 cm axial dimension. A sample image is given in Fig. 17 where a number of coronal sections are superimposed to improve the image statistics. Both ^{18}F -FDG and ^{64}Cu labeled to a

modified antibody protein called the minibody were the positron emitters used in this study. Again, as in the clinical case, the PET images are intrinsically tomographic unlike the gamma camera results. Therefore, the PET animal imagers have a theoretical advantage in biodistribution

Figure 16. Animal gamma camera image of a mouse thyroid. Iodine-123 was used as the tracer with a pinhole collimator to obtain an image of the normal organ.

Figure 17. A PET animal scanner murine image. Both FDG (Image a) and ^{64}Cu -minibody (Image b) were used as radiotracers. Images c and d show pathology and autoradiographic results, respectively.

assays. As mentioned there remains the difficulty of finding a suitable positron emitter and method of attachment for a particular imaging experiment.

Hybrid Animal Imaging Devices

Quantitation of radioactivity at sites within the mouse's body is more easily done with an animal gamma camera than in the comparable clinical situation. This follows since attenuation of photons is relatively slight for a creature only a few cm thick in most cross-sections. Because of this simplicity, the output of the small animal gamma camera imaging systems can be modified to yield percent-injected dose (%ID). In order to correct for organ perfusion, it is historically conventional in biodistribution work using sacrificed animals to obtain uptake in %ID/g of tissue. Given the organ %ID, this last parameter may be obtained if the total mass of the target organ can be determined. Two avenues are available; one may employ miniaturized CT or a reference table of organ sizes for the particular strain of animal being imaged. We should note that suitably sized CT scanners are produced commercially and may be used to estimate organ mass. Hybrid SPECT/CT, PET-CT and SPECT-PET-CT animal imagers are now available for mouse-sized test animals.

One caveat regarding the small-scale imaging devices should be added; these systems cannot give entirely comparable results to biodistribution experiments. In animal sacrifice techniques, essentially any tissue may be dissected for radioactivity assay in a well counter. Miniature cameras and PET systems will show preferentially the highest regions of tracer accumulation. Many tissues may not be observable as their activity levels are not above blood pool or other background levels. Hybrid animal scanners can reduce this limitation, but not eliminate it entirely. Those developing new pharmaceuticals may not be concerned about marginal tissues showing relatively low accumulation, but regulatory bodies, such as the U.S. Food and Drug Administration (FDA), may require their measurement by direct biodistribution assays.

INTRODUCTION

Nuclear medicine (NM) is a medical specialty where radioactive agents are used to obtain medical images for diagnostic purposes, and to a lesser extent treat diseases (e.g., cancer). Since imaging is where computers find their most significant application in NM, imaging will be the focus of this article.

Radioactive imaging agents employed to probe patient pathophysiology in NM consist of two components. The first is the pharmaceutical that dictates the *in vivo* kinetics

Figure 1. Images after a bone scan.

or distribution of the agent as a function of time. The pharmaceutical is selected based on the physiological function it is desired to image. The second component is the radionuclide that is labeled to the pharmaceutical and emits radiation that allows the site of the disintegration to be imaged by a specifically designed detector system (1). An example of an imaging agent is technetium-99 m labeled diphosphate, which is used to image the skeleton. The diphosphate is localized selectively on bone surfaces by 3 h postinjection and the technetium-99 m is a radionuclide that emits a high energy photon when it decays. A normal set of patient bone images of the mid-section is shown in Fig. 1. Another imaging agent example is thallium-201 chloride, which localizes in the heart wall in proportion to local blood flow. In this case, thallium-201 is both the radiopharmaceutical and radionuclide. A normal thallium-201 cardiac study is shown in Fig. 2. A final example is the use of an imaging agent called fluorodeoxyglucose (FDG), which is labeled by the positron emitting fluorine-18. As a glucose analog, FDG is concentrated in metabolically active tissue such as tumors. Figure 3 shows a patient study with FDG uptake in a patient with lung cancer. Dozens of tracers are available to study a variety of pathologies for almost all organs (heart, bones, brain, liver, thyroid, lungs, kidneys, etc.).

Because the amount of radioactivity and the imaging duration are kept at a minimum, NM images are typically noisy and lack detail, compared to images obtained with other modalities, such as X-ray computerized tomography (CT), and magnetic resonance imaging (MRI). However, CT and MRI provide mainly anatomical information. They provide less functional information (i.e., information regarding the way organs work) in the part because these techniques are based on physical properties (such as tissue density...) that are not strikingly different between normal and abnormal tissues. Actually, after recognizing the differences between the anatomically and physiologically based imaging techniques, the current trend in the diagnostic imaging strategies is, as seen below, to combine anatomical information (especially from CT) and functional information provided by NM techniques (2,3).

As seen below, computers play a number of fundamental roles in nuclear medicine (4). First, they are an integral part of the imaging devices where they perform a crucial role in correcting for imaging system limitations during data acquisition. If the acquired data is to be turned from two-dimensional (2D) pictures into a set of three-dimensional (3D) slices, then it is the computer that runs the reconstruction algorithm whereby this is performed.

Figure 2. Normal thallium-201 cardiac study. The first three rows show six slices of the left ventricle in three different axes (vertical long axis, short axis, horizontal long axis) of the heart. The fourth row shows how the images can be reoriented along each axis.

Once the final set of pictures are ready for clinical use, then it is the computer that is used for image display and analysis. The computer is also used for storage of the clinical studies and to allow their use by multiple readers at various sites and time points during patient care as required for optimal usage of the diagnostic information they provide. They are also very useful in research aimed at optimizing imaging strategies and systems, and in the education and training of medical personnel.

NM IMAGING

Computers play an essential role in NM as an integral part of the most common imaging device used in NM, which is a gamma camera, and in the obtention of slices through the body made in emission computerized tomography (ECT). Emission CT is the general term referring to the computer-based technique by which the 3D distribution of a radioactive tracer in the human body is obtained and presented as a stack of 2D slices. The acronym ECT should not be confused with CT (for computerized tomography), which refers to imaging using X rays. Historically, the use of two different kinds of radioactive tracers has led to the parallel

evolution of two types of ECT techniques: Single-photon emission computerized tomography (SPECT) and positron emission tomography (PET). The SPECT technology is used with gamma emitters, that is, unstable nuclei whose disintegration led to the emission of high energy photons, called γ rays. Gamma rays are just like X rays except that X rays are emitted when electrons loose a good amount of energy and γ rays are emitted when energy is given off as a photon or photons during a nuclear disintegration, or when matter and antimatter annihilate. As the name implies, the gamma camera is used with gamma emitters in planar imaging (scintigraphy) where 2D pictures of the distribution of activity within a patients body are made. An illustration of a three-headed SPECT system is shown in Fig. 4. The evolution of SPECT systems has led to a configuration with one, then two and three detectors that are gamma-camera heads. The positron emission tomography is used with emitters whose disintegration results in the emission of a positron (a particle similar to an electron, but with the opposite charge making it the antiparticle to the electron). When a positron that has lost all of its kinetic energy hits an electron, the two annihilate and two photons are emitted from the annihilation. These two photons have the same energy (511 keV) and opposite directions. To

Figure 3. The FDG study for a patient with lung cancer. Upper to lower rows: transverse, sagittal, and coronal slices.

detect these two photons, a natural configuration for a PET system is a set of rings of detectors. The two points of detection of the opposite detectors form a line, called the line of response (LOR). A state-of-the-art PET system combined with an X-ray CT system (PET/CT) is shown in Fig. 5.

A gamma camera has three main parts: the scintillating crystal, the collimator, and the photomultiplier tubes (PMT) (Fig. 6). When the crystal (usually thallium-activated sodium iodide) is struck by a high energy photon (γ or X ray), it emits light (it scintillates). This light is detected by an array of PMT located at the back of the camera. The sum of the currents emitted by all the PMT after one scintillation is proportional to the energy of the incoming

photon, so the γ rays can be sorted according to their energy based upon the electrical signal they generate. Because, for geometrical reasons, the PMT closer to the scintillation see more light than the PMT located farther away, the relative amounts of current of the PMT are used to locate the scintillation. This location alone would be of little use if the direction of the incoming photon was not known. The current way to know the direction is by using a collimator. The collimator is a piece of lead with one or more holes, placed in front of the scintillating crystal, facing the patient. Although different kinds of collimators exist, they are all used to determine, for each incoming photon, its direction before its impact on the crystal. To understand the role of the collimator, one can use the analogy of the gamma-camera with a camera that takes photographs. The

Figure 4. A three-headed SPECT system with the third head below the imaging bed the patient lays on.

Figure 5. Illustration of a state-of-the-art PET/CT system (Philips Medical Systems) with patient bed. The CT system is the first ring-shaped gantry and the PET system is the second ring-shaped gantry. (Reproduced with permission of Philips Medical Systems.)

Figure 6. Main parts of a SPECT camera and basic principle. A gamma photon going through the holes of the collimator strikes the crystal. The crystal restitutes the energy of the gamma photon by scintillation, that is, by emitting some transient ultraviolet (UV) light. Some of the UV light is collected by photomultiplier tubes, whose function is to ensure the transduction of the signal (i.e., the conversion of light into electricity). The location of the scintillation and the energy of the photon are estimated, digitized and sent to the computer.

collimator plays the role of the objective lens in a camera. An image acquired without a collimator would be totally blurry, as would be a photograph taken with a camera with no lens. This is because γ rays are emitted in all directions with equal probabilities, and without a collimator, the photons emitted from a radioactive point source would strike the detector almost uniformly. With a collimator, only the photons whose direction is parallel to the axis of the holes may be potentially detected, while others are stopped by the lead. As a result, the image of a source is (ideally) the projection of the source distribution onto the crystal plane (Fig. 7). Gamma rays can be stopped or scattered, but due to their high penetrating power, it is very difficult to bend them like light rays with lenses, and this is the reason why collimators are used instead of lenses. Photons emitted at different distances from the camera, but along the same direction parallel to a hole, are detected at the same location in the crystal. Thus, the image obtained is the projection of the 3D distribution of the tracer onto the 2D plane of the detector. In that sense, a projection is similar to a chest X ray, in which the images of all the organs (ribs, heart, spine, etc.) are overlaid on the film even though organs do not spatially overlap in the body. The overlay might not be a problem for relatively thin parts of the body, such as a hand, or when tracer-avid structures do not overlap, such as the skeleton. In that case, only one projection is obtained from the best angle of view for the gamma-camera head. As stated above, this technique is called planar imaging, or scintigraphy. However, for other thicker organs like the myocardium and the brain, for which one is interested in measuring the 3D tracer inner distribution, more information is gathered by rotating the heads to acquire projections from multiple angles of view (tomographic acquisition, presented later in this article).

Figure 7. The role of the collimator in a SPECT system.

In PET scanners, hundreds of small crystals arranged in rings are used so that the data can be simultaneously acquired along multiple LOR (Fig. 8). Thousands of photons hit the crystals every second, so how to know which two photons are the result of the same electron-positron annihilation? If two photons are detected almost simultaneously, chances are that they are of the same pair (it is called a true coincidence), so an electronic circuitry checks whether one photon is detected ~ 10 ns (the time window) at most after the previous one. It may happen that, although two photons are detected within that time window, they are not of the same pair, and such an event is called a random coincidence. Because in PET the direction of the photons is known (it is the LOR), collimators are not needed; however, because of the limited counting rate capabilities of older systems, septa made of lead may be used to limit the acquisition to the LORs roughly perpendicular to the axial direction, inside the same ring (2D acquisition). With modern PET systems having a high counting rate capability, a 3D acquisition is possible by detecting LORs even when the two photons hit crystals of different rings.

The computer plays an important role in the formation of the image coming from the gamma camera. As described above, the crystal is viewed by an array of 37 to > 100 , depending on the model, of PMT. These are analog devices that can drift with time. Also the positioning in the image of the location of the flash of light when a γ ray is absorbed in the crystal depends to some extent on where the ray interacts relative to the array of PMT. Such local variations lead to nonuniformity (uneven apparent sensitivity) and

Figure 8. Main parts of a PET system. Pairs of photons are detected in coincidence following the annihilation of a positron with an electron.

nonlinearity (straight lines of activity are bent in the image). Prior to the incorporation of computers into the gamma camera electronics, the impact of such local variations was minimized by allowing the light to spread out before reaching the PMT by passing it through a light guide. This resulted in more PMT receiving enough light to participate in determining the location of the interaction thus improving uniformity and linearity, but at the expense of spatial resolution (i. e., determination of where in the crystal the flash of light originated). Modern gamma cameras incorporate computers to correct for local variations in camera performance so that the light guide is virtually eliminated. This in turn has improved spatial resolution.

Computer correction of the camera image usually takes place in three steps (5). The first is energy correction. As we said, the total magnitude of the signal from all the PMT is related to the energy deposited in the crystal by the γ ray. However, if a large number of γ rays of exactly the same energy interact in the crystal, the magnitude of the electrical signal will vary due to the statistics of turning the light emitted into an electrical signal and local variation in camera performance. By placing a source that will uniformly irradiate the crystal, such as the commercial sheet source shown in Fig. 9, the local variation on average in the magnitude of the signal can be determined on a pixel by pixel basis by computer. The centering of the window employed to select electrical pulses for inclusion in image formation can then be adjusted to give a more uniform response.

Besides varying in the average size of the total electrical pulse detected from the PMT locally, gamma cameras vary in how well they map the true location of the flash of light into its perceived location in the image. Thus, in some regions, detected events are compressed together and in others they are spread apart. Correction of this nonlinear mapping constitutes the second step in computer correction of the gamma-camera image and is called linearity correction. Linearity correction is performed by placing an attenuating sheet with an exactly machined array of very small holes in a precise location between the gamma

Figure 9. Radioactive sheet source in front of the third head of a three-headed SPECT system in position for checking uniformity and loading correction factors.

Figure 10. Output from checking camera uniformity when a single PM on head 2 of the three-headed SPECT system of Fig. 9 has failed.

camera and the sheet source of Fig. 9. A high resolution image consisting of a large number of gamma-ray events is then acquired. The images of the holes do not match where they should appear. The vector displacement of the image of the hole back to its true location defines how the mapping from true to detected location is inaccurate at that location. By using the computer to interpolate between the array of measured distortions at the pixel level, a map is generated giving how each event detected at a location in the crystal should be displaced in the resulting image.

The final step in image correction is called flood correction. If an image of a large number of events from a sheet source is acquired with energy and linearity correction enabled, then any residual nonuniformity is corrected by determining with computer a matrix that when multiplied by this image would result in a perfectly uniform image of the same number of counts. This matrix is then saved and used to correct all images acquired by the gamma camera before they are written to disk.

An example of testing camera uniformity is shown in Fig. 10. Here again, a sheet source of radioactivity is placed in front of the camera head as shown in Fig. 9. High count images of the sheet source are inspected numerically by computer and visually by the operator each day before the camera is employed clinically. Heads 1 and 3 in Fig. 10 show both numerically and visually good uniformity. A large defect is seen just below and to the left of center in the image from head 2. This is the result of the failure of a single PMT. A single PMT affects a region much larger than its size because it is the combined output of all the PMT close to the interaction location of a gamma-ray that are used to determine its location.

Images can be classified in two types, mutually exclusive: analog or digital. A chest X ray on a film is a typical example of an analog image. Analog images are not divided into a finite number of elements, and the values in the image can vary continuously. An example of digital image is a photograph obtained with a digital camera. Much like roadmaps, a digital image is divided into rows and columns, so that it is possible to find a location given its row

Figure 11. Left: example of an 8×8 image. Each square represents a pixel. The dark gray borders of each square have been added here for sake of clarity, but are not present in the image when stored on the computer. Each pixel has a level of gray attached to it. Right: the values in each pixel. In its simplest form, the image is stored in a computer as a series of lexicographically ordered values. The rank of each value in the series defines the pixel location in the image (e.g., the 10th value of the series refers to the 10th pixel of the image). There is a 1:1 relationship between the brightness and the value. The correspondence between the color and the value is defined in a table called look-up table (LUT) or a color map. An image can be a shade of grays (black and white) or in color.

and column. The intersection of a row and a column defines one picture element, or pixel, of the image. Each pixel has a value that usually defines its brightness, or its color. A digital image can be seen as a rectangular array of values (Fig. 11), and thus be considered, from a mathematical point of view, as a matrix. Computers cannot deal with analog values, so whenever an analog measurement (here, the current pulse generated after the impact of a gamma photon in the crystal) is made, among the first steps is the analog-to-digital conversion (ADC), also called digitization. The ADC is the process during that an infinite number of possible values is reduced to a limited (discrete) number of values, by defining a range (i.e., minimum and maximum values), and dividing the range into intervals, or bins (Fig. 12). The performance of an ADC is defined by its ability to yield a digital signal as close as possible to the analog input. It is clear from Fig. 12 that the digitized data are closer to the analog signal when the cells are smaller. The width of the cells is defined by the sampling rate, that is, the number of measurements the ADC can convert per unit of time. The height of the cells is defined by the resolution of the ADC. A 12-bit resolution means that the ADC sorts the amplitude of the analog values among one of $2^{12} = 4096$ possible values. The ADC has also a range, that is, the minimum and maximum analog amplitudes it can handle. For example, using a 12-bit analog-to-digital converter with a -10 to $+10$ V range (i.e., a 20 V range), the height of each cell is $20/4096$ (i.e., ~ 0.005 V). Even if the analog signal is recorded with a 0.001 V accuracy, after ADC the digital signal accuracy will be at best 0.005 V. The point here is that any ADC is characterized by its sampling rate, its resolution and its range. Both the SPECT and PET systems measure the location and the energy of the photons hitting their detectors. The measurements are initially analog, and are digitized as described above before being stored on a computer. In SPECT, prior

Figure 12. (a) Example of an analog signal, for example the intensity of gray (vertical axis) along a line (horizontal axis) drawn on a photograph taken with a nondigital camera. (b) The process of ADC, for example when the photograph is scanned to be archived as an image file on a computer. The 2D space is divided into a limited number of rectangular cells as indicated by the tick marks on both axes. For sake of clarity, only the cells whose center is close to the analog signal are drawn in this figure, and this set of cells is the result of the ADC. (c) The digital signal is drawn by joining the center of the cells, so that one can compare the two signals.

to the beginning of the acquisition, the operator chooses the width and height (in pixels) of the digital image to be acquired. Common sizes are 64 by 64 pixels (noted 64×64 , width by height), 128×128 or 256×256 . Dividing the size of the field of view (in cm) by the number of pixels yields the pixel size (in cm). For example, if the usable size for the detector is 40×40 cm, the pixel size is $40/64 = 0.66$ cm for a 64×64 image. Because all devices are imperfect, a point source is seen as a blurry spot on the image. If two radioactive point sources in the field of view are close enough, their spots overlap each other. When the two sources get closer, at some point the spots cannot be visually separated in the image. The smallest distance between the sources that allows us to see one spot for each source is called the spatial resolution. The pixel size is not to be confused with the spatial resolution. While the pixel size is chosen by the operator, the spatial resolution is imposed by the camera characteristics, and most notably by the collimator now that thick light guides are no longer employed. The pixel size is chosen to be smaller than the resolution, so that we can get as much detail as the resolution allows us to get, but it is important to understand that using a pixel size much smaller than the resolution does not increase the image quality. If the pixel size is small (i.e., when the number of pixels in the field of view is large), then the spot spills over many pixels, but with no improvement to image resolution.

The energy resolution (i.e., the smallest change in energy the detector can measure) is limited, and its value has a great impact on image quality, as explained below. Between the points of emission and detection, photons with an energy < 1 MeV frequently interact with electrons by scattering, during which their direction changes and some of their energy is lost. Because their direction changes, an error is made on their origin. However, it is possible to know that a photon is scattered because it has lost some energy, so an energy window, called the photopeak window defined around the energy of nonscattered (primary) photons (the photopeak), is defined prior to the acquisition, and the scattered photons whose energy falls outside the

photopeak window can be identified by energy discrimination and ignored. Unfortunately, photons in the photopeak window can either be scattered photons, or a primary photon whose energy has been underestimated (due to the limited energy resolution of the detectors, an error can be made regarding the actual energy of the photons). If the photopeak window is wide, many scattered photons are accepted, and the image has a lot of scattered activity that reduces the contrast; if the energy window is narrow, many primary photons are rejected, and the image quality is poor because of a lack of signal. As the energy resolution increases, the energy window can be narrowed, so that most scattered photons can be rejected while most primary photons are kept.

As mentioned above, the 3D distribution of the tracer in the field of view is projected onto the 2D plane of the camera heads. As opposed to the list-mode format (presented later in this article), the projection format refers to the process of keeping track of the total number of photons detected (the events, or counts) for each pixel of the projection image. Each time a count is detected for a given pixel, a value of 1 is added to the current number of counts for that pixel. In that sense, a projection represents the accumulation of the counts on the detector for a given period of time. If no event is recorded for any given pixel, which is not uncommon especially in the most peripheral parts of the image, then the value for that pixel is 0. Usually, 16 bits (2 bytes) are allocated to represent the number of counts per pixel, so the range for the number of events is 0 to $2^{16}-1 = 65,535$ counts per pixel. In case the maximal value is reached for a pixel (e.g., for a highly active source and a long acquisition time), then the computer possibly stops incrementing the counter, or reinitializes the pixel value to 0 and restarts counting from that point on. This yields images in which the most radioactive areas in the image may paradoxically have a lower number of counts than surrounding, less active, areas.

Different acquisitions are possible with a gamma camera:

Planar (or static): The gamma-camera head is stationary. One projection is obtained by recording the location of the events during a given period from a single angle of view. This is equivalent to taking a photograph with a camera. The image is usually acquired when the tracer uptake in the organ of interest has reached a stable level. One is interested in finding the quantity of radiopharmaceutical that accumulated in the region of interest. Planar images are usually adequate for thin or small structures (relative to the resolution of the images), such as the bones, the kidneys, or the thyroid.

Whole body: This acquisition is similar to the planar acquisition, in the sense that one projection is obtained per detector head, but is designed, as the name implies, to obtain an image of the whole body. Since the human body is taller than the size of the detector ($\sim 40 \times 40$ cm), the detector slowly moves from head to toes. This exam is especially indicated when looking for metastases. When a cancer starts developing at a primary location, it may happen that

cancer cells, called metastases, disseminate in the whole body, and end up in various locations, especially bones. There, they may start proliferating and a new cancer may be initiated at that location. A whole-body scintigraphy is extremely useful when the physician wants to know whether one or more secondary tumors start developing, without knowing exactly where to look at.

Dynamic: Many projections are successively taken, and each of them is typically acquired over a short period (a few seconds). This is equivalent to recording of a movie. Analyzing the variations as a function of time allows us to compute parameters, such as the uptake rate, which can be a useful clinical index of normality.

Gated: The typical application of a gated acquisition is the cardiac scintigraphy. Electrodes are placed on the patient's chest to record the electrocardiogram (ECG or EKG). The acquisition starts at the beginning of the cardiac cycle, and a dynamic sequence of 8 or 16 images is acquired over the cardiac cycle (~ 1 s), so that a movie of the beating heart is obtained. However, the image quality is very poor when the acquisition is so brief. So, the acquisition process is repeated many times (i.e., over many heart beats), and the first image of all cardiac cycles are summed together, the second image of all cardiac cycles are summed together, and so on.

Tomographic: The detector heads are rotating around the patient. Projections are obtained under multiple angles of view. Through a process called tomographic reconstruction (presented in the next section), the set of 2D projections is used to find the 3D distribution of the tracer in the body, as a stack of 2D slices. The set of 1D projections of one slice for all projection angles is called a sinogram.

Tomographic gated: As the name implies, this acquisition is a tomographic one with gating information. The ECG is recorded during the tomographic acquisition, and for each angle of view, projections are acquired over many cardiac cycles, just as with a gated acquisition (see above). Thus, a set of projections is obtained for each point of the cardiac cycle. Each set is reconstructed, and tomographic images are obtained for each point of the cardiac cycle.

In contrast with the types of acquisition above in which the data are accumulated in the projection matrix for several seconds or minutes (frame-mode acquisition), a much less frequent type of acquisition called list-mode acquisition, can also be useful, because more information is available in this mode. As the name implies, the information for each individual event is listed in the list-mode file, and are not arranged in a matrix array. In addition to the coordinates of the scintillations, additional data are stored in the file. Figure 13 illustrates the typical list-mode format for a SPECT system. List-mode information is similar with a PET system, except that the heads location and X - Y coordinates are replaced with the location of the event on the detector rings. The list-mode file (~ 50 Mb

Figure 13. Example of data stored on-the-fly in a list-mode file data in a SPECT system. Gantry angle defines the location of the detectors. The X and Y coordinates are given in a 2048 × 2048 matrix. The energy is a 12-bit value (i.e., between 0 and 4,095), and a calibration is required to convert these values in usual units (i.e., kiloelectron volt, keV).

in size in SPECT) can be quite large relative to a projection file. The list-mode format is far less common than the projection format, because it contains information, such as timing, that would usually not be used for a routine clinical exam. The list-mode data can be transformed into projection data through a process called rebinning (Fig. 14). Since the timing is known, multiple projections can be created as a function of time, thus allowing the creation of “movies” whose rate can be defined postacquisition. A renewed interest in the list-mode format has been fueled these past years by the temporal information it contains, which is adequate for the temporal correlation of the acquisition with patient, cardiac, or respiratory motions through the synchronized acquisition of signal from motion detectors.

TOMOGRAPHIC RECONSTRUCTION

Tomographic reconstruction has played a central role in NM, and has heavily relied on computers (6). In addition to data acquisition control, tomographic reconstruction is the other main reason for which computers have been early introduced in NM. Among all uses of computers in NM, tomographic reconstruction is probably the one that symbolizes most the crunching power of computers. Tomographic reconstruction is the process by which slices of the 3D distribution of tracers are obtained based upon the projections obtained under different angles of view. Because the radioactivity emitted in the 3D space is projected on the 2D detectors, the contrast is usually low. Tomographic reconstruction greatly restores the contrast, by estimating the 3D tracer distribution. Reconstruction is possible using list-mode data (SPECT or PET), but mainly

Figure 14. Rebinning process. (a) The line joining pairs of photons detected in coincidence is called a line of response (LOR). (b and c) LOR are sorted so that parallel LOR are grouped, for a given angle.

Figure 15. The SPECT acquisition. Left. A three-head IRIX SPECT system (Philips Medical Systems). A subject is in the field of view while the camera heads are slowly rotating around him. Right. Physical model and geometric considerations. The 2D distribution of the radioactivity $f(x,y)$ in one slice of the body is projected and accumulated onto the corresponding 1D line $g(s,\theta)$ of detector bins.

for research purposes. The PET data, although initially acquired in list-mode format, are usually reformatted to form projections, so that the algorithms developed in SPECT can also be used with PET data. There are many different algorithms, mainly the filtered back-projection (FBP) and the iterative algorithms, that shall be summarized below (7–9).

In the following, focuses on tomographic reconstruction when input data are projections, which is almost always the case on SPECT systems. During a SPECT acquisition, the detecting heads rotate around the subject to gather projections from different angles of views (Fig. 15). Figure 16 presents the model used to express the simplified projection process in mathematical terms. Associated with the projection is the backprojection (Fig. 17). With back-projection, the activity in each detector bin g is added to all the voxels which project onto bin g . It can be shown (10) that backprojecting projections filtered with a special filter called a ramp filter (filtered backprojection, or FBP) is a way to reconstruct slices. However, the ramp filter is known to increase the high frequency noise, so it is usually combined with a low pass filter (e.g., Butterworth filter) to form a band-pass filter. Alternatively, reconstruction can be performed with the ramp filter only, and then the reconstructed images can be smoothed with a 3D low pass filter. The FBP technique yields surprisingly good results considering the simplicity of the method and its approximations, and is still widely used today. However, this rather crude approach is more and more frequently replaced by the more sophisticated iterative algorithms, in which many corrections can be easily introduced to yield

more accurate results. An example of an iterative reconstruction algorithm includes the following steps:

1. An initial estimate of the reconstructed is created, by attributing to all voxels the same arbitrary value (e.g. 0 or 1).
2. The projections of this initial estimate are computed.
3. The estimated projections are compared to the measured projections, either by computing their difference or their ratio.
4. The difference (resp. the ratio) is added (resp. multiplied) to the initial estimate to get a new estimate.
5. Steps 2–4 are repeated until the projections of the current estimate are close to the measured projections.

Figure 18 illustrates a simplified version of the multiplicative version of the algorithm. This example has been voluntarily oversimplified for sake of clarity. Indeed, image reconstruction in the real world is much more complex for several reasons: (1) images are much larger; typically, the 3D volume is made of $128 \times 128 \times 128$ voxels, (2) geometric considerations are included to take into account the volume of each volume element (voxel) that effectively project onto each bin at each angle of view, (3) camera characteristics, and in particular the spatial resolution, mainly defined by the collimator characteristics, are introduced in the algorithm, and (4) corrections presented below are applied during the iterative process. The huge number of operations made iterative reconstruction a slow process and prevented its routine use until recently, and FBP was

Figure 16. Projection. Each plane in the FOV (left) is seen as a set of values f (center). The collimator is the device that defines the geometry of the projection. The values in the projections are the sum of the values in the slices. An example is presented (right). preferred. Modern computers are now fast enough for iterative algorithms, and since these algorithms have many advantages over the FBP, they are more and more widely used.

A number of corrections usually need to be applied to the data during the iterative reconstruction to correct them for various well-known errors caused by processes associated with the physics of the detection, among which the more important are attenuation (11–13), Compton scattering (11,12), depth-dependent resolution (in SPECT) (11,12), random coincidences (in PET) (14), and partial volume effect (15). These sources of error below are briefly presented:

Attenuation occurs when photons are stopped (mostly in the body), and increases with the thickness and the density of the medium. Thus, the inner parts of the body usually appear less active than the more superficial parts (except the lungs, whose low density makes them almost transparent to gamma photons and appear more active than the surrounding soft tissues). Attenuation can be compensated by multiplying the activity in each voxel by a factor whose value depends upon the length and the density of the tissues encountered along the photons path. The correction factor can be estimated (e.g., by assuming a uniform attenuation map) or measured using an external radioactive source irradiating the subject. A third possibility, which is especially attractive with the advent of SPECT/CT and PET/CT systems (presented below), is to use the CT images to estimate the attenuation maps.

Photons may be scattered when passing through soft tissues and bones, and scattered photons are deflected from their original path. Because of the error in the estimated amount of the scattered photons, images are slightly blurred and contrast decreases. As mentioned in the previous section, the effects of scattering can be better limited by

Figure 18. A simplified illustration of tomographic reconstruction with an iterative algorithm. (a) The goal is to find the values in a slice (question marks) given the measured projection values 7, 10, 3, 6, 9, 5. (b) Voxels in the initial estimate have a value of 1, and projections are computed as described in Fig. 17. (c) The error in the projections is estimated by dividing the actual values by the estimated values. The ratios are then backprojected to get a slice of the “error”. (d) Multiplying the error obtained in c by the estimate in b yields a second estimate, and projections are computed again (g). After an arbitrary number of iterations (e, f), an image whose projections are close to the measured projections is obtained. This image is the result of the iterative tomographic reconstruction process. Such a process is repeated for the stack of 2D slices.

using detectors with a high energy resolution. Scatter can also be estimated by acquiring projection data in several energy windows during the same acquisition. Prior to the acquisition, the user defines usually two or three windows per photopeak (the photopeak window plus two adjacent windows, called the scatter windows). As mentioned, photons can be sorted based upon their energy, so they can be assigned to one of the windows. The amount of scatter is estimated in the photopeak window using projection data acquired in the scatter windows, and assuming a known relationship between the amount of scattering and the energy. Another approach to Compton scattering compensation uses the reconstructed radioactive distribution and attenuation maps to determine the amount of scatter using the principles of scattering interactions.

In SPECT, collimators introduce a blur (i.e., even an infinitely small radioactive source would be seen as a spot of several mm in diameter) for geometrical reasons. In addition, for parallel collimators (the most commonly used, in which the holes are parallel), the blur increases as the distance between the source and the collimator increases. Depth-dependent resolution can be corrected either by fil-

tering the sinogram in the Fourier domain using a filter whose characteristics vary as a function of the distance to the collimator (frequency–distance relationship, FDR) or by modelling the blur in iterative reconstruction algorithms.

In PET, a coincidence is defined as the detection of two photons (by different detectors) in a narrow temporal window of ~ 10 ns. As mentioned, a coincidence is true when the two photons are of the same pair, and random when the photons are from two different annihilations. The amount of random coincidences can be estimated by defining a delayed time window, such that no true coincidence can be detected. The estimation of the random coincidences can then be subtracted from the data including both true and random, to extract the true coincidences.

Partial volume effect (PVE) is directly related to the finite spatial resolution of the images: structures that are small (about the voxel size and smaller) see their concentration underestimated (the tracer in the structure appears as being diluted in the voxel). Spillover is observed at the edges of active structures: some activity spreads outside the voxels, so that although it stems from the structure, it is actually detected in neighboring voxels. Although several techniques exist, the most accurate can be implemented when the anatomical boundaries of the structures are known. Thus, as presented below, anatomical images from CT scanners are especially useful for PVE and spillover corrections, if they can be correctly registered with the SPECT or PET data.

IMAGE PROCESSING, ANALYSIS AND DISPLAY

Computers are essential in NM not only for their ability to control the gamma cameras and to acquire images, but also because of their extreme ability to process, analyze and display the data. Computers are essential in this respect because (1) the amount of data can be large (millions of pixel values), and computers are extremely well suited to handle images in their multimegabytes memory, (2) repetitive tasks are often needed and central processor units (CPUs) and array processors can repeat tasks quickly, (3) efficient algorithms have been implemented as computer programs to carry on complex mathematical processing, and (4) computer monitors are extremely convenient to display images in a flexible way.

Both the PET and SPECT computers come with a dedicated, user-friendly graphical environment, for acquisition control, patient database management, and a set of programs for tomographic reconstruction, filtering and image manipulation. These programs are usually written in the C language or in Fortran, and compiled (i.e., translated in a binary form a CPU can understand) for a given processor and a given operating system (OS), usually the Unix OS (The Open Group, San Francisco CA) or the Windows OS (Microsoft Corporation, Redmond WA). As an alternative to these machine-dependent programs, Java (Sun Microsystems Inc.) based programs have been proposed (see next section).

As seen in the first section, an image can be seen as a rectangular array of values, which is called, from a mathematical point of view, a matrix. A large part of image

processing in NM is thus based upon linear algebra (16), which is the branch of mathematics that deals with matrices. One of the problems encountered in NM imaging is the noise (random variations due to the probabilistic nature of the radioactive processes and to the limited accuracy of the measurements). A number of methods are available to reduce the noise after the acquisition, by smoothing the minor irregularities or speckles in the images (10). The most common way to filter images is by convolution (a pixel value is replaced by a weighted average of its neighbors) or by Fourier methods. Computers are extremely efficient at computing discrete Fourier transforms thanks to a famous algorithm called the fast Fourier transform (FFT) developed by Cooley and Tukey (17).

The NM images can be displayed or printed in black and white (gray levels) or in color. Pixel values can be visually estimated based on the level of gray or based on the color. Color has no special meaning in NM images, and there is no consensus about the best color map to use. Most often, a pixel value represents a number of counts, or events. However, units can be something else (e.g., flow units), especially after some image processing. So, for proper interpretation, color map and units should always accompany an image.

Regions of interest (ROIs) are defined by line segments drawn to set limits in images and can have any shape or be drawn by hand. The computer is then able to determine which pixels of the image are out and which are in the ROI, and thus computations can be restricted to the inside or to the outside of the ROI. ROIs are usually drawn with the mouse, based on the visual inspection of the image. Drawing a ROI is often a tricky task, due to the low resolution of the images and to the lack of anatomical information regarding the edges of the organs. In an attempt to speed up the process, and to reduce the variability among users, ROIs can also be drawn automatically (18). When a dynamic acquisition is available, a ROI can be drawn on one image and reported on the other images of the series, the counts in the ROI are summed and displayed as a time–activity curve (TAC), so that one gets an idea of the kinetics of the tracer in the ROI. The TAC are useful because with the appropriate model, physiological parameters such as pharmacological constants or blood flow can be determined based on the shape of the curve. An example of dynamic studies with ROI and TAC is the renal scintigraphy, whose goal is to investigate the renal function through the vascularization of the kidneys, their ability to filter the blood, and the excretion in the urine. A tracer is administered with the patient lying on the bed of the camera, and a two-stage dynamic acquisition is initiated: many brief images are acquired (e.g., 1 image per second over the first 60 s). Then, the dynamic images are acquired at a lower rate (e.g., 1 image per minute for 30 min). After the acquisition, ROIs are drawn over the aorta, the cortical part of the kidneys, and the background (around the kidneys), and the corresponding TAC are generated for analysis (Fig. 19). The TAC obtained during the first stage of the acquisition reflect the arrival of the tracer in the renal arteries (vascular phase). The rate at which the tracer invades the renal vascularization, relative to the speed at which it arrives in the aorta above indicates whether the kidneys

Figure 19. Output of a typical renal scintigraphy. Left: the TAC for both kidneys in the first minute after injection of the tracer. The slope of the TAC gives an indication of the state of the renal vascularization. Center: One-minute images acquired over 32 min after injection. The ascending part evidences the active tracer uptake by the kidneys, while the descending part shows the excretion rate. Right: Insert shows the accumulation of the tracer in the bean-shaped kidneys. The ROI are drawn over the kidneys and the background.

are normally vascularized. The renal TAC obtained in the second stage of the acquisition (filtration phase) show the amount of tracer captured by the kidneys, so that the role of the kidneys as filters can be assessed. When the tracer is no longer delivered to the kidneys, and as it passes down the ureters (excretion phase), the latest part of the renal curves normally displays a declining phase, and the excretion rate can be estimated by computing the time of half-excretion (i.e., the time it takes for the activity to decrease from its peak to half the peak), usually assuming the decrease is an exponential function of time.

The corrections presented at the end of the previous section are required to obtain tomographic images in which pixel values (in counts per pixel) are proportional to the tracer concentration with the same proportion factor (relative quantitation), so that different areas in the same volume can be compared. When the calibration of the SPECT or PET system is available (e.g., after using a phantom whose radioactive concentration is known), the images can be expressed in terms of activity per volume unit, (e.g., in becquerels per milliliters, $\text{Bq}\cdot\text{mL}^{-1}$; absolute quantitation). Absolute quantitation is required in the estimation of a widely used parameter, the standardized uptake value (SUV) (19), which is an index of the FDG uptake that takes into account the amount of injected activity and the dilution of the tracer in the body. The SUV in the region of interest is computed as $\text{SUV} = (\text{uptake in the ROI in } \text{Bq}\cdot\text{mL}^{-1}) / (\text{injected activity in } \text{Bq}/\text{body volume in mL})$. Another example of quantitation is the determination of the blood flow (in $\text{mL}\cdot\text{g}^{-1}\cdot\text{min}^{-1}$), based upon the pixel values and an appropriate model for the tracer kinetics in the area of interest. For example, the absolute regional cerebral blood flow (rCBF) is of interest in a number of neurological pathologies (e.g., ischemia, haemorrhage, degenerative diseases, epilepsy). It can be determined with xenon ^{133}Xe , a gas that has the interesting property of being washed out from the brain after its inhalation as a simple exponential function of the rCBF. Thus, the rCBF can be assessed after at least two fast tomographic acquisitions (evidencing the differential decrease in activity in the various parts of the brain), for example, using the Tomomatic 64 SPECT system (Medimatic, Copenhagen, Denmark) (20).

An example of image processing in NM is the equilibrium radionuclide angiography (ERNA) (21), also called multiple gated acquisition (MUGA) scan, for assessment of

the left ventricle ejection fraction (LVEF) of the heart. After a blood sample is taken, the erythrocytes are labelled with $^{99\text{m}}\text{Tc}$ and injected to the patient. Because the technetium is retained in the erythrocytes, the blood pool can be visualized in the images. After a planar cardiac gated acquisition, 8 or 16 images of the blood in the cardiac cavities (especially in the left ventricle) are obtained during an average cardiac cycle. A ROI is drawn, manually or automatically, over the left ventricle, in the end-diastolic (ED) and end-systolic (ES) frames, that is, at maximum contraction and at maximum dilatation of the left ventricle respectively. Another ROI is also drawn outside the heart for background activity subtraction. The number of counts nED and nES in ED and ES images, respectively, allows the calculation of the LVEF as $\text{LVEF} = (\text{nED} - \text{nES}) / \text{nED}$. Acquisitions for the LVEF assessment can also be tomographic in order to improve the delineation of the ROI over the left ventricle, and several commercial softwares are available (22) for largely automated processing, among which the most widely used are the Quantitative Gated SPECT (QGS) from the Cedars-Sinai Medical Center, Los Angeles, and the Emory Cardiac Tool box (ECTb) from the Emory University Hospital, Atlanta.

INFORMATION TECHNOLOGY

An image file typically contains, in addition to the image data, information to identify the images (patient name, hospital patient identification, exam date, exam type, etc.), and to know how to read the image data (e.g., the number of bytes used to store one pixel value). File format refers to the way information is stored in computer files. A file format can be seen as a template that tell the computer how and where in the file data are stored. Originally, each gamma-camera manufacturer had its own file format, called proprietary format, and for some manufacturers the proprietary format was confidential and not meant to be widely disclosed. To facilitate the exchange of images between different computers, the Interfile format (23) was proposed in the late 1980s. Specifically designed for NM images, it was intended to be a common file format that anyone could understand and use to share files. At the same period, the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA) developed their standard for NM, radiology, MRI and ultrasound images: the ACR-NEMA file format, version 1.0 (in 1985)

and 2.0 (in 1988). In the early 1990s, local area networks (LANs) connecting NM, radiology and MRI departments started to be installed. Because Interfile was not designed to deal with modalities other than NM, and because ACR-NEMA 2.0 was "only" a file format, and was not able to handle robust network communications to exchange images over a LAN, both became obsolete and a new standard was developed by the ACR and the NEMA, ACR-NEMA 3.0, known as Digital Imaging and Communications in Medicine (DICOM) (24). Although quite complex (the documentation requires literally thousands of pages), DICOM is powerful, general in its scope and designed to be used by virtually any profession using digital medical images. Freely available on the Internet, DICOM has become a standard among the manufacturers, and it is to be noted that DICOM is more than a file format. It also includes methods (programs) for storing and exchanging image information; in particular, DICOM servers are programs designed to process requests for handling DICOM images over a LAN.

DICOM is now an essential part of what is known as Picture Archiving and Communications Systems (PACS). Many modern hospitals use a PACS to manage the images and to integrate them into the hospital information system (HIS). The role of the PACS is to identify, store, protect (from unauthorized access) and retrieve digital images and ancillary information. A web server can be used as an interface between the client and the PACS (25). Access to the images does not necessarily require a dedicated software on the client. A simple connection to the Internet and a web browser can be sufficient, so that the images can be seen from the interpreting or prescribing physician's office. In that case, the web server is responsible for submitting the user's request to the PACS, and for sending the image data provided by the PACS to the client, if the proper authorization is granted. However, in practice, the integration of NM in a DICOM-based PACS is difficult, mainly because PACS evolved for CT and MR images (26,27), that is, as mostly static, 2D, black and white images. The NM is much richer from this point of view, with different kinds of format (list-mode, projections, whole-body, dynamic, gated, tomographic, tomographic gated, etc.) and specific postacquisition processing techniques and dynamic displays. The information regarding the colormaps can also be a problem for a PACS when dealing with PET or SPECT images fused with CT images (see next section) because two different colormaps are used (one color, one grayscale) with different degrees of image blending.

In the spirit of the free availability of programs symbolized by the Linux operating system, programs have been developed for NM image processing and reconstruction as plug-ins to the freely available ImageJ program developed at the U.S. National Institutes of Health (28). ImageJ is a general purpose program, written with Java, for image display and processing. Dedicated Java modules (plugs-in) can be developed by anyone and added as needed to perform specific tasks, and a number of them are available for ImageJ (29). Java is a platform-independent language, so that the same version of a Java program can run on different computers, provided that another program, the Java virtual machine (JVM), which is platform-dependent,

has been installed beforehand. In the real world, however, different versions of the JVM may cause the Java programs to crash or to cause instabilities when the programs require capabilities the JVM cannot provide (30). The advantage of the Java programs is that they can be used inside most Internet browsers, so that the user has no program to install (except the JVM). A Java-based program called JaRVis (standing for Java-based remote viewing station) has been proposed in that spirit for viewing and reporting of nuclear medicine images (31).

It is very interesting to observe how, as the time goes by, higher levels of integration have been reached: with the early scintigraphy systems, such as rectilinear scanners (in the 1970s), images were analog, and the outputs were film or paper hard copies. In the 1980s images were largely digital, but computers were mainly stand alone machines. One decade later, computers were commonly interconnected through LANs, and standard formats were available, permitting digital image exchange and image fusion (see next section). Since the mid-1990s, PACS and the worldwide web make images remotely available, thus allowing telemedicine.

HYBRID SPECT/CT AND PET/CT SYSTEMS

Multimodality imaging (SPECT/CT and PET/CT) combines the excellent anatomical resolution of CT with SPECT or PET functional information (2,3). Other advantages of multimodality are (1) the use of CT images to estimate attenuation and to correct for PVE in emission images, (2) the potential improvement of emission data reconstruction by inserting in the iterative reconstruction program prior information regarding the locations of organ and/or tumor boundaries, and (3) the possible comparison of both sets of images for diagnostic purposes, if the CT images are of diagnostic quality. The idea of combining information provided by two imaging modalities is not new, and a lot of work has been devoted to multimodality. Multimodality initially required that the data acquired from the same patient, but on different systems and on different occasions, be grouped on the same computer, usually using tapes to physically transfer the data. This was, ~ 20 years ago, a slow and tedious process. The development of hospital computer network in the 1990s greatly facilitated the transfer of data, and the problem of proprietary image formats to be decoded was eased when a common format (DICOM) began to spread. However, since the exams were still carried out in different times and locations, the data needed to be registered. Registration can be difficult, especially because emission data sometimes contain very little or no anatomical landmarks, and external fiducial markers were often needed. Given the huge potential of dual-modality systems, especially in oncology, a great amount of energy has been devoted in the past few years to make it available in clinical routine. Today, several manufacturers propose combined PET/CT and SPECT/CT hybrid systems (Fig. 20): The scanners are in the same room, and the table on which the patient lies can slide from one scanner to the other (Fig. 21). An illustration of PET/CT images is presented in Fig. 22.

Figure 20. Current commercial PET/CT scanners from 4 major vendors of PET imaging equipment: (a) Hawkeye (GE Medical Systems); (b) Biograph (Siemens Medical Solutions) or Reveal (CTI, Inc); (c) Discovery LS (GE Medical Systems); (d) Discovery ST (GE Medical Systems); (e) Gemini (Philips Medical Systems); (f) Biograph Sensation 16 (Siemens Medical Solutions) or Reveal XVI (CTI, Inc.). (Reproduced from Ref. 2, with permission of the Society of Nuclear Medicine Inc.)

Although patient motion is minimized with hybrid systems, images from both modalities are acquired sequentially, and the patient may move between the acquisitions, so that some sort of registration may be required before PET images can be overlaid over CT images. Again, computer programs play an essential role in finding the best correction to apply to one dataset so that it matches the other dataset. Registration may be not too difficult with relatively rigid structures, such as the brain, but tricky for chest imaging for which nonrigid transformations are needed. Also, respiratory motion introduces in CT images mushroom-like artifacts that can be limited by asking the patients to hold their breath at mid-respiratory cycle during CT acquisition, so that it best matches the average images obtained in emission tomography with no respiratory gating.

Dedicated programs are required for multimodality image display (1) to match the images (resolution, size, orientation); (2) to display superimposed images from both modalities with different color maps (CT data are

Figure 21. Schematic of PET/CT developed by CPS Innovations. Axial separation of two imaging fields is 80 cm. The coscan range for acquiring both PET and CT has maximum of 145 cm. (Reproduced from Ref. 2, with permission of the Society of Nuclear Medicine Inc.)

Figure 22. Image of a 66 years old male patient with history of head-and-neck cancer. In addition to ^{18}F FDG uptake in lung malignancy, intense uptake is seen on PET scan (a) in midline, anterior and inferior to bladder. Note also presence of lung lesion (arrowhead) due to primary lung cancer. $^{99\text{m}}\text{Tc}$ bone scan (b) subsequently confirmed that uptake was due to metastatic bone disease. PET/CT scan (c) directly localized uptake to pubic ramus (arrowed). (Reproduced from Ref. 2, with permission of the Society of Nuclear Medicine Inc.)

typically displayed with a gray scale, while a color map is used to display the tracer uptake); (3) to adjust the degree of transparency of each modality relative to the other in the overlaid images; and (4) to select the intensity scale that defines the visibility of the bones, soft tissues and lungs in the CT images. For the interpretation of SPECT/CT or PET/CT data, the visualization program has to be optimized, for so much information is available (dozens of slices for each modality, plus the overlaid images, each of them in three perpendicular planes) and several settings (slice selection, shades of gray, color map, the degree of blending of the two modalities in the superimposed images) are to be set. Powerful computers are required to be able to handle all the data in the computer random access memory (RAM) and to display them in real time, especially when the CT images are used at their full quality (512×512 pixel per slice, 16-bit shades of gray). Finally, these new systems significantly increase the amount of data to be archived (one hundred to several hundreds megabytes per study), and some trade-off may have to be found between storing all the information available for later use and minimizing the storage space required. An excellent review of the current software techniques for merging anatomic and functional information is available (32).

COMPUTER SIMULATION

Simulation is a very important application of computers in NM research, as it is in many technical fields today. The advantage of simulation is that a radioactive source and a SPECT or PET system are not required to get images similar to the ones obtained if there were real sources and systems. Simulation is cheaper, faster and more efficient to evaluate acquisition hardware or software before they are manufactured and to change its design for optimization. Thus, one of the applications is the prediction of the performance of a SPECT or PET system by computer simulation. Another application is to test programs on simulated images that have been created in perfectly known conditions, so that the output of the programs can be predicted and compared to the actual results to search for possible errors.

Computer simulation is the art of creating information about data or processes without real measurement devices, and the basic idea is the following: if enough information is provided to the computer regarding the object of study (e.g., the 3D distribution of radioactivity in the body, the attenuation), the imaging system (the characteristics of the collimator, the crystal, etc.), and the knowledge we have about the interactions of gamma photons with matter, then it is possible to generate the corresponding projection data (Fig. 23). Although this may seem at first very complex, it is tractable when an acquisition can be modeled with a reasonable accuracy using a limited number of relevant mathematical equations. For example, a radioactive source can be modeled as a material emitting particles in all directions, at a certain decay rate. Once the characteristics of the source: activity, decay scheme, half-life, and spatial distribution of the isotope are given, then basically everything needed for simulation purposes

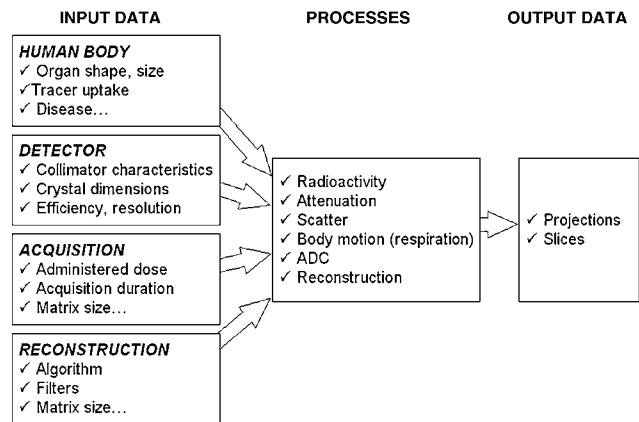

Figure 23. Principle of computer simulation in NM. Parameters and all available information are defined and used by the simulation processes (i.e., computer programs), which in turn generate output data that constitute the result of the simulation.

is known. Radioactive disintegrations and interactions between gamma photons and matter are random processes: one cannot do predictions about a specific photon (its initial direction, where it will be stopped, etc.), but the probabilities of any event can be computed. Random number generators are used to determine the fate of a given photon.

Let us say that we want to evaluate the resolution of a given SPECT system as a function of the distance from the radioactive source to the surface of the detector. The first solution is to do a real experiment: prepare a radioactive source, acquire images with the SPECT system, and analyze the images. This requires (1) a radioactive source, whose access is restricted, and (2) the SPECT system, which is costly. Because the resolution is mainly defined by the characteristics of the collimator, a second way to evaluate the resolution is by estimation (analytical approach): apply the mathematical formula that yield the resolution as a function of the collimator characteristics (diameter of the holes, collimator thickness, etc.). This approach may become tricky as more complex processes have to be taken into account. A third solution is to simulate the source, the gamma camera, and the physical interactions. It is an intermediate solution, between real acquisition and estimation. Simulation yields more realistic results than estimations, but does not require the use of real source or SPECT system. Simulation is also powerful because when uncertainties are introduced in the model (e.g., some noise), then it is possible to see their impact on the projection data.

Simulation refers either to the simulation of input data (e.g., simulation of the human body characteristics), or to the simulation of processes (e.g., the processes like the interaction between photons and matter). For simulation of input data, a very useful resource in nuclear cardiology is the program for the mathematical cardiac torso (MCAT) digital phantom developed at the University of North Carolina (33). The MCAT program models the shape, size, and location of the organs and structures of the human chest using mathematical functions called non-uniform rational B-splines (NURBS). The input of this program is a list of many parameters, among them: the amount of

radioactivity to be assigned to each organ (heart, liver, spleen, lungs, etc.), the attenuation coefficients of these organs, their size, the heart rate, and so on. This phantom used the data provided by the Visible Human Project and is accurate enough from an anatomical point of view for NM, and it can be easily customized and dynamic sets of slices can be obtained that simulate the effects of respiration and a beating heart. The output is the 3D distribution (as slices) of radioactivity (called emission data) and 3D maps of the attenuation (attenuation data) in the human torso. This output can then be used as an input for a Monte Carlo program to generate projection data. Monte Carlo programs (34,35) use computer programs called random number generators to generate data (for example, the projection data) based upon the probability assigned to any possible event, such as the scattering of a photon, or its annihilation in the collimator. The programs were named Monte Carlo after the city on the French Riviera, famous for its casinos and games based upon probabilities. Among the Monte Carlo simulation programs used in NM are: Geant (36), Simind (37), SimSET (38), and EGS4 (39). Programs, such as Geant and its graphical environment Gate (40), allow the definitions of both the input data (the body attenuation maps, the collimator characteristics) and the interactions to be modeled (photoelectric effect, scatter, attenuation, etc.).

EDUCATION AND TEACHING

As almost any other technical field, NM has benefited from the Internet as a prodigious way to share information. Clinical cases in NM are now available, and one advantage of computers over books is that an image on a computer can be manipulated: the color map can be changed (scale, window, etc.) and, in addition to images, movies (e.g., showing tracer uptake or 3D images) can be displayed. Websites presenting clinical NM images can be more easily updated with more patient cases and some on-line processing is also possible. One disadvantage is the sometimes transitory existence of the web pages, that makes (in the author's opinion) the Internet an unreliable source of information from this point of view. NM professionals can also share their experience and expertise on list servers (see Ref. 41 for a list of servers). The list servers are programs to which e-mails can be sent, and that distribute these e-mails to every registered person.

The Society of Nuclear Medicine (SNM) website hosts its Virtual Library (42), in which > 90 h of videos of presentations given during SNM meetings are available for a fee. The Joint Program in Nuclear Medicine is an example of a program including on-line education by presenting clinical cases (43) for > 10 years. More than 150 cases are included, and new cases are added; each case includes presentation, imaging technique, images, diagnosis, and discussion. Other clinical cases are also available on the Internet (44). Another impressive on-line resource is the Whole Brain Atlas (45) presenting PET images of the brain, coregistered with MRI images. For each case, a set of slices spanning over the brain is available, along with the presentation of the clinical case. The user can interactively select the transverse slices of interest on a sagittal slice. As the last example, a

website (46) hosts a presentation of normal and pathologic FDG uptake in PET and PET/CT images.

CONCLUSION

Computers are used in NM for a surprisingly large variety of applications: data acquisition, display, processing, analysis, management, simulation, and teaching/training. As many other fields, NM has benefited these past years from the ever growing power of computers, and from the colossal development of computer networks. Iterative reconstruction algorithms, which have been known for a long time, have tremendously benefited from the increase of computers crunching power. Due to the increased speed of CPUs and to larger amounts of RAM and permanent storage, more and more accurate corrections (attenuation, scatter, patient motion) can be achieved during the reconstruction process in a reasonable amount of time. New computer applications are also being developed to deal with multimodality imaging such as SPECT/CT and PET/CT, and remote image viewing.

ACRONYMS

ACR	American College of Radiology
ADC	Analog to Digital Conversion (or Converter)
CPU	Central Processing Unit
CT	(X-ray) Computerized Tomography
DICOM	Digital Imaging and COmmunications in Medicine
ECT	Emission Computerized Tomography
FBP	Filtered BackProjection
FDG	Fluoro-Deoxy Glucose
FDR	Frequency-Distance Relationship
FFT	Fast Fourier Transform
HIS	Hospital Information System
keV	kiloelectron Volt
LAN	Local Area Network
LOR	Line of Response
MCAT	Mathematical Cardiac Torso

INTRODUCTION

Parenteral nutrition, total parenteral nutrition (TPN), and hyperalimentation are terms referring to a variety of methods by which all required nutrients are provided intravenously, independent of alimentary tract function. Effective parenteral nutrition represents one of the major advances in medicine in the last 50 years and has led to intense interest in the incidence, consequences, and treatment of malnutrition, an area of study largely heretofore neglected because of a lack of effective therapy. The rationale for prescribing nutrients intravenously for patients unable to eat or receive tube feedings is based on the fact that malnutrition ultimately has an adverse impact on all organs and systems including the heart, lungs, gastrointestinal tract, and the immune system. The degree of morbidity and the rapidity of its onset depend on the magnitude and duration of nutritional deprivation. In addition, there are subtle, but perhaps quantitatively more important, indirect effects of nutritional deficits. Thus, nutritional derangements often have an adverse effect on the prognosis and treatment of concurrent illnesses. For example, malnourished patients who undergo elective surgery have a higher rate of postoperative sepsis and mortality. In addition, significant nutritional deficits may preclude the safe administration of optimal neoplastic chemotherapy because its inherent toxicity may be intolerable in the face of malnutrition.

DEVELOPMENT OF PARENTERAL NUTRITION

The adverse consequences of malnutrition became apparent to gastrointestinal (GI) surgeons during the first half of the twentieth century. Their patients with GI diseases were unable to eat, and the ensuing weight loss was associated with poor wound healing, anastomotic dysfunction and leakage, and poor surgical results. Such observations stimulated experimentation with intravenous nutrition. The early workers identified the nutrients required for human beings and further were able to pre-

pare these nutrients in solutions that could be safely administered intravenously (1,2). However, clinical application was hampered by the fact that available nutrient solutions prepared in isotonic concentration could not meet energy and protein requirements when given in physiologic volumes. Experimentally, massive infusions of isotonic solutions of glucose and protein hydrolysates were indeed capable of supporting the anabolic state, but the intensive care required to monitor fluid balance made it a clinically impractical method. Early attempts at concentrating these solutions in order to provide all the required nutrients in acceptable volumes failed because of the thrombophlebitis that inevitably developed in the peripheral veins through which the solutions were infused. This was the state of the art until the mid-1960s when Rhoads, Dudrick, Wilmore, Vars, and their associates at the University of Pennsylvania undertook experiments in which very concentrated solutions were infused directly into the superior vena cava or the right atrium where instantaneous dilution of the solution occurred (3,4). By using hypertonic solutions of glucose and protein hydrolysates, these investigators demonstrated for the first time, initially in animals and then in humans, that intravenous "hyperalimentation" could support normal growth and development (2).

ESSENTIAL COMPONENTS OF NUTRIENT SOLUTIONS

The essential ingredients of solutions designed to meet all known nutritional requirements include nonprotein calories, utilizable nitrogen for protein synthesis, minerals, essential fatty acids, trace elements, and vitamins (5). In addition, it is likely that other micronutrients are necessary for optimal human nutrition. Normally, these as yet unidentified factors are automatically provided in a well-rounded diet derived from natural foodstuffs. Dudrick et al. (2,3) used glucose exclusively for nonprotein energy. Now fat emulsions are available as an additional clinically useful caloric source. Protein hydrolysates, derived from the enzymatic degradation of fibrin or casein, provided the nitrogen source in the early studies of parenteral nutrition. Currently, synthetic amino acid solutions are used to supply nitrogen.

Meeting the therapeutic goal of homeostasis (nitrogen equilibrium) or growth or nutritional repletion (positive nitrogen balance) is dependent on a variety of factors, most important among which are the levels of energy and nitrogen consumption. At any given level of protein or nitrogen intake, nitrogen balance progressively improves to some maximum level as caloric intake increases from levels below requirements to levels exceeding requirements (6). Maximum protein sparing and optimal utilization of dietary protein are achieved when the energy sources include at least 100–150 g of carbohydrate daily. The remaining energy requirements of most individuals can be met equally effectively by carbohydrate, fat, or a combination of these two. The requirement for this minimum amount of carbohydrate is based on its unique ability to satisfy the energy requirements of the glycolytic tissues, including the central nervous system, erythrocytes, leukocytes, active fibroblasts, and certain phagocytes.

At any given level of energy intake, nitrogen balance improves as nitrogen consumption increases. This dose-response relationship is curvilinear, and the nitrogen balance plateaus at higher dosages of nitrogen intake (6). To avoid the limiting effects of calories on nitrogen or of nitrogen on calories, parenteral nutrition solutions are prepared so that the nitrogen provided bears a fixed relationship to the nonprotein calories provided. In studies of normal, active young men fed orally, optimal efficiency was achieved at a calorie/nitrogen ratio of ~300–350 kcal to 1 g of nitrogen (6,7). However, protein economy decreases during most serious illnesses, and nitrogen losses increase; therefore, dietary protein requirements rise. Nitrogen equilibrium or retention can usually be achieved, however, by approximately doubling the quantity of nitrogen required by a normal man at any given level of caloric intake. Thus, a calorie/nitrogen ratio of 150:1 is thought optimal for seriously ill patients, although the ratio actually may range between 100:1 and 200:1 (6).

Minerals required in amounts exceeding 200 mg day⁻¹ include sodium, potassium, calcium, magnesium, chloride, and phosphate. These macronutrients are essential for the maintenance of water balance; cardiac function; mineralization of the skeleton; function of nerve, muscle, and enzyme systems; and energy transformation. In addition, protein utilization is affected by the availability of sodium, potassium, and phosphorus in the diet; nitrogen accretion is impaired when any of these mineral nutrients is withdrawn from the diet. Nutritional repletion evidently involves the formation of tissue units containing protoplasm and extracellular fluid in fixed proportion and with fixed elemental composition (8). Thus, the retention of 1 g of nitrogen is characteristically associated with the retention of fixed amounts of phosphorus, potassium, sodium, and chloride.

Linoleic acid is the primary essential fatty acid for humans, and consequently it must be provided in order to avoid chemical and clinical evidence of deficiency. Linoleic acid requirements are generally met when a fat emulsion is used to provide at least 4% of calories as linoleic acid.

Micronutrients, or trace elements, presently recognized as essential for humans include iron, iodine, cobalt, zinc, copper, chromium, manganese, and possibly selenium. Cobalt is supplied as vitamin B₁₂, and iron is generally withheld because of poor marrow utilization in critical or chronic illness. The remaining trace elements are routinely supplied in the nutrient solution (Table 1).

The remaining essential components are the water and fat soluble vitamins. Guidelines for parenteral vitamin

Table 2. Vitamin Requirements^a

Thiamine (B ₁)	6 mg
Riboflavin (B ₂)	3.6 mg
Niacin (B ₃)	40 mg
Folic acid	600 mcg

administration have recently been revised by the Food and Drug Administration to include vitamin K, heretofore withheld, and increased amounts of vitamins B₁, B₆, C and folic acid (13–15) (Table 2).

The specific nutrient requirements for a given individual depend on the initial nutritional and metabolic status of the patient and his/her underlying disease process. Although the precise requirements for each nutrient can be determined by metabolic balance studies and direct or indirect calorimetry, such techniques are generally not employed in routine clinical practice. Instead, on the basis of data from clinical investigations applying such balance studies to patients with various diseases, injuries, and degrees of stress, requirements can be accurately estimated (16). As a result of these estimates, it is possible to formulate basic nutrient solutions of essentially fixed composition that can be used to meet the needs of most patients by varying only the volume of the basic formulation and by making simple adjustments in the electrolyte content of the solution. Thus, in clinical practice the caloric requirement is usually estimated from simple formulas that are adjusted for activity and stress. Although nitrogen requirements can likewise be determined or estimated, nitrogen needs are usually met as a consequence of the fixed calorie/nitrogen ratio of the nutrient solution. Thus, as the volume of infusate is increased to meet increased caloric demands, the additional nitrogen requirements, which generally parallel the rising caloric needs, are likewise met. Although such standard preparations can be used to satisfy the needs of most individuals, fluid-restricted patients, severely hypermetabolic patients, or those with renal or hepatic failure may require special nutrient formulations.

FORMULATING NUTRIENT SOLUTIONS

In current practice, nutrient solutions designed for parenteral administration are formulated to provide nonprotein calories as carbohydrate or a combination of carbohydrate and lipid. Glucose is the carbohydrate of choice since it is the normal physiologic substrate; it naturally occurs in blood; and it is abundant, inexpensive, and readily purified for intravenous administration. Glucose can be given in high concentrations and in large amounts that are well tolerated by most patients after a period of

Table 1. Trace Element Requirements^{a-c}

Chromium	10–15 mcg
Copper	0.5–1.5 mg
Iodine	1–2 mcg kg ⁻¹
Manganese	60–100 mcg
Zinc	2.5–4.0 mg

adaptation. Other carbohydrates such as fructose, sorbitol, xylitol, and maltose have been evaluated experimentally, but each has disadvantages that preclude clinical application at the present time. Glucose for parenteral infusion is commercially available in concentrations from 5 to 70% and is provided as glucose monohydrate with a caloric density of 3.4 kcal·g⁻¹. Although isotonic (5%) solutions of glucose are available, concentrated glucose solutions are necessary in parenteral nutrition protocols in order to provide required calories in physiologic volumes of fluid.

Lipid is the alternative clinically useful nonprotein caloric source. Fat emulsions derived from soybean and safflower oil were approved for use in the United States in 1975 and 1979, respectively. The soybean oil emulsions had been used in Europe for nearly 20 years prior to their introduction in the United States. Currently available fat emulsions are derived from soybean oil or are mixtures of soybean and safflower oil emulsions. The use of lipid emulsions in intravenous feeding regimens is attractive because of the high caloric density of fat (9 kcal·g⁻¹), and because they are isotonic solutions that can, therefore, provide many calories in relatively small volumes via peripheral veins. Although early experience with lipids using the cottonseed oil emulsion Lipomul was unsatisfactory because of the toxicity of that preparation, fat emulsions derived from soybean and safflower oil have proven safe for clinical use. These newer preparations are purified plant oils emulsified in water. Egg phospholipids are added to regulate the size of the fat particles, stabilize the emulsion, and prevent fusion of the oil drops. Glycerol is added to make the emulsion isotonic, since oil and water emulsions have no osmolal effect. The resulting fat droplets have characteristics that are similar to those of naturally occurring chylomicrons found in the circulation after absorption of dietary lipid from the small intestine. Thus the particle size and the plasma elimination characteristics of these fat emulsions appear comparable to those of chylomicrons (17,18).

Studies of the elimination kinetics of soybean emulsion triglycerides indicate that at very low concentrations the rate of removal from the plasma is dependent on the triglyceride concentration. Above a certain critical concentration representing saturation of binding sites of lipoprotein-lipase enzymes, a maximum elimination capacity is reached that is independent of concentration. This maximum elimination capacity is influenced by the clinical state of the patient. It is increased during periods of starvation, after trauma, and in severely catabolic states (18,19). The infusion of fats is associated with an increase in heat production and oxygen consumption, a decrease in respiratory quotient, and the appearance of carbon-14 (¹⁴C) in the expired air of patients receiving ¹⁴C-labeled fat. These observations indicate that the infused fats are in fact used for energy. Soybean and soybean-safflower oil emulsions are available in 10, 20, and 30% concentrations and are mixtures of neutral triglycerides of predominantly unsaturated fatty acids. The major component fatty acids are linoleic, oleic, palmitic, and linolenic. The total caloric value of the 10% emulsions, including triglyceride, phospholipid, and glycerol, is 1.1 kcal·mL⁻¹. The corresponding values for the 20 and 30% emulsions are 2 and 3 kcal·mL⁻¹,

respectively. In each of these preparations, ~0.1 kcal·mL⁻¹ of the total caloric value is derived from the added glycerol.

All nutrient solutions must provide at least 100–150 g of glucose day⁻¹ to meet the needs of the glycolytic tissues, as described above. The proportional distribution of glucose and fat to provide the remaining required nonprotein calories apparently can be widely variable with the expectation of achieving the same nutritional goals. Commonly cited guidelines suggest that fat should not provide >30% of nonprotein calories and that the daily dosage of fat not exceed 2.5 g kg⁻¹ in adults (11). However, evidence-based reports indicate infusions providing >80% of nonprotein calories as fat and daily dosages of as much as 12 g fat kg⁻¹ day⁻¹ have been tolerated with clinical benefit and no adverse effects (20–22).

Consequently, protocols for solution preparation vary from institution to institution. Practical considerations in choosing the amount of glucose and the amount of fat relate primarily to the route of administration and to the fluid status of the patient. Parenteral nutrition solutions providing all nonprotein calories as glucose are highly concentrated and require central venous administration (see below). As an increasing proportion of the caloric content of the nutrient solution is provided by an isotonic fat emulsion, the content of glucose is thereby reduced, and, consequently, the concentration of the resultant solution falls. Nutrient solutions with an osmolality not exceeding approximately three times normal serum levels can be successfully infused through peripheral veins (23); more concentrated solutions must be infused centrally. Parenteral nutrition solutions are formulated in accordance with one of three commonly used protocols: the glucose-based system, the lipid-based system, and a three-in-one system of variable composition.

The nutrient solution prescribed for a 24 h period usually is prepared in single container in a pharmacy under strict aseptic conditions. Manufacturing pharmacies responsible for preparing solutions for many patients often employ automated, computerized compounding apparatus that is programmed to add the specified nutrient components to the infusion container.

THE GLUCOSE SYSTEM

This is the original carbohydrate-based system developed by Dudrick and his associates at the University of

Table 3. The Glucose System^{a-d}

^dElectrolyte additives based on Travasol as the amino acid source.

Pennsylvania (3). The nutrient solution is prepared by the admixture of equal volumes of 50% glucose and 8.5% crystalline amino acids, and the addition of appropriate electrolytes, vitamins, and trace elements (Tables 1–3). A 1 L solution provides 850 nonprotein kilocalories, and ~7 g of nitrogen, equivalent to 44 g protein. Consequently, the solution has a calorie/nitrogen ratio of ~ 120:1. The nitrogen content and the calorie/nitrogen ratio will vary slightly depending on the brand of amino acid solution used. Due to the osmolar contribution of each of the constituents, this nutrient solution has a final concentration of ~ 2000 mOsm·L⁻¹. Such a solution can never be safely infused through peripheral veins; consequently, the glucose system must be delivered into a central vein where the infusate is immediately diluted. Vascular access is usually through a percutaneously placed subclavian venous catheter or, for short-term use, a peripherally inserted central venous catheter (PICC line). Other routes (eg, via jugular, saphenous, or femoral veins) are used occasionally with variable success. The incidence of morbidity associated with establishing and maintaining central venous access is influenced by the site and technique of insertion of the venous cannula and the diligence with which the apparatus is managed during the course of nutrition therapy.

Because of the high concentration of glucose in this form of parenteral nutrition, therapy should begin gradually to allow adaptation and thereby avoid hyperglycemia. Generally, on the first day a patient receives 1 L of nutrient solution, which is infused at a constant rate over the full 24 h period. Blood and urine glucose levels are monitored frequently, and if this initial rate of infusion is well tolerated, the volume prescribed is increased from day-to-day until the volume infused meets the caloric requirement of the individual patient. For the average patient, the nutritional requirements as well as the requirements for fluid and electrolytes are usually met by 2.5 L·day⁻¹ of the nutrient solution, providing 2125 nonprotein kilocalories.

Infusion of the glucose system at a constant rate is a critical feature of safe practice since abrupt changes in the rate of delivery may be associated with marked fluctuations in blood sugar levels. The constant rate of infusion is most efficiently achieved by using an infusion pump. At the conclusion of therapy, the rate of infusion should be tapered gradually over several hours to avoid hypoglycemia. When infusion must be abruptly terminated, a solution of 10% glucose is substituted for the nutrient solution.

THE LIPID SYSTEM

The system of total parenteral nutrition based on glucose as the major caloric source is simple in concept and the least expensive, but patients' glucose metabolism must be closely monitored, and administration of the infusate requires technical expertise to achieve and maintain the central venous access necessary for safe treatment. The use of lipid emulsions as the major caloric source is attractive because of the high caloric density and isotonicity of these products. These considerations have logically led to the preparation of nutrient solutions based on fat as the major caloric source, with the goal of providing all required nutrients by peripheral vein. An example of such

Table 4. The Lipid System^{a-e}

10% Fat emulsion	500 mL
50% Glucose	100 mL
8.5% Amino acids	350 mL
Sodium (as acetate)	35 meq

^aComposition per liter.

^bProvides 720 nonprotein kilocalories and 5.0 g nitrogen/L.

^cTrace elements and vitamins are provided daily (see Tables 1 and 2).

^dElectrolyte additives are based on Travasol as amino acid source.

^eApproximately 7 mM additional phosphorus derived from fat emulsion.

a lipid-based system of total parenteral nutrition is presented in Table 4. This nutrient solution was devised with the aim of maximizing caloric and amino acid content without producing a solution with a concentration that would preclude safe peripheral venous administration (23). Each liter provides 720-nonprotein kilocalories and 5.0 g of nitrogen, equivalent to 31 g of protein. The calorie/nitrogen ratio is 144: 1. The nitrogen content of the solution will vary slightly, depending on the amino acid product used in its preparation. As with the glucose system, sufficient volume is given to meet measured or estimated caloric requirements. The safety and efficacy of nutrient solutions utilizing lipid as the major caloric source were established by Jeejeebhoy and associates in their landmark investigation of lipid-based TPN in which 83% of nonprotein calories were supplied as fat (22). As many as 5 L daily of the lipid system described here have been infused for periods of weeks to months without apparent adverse effect.

THE THREE-IN-ONE SYSTEM

Innumerable nutrient solutions can be prepared with a distribution of glucose and lipid calories that differs from the two systems described above. Although there is no established biological advantage of differing proportions of fat and glucose as long as the minimum 100–150 g of carbohydrate are supplied, many clinicians prefer a profile of nutrients that mimics the optimal oral diet. Such a system calls for the admixture of amino acids, glucose, and lipids in which carbohydrate provides 65–85% of nonprotein calories and lipid 15–35% (11,12) (Table 5).

However, altering the lipid system described here by increasing the glucose content would have certain nonnutritional effects. Thus, a solution with a higher proportion of glucose calories could be produced by replacing some of the fat emulsion with isotonic glucose. The concentration of the final solution would remain unchanged, but a much greater total volume would be required to provide the same number of calories. If the substitution were made with hypertonic glucose, as called for in the three-in-one system

Table 5. A Three-in-One System^{a-d}

50% Glucose	300 mL
10% Fat emulsion	300 mL
10% Amino acids	400 mL
Sodium (as acetate)	25 meq
Sodium (as chloride)	5 meq
Sodium (as phosphate)	14.8 meq
Potassium (as chloride)	40 meq
Phosphate (as sodium salt)	1.1 mM
Magnesium sulfate	8 meq
Calcium gluconate	5 meq

^aComposition per liter.

^bProvides 840 nonprotein kilocalories and 6.8 g nitrogen/L.

^cTrace elements and vitamins are provided daily (Tables 4 and 5).

^dElectrolyte additives based on Travasol as the amino acid source.

described in Table 5, the final concentration of the nutrient solution would be so increased as to require central venous administration, thereby losing the advantage of peripheral venous delivery.

COMPLICATIONS OF PARENTERAL NUTRITION

Morbidity associated with intravenous feedings may be related to drug toxicity, difficulties with vascular access, sepsis, or metabolic derangements.

Drug Toxicity

Adverse reactions to the components of parenteral nutrition solutions are uncommon. Although glucose is virtually nontoxic, the hypertonic solutions employed in the glucose system of TPN may be associated with potentially serious complications usually related to alterations in blood glucose levels. Currently used solutions of synthetic amino acids provide all of the nitrogen in the form of free l-amino acids and, in contrast to previously used protein hydrolysates, no potentially toxic ammonia or peptide products are present. Toxicity associated with the intravenous infusion of the currently available fat emulsions also has been minimal. The most frequent acute adverse reactions are fever, sensations of warmth, chills, shivering, chest or back pain, anorexia, and vomiting. Similarly, adverse reactions associated with chronic infusions of fat emulsions are also quite uncommon. Anemia and alterations in blood coagulation have been observed during treatment, but the etiologic relationship to lipid infusions has been unconfirmed. The most serious adverse effects have been observed in infants and children. The "fat overload" syndrome associated with the older cottonseed emulsion has rarely been observed with the newer current preparations. Nevertheless, several reports have been published (24) in which children receiving fat emulsions have developed marked hyperlipidemia, GI disturbances, hepatosplenomegaly, impaired hepatic function, anemia, thrombocytopenia, prolonged clotting time, elevated prothrombin time, and spontaneous bleeding. These findings resolved when the fat emulsion was withdrawn.

Complications of Vascular Access

The lipid-based system of parenteral nutrition can be infused through the ordinary peripheral venous cannulae

used for the administration of crystalloid solutions. Local phlebitis and inflammation from infiltration and cutaneous extravasation occur with about the same frequency as that associated with the infusion of nonnutrient solutions. In contrast, a central venous catheter is required for infusion of the highly concentrated glucose and three-in-one systems. Insertion and maintenance of such catheters may be associated with a variety of complications. Complications that may occur during the placement of the catheter include improper advancement of the catheter tip into one of the jugular veins or the contralateral innominate vein, instead of into the superior vena cava. In addition, air embolization or cardiac arrhythmias may occur. Percutaneous jugular or subclavian cannulation may rarely result in an injury to an adjacent anatomic structure, such as the brachial plexus, great vessels, or thoracic duct. Pneumothorax, usually resulting from inadvertent entrance into the pleural cavity, is probably the most common complication of attempted subclavian catheterization and has been reported to occur in ~ 2–3% of attempts in large series. Late complications after successful central catheterization may include air embolism, catheter occlusion, central vein thrombophlebitis, and catheter-related sepsis.

Systemic Sepsis

Sepsis attributable primarily to the administration of parenteral nutrition should be an infrequent complication in modern practice. A variety of factors may contribute to the development of this complication. Hyperglycemia, which may be induced or aggravated by nutrient infusions (see below), has been associated with sepsis in critically ill patients. Maintaining blood glucose levels between 80 and 110 mg·dL⁻¹ has been shown to significantly reduce the incidence of septicemia (25). In addition, patients requiring TPN are often inordinately susceptible to infection because of serious illness, malnutrition, and chronic debilitation—all conditions associated with impaired immune responses. Patients receiving immunosuppressive therapy, cytotoxic drugs, or corticosteroids are likewise susceptible to infection. These drugs as well as prolonged administration of broad-spectrum antibiotics may subject patients to sepsis from unusual, ordinarily saprophytic, microorganisms.

In addition to these patient-related factors, several specific TPN-related factors contribute to the pathogenesis of sepsis. The various components of the nutrient solution can become contaminated during manufacture or at the time of component admixture in the hospital pharmacy. The ability of the nutrient solution to support microbial growth is well established, but with present techniques of solution preparation sepsis from contamination should be rare. The vascular access apparatus appears to be the most common source of TPN-associated sepsis. Contamination may take place when the infusion catheter is inserted; when containers of the nutrient solution are changed; when intravenous tubing is replaced; when in-line filters are inserted; or when the intravenous cannula is used for measurement of central venous pressure, blood sampling, or the infusion of medication or blood products. In addition, to-and-fro motion of a subclavian catheter due to inadequate fixation will allow exposed portions of the catheter to

enter the subcutaneous tract leading to the vein, which may result in infection. Hematogenous contamination of the infusion catheter may occasionally occur following bacteremia secondary to a distant focus of infection. More commonly, however, catheter-related sepsis is due to contamination of the catheter by organisms colonizing the skin surrounding the catheter insertion site. The incidence of sepsis varies greatly in reported series, but in recent years TPN has been administered with very low rates of infection. This improving trend is evidently due to adherence to rigid protocols of practice, and the employment in many hospitals of a dedicated, multidisciplinary team to manage the nutritional therapy. With this approach, TPN-related sepsis occurs in ~ 3% of patients receiving the glucose system. This complication is much less common among patients receiving the lipid-based system of parenteral nutrition through a peripheral vein (16).

Metabolic Complications

A variety of metabolic derangements have been observed during the course of total parenteral nutrition. These derangements may reflect preexisting deficiencies, or they may develop during the course of parenteral nutrition as a result of an excess or deficiency of a specific component in the nutrient solution. As would be expected, the standard solutions may not contain the ideal combination of ingredients for a given individual. In fact, adverse effects from an excess or deficiency of nearly every component of nutrient solutions have been described. Consequently, patients must be carefully monitored so that the content of the nutritional solution can be adjusted during the course of therapy. For example, minor alterations in electrolyte content are often necessary.

Abnormalities of blood sugar are the most common metabolic complications observed in patients receiving total parenteral nutrition. Hyperglycemia may be associated with critical illness independent of nutrient infusions. However, patients receiving the glucose-rich glucose and the three-in-one systems are particularly susceptible to elevated blood sugar levels. In addition, hyperglycemia may be manifest when the full caloric dosage of the glucose and three-in-one systems is inappropriately given initially and later if rates of infusion are abruptly increased. In addition, glucose intolerance may be a manifestation of overt or latent diabetes mellitus, or it may reflect reduced pancreatic insulin response to a glucose load, a situation commonly observed during starvation, stress, pain, major trauma, infection, and shock. Hyperglycemia also may be a reflection of the peripheral insulin resistance observed during sepsis, acute stress, or other conditions that are accompanied by high levels of circulating catecholamines and glucocorticoids. Decreased tissue sensitivity to insulin is also associated with hypophosphatemia, and hyperglycemia has been observed in patients with a deficiency of chromium. The latter trace metal probably acts as a cofactor for insulin. The incidence of hyperglycemia can be minimized by initiating therapy gradually with either of the two glucose-rich systems. Full dosage should be achieved over a 3 day period, during which time adaption to the glucose load takes place. In addition, careful meta-

bolic monitoring during this period will disclose any tendency to hyperglycemia. Subsequently, a constant rate of infusion is maintained. An inadvertent decrease in the rate of the infusion should not be compensated by abrupt increases in rate; such "catching up" is not allowed. When hyperglycemia supervenes despite these precautions, the etiology is sought. The common cause of hyperglycemia after a period of stability is emerging sepsis, the overt manifestations of which may not appear for 18–24 h after development of elevated glucose levels.

Recent evidence indicates that maintenance of blood sugars levels between 80 and 110 mg-dL⁻¹ in critically ill patients is associated with a significant reduction in mortality and the incidence of septicemia (25). Uncomplicated, moderate hyperglycemia is controlled initially by subcutaneous or intravenous administration of insulin; the TPN infusion is continued at the usual rate. Subsequently, the appropriate amount of insulin is added to the TPN solution during its aseptic preparation in the pharmacy. Providing insulin in the TPN solution has the advantage that inadvertent alterations in the rate of glucose delivery are automatically accompanied by appropriate adjustments in the amount of insulin administered. Patients with hyperglycemia complicated by massive diuresis, dehydration, neurologic manifestations, or the syndrome of hyperosmolar nonketotic coma are managed by immediate termination of the TPN infusion, fluid resuscitation, and insulin administration.

In contrast to the problem of hyperglycemia, blood sugar levels decrease when the rate of infusion of the glucose system is abruptly reduced. Symptomatic hypoglycemia is most likely to occur when the reduction of the infusion rate had been preceded by an increased rate. When the glucose system is to be discontinued electively, the rate of delivery should be tapered gradually over several hours. Patients who are hemodynamically unstable or who are undergoing surgery should not receive TPN, since fluid resuscitation may be inadvertently carried out using the TPN solution. Therefore, the TPN infusion is discontinued abruptly in such patients, and hypoglycemia is averted by infusing a solution of 10% glucose. Hypoglycemia may also reflect an excessive dosage of exogenous insulin. This most commonly occurs as a result of failure to recognize the resolution of peripheral insulin resistance and the associated decreased insulin requirement when the provoking condition responds to therapy.

Serum lipid profiles, which are routinely monitored during treatment with the lipid system, commonly reveal elevations of free fatty acids, cholesterol, and triglycerides. However, adverse clinical effects are uncommon (22,26). Nevertheless, triglyceride levels > 400 mg-dL⁻¹ should be avoided since hypertriglyceridemia of this magnitude may be associated with an increased risk of pancreatitis, immunosuppression, and altered pulmonary hemodynamics (11).

Deficiencies of the major intracellular ions may occur in the catabolic state, since the protein structure of cells is metabolized as an energy source, intracellular ions are lost, and the total body concentration of these ions, including potassium, magnesium, and phosphate, are decreased. Furthermore, during nutritional repletion, these ions, derived from the serum, are deposited or incorporated in

newly synthesized cells. When supplementation of these ions in nutrient solutions is insufficient, hypokalemia, hypomagnesemia, and hypophosphatemia ensue. Serum levels of these substances should be measured regularly during TPN since such monitoring will disclose deficiencies before the clinical manifestations develop. Symptoms of hypokalemia are unusual when serum levels of potassium $> 3.0 \text{ meq}\cdot\text{L}^{-1}$. Asymptomatic hypokalemia can be managed by increasing the potassium supplement added to the nutrient solution at the time of preparation. When cardiac arrhythmias or other significant symptoms develop, the rate of TPN infusion should be tapered promptly while serum glucose levels are monitored closely, and an intravenous infusion of potassium chloride is begun.

Intracellular consumption of inorganic phosphate during the synthesis of proteins, membrane phospholipids, DNA, and adenosine triphosphate (ATP) may produce a striking deficit in the serum phosphate level after only several days of intravenous feedings devoid of or deficient in phosphate. Symptoms of hypophosphatemia may occur when serum phosphate levels fall to $2 \text{ mg}\cdot\text{dL}^{-1}$. However, severe manifestations are particularly apt to occur as levels fall to $< 1 \text{ mg}\cdot\text{dL}^{-1}$. These include acute respiratory failure, marked muscle weakness, impaired myocardial contractility, severe congestive cardiomyopathy, acute hemolytic anemia, coma, and death. Hypophosphatemic patients who are asymptomatic can be managed by increasing the phosphate supplement in the nutrient solution. Symptomatic patients or those with serum phosphate levels $< 1 \text{ mg}\cdot\text{dL}^{-1}$ should be repleted intravenously through a separate infusion line. Parenteral nutrition should be stopped, and a 10% glucose solution should be infused to avert hypoglycemia. Since intracellular phosphate consumption is dependent on caloric intake, withdrawing TPN alone often results in an increased serum phosphate level within 24 h.

A variety of adverse effects comprising the *refeeding syndrome* has been associated with the rapid induction of the anabolic state in severely malnourished, cachectic patients using standard nutrient solutions (16). Cardiac decompensation, the most serious feature of the syndrome, may be due to overhydration and salt retention in the face of starvation-induced low cardiac reserve. Hypophosphatemia, consequent to rapid refeeding, is another important contributing factor to cardiac failure. Rapid nutritional repletion also is implicated in producing deficits of the other major intracellular ions, magnesium and potassium, as well as acute deficiencies of vitamin A (associated with night blindness), thiamine (associated with the high output cardiac failure of beriberi, Wernicke's encephalopathy, and lactic acidosis), and zinc (associated with diarrhea, cerebellar dysfunction, dermatitis, impaired wound healing, and depressed immunity). Refeeding alkalosis also has been described. To avoid the refeeding syndrome in the chronically starved patient, parenteral nutrition should be introduced more gradually than usual, perhaps reaching the full caloric and protein requirements over the course of 5–7 days (16).

Healthy or malnourished individuals who receive a constant parenteral infusion of a fat-free, but otherwise complete diet eventually develop clinical and biochemical manifestations that are completely reversed by the admin-

istration of linoleic acid. Thus, the syndrome of essential fatty acid deficiency in humans is due principally, if not exclusively, to a lack of linoleic acid. Exogenous linolenic acid is required by some species, but its essentiality for humans is unproven. The most commonly recognized manifestation of linoleic acid deficiency is an eczematous desquamative dermatitis largely, but not always, confined to the body folds. Other clinical findings may include hepatic dysfunction, anemia, thrombocytopenia, hair loss, and possibly impaired wound healing. Growth retardation has been observed in infants. Fatty acid deficiency is treated by the administration of linoleic acid, usually by infusing one of the currently available fat emulsions. Patients receiving the glucose-based system of parenteral nutrition should be treated prophylactically by providing 4% of calories as linoleic acid. This requirement is usually met by infusing $1 \text{ L}\cdot\text{week}^{-1}$ of a 10% fat emulsion.

Abnormalities in bone metabolism have been observed in patients receiving parenteral nutrition for prolonged periods, especially in home treatment programs. Such metabolic bone disease includes the common disorders of osteoporosis and osteomalacia and is characterized by hypercalciuria, intermittent hypercalcemia, reduced skeletal calcium, and low circulating parathormone levels. The clinical features have included intense periarticular and lower extremity pain. The pathogenesis of this syndrome is obscure, but hypotheses include an abnormality of vitamin D metabolism and aluminum toxicity (27–29). Most recently, vitamin K deficiency has been considered an etiologic factor since it has been recognized that this condition increases the risk of osteoporosis and fractures and that these risks can be reduced with vitamin K therapy. Vitamin K also appears to be necessary for the synthesis of a diverse group of proteins involved in calcium homeostasis (13,14,30,31). These findings have led to the recent recommendation to routinely add vitamin K to TPN solutions, as discussed above.

NON-NUTRITIONAL EFFECTS OF PARENTERAL NUTRITION

Effects on the Stomach

Gastric acid secretion is significantly increased during the initial period of treatment with the glucose system, but the duration of this effect is unknown. The acid secretory response observed is due primarily to the infusion of crystalline amino acids, and this effect of amino acids on gastric secretion is virtually abolished by the concurrent intravenous infusion of a fat emulsion. The effect of chronic TPN on gastric secretory function is less clear. Chronic parenteral nutrition in animals has been associated with decreased antral gastrin levels and atrophy of the parietal cell mass. This observation is consistent with anecdotal clinical reports in which gastric hyposecretion has been observed in patients receiving long-term parenteral nutrition at home (32).

Effects on the Intestinal Tract

Morphologic and functional changes occur in the small intestine and the colon when nutrition is maintained

exclusively by vein. A significant reduction in the mass of the small and large intestine occurs, and there is a marked decrease in mucosal enzyme activity. Enzymes affected include maltase, sucrase, lactase, and peroxidase. These changes are not in response to intravenous nutrition per se, but reflect the need for luminal nutrients for maintenance of normal intestinal mass and function. The mechanism by which food exerts a trophic effect is at least in part endocrine in that intraluminal contents stimulate the release of enterotrophic hormones such as gastrin (16,33,34).

Effects on the Pancreas

Similar morphologic and functional atrophy of the pancreas is observed during the course of parenteral nutrition. In contrast to the effect of fat consumed orally, intravenous lipids do not stimulate pancreatic secretion (16,35).

Effects on the Liver

Transient derangements of liver function indexes occur in the majority of patients receiving parenteral nutrition regardless of the proportion of glucose and lipid (36,37). Similar abnormalities also have been observed in patients receiving enteral nutrition (tube feedings) (38,39). The etiology of these changes is uncertain and probably multifactorial. One hypothesis is that glucose and protein infusions in amounts exceeding requirements may contribute to these changes. In addition, an infectious etiology, perhaps related to the underlying condition requiring nutritional support, has been suggested, since oral metronidazole has been reported to reverse the changes in some patients. Administration of ursodesoxycholic acid also has been associated with improvement of TPN-related cholestasis (40). In any case, the clinical course associated with the liver changes is nearly always benign so that TPN need not be discontinued. Nevertheless, patients receiving TPN for several years or more are at greater risk for developing severe or chronic liver disease, but again the etiologic relationship is unclear (36).

Effects on the Respiratory System

Fuel oxidation is associated with oxygen consumption and carbon dioxide production. Oxygenation and carbon dioxide elimination are normal pulmonary functions. Consequently, patients with respiratory failure receiving aggressive nutritional support may not be able to meet these demands of fuel metabolism. It is particularly important to avoid infusing calories in amounts exceeding requirements, since this aggravates the problem, increases tidal volume, respiratory rate, and PCO_2 , and offers no nutritional benefit (41).

INDICATIONS FOR PARENTERAL NUTRITION

Although the clinical benefits derived from nutritional substrates infused intravenously appear equivalent to those derived from substrates absorbed from the alimentary tract, feeding through the alimentary tract is preferable when feasible because this route of administration is less expensive, less invasive, and, most importantly, is associated with a significantly lower incidence of infectious

complications (42). Nevertheless, many hospitalized patients have conditions in which alimentary tract nutrition either by mouth or tube feeding is inadequate, inadvisable, or would require an operative procedure (e.g., gastrostomy or jejunostomy) to establish access. It is for these patients that parenteral feeding should be considered. Normally nourished patients unable to eat for as long as 7–10 days generally do not require parenteral nutrition. The protein-sparing effect of 100–150 g of glucose provided in a 5% solution is sufficient. Patients in this category include those undergoing GI surgery in whom only several days of ileus are anticipated postoperatively. However, if the resumption of adequate intake is not imminent after 7–10 days, parenteral feedings are recommended. In contrast, normally nourished patients should receive TPN promptly when initial evaluation discloses gastrointestinal dysfunction that is expected to persist beyond 7–10 days. In addition, malnourished or markedly hypercatabolic patients (e.g., those with severe burns, sepsis, or multiple trauma) with GI dysfunction are given parenteral nutrition immediately.

In some patients, parenteral feedings have benefits in addition to improved nutrition. When all nutrients are provided intravenously, a state of bowel rest can be achieved in which the mechanical and secretory activity of the alimentary tract declines to basal levels (see earlier). These nonnutritional effects may be beneficial in the management of GI fistulas and acute inflammatory diseases, such as pancreatitis and regional enteritis. Parenteral nutrition may also be useful as a “medical colostomy”. Thus, the reduction or elimination of the fecal stream associated with intravenous feedings may benefit patients with inflammation or decubitus ulcers adjacent to the anus or an intestinal stoma or fistula.

Any preexisting acute metabolic derangement should be treated before parenteral nutrition is begun. In addition, TPN should not be used during periods of acute hemodynamic instability or during surgical operations since the nutrient solution may be used inadvertently for fluid resuscitation. Parenteral nutrition is not indicated for patients with malnutrition due to a rapidly progressive disease that is not amenable to curative or palliative therapy.

COMPARING METHODS OF TOTAL PARENTERAL NUTRITION

Factors to be considered in comparing the glucose, the lipid, and the three-in-one systems of parenteral nutrition include the composition and nutrient value of the three systems, the relative efficacy of glucose and lipid calories, and the ease and safety of administration.

Comparative Composition of Parenteral Nutrition Systems

As outlined in Table 6, the lipid system provides fewer calories and less nitrogen per unit volume than the glucose and three-in-one systems. Thus, greater volumes of the lipid system are required to provide an isocaloric and isonitrogenous regimen. On the other hand, the lower osmolarity of the lipid system permits safe peripheral venous administration of all required nutrients, whereas

Table 6. Comparison of Parenteral Nutrition Systems

	Glucose System	Lipid System	Three-in-One System
Carbohydrate calorie	850 kcal·L ⁻¹	220 kcal·L ⁻¹	540 kcal·L ⁻¹
Lipid calories	0 kcal·L ⁻¹	500 kcal·L ⁻¹	300 kcal·L ⁻¹
Caloric density	0.85 kcal·mL ⁻¹	0.72 kcal·mL ⁻¹	0.84 kcal·mL ⁻¹
Nitrogen provided	7.1 g·L ⁻¹	5.0 g·L ⁻¹	6.8 g·L ⁻¹
Protein equivalent	44 g·L ⁻¹	31 g·L ⁻¹	42.5 g·L ⁻¹
Calorie/nitrogen ratio	120:1	144:1	124:1
Concentration (approximate)	2000 mOsm·L ⁻¹	900 mOsm·L ⁻¹	1500 mOsm·L ⁻¹

the higher concentration of the other two systems mandates central venous infusion.

Glucose Versus Lipid as a Caloric Source

The relative impact of glucose and lipid calories on nitrogen retention or body composition has been the subject of extensive investigation often with disparate conclusions, depending on the subset of patients studied (16). However, the preponderance of evidence supports the conclusion that the two caloric sources are of comparable value in their effect on nitrogen retention in normal persons or in chronically ill, malnourished patients. The major study supporting this conclusion is that of Jeejeebhoy and associates (22), who observed that optimal nitrogen retention with the lipid system requires a period of ~ 4 days to establish equilibrium, after which nitrogen balance is positive to a comparable degree with both the glucose and lipid systems. More recent data now attest to the equivalent efficacy of lipid as a major caloric source in critically illness and sepsis (43–45).

Ease and Safety of Administration

The glucose and three-in-one systems require central venous administration. Percutaneously inserted central venous catheters must be placed by physicians and peripherally inserted central venous catheters (PICC) by physicians or specially trained nurses under sterile conditions. Insertion and use of central catheters may be associated with certain complications discussed previously that are not seen with the peripherally administered lipid system.

The ordinary venous cannulae used for infusion of the lipid system can be easily inserted at the bedside and maintained by ward personnel. Whereas a central venous catheter requires special care and attention to prevent catheter sepsis, best provided by a dedicated team, the cannulae used in the lipid system require the same simple care as those used in the peripheral venous administration of crystalloid solutions. The peripherally-infused lipid system is rarely associated with systemic sepsis (16,23).

SELECTING THE TPN REGIMEN

For many patients, the nutritional requirements can be met equally well by any of the TPN systems discussed. The selection in these cases is often based on nonnutritional factors,

such as the experience of the physician, ease of administration, and anticipated duration of therapy. On the other hand, there are subsets of patients requiring intravenous nutritional support who have associated or concurrent medical conditions that influence the choice of treatment.

Fluid Restriction

The lipid system described here has the lowest caloric and nitrogen content per unit volume of the three standard regimens (Table 6). Thus, a greater volume has to be infused to provide the same nutrients. Fluid restriction is facilitated, therefore, by prescribing the more concentrated glucose or three-in-one system. For patients who must be severely fluid restricted, these two systems may be modified by substituting 70% glucose and 10–15% amino acids for the 50 and 8.5% preparations, respectively, in order to supply equivalent nutrient content in a smaller volume. The recently available 30% fat emulsion, providing 3 kcal·mL⁻¹, may prove useful in designing additional TPN regimens for fluid-restricted patients.

Acute Myocardial Ischemia

In some studies, lipid infusions have been associated with elevated circulating free fatty acid levels. The effect of the latter on patients with acute myocardial ischemia is controversial, but there is evidence that arrhythmias may be precipitated and the area of ischemic damage may be extended in patients with acute myocardial infarctions (46–48). In view of these data, the glucose system is recommended in this group of patients.

Glucose Intolerance

It appears that hyperglycemia due to stress or diabetes mellitus is more easily managed if less glucose is infused, as in the three-in-one and lipid systems (49–51).

HYPERLIPIDEMIA

The lipid infusions are contraindicated in patients with conditions in which the metabolism of endogenous lipids is abnormal. Here the glucose system is prescribed.

Pulmonary Disease

In patients with pulmonary insufficiency it is particularly important that lipogenesis induced by excess glucose be avoided because it results in an increase in total CO₂

production, which may in turn lead to elevated PCO_2 values. In addition, significantly less CO_2 is produced during the metabolism of isocaloric amounts of lipid compared to glucose. Thus, increasing the proportion of lipid calories in the nutrient solution, as in the three-in-one and lipid systems, may facilitate the clinical management of patients with chronic pulmonary insufficiency and hypercarbia (52–54). In contrast, impaired pulmonary function has been observed when patients with acute respiratory distress syndrome receive lipids infusions. The adverse effects reported include decreased PO_2 and compliance and increased pulmonary vascular resistance (55).

HOME PARENTERAL NUTRITION

Methods of TPN have become sufficiently standardized and simplified that such care can now be safely and effectively provided at home on an ambulatory basis. Candidates for such homecare include those in whom the acute underlying medical condition requiring initial hospitalization has resolved, but who still require intravenous nutrition for a prolonged or indefinite period or even permanently. Patients with anorexia nervosa, Crohn's disease, short bowel syndrome, or severe hyperemesis gravidarum are among those who have been successfully managed with ambulatory TPN. Other candidates for home therapy include cancer patients with anorexia associated with chemotherapy or radiation therapy and patients with controlled enterocutaneous fistulas, radiation enteritis, or partial intestinal obstruction.

While the general principles of TPN outlined previously are applicable here, there are certain specific considerations in homecare necessary to make this method safe, convenient, and practical. Home patients should receive their nutrient solution through a tunneled, cuffed, silicone rubber or polyurethane central venous catheter (Hickman-type catheter). Such catheters are of low thrombogenicity, and passing the cuffed catheter through a subcutaneous tunnel reduces the incidence of ascending infection. Central placement, usually through the subclavian vein or internal jugular vein, frees the patient's extremities from any apparatus.

Whereas inpatient TPN is infused around the clock, home TPN is often infused in cyclic fashion, usually during sleeping hours, so that patients may be free of the infusion apparatus for part of the day. Patients must adapt to the more rapid hourly rates of infusion necessary to provide the required volume in a shorter period. Alterations of blood sugar, the commonest acute metabolic abnormalities, are best prevented by gradually increasing the rate of delivery over 1–2 h at the beginning of therapy and tapering the rate over several hours at the conclusion of the daily treatment.

Finally, chronic TPN for months or years appears to be unmasking requirements for additional nutrients that are stored in significant quantities or that are required in minute amounts. For example, further investigation may indicate requirements for selenium, molybdenum, taurine, and probably other micronutrients.

University of Wisconsin,
Madison, Wisconsin

INTRODUCTION

Ophthalmology involves a study of diagnosis and management of eye diseases. The retina, also called the fundus oculi, constitutes a major component of the posterior segment of the eye. The central area of the fundus that is responsible for vision is called macula. The macula has a large number of photoreceptors that are specialized neurons containing colored light sensitive dyes (visual pigments). The center of macula is known as the fovea. The absorption of light initiates a cascade of events that bleaches these visual pigments and generates an electrochemical signal that is responsible for vision. This sequence of events is known as the visual cycle. Ocular fundus reflectometry is a noninvasive technique for an *in vivo* study of the visual cycle (1). It provides an objective and quantitative assessment of the kinetics of visual pigments.

Fundus reflectometry involves measuring the intensity of light of different wavelengths reflected by the ocular fundus (1). It has been primarily used to study reflectance properties of various structures in fundus, but also can be used for the study of oximetry and blood flow (2,3). However, the interpretation of measurement shows a lot of variation due to the effect of different types of photoreceptors with its own type of pigment, and spectral distortions. It is used in practice to characterize eye disorders with abnormalities in visual pigments, to detect autofluorescence of retinal lesions, and for various research studies in animals and humans (1).

HISTORICAL ASPECT

In 1851, a qualitative method for observation of the light reflected at the fundus was developed by Helmholtz. In 1952, the absorption spectrum of macular pigment was measured by Brindley and Willmer (4,5). In 1954–1971, the density and spectral properties of human rhodopsin was established by Rushton (6,7). He further developed a densitometer in 1971. A spectrophotographic technique that projects the entire spectrum of light was developed by Weale in 1953. This principle was used by Weale (8,9) to measure the density of cone pigments.

PHYSIOLOGIC BASIS AND PRINCIPLES

There are two types of photoreceptors in the human retina, namely, the rods and the cones. The rods are concerned

with scotopic vision (dim lighting conditions) and the cones are responsible for photopic (daytime vision) and color vision. The cones are present in large numbers in the macula. Ultrastructure of both the types of photoreceptors as studied by electronmicroscopy consists of an outer and inner segment. The outer segments are made of stack of disks containing the visual pigment. The inner segment is responsible for pigment production and regeneration of outer segments. The pigment in rods is an aldehyde of vitamin A and in combination with protein (opsin) forms a compound known as rhodopsin. Of the various isomeric forms, the 11-cis form is a vital component of visual cycle and is converted to all-trans state on absorption of a photon (8). This sequence of events is responsible for vision and a similar process occurs in the cones (9).

The ability of visual pigments to absorb certain wavelength of the projected light can be determined by spectrophotographic techniques. This forms the basis of fundus reflectometry. In *in vitro* conditions, a monochromatic light can be projected on a sample of pigment and the intensity of the emergent beam is measured. It is possible to deduce the absorbing effect of the pigment by again projecting the light without the pigment. By using various wavelengths, an absorbance spectrum can be calculated. However, this is not possible *in vivo*, and hence an alternative technique has been devised. It consists of measuring the intensity of the emergent beam before and after bleaching of the pigment *in vivo*. This constitutes the physiologic basis of fundus reflectometry (1).

METHODS OF FUNDUS REFLECTOMETRY

The reflectometers can be classified as either spectral or imaging reflectometers. The various types of spectral reflectometers are Utrecht, Boston 1, Jena, Boston 2, and Utrecht 2¹. These instruments measure the absolute spectral reflectance. The Utrecht reflectometer measures the foveal reflectance and determines the absorption characteristics of the cone visual pigments. The Utrecht 2 is a newer device and measures cone-photoreceptor directionality along with foveal reflectometry. The Boston 1 reflectometer was devised for oximetry and could simultaneously measure the reflectance at six wavelengths between 400 and 800 nm. The Boston 2 consisted of a modified Zeiss fundus camera, which could assess the orientation of foveal photoreceptors, their directionality, and the ratio of directional to diffuse flux (10–13). The Jena was a combination of a xenon lamp with a monochromator, and measured reflectance by photon-counting techniques.

The fundus imaging systems can also be modified to measure reflectance. This is called as imaging densitometry and has inferior resolution as compared to spectral densitometry. The various techniques used include fundus camera, video-based systems, scanning laser ophthalmoscope, and a charge-coupled device (CCD) camera. The

fundus camera and the video-based system generate maps of the visual pigment (14). However, there is an error in measuring reflectance due to stray light. Therefore a scanning laser ophthalmoscope (SLO) was developed in which a laser beam is moved in a raster pattern over the retina. In spite of high contrast and large dynamic range, the SLO did not provide a quantitative determination of fundus reflection. Around the same time, the CCD camera came into vogue and measured fundus reflectance spectra in 400–710 nm wavelength range.

The above-mentioned techniques of reflectometry have been used to develop models to quantify the spectral distribution of light pathways in human fundus. The various structures in the eye with reflectance properties include the cornea, lens, internal limiting membrane, nerve fiber layer, photoreceptors, retinal pigment epithelium, and sclera (15). On the contrary, the various structures that absorb light include lens, macular pigments, visual pigment, lipofuscin, melanin, and hemoglobin. Taking into consideration these various structures and their reflectance properties, numerous attempts have been made to study the visual cycle. These can be as simple as measuring light transmission by the retina to determining foveal fundus reflectance using spectral, directional (16–19) and bleaching effects.

CLINICAL APPLICATIONS OF FUNDUS REFLECTOMETRY

Fundus reflectometry is primarily used to estimate the optical density of various pigments in the eye (19,20). This includes the lens, macular, visual, and melanin pigments. In the lens and macular pigments, optical density measurement helps in determining the effects of aging. Visual pigments are vital component of the light cycle and densitometry can be used to classify photoreceptors on the basis of wavelength sensitive pigments. The extent of melanin pigmentation can be characterized by reflectometry and an index of pigmentation can be established (21).

Apart from measuring the pigment density, reflectometry is also used to study oxygen saturation, and orientation of foveal photoreceptors. These have applications in studying various congenital and acquired disorders of the retina including nutritional deficiency, infections, and degenerations (22–26). They can be used not only to characterize diseases, but also to study the effects of various treatment modalities (25). Moreover, sometimes it also contributes to early detection of particular diseases.

FUTURE DIRECTIONS

Fundus reflectometry has been principally used to measure the optical density of visual pigments and study the function of a normal and diseased retina. However, it is not used in routine patient care. The reason is because it is time consuming and requires complicated equipments. In addition the specificity is low, and so its use is limited only to research purposes. Therefore it has wide applications in epidemiologic studies, such as aging related ocular disorders (27,28).

Due to the ability to measure directionality and spatial distribution, fundus reflectometry is being tested in determining nerve fiber layer thickness, measurement of oxygen saturation, and to monitor the effects of laser therapy. As we move into a new era of prolonged longevity, due to advances in medicine, fundus reflectometry will be used to test new hypothesis and treatments.

INTRODUCTION

This chapter will discuss the different types of eye movements generated by the ocular motor system, the advantages and disadvantages of commonly used recording systems, the requirements for accurate calibration of those systems, and the use of eye-movement recordings in research.

What Can We Record and Why? A Brief Introduction to Types of Eye Movements and Why We Record Them

Humans are highly visually driven animals. Our hearing may be inferior to that of the owl and our sense of smell far poorer than a dog's, but our visual acuity is excelled by few other species. High resolution vision, however, creates a bandwidth problem—if we processed our entire visual field simultaneously at maximal resolution, we would need so many optic nerve fibers to carry visual information back to the brain that our eyes might not fit into our heads. The solution that has evolved is to make the resolution of the retina—the light-sensitive neural layer of the eye—inhomogeneous. Visual acuity in the central 1° of the visual

field is maximal, but it falls off rapidly as one moves toward the periphery. What keeps us from ever being aware of this fact is the nearly incessant motion of our eyes, which use a number of interconnected control systems to direct our gaze to an object of interest and to keep it fixated in the face of target and body movement. Considerable processing in the visual areas of the brain is needed to integrate the discontinuous flow of visual images into the clear, stable perception of the world that we usually experience.

EYE MOVEMENTS

The types of eye movements to be discussed here all play a part in the maintenance of vision. There are only 6 muscles per eye, arranged in opposing pairs and moving in a relatively constrained way by virtue of the anatomy of the orbit. Although each type of eye movement serves a specific purpose and is generated by partially distinct brain mechanisms, they nonetheless interact in the course of normal life. Examination and recording of eye movements has a surprisingly long history, going back to the pioneering work of Dodge and Cline (1). Eye-movement recording has enjoyed a number of advantages over the analysis of other motor control mechanisms. The following sections will briefly describe each type of eye movement, what purpose it serves, and why one might wish to record it.

Version and Vergence

The ocular motor system may be divided into two major subsystems: one that controls version (conjugate or conjunctive) eye movements, and one that controls vergence (disconjugate or disjunctive) eye movements. Saccades, pursuit, vestibuloocular, and optokinetic eye movements are types of version movements, and convergent and divergent refixations and pursuits are types of vergence eye movements. Patients may exhibit eye-movement abnormalities stemming from disorders in the version or vergence subsystem and both nystagmus and saccadic intrusions may be disconjugate, even uniocular. Recording systems used for all eye movements should be capable of independently recording data from both eyes, regardless of whether they are presumed to be conjugate, which is especially important when recording patients but is also applicable to normal individuals because conjugacy is not absolute. It is a common misconception that one can record “conjugate” movements from one eye only and presume the other eye is moving in exactly the same manner. In this chapter, only methods that fulfill this requirement are considered, regardless of either the experimental paradigm (version or vergence) or the subject population (normal or patient).

Saccades

Saccades are the fastest eye movements made, with velocities at times approaching 1000°/s. We make them nearly incessantly during our waking hours and during rapid eye movement sleep. Although at the end of each saccade only the most central area around the fixation location is seen with maximal acuity, our brains are able to integrate the

rapidly acquired series of such images into a single, unified perception of the world. Saccades may be horizontal, vertical, or oblique, which has implications for their recording, as will be discussed below. Evaluation of saccades may be grouped broadly into assessment of the saccades themselves and analysis of where they go as an individual views a scene or an image. Some eye trackers are more suitable for one sort of study than another. In particular, some methods are poorly suited to vertical and completely unsuited to torsional eye movements, where as others may have insufficient temporal resolution for assessment of latency or accuracy but excel at mapping sequences of fixations in two dimensions. In this discussion, a somewhat arbitrary distinction will be drawn between the detailed evaluation of individual saccades (as is often done clinically) and the assessment of scanpaths (as is sometimes used in a clinical setting but more often used in studies of man-machine interaction).

Inherent Saccadic Characteristics.

Accuracy. Saccadic accuracy is usually expressed in terms of gain (eye position/target position). Most commonly, if a refixation were comprised of multiple steps toward the target, the gain would be based only on the first step. Gain may be either abnormally high or abnormally low in different neurological conditions.

Latency. Latency is the time between stimulus onset and onset of eye movement. In humans, latency may range from 80 to several hundred ms, depending on the task and the age and health of the patient. Normally, saccades made in anticipation of target motion are excluded, unless stimuli with predictable location and timing are used. To be measured accurately, data must be acquired at a rate permitting the precise resolution of saccade timing (e.g., 500 Hz). Thus, a 25 or 30 Hz video-based system would be useless for this application.

Peak Velocity. Peak velocity can be measured either using analog electronics or, more commonly now, by off-line differentiation using software. Peak velocity is affected by fatigue, sedating drugs, and diseases that affect the cells in the brainstem that generate the fast, phasic component of saccadic innervation. Again, very low frame rates will make accurate calculation of peak velocity impossible, as it would not be possible to measure the rate of change in eye position. Indeed, if the sampling rate is too low, small saccades may be lost altogether, as they could be completed between samples (or video frames).

Scanpaths. Scanpaths can be divided into the descriptions of how individuals view a scene and nystagmus scanpaths that describe the eye trajectories about a fixation point in an individual with nystagmus. The former contain refixation saccades and periods of fixation whereas the latter contain the oscillatory nystagmus movements, braking, and foveating saccades, plus intervals of relatively stable fixation, if present.

Clinical Applications. Demonstration of how individuals (including patients) view a scene is probably the most

familiar application of eye movement recording. In these applications, the “fine structure” of each saccade is of less interest than knowledge of where the saccades take the eyes and in what sequence. The classic work of Yarbus demonstrated the stereotyped way in which individuals view faces (2). As these investigations are focused on how cognitive processes control gaze, such work can be used to examine how patients with Alzheimer’s disease (3) examine a novel scene or how individuals with schizophrenia attempt to judge the emotions expressed in a face. For scanpath analyses, high temporal resolution is unnecessary and spatial resolution on the order of a degree, not minute of arc, is acceptable. A wide linear range for vertical and horizontal eye movements is essential, however. Unobtrusiveness and minimal obstruction of the visual field are highly desirable when behavior is to be interfered with as little as possible.

Commercial Applications (Usability Studies, Man-Machine Interactions). Commercial applications are probably one of the most rapidly growing areas of eye movement research; it involves evaluating how humans interact with human displays. Here, the goal may be to see how a web page is examined or where a pilot is looking in a cockpit. The technical requirements for the eye tracker are essentially the same as for clinical applications. An exception is the area of gaze-contingent displays, where the endpoint of a saccade is predicted from recording its beginning, and the display is updated in high resolution only at that point. Such applications impose stricter temporal and spatial resolution criteria.

Nystagmus Scanpaths. Plots of the horizontal vs. vertical motion of nystagmus patients’ eye movements during fixation of a stationary target provide insight into their ability to foveate the target in a stable (i.e., low retinal-slip velocity) and repeatable (i.e., low variance in the mean positions of target foveation intervals) manner. Nystagmus phase-plane (eye position vs. eye velocity) and scanpath plots were developed to study the foveation periods present in many of the waveforms seen in infantile nystagmus (4–8). They are important methods that provide insight into how individuals with such oscillations can achieve high visual acuity. The recording equipment for nystagmus scanpaths and phase-planes needs to be both accurate and of sufficient bandwidth to record the small saccades imbedded in nystagmus waveforms.

Smooth Pursuit. A correlate of having only a small part of the retina—the fovea—with high spatial resolution is that if a moving object is to be seen clearly, it must be tracked precisely, so that its image remains on the fovea, which is the function of the smooth pursuit system. The brain substrates underlying smooth pursuit are, to a degree, separable from those of the saccadic system, but, as a recent review has noted (9), a high degree of parallelism exists. Given that the two systems must work together for successful tracking, this fact is not surprising. For example, if you hear a bird call in the sky and decide to follow it, you must first locate it with a saccade (and possibly a head movement). Your pursuit system then

keeps your gaze on the bird, but if it moves too swiftly for this system, it can be reacquired by a saccade and tracking can recommence. If it is lost again, the pattern repeats. Indeed, if pursuit gain (eye velocity/target velocity) is low or even zero, objects can still be tracked by repeated saccades, giving rise to the clinical observation of “cog-wheel pursuit.”

In contrast to the many roles that saccades serve, pursuit eye movements are rather specialized for tracking. We all can generate saccades at will, even in the absence of targets, but voluntary generation of smooth pursuit is extremely rare and of poor quality. When recorded, it may be examined qualitatively for the presence of saccades or the smooth tracking segments can be separated out and their gain analyzed. As a result of the bilateral organization of motor control in the brain, it is possible to have a unidirectional pursuit abnormality, which may be of diagnostic value. However, bilaterally reduced smooth pursuit is nonspecific, as it may result from boredom, inattention, alcohol, fatigue, as well as pathology. As the pursuit system cannot track targets moving at greater than approximately 2 Hz, the requirements for its recording are not very demanding. If pursuit velocity is to be derived, however, then a low-noise system with appropriate low-pass filtering is essential to prevent the velocity signal from being swamped by noise. A low-noise system is also crucial in computer analysis of smooth pursuit because the algorithm used to identify saccades must ensure that none of the saccade is included in the data segment being analyzed as pursuit. If the pursuit component of the eye movement is only 5°/s and portions of saccades with velocities $\leq 30^\circ/\text{s}$ are included, pursuit gain calculations may be highly inaccurate, which is a concern when commercial systems incorporating proprietary algorithms are being used in clinical settings where this possibility has not been anticipated. See Calibration (below) for more information.

Vestibulo-Ocular Response (VOR)

The VOR is a fast reflex whose purpose is to negate the effects of head or body movement on gaze direction. Acceleration sensors in the semicircular canals provide a head-velocity input to the ocular motor system that is used to generate an eye-velocity signal in the opposite direction. The sum of head and eye velocity cancel to maintain steady gaze in space. The VOR is tuned to negate fast head movements and works in concert with the optokinetic reflex (see below), which responds to lower frequency background motion.

Rotational Testing. For vision to be maximally effective, it must continue to work properly as humans move around in the environment. Consider what would happen if the eyes were fixed in the head as one walked about—the image falling on the retina would oscillate with every step. Every turn of the head would cause the point of regard to sweep away from the fovea. Relying on visual input to compensate would be far too slow to generate an accurate compensatory input. Therefore, humans possess the semicircular canals, three approximately (but not precisely) orthogonal transducers of rotational motion, as part of

each inner ear. Only three neurons separate the canals from the extraocular muscles that move the eyes. The canals are filled with fluid and, as the head moves, the inertia of the fluid causes it to lag behind, stimulating displacement-sensitive hair cells at the base of each canal. With only two synapses between sensory transducer and motor effector, the core of the VOR pathway can act very rapidly. Note, however, that constant velocity rotation elicits a signal that eventually decays to baseline, as the fluid eventually ceases to lag behind the canals (i.e., it moves with the same rotational velocity as the canals). Of course, prolonged constant velocity rotations are not part of our evolutionary history and are rarely encountered in daily life.

As the function of the VOR is to facilitate the maintenance of stable gaze as we move around in the environment, it makes intuitive sense to assess it in a moving subject. The most common way to make this assessment is to measure the horizontal component of the VOR as the patient is rotated while in the seated position. Spring-loaded Barany chairs were eventually superseded by electrically driven chairs, which could be driven with velocity steps, sinusoidally, or with more complex inputs. Step inputs may be used to quantify the time constant of decay of the VOR, whereas the other inputs can be used to generate gain and phase plots. Directional asymmetries or abnormal gains can be readily detected with such testing. Such tests are also carried out not only under baseline conditions, with the patient in complete darkness, but also with the VOR suppressed (patients fixate a target rotating with them) or enhanced (patients fixate an earth-fixed target).

Rotary chair testing has several shortcomings, particularly for low frequencies (e.g., 0.05 Hz). It takes a long time to obtain several cycles of data, during which time the patient may be lulled to sleep by the slow rotation in the dark. Alerting tasks (e.g., mental arithmetic) can be used to overcome this shortcoming, but the overall testing time may be quite long. Stimuli such as pseudo-random binary sequences have been used, with data analyzed by cross-correlation (10) in order to obtain results across a wide range of frequencies more rapidly. Another limitation, however, is that in order to obtain VOR data with a chair, the entire patient must be rotated, which limits the frequency range of the technique, because rotations of, for example, a 100 kg individual at 2 Hz would require very high forces. In addition, high frequency rotations increase the likelihood that because of inertia, the patient would not rotate precisely in phase or with the same amplitude as the chair. Systems are available that record eye movement and sense head movement during patient-initiated head shaking, which allows for testing at more physiological frequencies, but it requires a cooperative patient.

A fundamental problem with rotary chair testing is that although directional differences can be detected, localizing pathology to one ear is difficult. Obviously, rotating only one side of the head is impossible, and the “push-pull” nature of the vestibular system (due to the juxtaposed semicircular canals in the ears) makes lateralization difficult. For this reason, the next test remains valuable, in spite of its shortcomings.

Caloric Testing. Introduced by Barany in 1903, caloric testing is probably the most widely used of all vestibular tests. When carried out using EOG, it is still often referred to as “electronystagmography” (ENG), a term that is sometimes mistakenly applied to all forms of eye-movement recording. It involves the irrigation of the ear canal with either warm water or cold water, which alters the behavior of the horizontal semicircular canal on the side being irrigated. Cold water simulates reduced ipsilateral activity and warm water simulates an irritative lesion; the temperature of the water thus determines the direction of the resulting induced nystagmus fast phase in the way described by the acronym COWS: cold, opposite; warm, same. Vestibular nystagmus frequency and amplitude can readily be assessed for each ear at various temperature levels, which remains the only practical way to assess each side of the vestibular system independently. However, caloric stimulation has the appreciable shortcoming that it is a dc input to the vestibular system. It thus assesses the function of the system far from its physiological frequency range of several Hertz.

Optokinetic Response (OKR)

The OKR is a slow reflex whose purpose is to negate the effects of retinal image movement on gaze direction. Velocity sensors in the retina provide an input to the ocular motor system that is used to generate an eye-velocity signal in the same direction, maintaining gaze on the moving background. The OKR is tuned to respond to slow retinal image movement and works in concert with the VOR (see above), which responds to high frequency head motion.

Full-Field. The optokinetic nystagmus (OKN) response, like the VOR, may be induced in healthy individuals with appropriate visual stimuli. The fundamental form of the optokinetic response is induced by motion of all (or most) of the visual field, which elicits a slow eye movement in the direction of the stimulus, with a fast phase bringing the eyes back toward their initial position. This response continues as long as the stimulus continues. If one considers how the VOR decays with continuous motion and has low gain at very low frequencies, then it can be seen that the OKR and the VOR are functionally additive. Indeed, the relationship between OKR and VOR can be readily observed by anyone who has sat gazing out of a train window and felt himself moving, only to discover that it was the adjacent train which was pulling out of the station. The optokinetic stimulus evokes activity in the vestibular nuclei of the brain, and this activity elicits a sense of motion—the most common way to activate the vestibular system. This visually-induced motion percept is known as linearvection if the motion is linear and as circularvection if the stimulus is rotational. The nature of OKN differs depending on whether the stimulus is actively followed or passively viewed.

Small-Field (Hand-Held Drum, Tape). Although “train nystagmus” may be relatively easy to induce in the real world, presentation of a full-field OKN stimulus in a clinical setting requires a stimulus that essentially surrounds

the patient. For this reason, OKN is more often tested using either a small patterned drum or a striped tape, both of which can be easily held in the examiner’s hands. Although the OKN induced in this way looks no different than that deriving from a full-field stimulus, it is primarily a smooth pursuit response, whereas the full-field OKN includes both pursuit components as well as responses deriving from subcortical pathways, including the lateral geniculate body, accessory optic system, nucleus of the optic tract, and the brain stem and cerebellar circuitry governing eye movements.

Spontaneous Nystagmus & Saccadic Intrusions or Oscillations

Diagnostic Classification. In addition to induced nystagmus, some subjects exhibit either spontaneous or gaze-evoked nystagmus or saccadic intrusions or oscillations. The waveforms and other characteristics of these movements often have diagnostic value; accurate calibration of the data is necessary to extract diagnostic information or to deduce the mechanisms underlying the genesis of an intrusion or oscillation (nystagmus or saccadic).

Nystagmus Versus Saccadic Oscillations. The first distinction to be made when spontaneous oscillations are present is to distinguish between the many types of nystagmus and saccadic intrusions and oscillations. Both the slow-phase waveforms and their relationships to target foveation (placement of the target image on the small, high resolution portion of the retina) help in making this determination. Although the details of these determinations are beyond the scope of this chapter, the basic difference is that nystagmus is generated and sustained by the slow phases, whereas saccadic intrusions and oscillations are initiated by saccades that take the eyes off-target.

Congenital Versus Acquired Nystagmus. If nystagmus is present, determination of its origin is necessary (i.e., is it congenital or acquired?). Again, this field is complex and cannot be fully discussed here. Suffice is to say, certain nystagmus waveforms exist that are pathognomonic of congenital nystagmus; they, along with characteristic variations with gaze angle, convergence angle, or fixating eye, help to determine whether a nystagmus is congenital or acquired.

OCULAR MOTOR RECORDING SYSTEMS

Overview of Major Eye-Movement Recording Technologies

The following are descriptions of the more common technologies used to record the eye movements of both normals and patients. Technical descriptions, engineering, and physics of these and other methods may be found elsewhere in this volume (see “Eye Movement Measurement Techniques”). Emphasis in this chapter will be on the abilities of different types of systems and the calibration requirements to provide accurate eye-movement data in the basic and clinical research settings.

Electrooculography. Theory of Operation. Electrooculography (EOG) is the only eye-movement recording

method that relies on a biopotential, in this case, the field potential generated between the inner retina and the pigment epithelium. This signal may approach 0.5 mV or more in amplitude. If two electrodes are placed on either side of, and two more above and below, the orbit (along with a reference electrode on the forehead or ear), then as the eye rotates in the orbit, a voltage proportional to the eye movement may be recorded, because one electrode becomes more positive and the other more negative with respect to the reference electrode. The technique is one of the oldest and most widespread and has been the standard for assessment of eye movements related to vestibular function. When the term ENG is seen, it is generally EOG that is used.

Characteristics. EOG has the considerable advantage that it requires only a high impedance, low noise instrumentation amplifier for its recording and that the voltage is linearly proportional to eye movement over most of its range. Such amplifiers are relatively inexpensive in comparison with many other eye-tracking technologies. As the electrodes are placed on the skin adjacent to the eye, no contact occurs with the eye itself and no obstruction of any part of the visual field exists. It also is unaffected by head motion, because the electrodes move with the head.

Applications. In theory, the EOG can be used anywhere eye movements are to be recorded. However, as the following section will show, it has a number of inherent limitations that practically eliminate it from many applications. Its widest use remains in the assessment of vestibular function and for the recording of caloric nystagmus and the vestibulo-ocular reflex. It is unsuited for use in environments with changing levels of illumination, as normal physiological processes will change the resting potential of the EOG and thus alter its relationship with amplitude of eye movement. EOG can be used in the assessment of saccades and smooth pursuit, but the low-pass filtering generally required will lead to artificially lowered saccade peak velocities. EOG has occasionally been used in scan-path studies, but its instability and fluctuating gain make it undesirable for this application, because if scenes differing in mean luminance are presented, the EOG will gradually change amplitude.

Limitations. Although conceptually simple and easy to implement, EOG has many shortcomings. One is that because the electrodes are placed on the surface of the facial skin, the EOG is not the only signal they detect. If the patient is nervous or clenches his or her teeth, the resulting electromyographic (EMG) activity in the facial muscles will be recorded as well, with the result that the signal actually recorded is the sum of the desired EOG and the unwanted EMG. As the spectra of the two signals overlap, no amount of filtering can completely separate them.

Another significant problem with EOG is the fact that, like many biopotential recordings, it is prone to drift. Some of this drift may reflect electrochemical changes at the electrode, causing a shift in baseline, which was particularly a problem when polarizable electrodes were used in the early days of the technique. Even nonpolarizable electrodes such as the commonly used Ag-AgCl button electro-

des may still yield a varying baseline when first applied. Furthermore, the potential also shifts with changes in illumination. Indeed, assessment of this response to light is itself a clinical tool. This baseline variability can lead to the temptation to use an ac-coupled amplifier in the recording of the EOG, which has frequently been done, particularly in the ENG literature. Although not a problem if the only data required is nystagmus frequency, significant distortion occurs when ac-coupling is used to record saccades. The apparent drift back toward the center closely resembles a saccade whose tonic innervational component is inadequate. Noise and drift limit the resolution of EOG to eye movements of no less than 1° ; this threshold may be even higher in a nervous patient or an elderly patient with slack, dry skin. An additional limitation undercuts the EOG's otherwise significant advantage in being able to record vertical eye movements, which is the overshooting seen on vertical saccades. It has long been suggested that the lids, moving somewhat independently of the globe, act as electrodes on the surface of the globe, conducting current in parallel to the other current path between globe and electrodes (11).

Another more practical drawback to the use of EOG when used for recording the movements of both eyes horizontally and vertically is that a total of nine electrodes are required (see Fig. 1). Each must be individually adhered to the patient and must be carefully aligned if spurious crosstalk between horizontal and vertical motion is to be avoided. Even if only horizontal motion is to be recorded, five accurately placed electrodes are still needed. A common but unfortunate clinical shortcut has been to use only three—two at either outer canthus of the eye and one

Figure 1. EOG electrodes arranged to record the horizontal and vertical eye movements of both eyes. Reference electrode is in the center of the forehead.

Figure 2. False saccadic trajectory from bitemporal EOG electrodes resulting from the summation of the individual saccadic trajectories shown below.

for reference. This shortcut effectively records a “cyclopean” eye by summing the potentials obtained from each eye. Although eye movements other than vergence are conjugate in normal individuals, it is not generally normal individuals who are seen for clinical evaluation. Figure 2 illustrates how an overshooting and an undershooting eye movement may be combined to give the appearance of a perfect saccade. For this reason, both ac-coupling and bitemporal electrode placement should be avoided when anything other than the crudest information about eye movement is desired.

Infrared Reflectance.

Theory of Operation. Although photographic recording of eye movements dates back to 1901 (1), such methods remained cumbersome to use, especially when they required frame-by-frame analysis of the location of some marker on the eye. Optical levers, where a beam of light was reflected from a mirror attached by a stalk to a scleral contact lens, offered the opportunity for precise registration of eye position, but occluded the view of the eye being recorded. As might be imagined, they were also unpleasant to wear. An alternative recording method that also makes use of reflected light relies on the differential reflectivity of the iris and sclera of the eye to track the limbus—the boundary between these structures. The earliest versions of this system were developed by Torok et al. (12) and refined by several investigators over the years (13–15). Although the number of emitters and detectors vary between designs, they share the same fundamental principle; that is, the eye is illuminated by chopped, low intensity infrared light (to eliminate the effects of variable ambient lighting). Photodetectors are aimed at the limbus on either side of the iris. As the eye moves, the amount of light reflected back onto some detectors increases and onto

others decreases. The difference between the two signals provides the output signal. As would be expected, these signals are analog systems, so that the output of the photodetectors is electronically converted into a voltage that corresponds to eye position. Figure 3 shows an IR system mounted on an earth-fixed frame (a), spectacle

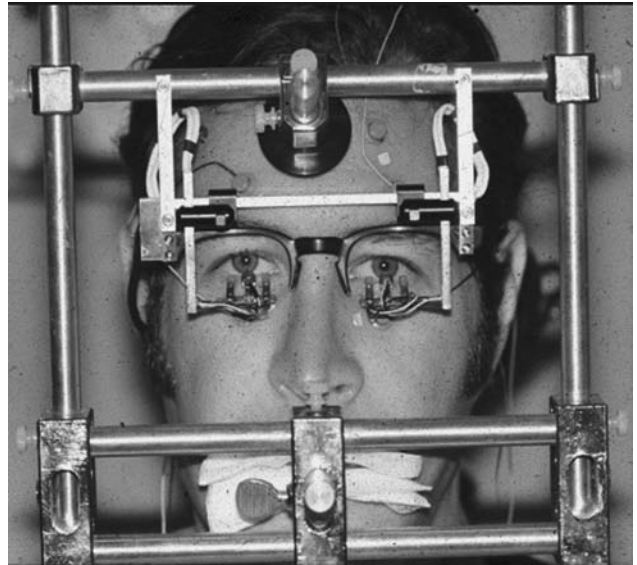

Figure 3. IR system to measure the horizontal eye movements of both eyes shown mounted on an earth-fixed frame (a) and spectacle frame (b) for human subjects and on a spectacle frame for a canine subject (c).

Figure 3. (Continued)

frame (b), and spectacle frame on a dog (c). Figure 4 shows an IR system mounted in goggles on a child (a) and a dog (b).

Characteristics. These systems offer a number of advantages over EOG, at least for the examination of horizontal

Figure 4. IR system to measure the horizontal and vertical eye movements of both eyes shown mounted in goggles for a human subject (a) and a canine subject (b).

eye movements. As the signal is not a biopotential, it is free of the instability found in the EOG; it is also immune to interference from muscle artifact and changes in electrode potentials. Unlike some earlier photographic methods, the device does not occlude the eyes, as the sensors and emitters are positioned above or below the eye. The field of view is somewhat obstructed by the emitter/detector, in contrast to EOG. Resolution is of the order of minutes of arc. Assuming that nothing disturbs the sensors, a shaken head or a rubbed eye, for example, stability is excellent. Thus, the question of using ac-coupling, as in many electronystagmographic applications of the EOG, never occurs. System bandwidth is generally on the order of 100 Hz, which is sufficient to capture fine details of saccades.

The linear range of these systems generally is between $\pm 15^\circ$ and 20° in the horizontal plane and half this amount or less in the vertical plane (which requires vertical orientation of the detectors or summation of the signals from horizontally-oriented detectors).

Applications. IR limbus trackers are probably second only to EOG in their range of applications. Their ability to resolve fine detail with low noise makes them excellent for conditions where subtle features of the eye movement are important; examples include analyses of saccadic trajectories or analysis of small corrective saccades within a nystagmus waveform. An important advantage over EOG is that if eye velocity is to be calculated, the resulting signal is far less noisy than the derivative of an EOG recording, especially where broadband EMG noise has contaminated the signal developing from the eye. These systems are well suited to studies of any sort of eye movement that falls within their linear operating range in the horizontal plane. As they are generally head-mounted, they will tolerate modest head movement, but if the stimuli are fixed in the environment, such movement will certainly cause a loss of baseline and may move the tracker outside its linear range, which makes head stabilization highly desirable, especially when stimuli are presented at gaze angles where subjects would normally make both a head movement and an eye movement to acquire the target. Finally, IR systems are noninvasive, a major advantage for many patients and for children.

Limitations. One of the biggest shortcomings of these systems is their poor performance for vertical eye movement, their near-uselessness for oblique eye movements, and their complete lack of value for torsional eye movements. Although the limbus is clearly visible over a wide range of eye positions in the horizontal plane, the eyelids obscure its top and bottom margins. Although a degree of vertical tracking can be obtained by virtue of the differential reflectivity of the iris and pupil, the range over which this is possible is limited, again in part because of occlusion of the lids. Oblique movement suffers from inherent cross-talk because, as eye position changes in one plane, the sensitivity to motion in the other plane will vary, which is a hindrance to using these systems for studies of reading, scanpath analysis, or other applications where 2D eye movements are important. The use of the systems in rotational testing is also limited by the range of allowable gaze

angles and by the possible slippage of the head mounting on the head if accelerations are sufficiently high. Their suitability for small children also varies; some of the systems do not fit small heads well, although if precise calibration is not important, one can generally record patients as young as 3 years. These systems are not generally appropriate for use with infants. The one exception is for diagnosing nystagmus from its waveform by simply holding the sensors in front of the eyes, which can be done for even the smallest infants (e.g., a premature infant still in an incubator).

Scleral Search Coil.

Theory of Operation. Robinson developed the Scleral Search Coil technique in 1963 (16). It relies on the principle that a coil of wire in an alternating magnetic field induces a voltage proportional to the area of the coil, the number of turns, and the number of field lines. This latter measure will vary with the sine of the angle the coil makes with the magnetic field. In the basic configuration, two orthogonal pairs of field coils are used, each modulated by phase-locked square wave sources either operating in quadrature (i.e., one signal 90° phase-shifted relative to the other) (16) or at a different frequency (e.g., 50 and 75 kHz) (17). An annular contact lens with a very fine coil of wire is placed on the eye, so that it surrounds the cornea (or in animals, is surgically implanted under the conjunctiva). Figure 5 shows an annular search-coil contact lens on the eye of a subject. Components of the induced voltage generated by the horizontal and vertical signals can be separated via phase-sensitive detectors. Note that this method of recording horizontal and vertical components of eye movement eliminates the crosstalk present in 2D recordings made by limbus trackers. With an appropriately wound coil added to the lens, torsional eye movements may also be recorded. This technique is the only one able to record torsion with high bandwidth.

Figure 5. An annular search-coil contact lens used to measure the horizontal and vertical eye movements of a human subject. The fine wire from the imbedded coil exits at the nasal canthus.

Characteristics. This technology serves as the “gold standard” for eye-movement recording. Resolution is in seconds of arc and the linear range $\pm 20^\circ$, with linearization possible outside this range, because the nonlinearity follows the sine function. The signals are extremely stable, because their source is determined by the geometry of coil and magnetic field alone. In the usual configuration, the maximum angle that can be measured is 90° . Although the eyes cannot rotate this far in the head, if the head is also allowed to turn (and its position recorded by a head coil), a net change of eye position $> 90^\circ$ is possible. A solution to this problem was developed whereby all the field coils were oriented vertically, generating a magnetic field whose vector rotates around 360° . Now, the phase of the field coil varies linearly over 360° of rotation (18,19), which is most often used for horizontal eye movements, with vertical and torsional eye movements recorded using the original Robinson design.

Applications. As the search-coil system provides such high quality data, it can be used in nearly any application where stability, bandwidth, and resolution are paramount and free motion by the subject is not essential. However, recent evidence suggests that the coils themselves may alter the eye movements being measured (20). Nonetheless, the low noise level and ability to independently record horizontal, vertical, and torsional movements at high bandwidth and high resolution still make this the gold standard of eye-movement recording techniques.

Limitations. As a result of their size, search-coil systems are clearly not suited for ambulatory studies or those carried out in other real-world settings such as a vehicle. The system also cannot be adapted to use in fMRI scanners, unlike IR limbus trackers or video-based systems. Search coils are invasive, making them unsuitable for some adult patients and for most children. A small risk of corneal abrasion exists when the coil is removed, but this risk is generally minor. Use of the coil in infants or small children would be undesirable, because they could not be instructed not to rub their eyes while the coil was in place. Another practical issue associated with the technology is the cost of the coils, which have a single supplier, have a limited lifetime, and are relatively expensive ($> \text{US}\$100$ each). As recommended duration of testing with the coils is 30 minutes or less, long duration studies are also precluded.

Digital Video.

Theory of Operation. Although electronic systems that locate and store the location of the center of the pupil in a video image of the eye were developed in the 1960s, often in combination with pupil diameter measurement (21,22), video-based eye trackers became a major force in eye-tracking technology when digital rather than analog image analysis was implemented. If the camera is rigidly fixed to the head, then simply tracking this centroid is sufficient to identify the location of the eye in its orbit. However, if there is even slight translational movement of the camera with respect to the eye, a large error is introduced: 1 mm of translation equals 10° of angular rotation in the image. For

this reason, video systems also track the specular reflection of a light source in the image in addition to the pupil centroid. As this first Purkinje image does not change with rotation but does change with translation, whereas the pupil center changes with eye rotation as well as translation, their relative positions can be used to compensate for errors induced by relative motion occurring between the head and camera. Figure 6 shows a digital video system in use on a human subject (a) and on dogs (b and c).

Figure 6. A high-speed digital video system to measure the horizontal and vertical eye movements of both eyes for a human subject (a) and canine subjects (b and c).

Figure 6. (Continued)

Characteristics. Assuming that the axes of the head and camera are aligned, then video-based systems are capable of recording both horizontal and vertical eye movements over a relatively wide range (often $\pm 30^\circ$ horizontally, somewhat less vertically). Resolution is better than EOG but generally somewhat less than for IR or search-coil systems, often in the range of 0.5° . As analog video systems use a raster scan to represent an image, spatial resolution is limited by the nature of the video system used (e.g., PAL or NTSC). Bandwidth is limited by the frame rate of the video system. If conventional analog video is used, then frame rates are 50 Hz for PAL and 60 Hz for NTSC. These rates impose a maximum bandwidth of 25 and 30 Hz, respectively. Although adequate for examination of slow eye movements, these frame rates are inadequate for assessment of saccades; indeed, very small saccades could be completed within the inter-frame interval. Systems using digital video are free from the constraints imposed by broadcast TV standards and can make use of higher frame rate cameras—several now operate at 250 or 500 Hz. Generally, a frame rate versus resolution trade-off exists—higher frame rates imply lower image resolution. However, continued improvement in digital video technology and ever faster and cheaper computers continue to improve performance.

Although older video tracking systems often required a good deal of “tweaking” of brightness and contrast settings in an effort to obtain a reliable image of the pupil, many recent systems have more streamlined set-up protocols. In the past, some systems internally monitored fixation on calibration targets and rejected data that were unstable, thereby making the systems unsuitable for use with patients with nystagmus. However, default calibration settings generally permit data to be taken and the nystagmus records can then be retrospectively calibrated.

Applications. In principle, digital video is the most flexible of all eye-movement recording technologies. Some systems use cameras mounted on the head, using either helmets or some other relatively stable mounting system. Other systems use remote cameras, often mounted adjacent to or within a computer stimulus display. Systems used in vehicles may use either remote cameras or

helmet-mount cameras. In addition to conventional clinical eye-movement testing, video systems, especially remote camera models, are increasingly being used in commercial applications such as advertising studies and usability analyses of websites. For such applications, the unobtrusiveness of the technology and the need to only monitor fixations rather than to study saccade dynamics makes even relatively low-frame-rate video ideal. Such systems are also excellent for use with infants and small children, who may be induced to look at some attractive display on a screen but who generally respond poorly to head-mounted apparatus. Remote systems that track more than one first Purkinje image can cope with a wider range of head movements, making the systems even less restrictive for the subjects. Some video systems can also analyze torsional eye movements by identifying some feature on the iris and then tracking changes in its orientation from frame to frame. High-speed (500 Hz) digital video systems are seeing increased use in basic and clinical laboratories, challenging magnetic search coils as the method of choice.

Limitations. The problems associated with calibrating patients whose eyes are never still have already been discussed. As noted before, the other serious limitations of some of these systems are their somewhat limited spatial resolution and bandwidth. Both parameters can be optimized, but doing so leads to marked increases in price. However, unlike other eye-tracking technologies, the limiting factors for high-speed, digital video eye-movement recording systems are the cameras and computing power. As the enormous general consumer market rather than the quite small eye-movement recording market drives improvements in both technologies, improvements can be anticipated to occur much faster than they would otherwise. Even within the eye-tracking field, the development of commercial uses for the technology will facilitate its advance faster than the smaller and less prosperous academic research community.

OCULAR MOTOR RECORDING TECHNIQUES

How Do We Record and Later Calibrate and Analyze Subjects' Eye Movements?

The initial recording and *post-hoc* calibration and analysis of eye movements require following a protocol conducive to both accurate calibration and obtaining the data specific to a particular study. Decades of experience have resulted in the following recording procedures and caveats and in the development of software that allows accurate calibration and linearization of the data.

Real-Time Monitoring. When recording subjects (especially patients), it is necessary to monitor the eye channels in real-time to ensure that the subject is following instructions, which is also imperative when calibrating subjects (see below). Unlike highly dedicated and motivated graduate students, most subjects quickly become bored by the task at hand or distracted and fail to fixate or pursue the stimuli; others may have difficulty doing so. Real-time monitoring via a strip chart or computer display allows

the experimenter to detect and correct such failures with a simple verbal instruction encouraging the subject (e.g., "follow the target" or "look at the target").

Monocular Calibration. The key to obtaining accurate eye-movement data that will allow meaningful analysis is monocular calibration; that is, calibration of each eye independently while the other is behind cover. Too often, potentially accurate, commercially available recording systems are seriously compromised by built-in calibration techniques that erroneously presume conjugacy, even for so-called normal subjects. Just as bitemporal EOG makes it impossible to determine the position of either eye individually (see Fig. 2), so do calibration techniques carried out during binocular viewing of the stimuli. Most commercially available software calibration paradigms suffer from this fatal flaw, rendering them totally inappropriate for most clinical research and seriously compromising studies of presumed normal subjects. For methods that depend on subject responses to known target positions (e.g., IR or digital video), both the zero-position adjustment and gains at different gaze amplitudes in each direction must be calibrated for each eye during short intervals of imposed monocular fixation (i.e., the other eye occluded); for methods where precalibration is possible (e.g., magnetic search coils), the zero adjustment for each eye in each plane must also be made during imposed monocular fixation.

Linearization and Crosstalk Minimization. In addition to monocular calibration, linearization is required of most systems, even within the stated "linear" regions of those systems. As a result of different facial geometries and the inability to position the sensors in the precisely optimal positions for linearity, these systems are usually not linear over the range of gaze angles needed for many studies. System responses may be linearized by taking data during short intervals (5 s) of monocular fixation at all gaze angles of interest (e.g., 0° , $\pm 15^\circ$, $\pm 20^\circ$, $\pm 25^\circ$, and $\pm 30^\circ$) and applying post-recording linearization software. Even Robinson-type search coils need an arcsine correction for a linear response. For IR and video-based systems measuring eye motion in both the horizontal and vertical planes, crosstalk is a major problem due to sensor placement. Crosstalk can also be minimized post recording, using software written for that purpose. However, IR systems suffer from the additional problem that, as vertical eye position changes, a change may occur in the sensors' aim regions at the left and right limbal borders, which means that for a diagonal eye movement, the horizontal gain is an unknown function of vertical eye position, making IR systems essentially unsuitable for the recording of oblique eye movements.

All of the problems discussed above are accentuated when recording subjects with ocular motor oscillations, such as nystagmus. In these cases, the experimenter must be familiar with the type of nystagmus the subject has and be able to identify the portions of their waveforms that are used for target foveation. It is the "foveation periods" that are used to set the zero-position and gains at each target position; without them, accurate calibration is impossible.

Figure 7. Monocular fixation pre-calibration and postcalibration (horizontal) records for the right (REH) and left (LEH) eye. Compare the offsets and nonlinear precalibration responses to the bias-adjusted, calibrated, and linearized postcalibration responses. Note the failure of the subject to look at the -30° target during LE fixation. In this figure and Fig. 8, target position is shown by the alternating direction, increasing offset, solid line.

The rest of the nystagmus waveform is irrelevant to target foveation and should be ignored during calibration. With a little practice, investigators can easily determine exactly where the subject with nystagmus is looking, which eye is fixating, and where the other eye is located with respect to the target; they can also determine periods of inattention by the associated waveform changes. Figure 7 demonstrates precalibration and postcalibration (horizontal) records of each eye made under imposed monocular fixation, and Fig. 8 shows the results of applying those calibration factors to a record made during binocular “viewing” of the targets. Note that the fixating eye is easily determined as well as the angle/position of the strabismic eye. Unfortunately, investigators with little or no experience in recording subjects with nystagmus are often reduced to using the average eye position during long periods of presumed binocular fixation to approximate calibration of subjects with nystagmus (and probably strabismus). Averaging anathema to accurate calibration and renders most potentially accurate recording systems (e.g., search coils) no better than bitemporal EOG. Needless to say, the results and conclusions of such studies must be highly suspect and are often incorrect; they exemplify how even the most sophisticated hardware and software can be misused, and prove the old adage, “garbage in, garbage out.”

CONCLUSIONS

During the past 40 years, advances in eye-movement recording systems, coupled with the control-systems

approach brought to the field by biomedical engineers, have resulted in an explosion of basic and clinical ocular motor research, at the systems as well as single-cell levels. Using the measurement systems and recording and calibration techniques described above, great strides have been made in our understanding of the ocular motor system. Animal studies have provided understanding at the single-cell and cell-network (bottom-up) levels, giving rise to computer models of small portions of the ocular motor system with neuroanatomical correlations. Normal human studies have allowed characterization of ocular motor behavior under a variety of stimulus conditions, giving rise to functional, top-down computer models of ocular motor behavior. Finally, studies of patients with many congenital and acquired ocular motor disorders have provided insights into the functional structure of the ocular motor system, which was not forthcoming from studies of normals (23,24). These latter studies have resulted in robust, behavioral models of the ocular motor system that are able to simulate normal responses and patient responses to a variety of ocular motor stimuli (25–27).

At present, accurate eye-movement recordings are an integral part of the diagnosis of both congenital and acquired forms of nystagmus, and of saccadic intrusions and oscillations. In addition, they provide objective measures of therapeutic efficacy that are related to visual function in patients afflicted with disorders producing ocular motor dysfunction. Indeed, ocular motor studies of the effects of a specific surgical procedure for congenital nystagmus produced an entirely new type of “nystagmus” surgery for both congenital and acquired nystagmus (28–31). This surgery (named “tenotomy”) simply requires

Figure 8. Calibrated binocular viewing records of both eyes (a) and final primary-position segment (b). Note the preference for RE fixation in left gaze and in the final primary-position segment, with the LE 3–5° esotropic. Note also how well the flat foveation periods of the RE line up on the 0° target despite the alternating direction of the nystagmus.

removal and reattaching, at their original insertion points, each of the four extraocular muscles in the plane of the nystagmus. Tenotomy represents a radical paradigm change from the “strabismus” surgeries that preceded it

and has resulted in new insights into the anatomic structures responsible for proprioceptive signals from the extraocular muscles and their neurophysiologic role in the control of eye movements (32–34).

INTRODUCTION

The purpose of this article is to help people in fields, such as healthcare, engineering, sales, manufacturing, consulting, and accounting to understand office automation systems

from the viewpoint of a business professional. This is important because personal association with office automation systems is almost unavoidable in today's business world. The widespread adoption of personal computers in conjunction with the development of graphically driven operating systems gave people a more natural and intuitive way of visualizing and manipulating information. The applications that were developed, from word processors to spreadsheets, to take benefit of these new operating systems, led to a growth in the use and acceptance of personal computers that significantly altered the manner organizations conduct their daily business.

Healthcare enterprises involve complex processes that span diverse groups and organizations. These processes involve clinical and administrative tasks, large volumes of data, and large numbers of patients and personnel. The tasks can be performed either by humans or by automated systems. In the latter case, the tasks are supported by a variety of software applications and information systems that are very often heterogeneous, autonomous, and distributed. The development of systems to manage and automate these processes has increasingly played an important role in improving the efficiency of healthcare enterprises.

Office Automation Systems (OAS) are computer-based automated information systems that are used to execute a variety of office operations, such as word processing, electronic spreadsheet, e-mail, and video conferencing. These different office automation systems allow the automation of much of the administrative work in the office and typically focuses on the more repeatable and predictable aspects of individual and group work. They are more and more frequently used by managers, engineers, and clerical employees to increase efficiency and productivity. They support the general activities of workers and underlie the automation of document-centric tasks performed by production office workers.

The OAS encompass a broad set of capabilities, and provide much of the technological basis for the electronic workplace. The focus of OAS have typically been used in supporting the information and communication needs of office workers, and its use by organizations supporting the white-collar work force has revealed itself crucial.

HISTORICAL PERSPECTIVE

In its early days, office automation systems focused on needs generally found in all offices, such as reading and writing. Before the 1950s, electromechanical and electronic devices were used to carry out financial and other numerical record-keeping tasks. During the evolution of OAS solutions, manual typewriters have been replaced by the electric typewriter and the electronic typewriter.

The electronic typewriter, introduced in the early 1970s, was the first of the automated office systems. It could store and retrieve information from memory providing automated functions such as center, bold, underline, and spell check.

The advances in the development of mainframes have caused electromechanical devices to be increasingly

replaced by computers. In the 1970s, integrated circuit technology made the production of small and relatively inexpensive personal computers possible. Yet, even with this available technology, many computer companies chose not to adopt personal computers. They could not imagine why anyone would want a computer when typewriters and calculators were sufficient.

In the mid-1970s, computers began to support offices and organizations in more complex ways. The rapid growth of computers furnished the market with sophisticated office automation devices.

In the late 1970s, several researchers started to describe the needs of office automation systems. Computer terminals had replaced electronic typewriters. With the rapid evolution of electronic technology, office information systems were developed to provide for the storage, manipulation, computation, and transmission of large amounts of information. The first sophisticated OAS prototypes included the SCOOP project (1), which was oriented to the automation of office procedures, and Officetalk (2), which provided a visual electronic desktop metaphor, a set of personal productivity tools for manipulating information, and a network environment for sharing information.

In 1981, IBM introduced the IBM PC (Personal Computer). The PC was a milestone and proved that the computer industry was more than a trend, and that the computer was in fact a necessary tool for the business community. Computers, designed solely for word processing and financial tasks, became common. At first, the PC was utilized to replace traditional typewriters and calculators, but persistent technological advances and innovation over the past two decades have put powerful PCs at the center of daily activities for people worldwide.

The growth and widespread adoption of PCs, networks, graphical user interfaces, and communications as allowed the development of complete OAS package suites. For example, in 1985 the Lotus Notes (3) groupware platform was introduced. The term groupware refers to applications that enhance communication, collaboration, and coordination among groups of people. This system included online discussion, e-mail, phone books, and document databases. Throughout the years, continuous improvements were made to Lotus Notes. Nowadays, this system includes new features, such enterprise-class instant messaging, calendaring, and scheduling capabilities with a strong platform for collaborative applications.

In 1992, Microsoft launched its new operating system (OS), Microsoft for Workgroups (4). This OS allowed the sending of electronic mail and provided advanced networking capabilities to be used as a client on existing networks. This was an important stage in the vast evolution of the world's most popular operating system since it enabled the collaboration of groups of people. Microsoft has also invested in the development of full OAS suites, which are commonly available nowadays. The most well-known and widespread productivity software suite is Microsoft Office (5). Microsoft Office helps workers to complete common business tasks, including word processing, e-mail, presentations, data management and analysis.

ORGANIZATIONAL INFORMATION SYSTEMS AND OAS

While we are interested in studying office automation systems (OAS), it is important to relate this type of systems with other information systems (IS) commonly used inside an organization. An information system can be defined as a set of interrelated components that retrieve, process, store and distribute information to support decision making and control in an organization. The main role of IS is to assist workers in managing resources and information at each level in the organization.

This article, is primarily concerned with OAS and how they can be used in the medical community. For completeness, some other types of information systems commonly used by organizations are also mentioned. There will be no description of how such systems are developed, however, a brief description of their objectives will be given. Organizational information systems (OIS) are systems that support several functions in an organization and can be classified by the activity that they support. The OIS are usually split into six major types: Transaction Processing System, Knowledge Work Systems, Office Automation System, Management Information System, Decision Support System, and Executive Information System. These systems are illustrated in Fig. 1.

It is important to be able to distinguish the objectives and the level in the organization where a particular application or system can be used. For example, Transaction Processing Systems are employed to records daily routine transactions to produce information for other systems, while Office Automation Systems are oriented to increase that productivity of data workers using applications such as word processing and electronic mail applications.

Transaction Processing System (TPS): Is useful for daily transactions that are essential to the organization such as order processing, payroll, accounting, manufacturing, and record keeping.

Office Automation System (OAS): Aids office workers in the handling and management of documents, schedules, e-mails, conferences and communications. Data workers process information rather than create information and are primarily involved in information use, manipulation or dissemination.

Knowledge Work System (KWS): Promotes the creation of new information and knowledge and its dissemination and integration within the organization. In general, knowledge workers hold professional qualifications (e.g., engineers, managers, lawyers, analysts).

Management Information System (MIS): Provides middle-level managers with reports containing the basic operations of the organization which are generated by the underlying TPS. Typically, these systems focus on internal events, providing the information for short-term planning and decision making.

Decision Support System (DSS): Focuses on helping managers to make decisions from semistructured or unstructured information. These systems use internal information from TPS and MIS, but also information from external data sources, providing tools to support 'what-if' scenarios.

Executive Information System (EIS): Supports senior and top-level managers. They incorporate data from internal and external events, such as new legislation, tax laws, and summarized information from the

Figure 1. Types of information systems (6).

Figure 2. Support of OIS to the different organizational levels.

internal MIS and DSS. EIS software displays data graphically to provide easy-to-use representations of complex information.

Office information systems can also be classified by the organizational level they support. The human resources of an organization work in different areas and levels of operations, are in charge of different functions, and use different OIS. Any organization can be viewed as a multilevel entity with each level representing a different level of control. The levels of an organization can be arranged in a pyramid (Fig. 2).

The pyramid is divided into five horizontal sections:

- Clerical level: Employees who support managers at all levels of the organization.
- Operational level: First-line managers who make routine decisions and deal with the day-to-day operations of the organization.
- Knowledge-work level: Advisors to both top and middle management who are often experts in a particular area.
- Tactical level: Middle managers who deal with planning, organizing and the control of the organization.
- Strategic level: Strategic managers who make decisions that guide the manner in which business is done.

Each successively lower level has different OIS requirements and a different, and less extensive, view of the

organization. Obviously, the higher the level, the more interrelated the business functions become until, at the very top, they are viewed as one homogeneous organization with one continuous data flow.

Office automation systems can be effectively utilized in all the clerical, operational, knowledge-work, tactical, and strategic levels, as illustrated in Fig. 2. They can assist workers who work with word processors, electronic mail, and spreadsheets to use, manipulate, disseminate information, and help managers in planning, organizing, control and taking decisions.

OFFICE AUTOMATION SYSTEMS

Typical office automation systems handle and manage documents through word processing, desktop publishing, document imaging, and digital filing, scheduling through electronic calendars, and communication through electronic mail, voice mail, or video conferencing. In this section, 18 different types of OIS are discussed and described that are classify into four categories: productivity tools, digital communication systems, groupware applications, and teleconferencing systems (Fig. 3).

Productivity Tools

Productivity tools are software programs used to create an end product, such as letters, e-mails, brochures, or images. The most easily recognized tool is a word processing program, such as Microsoft Word (7) or Corel WordPerfect (8).

Figure 3. Office information systems.

Other tools help you view, create and modify general office documents such as letters, spreadsheets, memos, presentations, and images.

Word Processing. Of all computer applications, word processing is the most common. Almost every computer has a word processing program of some kind: whether it came free with the operating system or whether it was purchased separately.

In order to perform word processing, it is necessary to acquire a computer, a word processor, and a printer. A word processor enables you to create a document, store it, display it on the computer screen, modify it, and print it using a printer. There are many different word processing programs available, each offering different tools that make it easier to write everything from letters and term papers to theses and Web pages.

Most people use a word processor rather than a typewriter because it allows greater flexibility and control. It is possible to make changes without retyping the entire document. If mistakes are made while typing a text, the cursor can be used to correct errors. Word processors allow text rearranging, changing the layout, formatting the text, and inserting pictures, tables, and charts.

Most word processors available today allow more than just creating and editing documents. They have a wide range of other tools and functions, which are used in formatting documents. The following are the main features of word processors:

Insert, delete, copy, cut, and paste text: Allow to insert, erase, and copy text anywhere in the document. Cut and paste allow removing (cut) a section of text from one place and inserting (paste) it somewhere else in the document.

Search and replace: Allow searching for a particular word and also replacing groups of characters.

Font specifications: Allow to change fonts within a document. For example, you can specify bold, italics, font size and underlining.

Graphics: Allow adding pictures into a document.

Captions and cross-references: Allow placing captions to describe tables and pictures and creating references to them anywhere in the document.

Page setup, headers, and footers: Margins and page length can be adjusted as desired. Allow to specify customized headers and footers that the word processor will put at the top and bottom of every page.

Layout: Allows specifying different margins within a single document and to specify various methods for indenting paragraphs.

Spell checker and thesaurus: Spelling can be checked and modified through the spell check facility. The thesaurus allows the search for synonyms.

Tables of contents and indexes: Allow creating table of contents and indexing.

Print: Allows sending a document to a printer to get a hardcopy.

Spreadsheet. A spreadsheet is a computer program that presents data, such as numbers and text, in a grid of rows and columns. This grid is referred to as a worksheet. You can define what type of data is in each cell and how different cells depend on one another. The relationships between cells are called formulas, and the names of the cells are called labels.

There are a number of spreadsheet applications on the market, Lotus 1-2-3 (9) and Microsoft Excel (10) being among the most famous. In Excel, spreadsheets are referred to as workbooks and a workbook can contain several worksheets. An example of an Excel worksheet is shown in Fig. 4.

Figure 4. Microsoft Excel spreadsheet program.

Figure 5. Editing a document with Microsoft Publisher.

Desktop Publishing. Desktop publishing is the use of the computer and specialized software to create high quality documents for desktop or commercial printing. Desktop publishing is the process of editing and layout of printed material intended for publication, such as books, magazines, brochures, and flyers using a personal computer.

Desktop publishing started in 1985, with the commercialization of the software Aldus PageMaker (11) (now from Abode). Nowadays, there are many software programs available for desktop publishing. QuarkXPress (12), Adobe InDesign (13), Abobe PageMaker (11), and Microsoft Publisher (14) are the most widespread. Figure 5 shows a document being created and edited with Microsoft Publisher.

As word processing programs become more sophisticated, the line separating such programs from desktop publishing systems is becoming fuzzy. Cutting-edge word processing programs give you most of the features you could want in a desktop publishing program. Such programs do not generally replace word processors and graphic applications, but are used to aggregate the text and graphic content created in these programs. The most powerful desktop publishing systems enable the creation of illustrations; while less powerful systems let you insert illustrations created by other programs.

Initial desktop publishing solutions were expensive due to the cost of specialized computing systems and accessories, such as printers and scanners. The cost of computers and printers has fallen dramatically in recent years (e.g., inkjet printers are amazingly inexpensive and most can print in color), allowing most personal users to acquire desktop publishing systems.

Calendars and Schedulers. A calendar program enables us to record events and appointments on an electronic calendar. Calendars allow scheduling, project management, and coordination among many people, and may provide support for scheduling equipment as well. Typical features identify conflicts in schedules, find meeting times that will work for everyone, signal upcoming events, and automatically fill in entries for regular events.

A special type of calendar, called a scheduler, is a solution to manage the daily scheduling needs of a business, such as scheduling appointments, equipment, staff (technicians, professionals, healthcare workers, others), vehicles, resources, projects, and meeting rooms. Scheduling software is an important investment for any type of business that wants to improve its scheduling processes. Every employee can have instant access to whom or what is available at any time of the day, week, month, or year and print detailed list reports. It is also possible to export schedules that may be easily opened in a word processor or spreadsheet.

Paint and Draw Program. A paint program or a graphics program enables the creation of pictures, backgrounds, buttons, lines, and other creative art. Paint programs provide easy ways to draw common shapes, such as straight lines, rectangles, circles, and ovals. Some programs also have photoediting capabilities and are optimized for working with specific kinds of images, such as photographs, but most of the smaller paint programs do not have this option. Paint programs are pixel based. They use "raster" images made up of small dots called pixels. As each dot is an individual, it can be difficult to move shapes around the screen.

A draw program is different from a paint program. Draw programs are object based, where an object is a geometrical shape, such as a line, a circle, a curve, a rectangle, a polygon, or a Bezier curve (curves that have hooks along their length so you can alter the angle of the curve at any point.) With draw programs, images are stored as mathematical information in the form of vectors for the lines and curves of each shape. Sophisticated programs often blur the difference between draw and paint, so it is possible to find programs that are able to do both types of work.

Digital Communication Systems

Nowadays, more and more computers are not isolated but, instead, are connected into a computer network that is often connected to other computer networks in much the same way as telephone systems connect telephones. If a computer is connected to such a network, it is possible to communicate with people whose computers are connected to the same network.

Electronic Mail. Electronic mail, or e-mail for short (another common spelling for e-mail is email), is one of the most popular uses of the Internet. It is a simple tool for exchanging brief messages between individuals or among a larger audience. Most mainframes, minicomputers, and computer networks have an e-mail system.

An e-mail address identifies a person and the computer for purposes of exchanging electronic mail messages. It consists of two parts: user name and mail domain or domain name. The user name identifies a particular person. The mail domain identifies the place on the Internet to which the e-mail for that person should be sent. An e-mail address is read from left to right. An example is illustrated in Fig. 6.

With an e-mail account, it is possible to send a message to anyone with an e-mail account. Just as a written letter can be sent to multiple recipients, an electronic mail message can be sent to one or more e-mail addresses. An e-mail can be broken down into several basic fields that include 'From', 'To', and 'Cc'. The 'From' field contains the address of the sender of the message. The 'To' field indicates the addresses of one or more recipients who are the primary audience. All recipients can see every address listed in this field. Finally, the 'Cc' field (Cc - Carbon Copy) contains the addresses of recipients who are not the primary audience for the e-mail.

An electronic mail message is not limited to text. Other types of files can be added to mail messages as attachments. Attachments can be text files or binary files such as word processed documents, spreadsheets, images, files of

sound and video, and software. To see if you have any e-mail, you can check your electronic mailbox periodically, although many programs can be configured to alert users automatically when mail is received. After reading an e-mail, it may be stored, deleted, replied to, forwarded to others, or printed.

One of the serious problems with reading e-mail on a PC computer running Windows operating system is that the computer can become infected with an e-mail virus program. It is always advisable to install and use anti-virus software. Such software will offer protection against known malicious programs. A malicious program may be a virus, a worm, a trojan horse, or a spyware. Once it is on your system, a malicious program cause disorder by corrupting, erasing, attaching to, or overwriting other files. In some cases malicious program, such as spyware, have the solely intent of monitoring Internet usage and delivering targeted advertising to the affected system. Unexpected e-mail attachments should not be opened since they are one of the most common ways for computer viruses to spread.

Newsgroups and Discussion Boards. Newsgroups, also known as Usenet, are comparable in essence to e-mail systems except that they are intended to disseminate messages among large groups of people instead of one-to-one communication (Fig. 7).

A newsgroup is a collection of messages posted by individuals to a news server. The concept of newsgroups was started in 1979 at the University of North Carolina and Duke University to create a place, where anyone could post messages.

Although some newsgroups are moderated, most are not. Moderated newsgroups are monitored by an individual (the moderator) who has the authority to block messages considered inappropriate. Therefore, moderated newsgroups have less spam than unmoderated ones. Anyone who has access to the board of a newsgroup can read and reply to a message that, in turn, will be read and replied to by anyone else who accesses it. If you have an interest in a certain topic, chances are it has its own newsgroup. A few examples of newsgroups are shown in Table 1.

Discussion boards (also called message boards) and newsgroups in general both accomplish the same task. They each have general topics, and visitors can post messages about specific topics. Discussion boards are usually read through a web browser, while newsgroups are usually read through a special program called a newsgroup reader. Nowadays, most people prefer discussion boards on the Web to newsgroups because they are easier to use.

Figure 6. E-mail address structure.

Figure 7. Newsgroup architecture.

Mailing Lists. The main difference between newsgroups and mailing lists is that newsgroups only show messages to a user when they are explicitly requested, while mailing lists deliver messages as they become available. Mailing lists are e-mail addresses that are used to distribute e-mail to many people. Typically, a list subscriber sends a message to the list address, and the message is then distributed to all the list subscribers for everyone to read.

Mailing lists are simple in operation. The first thing to do is to subscribe to a particular list; afterward the user can send messages to the mail server. The following steps are involved: (1) send a message (e-mail) to a mail server; (2) the mail server sends the message to everyone who is subscribed to the list; and (3) if someone replies to the message, then their reply goes to the mail server and is disseminated to everyone on the list.

Blogs. A weblog, or “blog”, is a personal journal on the Web, although it can also be owned by a small group. The blog owner periodically writes entries and publishes them onto their blog. Weblogs cover as many different topics and express as many opinions, as there are people writing them.

A blog is used to show an up-to-date view of the owner’s work, ideas, and activities. It provides a continuous record of activities, progress, and development. This type of systems can be effectively used by the healthcare community to discuss specific topics of interest. Examples of blog topics include product reviews, scientific endeavors, and any area of information where people have a deep expertise and a desire to express it. The power of blogs is that they are a fluid and dynamic medium that allow several people to easily publish their ideas and opinions, and allow other people to comment on them.

File Transfer Protocol. The ability to share information throughout organizations is essential in today’s business environment. With the explosion of content creation and information in electronic formats, there is simply more electronic data today than ever before. File Transfer Protocol (FTP) is a standard method for sending files from one computer to another over networks, such as the Internet. Applications allow sharing and managing data between multiple remote, local, and home folders. It provides the ability to seamlessly work from a healthcare facility, a remote office, or home and is most commonly used to download a file from a server or to upload a file to a server.

Table 1. Examples of Newsgroups

Newgroup name	Description
comp.ai	Artificial intelligence discussions
sci.cognitive	Perception, memory, judgment and reasoning
comp.groupware	Hardware & software for facilitating group interaction
comp.multimedia	Interactive multimedia technologies of all kinds
comp.infosystems	Any discussion about information systems
comp.graphics	Computer graphics, art, animation, image processing
alt.comp.blind-users	Discussion of the needs of blind users
comp.windows.misc	General issues regarding the use of windows

Groupware Systems

Groupware refers to any computer-related tool that improves the effectiveness of person-to-person communication and collaboration. It is intended to create an environment that fosters the communication and coordination among a group of people. Where a traditional user interface generally focuses on the use of only one person, groupware relates to groups and understanding how people work and function in a group.

The groupware concept takes various applications and functionalities under the umbrella of communication and collaboration and integrates them together as a single client application. Groupware systems generally include some of the following systems: chat systems, whiteboarding, collaborative writing, workflow systems, and hyper-text linking. Groupware packages are diverse in the

Figure 8. Web-based chat system.

functions they offer. Some include group writing, chat and/or e-mail. Sophisticated workgroup systems allow users to define workflows so that data is automatically forwarded to appropriate people at each stage of a process.

Chat Systems. Chat systems enable a type of group communication in which people located in different geographical locations get together in a virtual room and interact with each other by typing text. Chat systems make it possible for many people to write messages in a public space or virtual room. As each person submits a message, it appears on the screen of the other users located in the same virtual room. Chat groups are usually formed via listing chat rooms by name, location, number of people, topic of discussion, and so on.

Recently, systems accessible on the World Wide Web became widely spread among chat users. These types of chat systems are referred to as Web-based chat because they are accessible using a typical browser. One example of Web-based chat can be found at Yahoo.com (see Fig. 8).

Compared to e-mail, a chat system is a real-time synchronous system, while e-mail is neither real-time nor synchronous. When a user types a comment in a chat system, it is seen almost immediately by the others users present in the same virtual room. All the users are connected to the system at the same time. With e-mail, on the other hand, the two parties involved in the exchange of a message do not need to be connected to the system at the same time. For example, when reading an e-mail message the person who writes it may or may not be sitting in front of their computer at that time.

Whiteboard. A whiteboard provides real-time communication over the Internet and has a visual or graphical component in addition to text-based communication. Using a whiteboard, multiple users can simultaneously review, create, and update documents, images, graphs, equations, text, and information. All changes made by one user to the whiteboard area are displayed to all the other whiteboard users. The whiteboard allows participants to manipulate

the contents by clicking and dragging with the mouse. In addition, they can use a remote pointer or highlighting tool to point out specific contents or sections of shared pages.

Most whiteboards are designed for informal conversation, but they may also serve structured communications or more sophisticated drawing tasks, such as collaborative graphic design, publishing, or engineering applications. For example, executives can meet and collaborate on slides for a presentation and architects can revise building plans.

Collaborative Writing Systems. Collaborative writing systems are applications that aim to help the joint editing of text documents by several authors. Coauthors, spread out across different network locations, can work together sharing common documents. When the interactions happen at the same time, they are called synchronous or real-time interactions. Otherwise, they are called asynchronous or non-real-time interactions.

Word processors may provide asynchronous support by showing authorship and by allowing users to track changes and make annotations to documents. It is possible to determine that only certain sections of documents may be modified by specific people to better protect how documents are modified and reduce the number of conflicting comments received. Reviewers can be prevented from making changes unless they turn revision marks on.

Workflow Systems. Workflow management systems (WfMS) appeared in the 1980s, but there is some consensus that the office information systems field is the predecessor of workflow systems (15). Advances in transaction processing and integrated office systems made workflow systems popular in the 1990s. They were innovative and had gained a high level of popularity. Commercial products include IBM MQSeries Workflow, Staffware, TIBCO InConcert, and COSA Workflow. General information on WfMSs can be found at the web sites of the Workflow and Reengineering International Association (16) and the Workflow Management Coalition (17).

A WfMS is implemented in accordance with a business process specification and execution paradigm. Under a WfMS, a workflow model is first created to specify organizational business processes, and then workflow instances are created to carry out the actual steps described in the workflow model. During the workflow execution, the workflow instances can access legacy systems, databases, applications, and can interact with users.

Workflow systems have been installed and deployed successfully in a wide spectrum of organizations. Most workflow management systems, both products and research prototypes, are rather monolithic and aim at providing fully fledged support for the widest possible application spectrum. The same workflow infrastructure can be deployed in various domains, such as bioinformatics, healthcare, telecommunications, military, and school administration.

In Fig. 9, a workflow process from the field of genomics exemplifies how workflow systems can be used to design business processes.

A major task in genomics is determining the complete set of instructions for making an organism. Genome projects are very demanding, and incur high costs of skilled manpower. There are many different types of tasks that must be performed, such as sequencing, sequence finishing, sequence processing, data annotation, and data submission. A single genomic workflow may be spread across multiple research centers, and the individual tasks in a workflow may be carried out at one or more of the participating centers. Many of the challenges of building an information system to manage a physically distributed genome project can be addressed by a workflow system.

The workflow model for such a workflow graphically specifies the control and data flow among tasks. For example, the workflow model in Fig. 9 is composed of several tasks and subworkflows. The tasks illustrated with machine gears represent automatic tasks, while the ones illustrated with boxes represent subworkflows.

At runtime, the workflow system reads the model specifications and transparently schedules task executions,

providing the right data at the right time to the right worker. It manages distributed genomic tasks located at different research centers, such as DNA sequencing machines, matching algorithms, and human resources. Further, the workflow system provides a framework to easily reengineer a genomic workflow when new technological, biological, and chemical advances are made.

Teleconferencing

The term teleconferencing refers to a number of technologies that allow communication and collaboration among people located at different sites. At its simplest, a teleconference can be an audio conference with one or both ends of the conference sharing a speakerphone. With considerably more equipment and special arrangements, a teleconference can be a conference, called a videoconference, in which the participants can see still or motion video images of each other. Using teleconferencing systems, organizations can decrease costs and complexity, while increasing efficiency and productivity.

Audio Conferencing. Audio conferencing is the interaction between groups of people in two or more sites in real time using high quality, mobile, hands-free telephone technology. The interaction is possible with an audio connection via a telephone or network connection. It makes use of conventional communication networks such as POTS (Plain Old Telephone Service), ISDN (Integrated Services Digital Network), and the Internet.

Data Conferencing. Data conferencing is the connection of two or more computer systems, allowing remote groups to view, share, and collaborate on prepared documents or information. Data conferencing platforms make it possible to share applications and files with people in other locations. Everyone can see the same document at the same time and instantly view any changes made to it.

A user can share any program running on one computer with other participants in a conference. Participants can watch as the person sharing the program works, or the

Figure 9. Genomic workflow example.

Figure 10. Microsoft NetMeeting with data, audio, and video conferencing (18).

person sharing the program can allow program control to other meeting participants.

Participants in a data conference can use a chat application to communicate in the absence of audio support. Chat can also be used to type text messages to share common ideas or topics with other conference participants or record meeting notes as part of a collaborative process.

Video Conferencing. Video conferencing uses telecommunications of audio and video to bring geographically dispersed people at different sites together for a meeting. Video conferencing is a valuable strategic tool for millions of individuals and small businesses for face-to-face meetings, team collaborations, brainstorming and training. There are two types of video conferencing: point-to-point and multipoint.

Point-to-point. A point-to-point conference is a connection between two video terminals. Each participant has a video camera, microphone, and speakers connected to a computer. As the two participants speak to one another, their voices are carried over the network and delivered to the other speakers, and images that appear in front of the video camera appear in a window on the other participants' monitor. Connecting two locations can be arranged simply by having one location dial the other, just as in a regular telephone call. No outside assistance is necessary.

Multipoint. A multipoint conference involves a connection among several video terminals connecting several sites with more than one person at different sites. This type of connection requires the assistance of a service to bridge the sites together into one conference. Until the mid-1990s, hardware costs made video conferencing prohibitively expensive for most organizations, but that situation is changing rapidly.

A video conference can involve just video, but some systems combine video, audio and data to provide a complete conferencing solution. One of the first and most popular video conferencing systems is NetMeeting (18). A product developed by Microsoft Corporation that enables

groups to teleconference using the Internet as the transmission medium. NetMeeting (Fig. 10) supports video and audio conferencing, chat sessions, a whiteboard, and application sharing.

NetMeeting has been updated and extended with significant new capabilities designed to make it the most effective online meeting solution for integrated, interactive, and easy-to-use conferencing. The new version of this powerful application is now called Live Meeting (19).

Another well-known video conferencing program to transmit audio and video signals is CU-SeeMe. Originally developed by Cornell University, CU-SeeMe uses the standard bandwidth available on the Internet. Currently, CU-SeeMe is a low-cost software solution to the problem of electronic communication over the Internet.

IP Telephony. IP Telephony, also called 'Internet Telephony', allows voice and data to be transmitted over the same network using an open standards-based Internet Protocol (IP). It makes possible to exchange voice, fax, and other forms of information that have traditionally been carried over the dedicated circuit-switched connections of the public switched telephone network (PSTN). By combining different types of information on a single network connection, small and medium-sized businesses offices can decrease the costs of their voice and data networks.

IP Telephony is essential not just for its capability to reduce costs by combining voice and data communications, but also for its flexibility in supporting branch offices, mobile workers, and telecommuters that were not effective with PSTN. This technology allows an agile application deployment across the enterprise, increased personal and work group productivity, and permits a rapid return on investment.

CONCLUSIONS

Office Automation Systems specializes in allowing information workers to work, communicate, and collaborate. These systems are interactive and have the ability to allow workers to show and share documents or applications. These systems help workers worldwide to minimize the

costs of business travel and streamline communications with co-workers, business partners, and customers.

Healthcare processes are very complex, involving both clinical and administrative tasks, large volumes of data, and a large number of patients and personnel. For example, an out-patient clinic visit involves administrative tasks performed by an assistant and clinical tasks performed by a doctor or by a nurse. For an in-patient hospital visit, this scenario involves more activities, and the process entails a duration that lasts at least as long as the duration of patient hospitalization. Healthcare processes are also very dynamic. As processes are instantiated, changes in healthcare treatments, drugs, and protocols may invalidate running instances, requiring reparative actions. Common problems reported by healthcare organizations include delays due to the lack of timely communication; time invested in completing and routing paper-based forms; errors due to illegible and incomplete patient information; frustration due to the amount of time spent on administrative tasks instead of patient interactions; long patient wait times caused by slow communication of patient information.

Office automation systems are a major asset to solve many of the problems identified by the healthcare community. For example, using Workflow management systems, paper forms can be easily converted into digital forms for use by caregivers. These electronic forms can be used throughout the patient care process from registration and triage to placing lab orders and charting treatment plans. These forms can be easily modified to accommodate changing business processes. By automating clinical forms processes and eliminating manual systems, caregivers can streamline patient information management and treatment flow. Workflow management systems can connect the data and processes in clinical forms with other systems, such as a lab or patient records system. As another example, using whiteboard technologies, caregivers and administrators can access a central location to view patient information and status including triage category, and lab order status. This level of access can help to quickly determine the next steps in each patient's care. Blogs can also be effectively used by healthcare professionals to discuss specific topics of interest, such as product reviews, scientific endeavors, patient's treatments, and any area of information where people have a deep expertise and a desire to express it.

OPTICAL SENSORS

YITZHAK MENDELSON
Worcester Polytechnic Institute

INTRODUCTION

Optical sensing techniques have attracted extraordinary interest in recent years because of the key role they play in the development of medical diagnostic devices. Motivated by the expense and time constraints associated with traditional laboratory techniques, there is a growing need to continue and develop more cost-effective, simpler, and rapid methods for real-time clinical diagnostics of vital physiological parameters.

Optical sensors play a pivotal role in the development of highly sensitive and selective methods for biochemical analysis. The number of publications in the field of optical sensors used for biomedical and clinical applications has grown significantly during the past two decades. Numerous books, scientific reviews, historical perspectives, and conference proceedings have been published on biosensors including optical sensors and the reader interested in this

rapidly growing field is advised to consult these excellent sources for additional reading (see Reading List). Some of these references discuss different optical sensors used in research applications and optical-based measurement techniques employed primarily in bench-top clinical analyzers. The emphasis of this article is on the basic concept employed in the development of optical sensors including specific applications highlighting how optical sensors are being utilized for real-time *in vivo* and *ex vivo* measurement of clinically significant biochemical variables, including some examples of optical sensor used for *in vitro* diagnosis. To narrow the scope, this article concentrates on those sensors that have generally progressed beyond the initial feasibility phase and have either reached or have a reasonable good potential of reaching the commercialization stage.

GENERAL PRINCIPLES OF OPTICAL BIOSENSING

The fundamental principle of optical sensors is based on the change in optical properties of a biological or physical medium. The change produced may be the result of the intrinsic changes in absorbance, reflectance, scattering, fluorescence, polarization, or refractive index of the biological medium. Optical sensors are usually based either on a simple light source–photodetector combination, optical fibers, or a planar waveguide. Some types of optical sensors measure changes in the intrinsic optical properties of a biological medium directly and others involve a specific indicator.

Biosensors are typically considered a separate subclassification of biomedical sensors. A biosensor, by definition, is a biomedical sensor consisting of an integrated biological component that provides the selectivity and a physical transducer to provide a solid support structure. Two major optical techniques are commonly available to sense optical changes at optical biosensor interfaces. These are usually based on evanescent wave, which was employed in the development of fiber optic sensors (see the section on Fiber Optic Sensors), and surface plasmon resonance principles, which played a pivotal role in the development and recent popularity of many optical biosensors. The basic principle of each measurement approach will be described first followed by examples arranged according to specific clinical applications.

Evanescent-Wave Spectroscopy

The propagation of light along a waveguide (e.g., a planar optical slab substrate or optical fiber) is not confined to the core region. Instead, when light travels through a waveguide at angles approaching the critical angle for total internal reflection, the light penetrates a characteristic short distance (on the order of one wavelength) beyond the core surface into the less optically dense (known as the cladding) medium as illustrated in Fig. 1. This effect causes the excitation of an electromagnetic field, called the “evanescent” wave, which depends on the angle of incidence and the incident wavelength. The intensity of the evanescent-wave decays exponentially with distance, starting at the interface and extending into the cladding medium.

Figure 1. Principal diagram illustrating evanescent-wave spectroscopy sensing. Part of the incident light traveling through the waveguide at the critical angle (ϕ) penetrates a short distance into the substrate to be sensed and the remaining light is refracted.

The evanescent-wave can interact with molecules that are present within the penetration depth distance. This interaction causes attenuation of the incident light intensity and is related to the concentration of the molecules. This phenomenon can be exploited in the development of optical biosensors. For example, if the cladding is stripped and a substrate (such as a ligand) is immobilized on the core, the light will travel through this layer into the sample medium. Reactions close to the interface will perturb the evanescent field and the change in signal can be related to the amount of binding between the target and immobilized ligand at the interface. The measured parameter may be absorbance, fluorescence, or refractive index.

The method was first used as a means to study ultrathin films and coatings, and later was widely exploited to construct different types of optical sensors for biomedical applications. Because of the short penetration depth and the exponentially decaying intensity, the evanescent wave is absorbed by compounds that must be present very close to the surface. The principle can be utilized to characterize interactions between receptors that are attached to the surface of the optical sensor and ligands that are present in the solution probed by the sensor.

The key component in the successful implementation of evanescent-wave spectroscopy is the interface between the sensor surface and the biological medium. Receptors must retain their native conformation and binding activity and sufficient binding sites must be present for multiple interactions with the analyte. In the case of analytes having weakly optical absorbing properties, sensitivity can be enhanced by combining the evanescent-wave principle with multiple internal reflections along the sides of an unclad portion of a fiber optic tip. Alternatively, instead of an absorbing species, a fluorophore can be coated onto

the uncladded fiber. Light propagating along the fiber core is partially absorbed by the fluorophore, emitting detectable fluorescent light at a higher wavelength and thus providing improved sensitivity.

Surface Plasmon Resonance

When monochromatic polarized light (e.g., from a laser source) impinges on a transparent medium having a conducting metalized surface (e.g., Ag or Au), there is a charge density oscillation at the interface. When light at an appropriate wavelength interacts with the dielectric-metal interface at a defined angle, called the resonance angle, there is a match of resonance between the energy of the photons and the electrons at the metal interface. As a result, the photon energy is transferred to the surface of the metal as packets of electrons, called plasmons, and the light reflection from the metal layer will be attenuated. This results in a phenomenon known as surface plasmon resonance (SPR) as illustrated schematically in Fig. 2. The resonance is observed as a sharp dip in the reflected light intensity when the incident angle is varied. The resonance angle depends on the incident wavelength, the type of metal, polarization state of the incident light, and the nature of the medium in contact with the surface. Any change in the refractive index of the medium will produce a shift in the resonance angle, thus providing a highly sensitive means of monitoring surface interactions.

The SPR is generally used for sensitive measurement of variations in the refractive index of the medium immediately surrounding the metal film. For example, if an antibody is bound to or adsorbed into the metal surface, a noticeable change in the resonance angle can be readily observed because of the change of the refraction index at the surface assuming all other parameters are kept constant. The advantage of this concept is the improved ability to detect the direct interaction between antibody and antigen as an interfacial measurement.

Optical Fibers

An optical fiber consists of two parts: a core (typically made of a thin glass rod) with a refractive index n_1 , and an outer layer (cladding) with a refractive index n_2 , where $n_1 > n_2$.

Figure 2. Principle of a SPR detection system. Courtesy of Biacore AB. An increased sample concentration causes a corresponding increase in refractive index that in turn alters the angle of incidence required to create the SPR angle.

The refractive indexes of the core and cladding depend on their material properties. Optical fibers are based on the principle of total internal reflection where incident light is transmitted through the core of the fiber with very little loss. The light strikes the cladding at an angle greater than the so-called critical angle, so that it is totally internally reflected at the core-cladding interface.

Several types of biomedical measurements can be made using either a plain optical fiber as a remote device for detecting changes in the intrinsic spectral properties of tissue or blood, or optical fibers tightly coupled to various indicator-mediated transducers. The measurement relies either on direct illumination of a sample through the end-face of the fiber or by excitation of a coating on the sidewall surface through evanescent wave coupling. In both cases, sensing takes place in a region outside the optical fiber itself. Light emanating from the fiber end is scattered or fluoresced back into the fiber, allowing measurement of the returning light as an indication of the optical absorption or fluorescence of the sample at the fiber tip.

A block diagram of a generic instrument for an optical fiber-based sensor is illustrated in Fig. 3. The basic building blocks of such an instrument are the light source, various optical coupling elements, an optical fiber guide with or without the necessary sensing medium incorporated at the distal tip, and a photodetector.

Probe Configurations

A number of different methods can be used to implement fiber optic sensors. Most fiber optic chemical sensors employ either a single fiber configuration, where light travels to and from the sensing tip in one fiber, or a double-fiber configuration, where separate optical fibers are used for illumination and detection. A single fiber optic

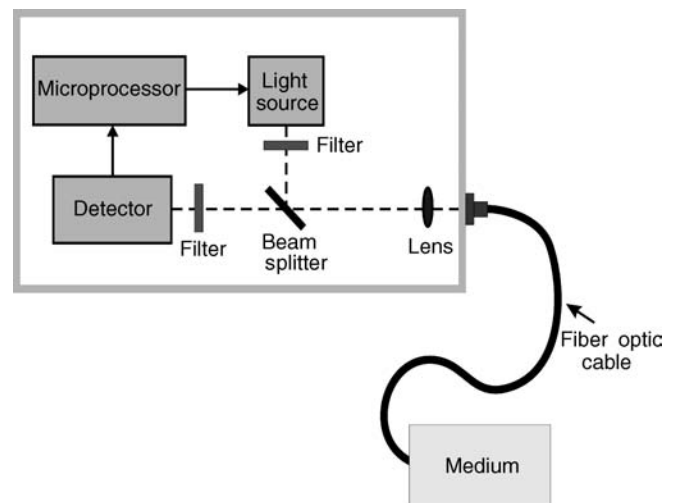

Figure 3. General building blocks of a fiber optic-based instrument for biomedical sensing applications. Typically, a microprocessor is used to control the light intensity and can be used to select either a fixed or a range of wavelengths for sample illumination. The microprocessor is also used to process the output of the photodetector.

configuration offers the most compact and potentially least expensive implementation. However, additional challenges in instrumentation are involved in separating the returning illuminating from the incident light illumination.

Intravascular fiber optic sensors are introduced into a vessel via a catheter. The design of intravascular fiber optic sensors requires additional considerations related to the sterility and biocompatibility of the catheter. For example, intravascular fiber optic sensors must be sterilizable and their material has to be nonthrombogenic and resistant to platelet and protein deposition. Therefore, these catheters are typically made of materials covalently bound with heparin or antiplatelet agents. The catheter is normally introduced via venous or arterial puncture and a slow heparin flush is maintained while the catheter remains in the body for short-term sensing, typically only for a few hours.

Indicator-Mediated Transducers

Indicator-mediated transducers are based on the coupling of light to a specific recognition element so that the sensor can respond selectively and reversibly to a change in the concentration of a particular analyte. The problem is that only a limited number of biochemical analytes have an intrinsic optical absorption that can be measured directly by spectroscopic methods with sufficient selectivity. Other species, particularly hydrogen ions and oxygen, which are of primary interest in diagnostic applications, do not have an intrinsic absorption and thus are not suitable analytes for direct photometry. Therefore, indicator-mediated transducers have been developed using specific reagents that can be immobilized on the surface of an optical sensor. These transducers may include indicators and ionophores (i.e., ion-binding compounds) as well as a wide variety of selective polymeric materials.

Figure 4 illustrates typical indicator-mediated fiber optic sensor configurations. In Fig. 4a, the indicator is immobilized directly on a membrane positioned at the end of a fiber. An indicator can be either physically retained in position at the end of the fiber by a special permeable membrane (Fig. 4b), or a hollow capillary tube (Fig. 4c). Polymers are sometimes used to enclose the indicator and selectively pass the species to be sensed.

Advantages and Disadvantages of Optical Fiber Sensors

Advantages of fiber optic sensors include their small size and low cost. In contrast to electrical measurements, fiber optic are self-contained, and therefore do not require an external reference signal from a second electrode. Because the signal that is transmitted is an optical signal, there is no electrical risk to the patient and the measurement is immune from interference caused by surrounding electric or magnetic fields. This makes fiber optic sensors very attractive for applications involving intense electromagnetic or radiofrequency fields, for example, near a magnetic resonance imaging (MRI) system or electrosurgical equipment. Chemical analysis can be performed in real-time with almost an instantaneous response. Furthermore, versatile sensors can be developed that respond to

Figure 4. Typical configuration of different indicator-mediated fiber optic sensor tips showing different methods for placement of a reagent. Reprinted with permission from *Fiber optic chemical sensors and biosensors*, Vol. I, Wolfbeis OS, editor, CRC Press, Boca Raton, FL, c1991.

multiple analytes by utilizing multiwavelength measurements.

Despite unique advantages and promising feasibility studies, optical fiber sensors exhibit several shortcomings. Sensors with immobilized dyes and other indicators have limited long-term stability *in vivo* and their shelf-life degrades significantly over time.

INSTRUMENTATION

Instrumentation for optical measurements generally consist of (1) a light source to illuminate the medium, (2) optical components to generate a light beam with specific characteristics and to direct this light to some sensing agent or physical compartment, and (3) a photodetector for converting the optical signal to an electrical signal. The actual implementation of instrumentation designed to construct or interface with optical sensors vary greatly depending on the type of optical sensor used and its intended medical application.

Light Sources

Wide selections of light sources are available commercially for use in optical sensor applications. These include: narrow-band semiconductor diode lasers, broad spectral band incandescent lamps, and solid-state light emitting diodes (LEDs). The important requirement of a light source is obviously good stability. In certain applications, for example, in portable instrumentation, LEDs have significant advantages over other light sources since they are small, inexpensive, consume less power, produce selective wavelengths, and are easy to work with. In contrast, tungsten

lamps produce a broader range of wavelengths, have higher intensities, but require a stable and sizable power supply. Furthermore, incandescent lamps produce significant heat that can degrade or destroy delicate biological samples so special provisions must be made for thermal dissipation of excessive heat.

Optical Elements

Different optical elements can be used to manipulate light in optical instrumentation. These may include mirrors, lenses, light-choppers, beam-splitters, and couplers for directing the light from the light source to the measurement site and back to the photodetector. If special waveguides are involved, additional components may be required to direct the light into the small aperture of an optical fiber or a specific area on a waveguide surface, and collecting the light from the sensor before it is processed by the photodetector. For a narrow wavelength selection when a broad bandwidth incandescent light source is utilized, optical filters, prisms, or diffraction gratings are the most common used components.

Photodetectors

Several specifications must be considered in choosing photodetectors for optical sensors. These include: detector sensitivity, noise level, spectral response, and response time. The most popular photodetectors employed in biomedical sensors are semiconductor quantum photodetectors, such as Silicon photodiodes. The choice, however, is somewhat dependent on the wavelength region of interest. Often, dual photodetectors are used in spectrophotometric instrumentation because it is frequently necessary to include a separate reference photodetector to track fluctuations in source intensity and temperature. By taking a ratio between the reference photodetector, which measures part of the light that is not affected by the measurement, and the primary photodetector, which measures the light intensity that interacts with the analyte, it is possible to obtain a more accurate and stable measurement.

Signal Processing

The signal obtained from a photodetector typically provides a current or voltage proportional to the measured light intensity. Therefore, simple analog circuitry (e.g., a current-to-voltage converter or connection to a programmable gain voltage amplifier) is required. Sometimes, the output from a photodetector is connected directly to a pre-amplifier before it is applied to a sampling and analog-to-digital conversion circuitry. More recently, advanced Sigma-Delta type analog-to-digital converters became available commercially that can accept input current directly from a photodiode, thus eliminating the need for a separate current-to-voltage converter stage.

Frequently, two different wavelengths of light are utilized to perform a specific measurement. One wavelength is usually sensitive to changes in the analyte being measured, while the other wavelength is unaffected by changes in the analyte concentration. In this manner, the unaf-

ected wavelength is used as a reference to compensate for fluctuations in instrumentation properties over time. In other applications, additional discriminations, such as pulse excitation or electronic background subtraction utilizing a synchronized lock-in amplifier, are useful to gain significant improvement in selectivity and sensitivity.

IN VIVO APPLICATIONS

Glucose Sensors

Research has shown that tightly controlling blood sugar levels can prevent or slow down the development of problems related to diabetes. Presently, the conventional method for measuring blood glucose requires a drop of blood and relies on an electrochemical reaction of glucose with a glucose-specific enzyme such as glucose oxidase. During the past 20 years, numerous attempts have been made to develop optical sensors for continuous invasive and noninvasive measurement of blood glucose. The main driving forces for developing a blood glucose sensor is to enable the development of a closed-loop artificial endocrine pancreas for optimizing the treatment of diabetes. Continuous monitoring of blood glucose would provide the patient more useful information on daily fluctuations in glucose levels, will increase patient's motivation and compliance for daily self-monitoring, and would aid in the optimization of insulin therapy resulting in better metabolic control. If perfected, such a system could provide reliable early warning of large excursions in blood glucose levels that may lead to hypo- and hyperglycemic conditions. Therefore, it would be valuable in preventing long-term complications associated with diabetes, such as coronary artery disease, neuropathy, retinopathy, and hypertension.

A fiber optic sensor for measuring blood glucose *in vivo* utilizing the concept of competitive binding was described by Schultz et al. (1). The idea was based on an analyte (glucose) that competes for binding sites on a substrate (the Lectin Concanavalin A) with a fluorescent indicator-tagged polymer [fluorescein isothiocyanate (FITC)-dextran]. The sensor was arranged so that the substrate is fixed in a position out of the optical path of the fiber end. The substrate is bound to the inner wall of a glucose-permeable hollow fiber tubing and fastened to the end of an optical fiber. The hollow fiber acts as the container and is impermeable to the large molecules of the fluorescent indicator. The light beam that extends from the fiber "sees" only the unbound indicator in solution inside the hollow fiber, but not the indicator bound on the container wall. Excitation light passes through the fiber and into the solution, causing the unbound indicator to fluoresce, and the fluorescent light passes back along the same fiber to a measuring system. The fluorescent indicator and the glucose are in competitive binding equilibrium with the substrate. The interior glucose concentration equilibrates with its concentration exterior to the probe. If the glucose concentration increases, the indicator is driven off the substrate to increase the concentration of the indicator. Thus, fluorescence intensity as seen by the optical fiber follows changes in the glucose concentration. *In vivo* studies

demonstrated fairly close correspondence between the sensor output and actual blood glucose levels. Another novel approach based on fluorescent molecules was suggested by Pickup et al.(2). The idea relied on the covalent binding of a fluorescent dye to glucose that results in a reduction of its fluorescence intensity when excited by light.

Although the measurement of glucose in plasma and whole blood *in vitro* is feasible (3), a more attractive approach for measuring blood glucose involves noninvasive measurement (4–6). The basic premise is to direct a light beam through the skin or laterally through the eye and analyze either the backscattered or transmitted light intensity. Three methods have been commonly attempted based either on changes in light absorption, polarization, or light scattering induced by variations in blood glucose. Although light in the visible and lower part of the near-infrared (NIR) region of the spectrum (700–2400 nm) can penetrate safely down to the vascular layer in the skin without significant attenuation there are major obstacles associated with noninvasive glucose measurement using spectrophotometry. Specifically, the concentration of glucose in tissue and blood is relatively low and light absorption in the NIR region is profoundly dependent on the concentration of water and temperature. Moreover, glucose has no unique absorption peaks in the visible or NIR region of the spectrum. Therefore, physiological variations in blood glucose induce only small and nonspecific changes in backscattered light intensity. Since measurements in the NIR region are due to low energy electronic vibrations, as well as high order overtones of multiple bands, NIR spectroscopy remains purely empirical. Thus, to extract accurate quantitative information related to variations in blood glucose, it is necessary to employ multivariate statistical calibration techniques and extensive chemometric analysis.

In principle, changes in light scattering caused by variations in blood glucose may offer another potential method for measuring glucose noninvasively. The fundamental principle exploited assumes that the refractive index of cellular structures within the skin remains unchanged while an increase in blood glucose leads to a subsequent rise in the refractive index of the blood and interstitial fluid. Limited studies involving glucose tolerance tests in humans (7,8) showed that changes in blood glucose could be measured from changes in light scattering. However, obtaining reliable and accurate measurement of blood glucose noninvasively using NIR spectroscopy remains challenging, mainly because other blood analytes (proteins, urea, cholesterol, etc.), as well as confounding physiological factors such as variations in blood flow, temperature, water content, and physical coupling of the sensor to the skin, are known to influence the measurement.

The implementation of an artificial pancreas would ultimately represent a major technological breakthrough in diabetes therapy. To date, however, inadequate specificity and insufficient accuracy within the clinically relevant range provide major obstacle in achieving this milestone with noninvasive blood glucose sensors using optical means.

Oximetry

Oximetry refers to the colorimetric measurement of the degree of oxygen saturation (SO_2), that is, the relative amount of oxygen carried by the hemoglobin in the erythrocytes. The measurement is based on the variation in the color of deoxyhemoglobin (Hb) and oxyhemoglobin (HbO_2). A quantitative method for measuring blood oxygenation is of great importance in assessing the circulatory and respiratory status of a patient.

Various optical methods for measuring the oxygen saturation in arterial (SO_2) and mixed-venous (SvO_2) blood have been developed, all based on light transmission through, or reflection from, tissue and blood. The measurement is performed at two specific wavelengths: λ_1 , where there is a large difference in light absorbance between Hb and HbO_2 (e.g., 660 nm red light), and a second wavelength, λ_2 , which can be an isobestic wavelength (e.g., 805 nm IR light), where the absorbance of light is independent of blood oxygenation, or a higher wavelength in the near-IR region, typically between 805 and 960 nm, where the absorbance of Hb is slightly smaller than that of HbO_2 .

The concept of oximetry is based on the simplified assumption that a hemolyzed blood sample consists of a two-component homogeneous mixture of Hb and HbO_2 , and that light absorbance by the mixture of these two components is additive. Hence, a simple quantitative relationship can be derived for computing the oxygen saturation of blood based on the relationship:

$$SO_2 = K_1 - K_2[OD(\lambda_1)/OD(\lambda_2)]$$

where K_1 and K_2 are empirically derived coefficients that are functions of the specific absorptivities (also called optical extinction) of Hb and HbO_2 , and OD (optical density) denotes the corresponding absorbance of the blood at a specific wavelength.

Since the original discovery of this phenomenon > 50 years ago (9), there has been progressive development in instrumentation to measure SO_2 along three different paths. Bench-top oximeters for clinical laboratories, which measure the concentration of Hb and HbO_2 from a small sample of arterial blood, fiber optic catheters for intravascular monitoring, and transcutaneous sensors, which are noninvasive devices placed on the skin.

Mixed-Venous Fiber Optic Catheters

Fiber optic oximeters for measuring mixed-venous oxygen saturation (SvO_2) were first described in the early 1960s by Polanyi and Hehir (10). They demonstrated that in a highly scattering medium, such as blood, it is feasible to use reflectance measurement to determine SO_2 in a flowing blood medium. Accordingly, they showed that a linear relationship exists between SO_2 and the ratio of the infrared-to-red (IR/R) light that is backscattered from blood:

$$SO_2 = A - B(IR/R)$$

where, A and B are empirically derived calibration coefficients.

The ability to rely on light reflectance for measurement of SO_2 *in vivo* subsequently led to the commercial development of fiber optic catheters for intravascular monitoring of SvO_2 inside the pulmonary artery.

Under normal conditions, oxygen consumption is less than or equal to the amount of oxygen delivered. However, in critically ill patients, oxygen delivery is often insufficient for the increased tissue demands, because many such patients have compromised compensatory mechanisms. If tissue oxygen demands increase and the body's compensatory mechanisms are overwhelmed, the venous oxygen reserve will be tapped, and that change will be reflected as a decreased SvO_2 . Venous oxygen saturation in the pulmonary artery is normally $\sim 75\%$. Although no specific SvO_2 level has been correlated with adverse physiological effects, an SvO_2 level of 53% has been linked to anaerobic metabolism and the production of lactic acid (11), while an SvO_2 level of 50% or less indicates that oxygen delivery is marginal for oxygen demands, and thus venous oxygen reserve is reduced. Thus, continuous SvO_2 monitoring can be used to track the available venous oxygen reserve.

A fiber optic pulmonary artery catheter, with its tip in the pulmonary artery, can be used to sample the outflow from all tissue beds. For this reason, SvO_2 is regarded as a reliable indicator of tissue oxygenation (12) and therefore is used to indicate the effectiveness of the cardiopulmonary system during cardiac surgery and in the ICU.

Fiber optic SvO_2 catheters consist of two separate optical fibers; one fiber is used for transmitting the light to the flowing blood and a second fiber directs the backscattered light to a photodetector. The catheter is introduced into the vena cava and further advanced through the heart into the pulmonary artery by inflating a small balloon located at the distal end. The flow-directed catheter also contains a small thermistor for measuring cardiac output by thermol-dilution.

Several problems limit the wide clinical application of intravascular fiber optic oximeters. These include the dependence of the optical readings on hematocrit and motion artifacts due to catheter tip "whipping" against the blood vessel wall. Additionally, the introduction of the catheter into the heart requires an invasive procedure and can sometimes cause arrhythmias.

Pulse Oximetry

Noninvasive monitoring of SaO_2 by pulse oximetry is a rapidly growing practice in many fields of clinical medicine (13). The most important advantage of this technique is the capability to provide continuous, safe, and effective monitoring of blood oxygenation.

Pulse oximetry, which was first suggested by Aoyagi et al. (14) and Yoshiya et al. (15), relies on the detection of time-variant photoplethysmographic (PPG) signals, caused by changes in arterial blood volume associated with cardiac contraction. The SaO_2 is derived by analyzing the time-variant changes in absorbance caused by the pulsating arterial blood at the same R and IR wavelength used in conventional invasive-type oximeters. A normalization process is commonly performed by which the pulsatile (ac) component at each wavelength, which results from

Figure 5. A disposable finger probe of a noninvasive transmission pulse oximeter. Reprinted by permission of Nellcor Puritan Bennett, Inc., Pleasanton, California. The sensor is wrapped around the fingertip using a self-adhesive tape backing.

the expansion and relaxation of the arterial bed, is divided by the corresponding nonpulsatile (dc) component of the PPG, which is composed of the light absorbed by the blood-less tissue and the nonpulsatile portion of the blood compartment. This effective scaling process results in a normalized R/IR ratio, which is dependent on SaO_2 , but is largely independent of the incident light intensity, skin pigmentation, tissue thickness, and other nonpulsatile variables.

Pulse oximeter sensors consist of a pair of small and inexpensive R and IR LEDs and a highly sensitive silicon photodiode. These components are mounted inside a reusable rigid spring-loaded clip, a flexible probe, or a disposable adhesive wrap (Fig. 5). The majority of the commercially available sensors are of the transmittance type in which the pulsatile arterial bed (e.g., ear lobe, fingertip, or toe) is positioned between the LEDs and the photodiode. Other probes are available for reflectance (backscatter) measurement, where both the LEDs and photodiode are mounted side-by-side facing the skin (16,17).

Numerous studies have evaluated and compared the accuracy of different pulse oximeters over a wide range of clinical conditions (18–21). Generally, the accuracy of most noninvasive pulse oximeters is acceptable for a wide range of clinical applications. Most pulse oximeters are accurate to within $\pm 2\text{--}3\%$ in the SaO_2 range between 70 and 100%.

Besides SaO_2 , most pulse oximeters also offer other display features, including pulse rate and analogue or bar graph displays indicating pulse waveform and relative pulse amplitude. These important features allow the user to assess in real time the quality and reliability of the measurement. For example, the shape and stability of the PPG waveform can be used as an indication of possible motion artifacts or low perfusion conditions. Similarly, if the patient's heart rate displayed by the pulse oximeter differs considerably from the actual heart rate, the displayed saturation value should be questioned.

Several locations on the body, such as the ear lobes, fingertips, and toes, are suitable for monitoring SaO_2 with transmission pulse oximeter sensors. The most popular sites are the fingertips since these locations are convenient to use and a good PPG signal can be quickly obtained.

Other locations on the skin that are not accessible to conventional transillumination techniques can be monitored using a reflection (backscatter) SaO_2 sensor. Reflection sensors are usually attached to the forehead or to the temples using a double-sided adhesive tape.

Certain clinical and technical situations may interfere with the proper acquisition of reliable data or the interpretation of pulse oximeter readings. Some of the more common problems are low peripheral perfusion associated, for example, with hypotension, vasoconstriction, or hypothermia conditions. Also, motion artifacts, the presence of significant amounts of dysfunctional hemoglobins (i.e., hemoglobin derivatives that are not capable of reversibly binding with oxygen), such as HbCO and methemoglobin, and intravenous dyes introduced into the blood stream (e.g., methylene blue).

Pulse oximetry is widely used in various clinical applications including anesthesia, surgery, critical care, hypoxemia screening, exercise, during transport from the operating room to the recovery room, in the emergency room, and in the field (22–26). The availability of small and lightweight optical sensors makes SaO_2 monitoring especially applicable for preterm neonates, pediatric, and ambulatory patients. In many applications, pulse oximetry has replaced transcutaneous oxygen tension monitoring in neonatal intensive care. The main utility of pulse oximeters in infants, especially during the administration of supplemental oxygen, is in preventing hyperoxia since high oxygen levels in premature neonates is associated with increased risk of blindness from retrolental fibroplasia.

During birth, knowing the blood oxygenation level of the fetus is of paramount importance to the obstetrician. Lack of oxygen in the baby's blood can result in irreversible brain damage or death. Traditionally, physicians assess the well being of the fetus by monitoring fetal heart rate and uterine contractions through the use of electronic fetal monitoring, which are sensitive, but generally not specific. Approximately one-third of all births in the United States are marked by a period in which a nonreassuring heart rate is present during labor. Without a reliable method to determine how well the fetus is tolerating labor and when dangerous changes in oxygen levels occur, many physicians turn to interventions, such as cesarean deliveries.

Recently, the FDA approved the use of new fetal oxygen monitoring technology, originally developed by Nellcor (OxiFirst, Tyco Healthcare). The pulse oximeter utilizes a disposable shoehorn-shaped sensor (Fig. 6), which is inserted through the birth canal during labor, after the amniotic membranes have ruptured and the cervix is dilated at least 2 cm. The sensor, which comprises the same optical components as other pulse oximeter sensors used for nonfetal applications, rests against the baby's cheek, forehead, or temple, and is held in place by the uterine wall. The fetus must be of at least 36 weeks

Figure 6. Optical probe and a fetal pulse oximeter. Reprinted by permission of Nellcor Puritan Bennett, Inc., Pleasanton, California. The shape of the optical sensor is contoured to enable proper placement of the sensor against the fetus face.

gestation with the head in the normal vertex position for delivery. A controlled, randomized clinical trial, has demonstrated the safety and effectiveness of this new technology (27,28). While some clinical studies found that the rate of caesarean section for nonreassuring heart rate was significantly lower among the group of women monitored by the OxiFirst system, it is not yet clear whether the use of a fetal pulse oximeter may lead to a reduction in the number of Caesarean sections performed. Therefore, the American College of Obstetrics and Gynecology has not yet endorsed the use of this technology in clinical practice.

Noninvasive Cerebral Oximetry

Somanetics, Inc. (Troy, MI) has developed a noninvasive cerebral oximeter (INVOS) for monitoring of changes in brain oxygen saturation that can be used to alert clinicians to changes in the critical balance between arterial oxygen delivery and cerebral consumption (29–31). The method is based on NIR light photons injected by a light source into the skin over the forehead as illustrated in Fig. 7. After being scattered inside the scalp, skull, and brain, some fraction of the incident photons return and exit the skin. By measuring the backscattered light intensity as a function of two wavelengths, 730 and 810 nm, it is possible to

The mean photon path in tissue is a "banana" shape

Figure 7. Principle of the INVOS cerebral oximeter. Courtesy of Somanetics, Corp, Troy, MI. Two photodetectors are used to capture the backscattered light from different depths in the brain.

measure changes in regional hemoglobin oxygen saturation (rSO₂ index).

The measurement is intuitively based on the fact that the greater the separation of source and detector, the greater the average depth of penetration. Photons that happen to meander close to the surface are very likely to be lost out of the skin before getting to a distant detector. Large source-detector separation is therefore biased against “shallow” photons except in the tissues directly under the optical sensor. On the other hand, geometry and absorption also make it statistically unlikely that very deeply penetrating photons will find their way back to the detector. Most of the photons reaching the detector tend to take some optimum middle course. This mean photon path is shaped approximately like a “banana” with ends located at the light source and photodetector.

To reduce extraneous spectroscopic interference that is dominated by light scattered by the surrounding bone, muscle, and other tissues, the INVOS SomaSensor[®] oximeter uses two source-detector separations: a “near” (shallow) spacing and a “far” (deep) spacing. The dual detectors sample about equally the shallow layers in the illuminated tissue volumes positioned directly under the light sources and photodetectors, but the far-spaced detector “sees” deeper than the near-spaced detector. By subtracting the two measurements, the instrument is able to suppress the influence of the tissues outside the brain to provide a measurement of changes in brain oxygen saturation.

Measurement of Blood Gases

Accurate measurement of arterial blood gases, that is, oxygen partial pressure (pO_2), carbon dioxide partial pressure (pCO_2), and pH, is one of the most frequently performed tests in the support of critically ill patients. The measurement is essential for clinical diagnosis and management of respiratory and metabolic acid–base problems in the operating room and the ICU. Traditionally, blood gases have been measured by invasive sampling, either through an indwelling arterial catheter or by arterial puncture, and analyzed in a clinical laboratory by a bench-top blood gas analyzer. However, this practice presents significant drawbacks: Sampling is typically performed after a deleterious event has happened, the measurement is obtained intermittently rather than continuously so physicians can not immediately detect significant changes in a patient’s blood gas status, there could be a considerable delay between the time the blood sample is obtained and when the readings become available, there is an increased risk for patient infection, and there is discomfort for the patients associated with arterial blood sampling. Furthermore, frequent arterial blood gas sampling in neonates can also result in blood loss and may necessitate blood transfusions.

In view of the above drawbacks, considerable effort has been devoted over the last three decades to develop either disposable extracorporeal sensors (for *ex vivo* applications) or intraarterial fiber optic sensors that can be placed in the arterial line (for *in vivo* applications) to enable continuous trending that is vital for therapeutic interventions in ICU patients who may experience spontaneous and often

unexpected changes in acid–base status. Thus, with the advent of continuous arterial blood gas monitoring, treatment modalities can be proactive rather than reactive. Although tremendous progress has been made in the miniaturization of intravascular blood gas and pH sensors, in order to be acceptable clinically, further progress must be achieved on several fronts. Specifically, there is a need to improve the accuracy and reliability of the measurement especially in reduced blood flow and hypotensive conditions. Additionally, sensors must be biocompatible and nonthrombogenic, the readings must be stable and respond rapidly to changes in physiological conditions, and the disposable sensors need to be inexpensive and more cost effective.

Intravascular Optical Blood Gas Catheters

In the early 1970s, Lubbers and Opitz (32) originated what they called “optodes” (from the Greek word ‘*optical path*’) for measurements of important physiological gases in fluids and in gases. The principle upon which these sensors were designed originally was based on a closed compartment containing a fluorescent indicator in solution, with a membrane permeable to the analyte of interest (either ions or gases) constituting one of the compartment walls. The compartment was coupled by optical fibers to a system that measured the fluorescence inside the closed compartment. The solution equilibrates with the pO_2 or pCO_2 of the medium placed against it, and the fluorescence intensity of an indicator reagent in the solution was calibrated to the partial pressure of the measured gas.

Intraarterial blood gas optodes typically employ a single or a double fiber configuration. Typically, the matrix containing the indicator is attached to the end of the optical fiber. Since the solubility of O₂ and CO₂ gases, as well as the optical properties of the sensing chemistry itself, are affected by temperature variations, fiber optic intravascular sensors include a thermocouple or thermistor wire running alongside the fiber optic cable to monitor and correct for temperature fluctuations near the sensor tip. A nonlinear response is characteristic of most chemical indicator sensors, so they are designed to match the concentration region of the intended application. Also, the response time of optodes is somewhat slower compared to electrochemical sensors.

Intraarterial fiber optic blood gas sensors are normally placed inside a standard 20-gage arterial cannula, which is sufficiently small thus allowing adequate spacing between the sensor and the catheter wall. The resulting lumen is large enough to permit the withdrawal of blood samples, introduction of a continuous heparin flush, and the recording of a blood pressure waveform. In addition, the optical fibers are encased in a protective tubing to contain any fiber fragments in case they break off. The material in contact with the blood is typically treated with a covalently bonded layer of heparin, resulting in low susceptibility to fibrin deposition. Despite excellent accuracy of indwelling intraarterial catheters *in vitro* compared to blood gas analyzers, when these multiparameter probes were first introduced into the vascular system, it quickly became evident that the readings (primarily pO_2) varies frequently

Figure 8. Principle of an indwelling arterial optical blood gas catheter. Courtesy of Diametrics, Inc, St Paul, MN. A heparin-coated porous polyethylene membrane encapsulates the optical fibers and a thermistor.

and unpredictably, mainly due to the sensor tip intermittently coming in contact with the wall of the arterial blood vessel and intermittent reductions in blood flow due to arterial vasospasm (33–35).

Recently, a more advanced multiparameter disposable probe (Fig. 8) consisting of a pO_2 , pCO_2 , and pH sensors was developed by Diametrics Medical, Inc. (36–38). Several technical issues discovered during clinical evaluations of earlier probes were successfully addressed by this new product, and multiple clinical studies confirmed that the system is adequate for trend monitoring. The device has been evaluated in neurosurgical patients for continuous monitoring in the brain and in critically ill pediatric patients (39–41).

Although significant progress has been made, most of the intravascular probes are adversely affected by patient–probe interfacing problems and high manufacturing cost. These problems must be fully overcome before continuous intravascular blood gas monitoring can be performed reliably and cost effectively in widely divergent patient groups. Continuous arterial blood gas monitoring will not completely replace traditional invasive blood sampling. Nevertheless, it may extend the clinician’s ability to recognize and intervene more effectively to correct potentially life-threatening conditions.

pO_2 Sensors

The basic principle of measuring pO_2 optically relies on the fluorescence quenching effect of oxygen. Fluorescence quenching is a general property of aromatic molecules. In brief, when light is absorbed by a molecule, the absorbed energy is held as an excited electronic state of the molecule. It is then lost by coupling to the mechanical movement of the molecule (heat), reradiated from the molecule in a

mean time of ~ 10 ns (fluorescence), or converted into another excited state with much longer mean lifetime (phosphorescence). Quenching reduces the intensity of the emitted fluorescence light and is related to the concentration of the quenching molecules. The quenching of luminescence by oxygen was initially described by Kautsky in 1939 (42).

Opitz and Lubbers (43) and Peterson et al. (44) developed a fiber optic sensor for measuring pO_2 using the principle of fluorescence quenching. The dye is excited at ~ 470 nm (blue) and fluoresces at ~ 515 nm (green) with an intensity that depends on the pO_2 . The optical information is derived from the ratio of light intensities measured from the green fluorescence and the blue excitation light, which serves as an internal reference signal. The original sensor contained a Perylene Dibutyrate dye contained in an oxygen-permeable porous polystyrene envelope (45). The ratio of green to blue intensity is processed according to the Stern–Volmer equation (46):

$$I_0/I = 1 + KpO_2$$

where I and I_0 are the fluorescence emission intensities in the presence and absence (i.e., $pO_2 = 0$) of the quencher, respectively, and K is the Stern–Volmer quenching coefficient. The method provides a nearly linear readout of pO_2 over the range of 0–150 mmHg (0–20 kPa), with a precision of ~ 1 mmHg (0.13 kPa). The original sensor was 0.5 mm in diameter its 90% response time in an aqueous medium was ~ 1.5 min.

pH Sensors

Peterson and Goldstein et al. (47) developed the first fiber optic chemical sensor for physiological pH measurement by placing a reversible color-changing indicator at the end of a

pair of optical fibers. In the original development, the popular indicator phenol red was used since this dye changes its absorption properties from the green to the blue part of the spectrum as the acidity is increased. The dye was covalently bound to a hydrophilic polymer in the form of water-permeable microbeads that stabilized the indicator concentration. The indicator beads were contained in a sealed hydrogen ion-permeable envelope made out of hollow cellulose tubing. In effect, this formed a miniature spectrophotometric cell at the end of the fibers.

The phenol red dye indicator is a weak organic acid, and its unionized acid and ionized base forms are present in a concentration ratio that is determined according to the familiar Henderson–Hasselbalch equation by the ionization constant of the acid and the pH of the medium. The two forms of the dye have different optical absorption spectra. Hence, the relative concentration of one of the forms, which varies as a function of pH, can be measured optically and related to variations in pH. In the pH sensor, green and red light emerging from the distal end of one fiber passes through the dye where it is backscattered into the other fiber by the light-scattering beads. The base form of the indicator absorbs the green light. The red light is not absorbed by the indicator and is therefore used as an optical reference. The ratio of green to red light is measured and is related to the pH of the medium.

A similar principle can also be used with a reversible fluorescent indicator, in which case the concentration of one of the indicator forms is measured by its fluorescence rather than by the absorbance intensity. Light, typically in the blue or ultraviolet (UV) wavelength region, excites the fluorescent dye to emit longer wavelength light. The concept is based on the fluorescence of weak acid dyes that have different excitation wavelengths for the basic and acidic forms but the same emitted fluorescent wavelength. The dye is encapsulated in a sample chamber that is permeable to hydrogen ions. When the dye is illuminated with the two different excitation wavelengths, the ratio of the emitted fluorescent intensities can be used to calculate the pH of the solution that is in contact with the encapsulated dye.

The prototype device for measuring pH consisted of a tungsten lamp for illuminating the optical fiber, a rotating filter wheel to select the red and green light returning from the fiber, and signal processing to provide a pH output based on the ratio of the green-to-red light intensity. This system was capable of measuring pH in the physiologic range between 7.0 and 7.4 with an accuracy and precision of 0.01 pH units. However, the sensor was susceptible to ionic strength variations.

Further development of the pH probe for practical use was continued by Markle et al. (48). They designed the fiber optic probe in the form of a 25-gage ($\phi = 0.5$ mm) hypodermic needle, with an ion-permeable side window, using 75- μ m diameter plastic optical fibers. With improved instrumentation, and with a three-point calibration, the sensor had a 90% response time of 30 s and the range was extended to ± 3 pH units with a precision of 0.001 pH units.

Different methods were suggested for fiber optic pH sensing (49–52). A classic problem with dye indicators is the sensitivity of their equilibrium constant to variations in

ionic strength. To circumvent this problem, Wolfbeis and Offenbacher (53) and Opitz Lubber (54) demonstrated a system in which a dual sensor arrangement can measure ionic strength and pH while simultaneously correcting the pH measurement for ionic strength variations.

$p\text{CO}_2$ Sensors

The $p\text{CO}_2$ of a sample is typically determined by measuring changes in the pH of a bicarbonate solution. The bicarbonate solution is isolated from the sample by a CO_2 -permeable membrane, but remains in equilibrium with the CO_2 gas. The bicarbonate and CO_2 , as carbonic acid, form a pH buffer system and, by the Henderson–Hasselbalch equation,

$$\text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{p\text{CO}_2}$$

the hydrogen ion concentration is proportional to the $p\text{CO}_2$ of the sample. This measurement is done with either a pH electrode or a dye indicator. Both absorbance (55) and fluorescence (56) type $p\text{CO}_2$ sensors have been developed.

Vurek et al. (57) demonstrated that the same technique could be used also with a fiber optic sensor. In his design, one optical fiber carries light to the transducer, which is made of a silicone rubber tubing ~ 0.6 mm in diameter and 1.0 mm long, filled with a phenol red solution in a 35-mM bicarbonate. Ambient $p\text{CO}_2$ controls the pH of the solution that changes the optical absorption of the phenol red dye. The CO_2 permeates through the rubber to equilibrate with the indicator solution. A second optical fiber carries the transmitted signal to a photodetector for analysis. A different design by Zhujun and Seitz (58) used a $p\text{CO}_2$ sensor based on a pair of membranes separated from a bifurcated optical fiber by a cavity filled with bicarbonate buffer.

Extracorporeal Measurement

Several extracorporeal systems suitable for continuous on-line *ex vivo* monitoring of blood gases, base-access, and HCO_3^- during cardiopulmonary bypass operations (Fig. 9) are available commercially (59–61). While this approach circumvents some of the advantages of continuous *in vivo* monitoring, this approach is useful in patients requiring frequent measurements of blood gases. The basic approach is similar to the optical method utilized in intravascular probes, but the sensors are located on a cassette that is placed within the arterial pressure line that is inserted into the patient's arm. The measurement is performed extracorporeally by drawing a blood sample past the in-line sensor. After the analysis, which typically takes ~ 1 min, the sample can then be returned to the patient and the line is flushed. The sensor does not disrupt the pressure waveform or interfere with fluid delivery. Several clinical studies showed that in selected patient groups, the performance of these sensors is comparable to that of conventional *in vitro* blood gas analyzers (62–66).

Hematocrit Measurement

In recent years, an optical sensor has been developed by Hemametrics (Kaysville, UT) for monitoring hematocrit,

Figure 9. Principle of the GEM SensiCath fiber optic-based blood gas system. Courtesy of Optical Sensors, Inc., Minneapolis, MN.

oxygen saturation and blood volume *ex vivo* during hemodialysis (67–69). It provides vital and real time trending information that can be used to alert clinicians instantaneously to rapid changes during renal therapy (e.g., gastrointestinal bleeding or hemolysis). The optical measurements are based on detecting variations in scattering and absorption by blood flowing through a disposable cuvette that is connected to the arterial side of the dialyzer. A noninvasive version of this technology (CritScan) was recently cleared by the FDA for measuring absolute hematocrit and oxygen saturation by resting a fingertip against an optical sensor array of LEDs and photodetectors. One potential applications of this device, which was developed for spot checking, is for use in blood banking as an anemia screening tool to qualify blood donors, eliminating the need for performing hematocrit measurement based on the traditional and painful needle-stick approach.

Transcutaneous Bilirubin Measurement

Jaundice (hyperbilirubinemia) in newborn babies is evident in > 50% of newborns during the first week of birth. While hyperbilirubinemia (i.e., total serum bilirubin

> 1.0 mg/dL) occurs in nearly all infants, moderate to significant hyperbilirubinemia usually peaks between 3 and 7 days of age and typically requires phototherapy and/or exchange blood transfusions. If the condition is not recognized and treated properly, it can lead to potentially irreversible bilirubin-induced neurotoxicity and neurologic dysfunction. Visual recognition of jaundice is often inaccurate and unreliable, but excessive hyperbilirubinemia can be diagnosed by laboratory-based assay of total serum bilirubin obtained from a heel stick or an umbilical line.

To achieve a more objective measurement of jaundice, Yamanouchi et al. (70) developed a hand-held transcutaneous bilirubinometer developed by the Minolta Company. The meter used a dual optical filter design to measure a hemoglobin-corrected yellow color that is a distinctive skin color in jaundice patients. The measurement gives a reflectance value that must first be correlated to patient's serum bilirubin. Clinical testing of this device revealed significant inaccuracies and patient dependent variability compared with serum bilirubin determinations due to the presence of melanin pigmentation in the skin and variations in hemoglobin content.

More recently, several companies introduced more advance hand-held devices that uses multiwavelengths to measure bilirubin based on spectral analysis of light reflectance from the skin pioneered by Jacques (71) and others (72–74). The device consists of a light source, a fiberoptic probe, and a photodetector, essentially functioning as a microspectrophotometer. The unit is housed in a hand-held assembly that is positioned against the infant's forehead.

Pressure Sensors

In vivo pressure measurements provide important diagnostic information. For example, pressure measurements inside the heart, cranium, kidneys, and bladder can be used to diagnose abnormal physiological conditions that are otherwise not feasible to ascertain from imaging or other diagnostic modalities. In addition, intracranial hypertension resulting from injury or other causes can be monitored to assess the need for therapy and its efficacy. Likewise, dynamic changes of pressure measured inside the heart, uterus, and bladder cavities can help to assess the efficiency of these organs during muscular contractions.

There has long been an interest in developing fiber optic transducers for measuring pressure inside the cranium, vascular system, or the heart. Several approaches have been considered in the development of minimally invasive miniature pressure sensors. The most common technique involves the use of a fiber optic catheter. Fiber optic pressure sensors have been known and widely investigated since the early 1960s. The major challenge is to develop a small enough sensor with a high sensitivity, high fidelity, and adequate dynamic response that can be inserted either through a hypodermic needle or in the form of a catheter. Additionally, for routine clinical use, the device must be cost effective and disposable.

A variety of ideas have been exploited for varying a light signal in a fiber optic probe with pressure (75–77). Most designs utilize either an interferometer principle or measure changes in light intensity. In general, interferometric-based pressure sensors are known to have a high sensitivity, but involve complex calibration and require complicated fabrication. On the other hand, fiber optic pressure sensors based on light intensity modulation have a lower sensitivity, but involve simpler construction.

The basic operating principle of a fiber optic pressure sensor is based on light intensity modulation. Typically, white light or light produced by a LED is carried by an optical fiber to a flexible mirrored surface located inside a pressure-sensing element. The mirror is part of a movable membrane partition that separates the fiber end from the fluid chamber. Changes in the hydrostatic fluid pressure causes a proportional displacement of the membrane relative to the distal end of the optical fiber. This in turn modulates the amount of light coupled back into the optical fiber. The reflected light is measured by a sensitive photodetector and converted to a pressure reading.

A fiber optic pressure transducer for *in vivo* application based on optical interferometry using white light was recently developed by Fisco Technologies (Fig. 10). The

Figure 10. Fiber optic *in vivo* pressure sensor. Courtesy of Fisco Technologies, Quebec, Canada.

sensing element is based on a Fabry–Perot principle. The Fabry–Perot cavity is defined on one end by a stainless steel diaphragm and on the opposite side by the tip of the optical fiber. When an external pressure is applied to the transducer, the deflection of the diaphragm causes variation of the cavity length that in turn is converted to a pressure reading.

IN VITRO DIAGNOSTIC APPLICATIONS

Immunosensors

The development of immunosensors is based on the observation of ligand-binding reaction products between a target analyte and a highly specific binding reagent (78–80). The key component of an immunosensor is the biological recognition element typically consisting of antibodies or antibody fragments. Immunological techniques offer outstanding selectivity and sensitivity through the process of antibody–antigen interaction. This is the primary recognition mechanism by which the immune system detects and fights foreign matter and has therefore allowed the measurement of many important compounds at micromolar and even picomolar concentrations in complex biological samples.

In principle, it is possible to design competitive binding optical sensors utilizing immobilized antibodies as selective reagents and detecting the displacement of a labeled antigen by the analyte. In practice, however, the strong binding of antigens to antibodies and vice versa causes difficulties in constructing reversible sensors with fast dynamic responses. Other issues relate to the immobilization and specific properties related to the antibody-related reagents on the transducer surface.

Several immunological sensors based on fiber optic waveguides have been demonstrated for monitoring antibody–antigen reactions. Typically, several centimeters of cladding are removed along the fiber's distal end and the recognition antibodies are immobilized on the exposed core surface. These antibodies bind fluorophore–antigen

Figure 11. Typical principle of an immunodiagnostic sensor. Courtesy of Biacore AB. The sensor chip consists of a glass surface, coated with a thin layer of gold modified with a Dextran layer for binding of different biomolecules.

complexes within the evanescent wave. The fluorescent signal excited within the evanescent wave is then transmitted through the cladded fiber to a fluorimeter for processing.

Despite an overwhelming number of papers describing immunosensing techniques, there are still only few commercial instruments based upon immunosensors in clinical diagnostics today. Among them is the technology introduced by Biacore (Uppsala, Sweden) (81), which utilizes SPR as the principal probing method (Fig. 11) for real time monitoring of binding events without labeling or often purification of the substances involved. The sensor chip of the Biacore SPR system consists of a glass surface, coated with a thin layer of gold that is modified with a carboxymethylated dextran layer. This dextran hydrogel layer, which provides a hydrophilic environment for attached biomolecules, preserving them in a nondenatured state, forms the basis or a range of specialized surfaces designed to optimize the binding of a variety of molecules that occurs between active biomolecules. The IAsys from Affinity Sensors (Cambridge, UK) (82) also exploits the evanescence field principle, but the method is based on measuring the difference in the phase of a laser beam interacting with a waveguide structure. The method is utilized to study and measure the interactions of proteins binding to nucleic acids, lipids, and carbohydrates and can be used in molecular recognition experiments to study for example the DNA kinetics interactions.

Optical Biosensors in Drug Discovery

Optical biosensors exploit evanescent waves or SPR techniques, where binding of molecules in solution to surface-immobilized receptors causes an alteration of the refractive index of the medium near the surface. This optical change can be used to measure the amount of bound analyte using very low amounts of compound without the need for prior

chemical labeling. Hence, evanescent waves and SPR techniques can be used in screening compounds for receptor binding affinity or to study the kinetic analysis of molecular interactions throughout the process of drug development (83). These methods also allow researchers to study *in vitro* the interaction between immobilized receptors and analytes and the general interrogation of intermolecular interactions (84–88). These sensors have become a standard method for characterizing biomolecular interactions and are useful tools to study, for example, if a certain analyte binds to a particular surface, how strong is the binding mechanism, and how much of the sample remains active. The recent development of highly multiplexed optical biosensor arrays has also accelerated the process of assay development and target identification that can speed up the tedious and time-consuming process involved in screening and discovery of new drugs.

OPTICAL TWEEZERS

HENRY SCHEK III
ALAN J. HUNT
University of Michigan
Ann Arbor, Michigan

INTRODUCTION

Since the invention of the microscope, scientists have peered down at the intricate workings of cellular machinery, laboring to infer how life is sustained. Doubtlessly, these investigators have frequently pondered What would

happen if I could push on that, or pull on this? Today, these formerly rhetorical thought experiments can be accomplished using a single-beam optical gradient trap, more commonly known as “optical tweezers”. This article surveys the history, theory and practical aspects of optical trapping, especially for studying biology. We start by reviewing the early demonstrations of optical force generation, and follow this with a discussion of the theoretical and practical concerns for constructing, calibrating, and applying an optical tweezers device. Finally, examples of important optical tweezers experiments and their results are reviewed.

OPTICAL TWEEZERS SYSTEMS

History

In 1970, Arthur Ashkin published the first demonstration of light pressure forces manipulating microscopic, transparent, uncharged particles, a finding that laid the groundwork for optical trapping (1). Significant application of optical forces to study biology would not occur until almost two decades later, after the first description of a single-beam optical gradient trap was presented in 1986 (2). Soon after, the ability to trap living cells was demonstrated (3,4) and by the late 1980s biophysicists were applying optical tweezers to understand diverse systems, such as bacterial flagella (5), sperm (6), and motor proteins, such as kinesin (7). Today, optical tweezers are a primary tool for studying the mechanics of cellular components and are rapidly being adapted to applications ranging from cell sorting to the construction of nanotechnology (8,9).

Trapping Theory

Ashkin and co-workers 1986 description of a single-beam trap presented the necessary requirements for stable trapping of dielectric particles in three dimensions (2). For laser light interacting with a particle of diameter much larger than the laser wavelength, $d \gg \lambda$, that is the so-called Mie regime, the force on the particle can be calculated using ray optics to determine the momentum transferred from the refracted light to the trapped particle. Figure 1a–c schematically shows the general principle; two representative rays are bent as they pass through the spherical particle producing the forces that push the trapped particle toward the laser focus. A tightly focused beam that is most intense in the center thus pulls the trapped object toward the beam waist. More rigorous treatment and calculations can be found in (2,10).

In the Rayleigh regime, $d \ll \lambda$, the system must be treated in accordance with wave optics, and again the tight focusing results in a net trapping force due to the fact that the particle is a dielectric in a non-uniform electric field. Figure 1d shows a simplified depiction of force generation in this regime. The electric field gradient from the laser light induces a dipole in the dielectric particle; this results in a force on the particle directed up the gradient toward the area of greatest electric field intensity, at the center of the laser focus. Detailed calculations can be found in Ref. 11.

Figure 1. Optical forces on a dielectric sphere. (Adapted from Ref. 2.) Parts a–c show three possible geometries in the ray optics regime: particle above, particle below, and particle to the right of the laser focus, respectively. In each case, two representative rays are shown interacting with the particle. The two rays change direction upon entering and exiting the sphere causing a net transfer of momentum to the particle. Dotted lines show the focus point in the absence of the sphere. The forces resulting from each ray are shown in gray along with the summed force. (Please see online version for color in figure.) In each case the net force pushes the particle toward the focus. A highly simplified mechanism for the generation of force in the Rayleigh regime. An electric field profile is shown above a representative particle. The labels on the sphere show the net positioning of charges due to the formation of the dipole and the arrows show the forces. The induced dipole results in the bead being attracted to the area of most intense electric field, the laser focus.

In either regime, the principal challenge to producing a stable trap is overcoming the force produced by light scattered back in the direction of the oncoming laser, which imparts momentum that pushes the particle in the direction of beam propagation, and potentially out of the trap. When the trapping force that pulls the particle up the laser toward the beam waist is large enough to balance this scattering force, a stable trap results. From examination of Fig. 1a, it is apparent that the most important rays providing the force to balance the scattering force come at steep angles from the periphery of the focusing lens. For this reason, a tightly focusing lens is critical for forming an optical trap; typically oil-immersion lenses with a numerical aperture in excess of 1.2 are used. Furthermore, the beam must be expanded to slightly overfill the back aperture of the focusing lens so that sufficient laser power is carried in the most steeply focused periphery of the beam.

For biological experiments the preferred size of the trapped particle is rarely in the range appropriately treated in either the Mie or Rayleigh regime; typically particles are on the order of $1 \mu\text{m}$ in diameter, or approximately equal to the laser wavelength. Theoretical treatment then requires generalized Lorenz–Mie theory (12,13). In

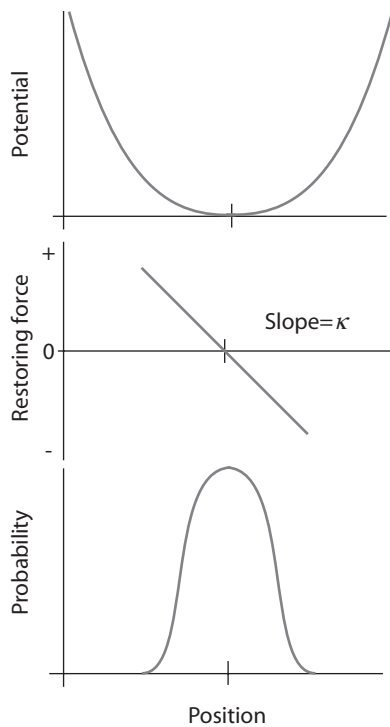

Figure 2. Relationship between potential, force, and bead position probability. The interaction of the tightly focused laser and dielectric results in a parabolic potential well, the consequence of which is a linear restoring force; the trap behaves as a linear radial spring. Here a positive force pushes the particle to the right. When driven by thermal events in solution a particle's position has a Gaussian distribution.

practice, theoretical analysis of specific trapping parameters is not necessary because several methods allow direct calibration of trapping forces. Regardless of particle size, a tightly focused laser with a Gaussian intensity profile (TEM_{00} mode) interacting with a spherical particle, traps the particle in a parabolic potential well. The parabolic potential is convenient because it results in a trap that

behaves like a Hookian spring: restoring force that pushes the particle back toward the focus increases linearly with the displacement from the focus. Figure 2 schematically illustrates the potential well, force profile, and distribution of particle positions for a hypothetical trapped sphere. This convenient relationship results in spherical particles being the natural choice for most trapping applications including gradient. These particles are often referred to as beads, microbeads, or microspheres interchangeably.

Optical Tweezers Systems

Implementations of optical tweezers as they are applied to biology are variations on a theme: most systems share several common features although details vary and systems are often optimized for the application. Figures 3 and 4 show a photograph and a diagram of an example system. Generally, the system begins with a collimated, plane-polarized laser with excellent power and pointing stability. The optimal laser light wavelength depends on the application, but near-infrared (IR) lasers with a wavelength $\sim 1 \mu\text{m}$ are a typical choice for use with biological samples; such lasers are readily available and biological samples generally exhibit minimal absorption in the near-IR. A light attenuator allows for adjustment of laser power and therefore trap stiffness. In the example system this is accomplished with a variable half-wave plate that adjusts the polarity prior to the beam passing through a polarized beam splitting cube that redirects the unwanted laser power. Most systems then contain a device and lenses to actively steer the beam. In the case of the example system, a piezo-actuated mirror creates angular deflections of the beam that the telescope lenses translate into lateral position changes of the laser focus at the focal plane of the objective. This is accomplished by arranging the telescope so that a virtual image of the steering device is formed at the back aperture of the microscope objective lens. This arrangement also assures that the laser is not differentially clipped by the objective aperture as the trap is steered. Following the steering optics, the laser enters a microscope, is focused by a high numerical

Figure 3. Photograph of an optical tweezers instrument. Note the vibration isolation table that prevents spurious vibrations from affecting experiments. The clear plastic cover minimizes ambient air convection that might affect the laser path in addition to limiting access of dust and preventing accidental contact with the optics.

Figure 4. Optical tweezers schematic showing major system components.

aperture objective, and encounters the sample. After passing through the trapping/image plane, the laser usually exits the microscope and enters a detection system, which in this case employs back-focal-plane interferometry to measure the position of the bead relative to the trap (14–16).

There are many optical tweezers designs that can produce stable, reliable trapping. In most cases, the system is integrated into an inverted, high quality research microscope (17,18), although successful systems have been incorporated into upright (e.g., 15) or custom built microscopes (14). Some use a single laser to form the trap (7,15) while a more complicated arrangement uses two counterpropagating lasers (19,20).

Various implementations for detecting the bead position include image analysis (21,22), back focal plane interferometry (BFPI) (14,16), and a host of less frequently applied methods based on measurements of scattered or fluorescent light intensity (23–25) or interference between two beams produced using the Wollaston prisms associated with differential interference contrast microscopy (26). Trap steering can be accomplished with acousto-optic deflectors (15,27,28), steerable mirrors (23), or actuated lenses (14). Figure 5 shows a silica microsphere in a trap being moved in a circle at > 10 revolutions s^{-1} using acousto-optic deflectors, resulting in the comet tail in the image. Alternatively, the sample can be moved with a motorized or piezoactuated nanopositioning stage. In addition, splitting the laser into two orthogonally polarized beams, fast laser steering to effectively multiplex the beam by rapidly jumping the laser between multiple positions (29), or holographic technology (9) can be used to create arrays of multiple traps. Figure 6 shows an image of a 3×3 array of optical traps created using fast beam steering to multiplex a single beam. Five traps are holding beads while four, marked with white circles are empty. Specific optical tweezers designs can also allow incorporation of other advanced optical techniques often used in biology, including, but not limited to, total internal reflection microscopy and confocal microscopy (30).

Figure 5. Micrograph of $1 \mu\text{m}$ bead being manipulated in a circle with an optical tweezers device. The comet tail is the result of the bead moving faster than the video frame rate.

Figure 6. Micrograph of a 3×3 array of traps produced by time sharing a single laser between nine positions. The traps at the four locations marked with white circles are empty while the other five hold a $1 \mu\text{m}$ diameter silica microsphere.

Detection

Determining the force on a trapped sphere requires measurement of the displacement of the trapped particle from the center of the optical trap. Back focal plane interferometry (BFPI) is the most popular method, and allows high speed detection with nanometer resolution. Rather than following an image of the bead, which is also a viable detection technique, BFPI tracks the bead by examining how an interference pattern formed by the trapping laser is altered by the bead interacting with the laser further up the beam at the microscope focal plane. This interference pattern is in focus at the back focal plane of the condenser lenses of the microscope, thus the name of the technique.

Laser light interacting with the bead is either transmitted or scattered. The transmitted and scattered light interfere with one another resulting in an interference pattern that is strongly dependent on the relative position of the bead within the trap. This interference pattern is easily imaged onto a quadrant photodiode (QPD) detector positioned at an image plane formed conjugate to the back focal plane of the condenser lenses by supplemental lenses (e.g., BFPI imaging lens in Fig. 4). A simple divider-amplifier circuit compares the relative intensity in each quadrant according to the equations shown in Fig. 7. This results in voltage signals that follows the position of the bead in the trap.

Back focal plane interferometry has several important advantages compared with the other commonly used bead tracking techniques. Typically, image analysis limits the data collection rate to video frame rate, 30 Hz, or slower if images must be averaged, while BFPI easily achieves sampling frequencies in the tens of kilohertz. Under ideal conditions, image analysis can detect particle positions with ~ 10 nm resolution, while BFPI achieves

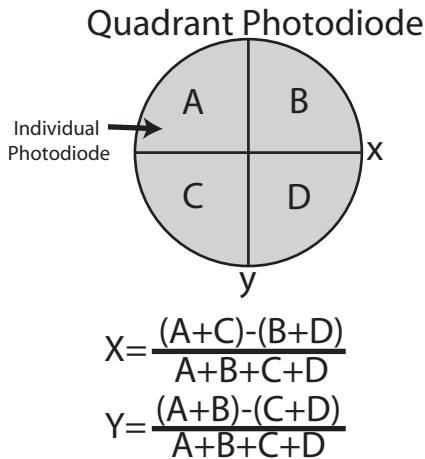

Figure 7. Quadrant photodiode operation. The circular quadrant photodiode detector is composed of four individual detectors (A–D) each making up one quarter of the circle. Each diode measures the light intensity falling on the surface of that quadrant and the associated electronics compares the relative intensities according to the equations shown in the figure. The resulting voltages are calibrated to the intensity shifts caused by the bead as it moves to different positions in the trap.

subnanometer resolution. Speeds and resolution similar to BFPI can be achieved by directly imaging a bead onto a QPD, however, it can be inconvenient in systems where trap steering is employed because the image of the particles will move across the detector as the trap moves in the image plane of the microscope, thus requiring frequent repositioning of the detector. With BFPI, the position of the interference pattern at the back focal plane of the condenser does not move as the trap is steered, so the detector can remain stationary.

Calibration

Although BFPI provides a signal corresponding to bead position, two important system parameters must be measured before forces and positions can be inferred. The first is the detection sensitivity, β , relating the detector signal to the particle position. The second is the Hookian spring constant, κ , where

$$F = -\kappa x \quad (1)$$

where x is the displacement of the particle from the center of the trap. Both sensitivity and stiffness depend on the diameter of the particle and the position of the trap relative to nearby surfaces. Stiffness is linear with laser power while sensitivity, when using BFPI, does not depend on laser power as long as the detector is operating in its linear range. Ideally, these parameters are determined in circumstances as near to the experimental conditions as possible. Indeed whenever reasonably possible, it is wise to account for bead and assay variation by determining these parameters for each bead used in an experiment.

Direct Calibration Method

Sensitivity can be measured by two independent methods. The most direct is to move a bead affixed to a coverslip through the laser focus with a nanopositioning piezocontrolled stage, or conversely by scanning the laser over the immobilized bead while measuring the detector signal. An example calibration curve is shown in Fig. 8 for a system using BFPI. The linear region within ~ 150 nm on either side of zero is fit to a line to arrive at the sensitivity, β , equal to $6.8 \times 10^{-4} \text{ V}\cdot\text{nm}^{-1}$. The second method is discussed below under calibration with thermally driven motion.

Figure 8. Optical tweezers sensitivity curve acquired with the direct method of moving the laser past an immobilized bead. The full curve is shown in a. The central linear region shown in b is fit to give a sensitivity of $6.8 \times 10^{-4} \text{ V}\cdot\text{nm}^{-1}$.

Figure 9. Schematic of drag force calibration. Uniform fluid flow from the left produces a force on the bead that can be calculated with the equations in the text. The bead is displaced to a distance, where the force due to fluid flow is balanced by the force due to the trap.

The direct calibration for sensitivity has the disadvantage of requiring the bead to be immobilized, typically to the coverslip, whereas experiments are typically conducted several microns from the surface. Additionally, with the bead fixed to a surface, its z -axis position is no longer controlled by the trapping forces, resulting in the possibility that the measured sensitivity does not correspond to the actual z axis position of a trapped particle. Estimates of sensitivity may also be rendered inaccurate if attachments to the surface slip or fail. Consequently, thermal force based calibration discussed in the next section are often more reliable.

The trap stiffness, κ , can be measured by applying drag force from fluid flow to the trapped particle. Figure 9 shows a schematic representation of the trap, particle, and fluid movement. Typically, a flow is induced around the bead by moving the entire experimental chamber on a motorized or piezodriven microscope stage. In the low Reynolds number regime where optical traps are typically applied, the drag coefficient, γ , on a sphere in the vicinity of a surface can be accurately calculated:

$$\gamma = 6\pi r c \eta \quad (2)$$

where r is the radius of the microsphere, η is the viscosity of the medium, and c is the correction for the distance from a surface given by

$$c = 1 + \frac{9}{16} \frac{r}{h} \quad (3)$$

where h is the distance from the center of the sphere to the surface. Equation 3 is an approximation and can be carried to higher order for greater accuracy (31).

The force due to fluid flow is readily calculated

$$F = \gamma V \quad (4)$$

where V is the velocity of the particle relative to the fluid medium.

When a flow force is applied to the trapped microsphere, the bead moves away from the center of the trap to an equilibrium position where the flow force and trapping force balance. Applying several drag forces (using a range of fluid flow velocities) and measuring the deflection in each case allows one to plot force of the trap as a function of bead position. The slope of this line is the trap stiffness, κ .

Figure 10. Results of a typical drag force calibration. (a) Typical signal of five averaged applications of uniform drag force on a trapped microsphere. In the region labeled 1, the bead quickly achieves a stable displacement due to the constant velocity. In region 2, the bead briefly returns to the center of the trap as the stage stops. In region 3, the bead is again displaced as the stage moves back to its home position and in region 4 the stage is at rest in its home position. The displaced position () in region 1 is averaged to determine the displacement for a given flow force. (b) Example of data from several different forces applied to the trapped microsphere reveal a linear relation to displacement.

Figure 10a shows a trace of a bead being displaced by fluid drag force provided by a piezoactuated stage moving at a known velocity. In the first region the bead quickly achieves and holds a stable position as long as the stage moves at a constant velocity, making measurement of the displacement relatively simple. When the stage stops the bead returns to the center of the trap as is seen in the second section of the record. The subsequent negative deflection in the third section is the result of the stage returning to its original position at a non-uniform speed. Figure 10b shows force as a function of position for two laser powers; the linear fitting coefficient gives the trap stiffness in each case.

In practice, calibration by viscous drag can be quite labor intensive, and the requirement for the sample to be moved repeatedly and rapidly is too disruptive to be performed “on the fly” during many types of experiments. A more efficient and less disruptive alternative relies on the fact that the thermal motion of the fluid molecules exerts significant, statistically predictable forces on the trapped microsphere; these result in fluctuations in bead position measurable with the optical tweezers.

Thermal Force Based Calibration Methods

At low Reynold's (Re) number the power spectrum of the position of a particle trapped in a harmonic potential well subject only to thermal forces takes the form of a Lorentzian (32):

$$S_x(f) = \frac{B}{f_c^2 + f^2} \quad (5)$$

with

$$B = \frac{k_B T}{\gamma \pi^2} \quad (6)$$

where k_B is the Boltzmann constant, f is the frequency, f_c is a constant called the corner frequency, and

$$f_c = \frac{\kappa}{2\pi\gamma} \quad (7)$$

There are several important practical considerations for applying the power spectrum to calibrate optical tweezers. The mathematical form of the power spectrum does not account for the electrical noise in the signal, so a large signal to noise ratio is required for accurate calibration. In addition, records of bead position must be treated carefully, especially with respect to instrument bandwidth and vibrations, to yield the correct shape and magnitude of the power spectrum.

A typical calibration begins by setting the position of the bead relative to any nearby surface, typically a microscope sample coverglass. With the bead positioned, a record of thermal motion of the bead is taken. For the example system in Figs. 3 and 4 a typical data collection for a calibration is 45 s at maximum bandwidth of the QPD and associated electronics. The data is then low pass (antialias) filtered using a high order Butterworth filter with a cut-off frequency set to one-half of the bandwidth.

Following acquisition and filtering, the power spectrum of the record of bead position is calculated. In practice, many power spectra should be averaged to reduce the inherently large variance of an individual power spectrum. For example, the 45 s of data is broken into 45, 1 s records of bead position, the power spectrum for each is calculated and the spectra are averaged together. To accurately compute the power spectrum the data must be treated as continuous; this is achieved by wrapping the end of the record back to meet the beginning. To avoid a discontinuity where the beginning and end are joined, each record is windowed with a triangle or similar function that forces the ends to meet but maintains the statistical variance in the original record. Figure 11a shows an example of an averaged power spectrum. Note the units on the y axis: often, power spectra are presented in different units according to their intended use. Accurate calibration of optical tweezers requires that the power spectrum be in $\text{nm}^2 \cdot \text{Hz}^{-1}$ or, provided volts are proportional to displacement, $\text{V}^2 \cdot \text{Hz}^{-1}$.

The average power spectrum is expected to fit the form of equation 5. To avoid aliased high frequency data corrupting the fit to the power spectrum, the spectrum is cropped well below the cut-off frequency of the antialiasing

Figure 11. Example power spectrum calibration. (a) An example power spectrum (gray) and Lorentzian fit (black). (b) Power spectrum calibrations for five separate laser powers showing the linear dependence of stiffness on laser power.

filter. The average, cropped power spectrum can be visually inspected for evidence of noise (e.g., spikes or other deviations from the expected Lorentzian form) and fit to equation 5, with f_c and B as fitting parameters. The drag coefficient is calculated using equations 2 and 3 and the stiffness, κ , is then calculated with a simple rearrangement of equation 7. The sensitivity, β , can also be calculated by recognizing that the value of B produced by the fit is proportional to the signal power. The value of B can be calculated from first principles by applying equation 6. In practice, the value of B is determined by fitting equation 5 with B as a parameter. Equation 6 gives B in units of $\text{nm}^2 \cdot \text{Hz}^{-1}$ while the fitted value of B will typically be $\text{V}^2 \cdot \text{Hz}^{-1}$. The parameter β is then determined by dividing the fitted value by the theoretical value and taking the square root. Figure 11b shows an example power spectrum used to calculate the trap stiffness and the sensitivity of the detection system with a $0.6 \mu\text{m}$ bead.

Inspection of the power spectrum in Fig. 11a shows two distinct regions: the low frequency plateau and the high frequency roll off. These two sections can be qualitatively understood as representing two aspects of the motion of the trapped particle. The high frequency roll-off is representative of small, rapid oscillations of the bead in the trap. Since the distance the bead moves over these short time scales is generally small, the bead does not “feel” large changes in the force of the trap pushing it back to the center, and hence this motion has the character of free diffusion. At lower frequency, the spectrum is flat, because large-scale oscillations are attenuated by the trap pushing the bead back to the center. As a result low frequency oscillations do not exhibit the character of free diffusion; the bead feels the trap when it makes a large excursion.

The methods for calculating and then fitting the power spectrum above are adequate in most cases and for most experiments. However, several additional considerations can be added to this relatively simple approach to improve the accuracy in some situations. These include, but are not limited to, accounting for the frequency dependence of the drag coefficient, and theoretically accounting for aliasing that may be present in the signal (54).

Two other calibration methods also take advantage of thermal forces acting on trapped beads. These methods are not conceptually distinct from the power spectrum method, but treat the data differently, are susceptible to different errors, and thus provide a good cross-check with the power spectrum and direct methods above.

As one would expect, the range of bead position should decrease with increasing trap stiffness. For an overdamped harmonic potential, such as a spherical bead in an optical trap, this relation has a specific mathematical form:

$$\kappa = \frac{k_B T}{\text{var}(x)} \quad (8)$$

where the $\text{var}(x)$ is the variance of the bead position in the trap, k_B is Boltzmann's constant and T is absolute temperature. This equation results from the equipartition theorem: the average thermal energy for a single degree of freedom is $1/2 k_B T$, and that the average potential energy stored in a Hookean trap is $1/2 \kappa \langle x^2 \rangle$. Setting these equal, rearranging and assuming that $\langle x \rangle = 0$ = the center of the trap, results in equation 8. Thus by simply measuring the variance of the bead position and the temperature, one can determine the trap stiffness.

Alternatively the autocorrelation function of the bead position is used to determine the trap stiffness (33). This method is little different in principal than using the power spectrum, as the spectrum is the Fourier transform of the autocorrelation. The autocorrelation function is expected to exhibit an exponential decay with time constant τ , where

$$\tau = \frac{\gamma}{\kappa} \quad (9)$$

It is often easier to achieve a reliable fit to the autocorrelation than to the power spectrum, making the autocorrelation an attractive alternative to the more common power spectrum methods.

Each calibration method has its distinct advantages over the others. The methods involving direct manipulation are most often used in the course of building an optical tweezers device to verify that the thermal motion calibrations work properly. Once verified the thermal motion calibrations are much less labor intensive, and can be performed "on the fly". This allows sensitivity and stiffness for each bead to be calibrated as it is used in an experiment.

Each method relies on slightly different parameters and thus provides separate means to verify calibration accuracy. For example, the corner frequency of the power spectrum, and hence the stiffness can be determined with no knowledge of the detector sensitivity. However, this does depend on accurately calculating the drag coefficient. By calculating the stiffness from the variance one can avoid

considering the drag coefficient altogether, but this method relies on accurate estimation of the sensitivity squared (β^2). Furthermore, the variance method can lead to inaccurate stiffness measurements because system drift will inflate the variance, leading to underestimated trap stiffness.

A safe course is to (1) inspect the power spectrum for evidence of external noise, (2) calculate the stiffness and sensitivity by fitting the power spectrum, (3) recalculate the stiffness with the variance method using the sensitivity determined from the power spectrum, and (4) compare the stiffness results from each method. If the stiffness agrees between the two it indicates that the drag coefficient and sensitivity are both correct. The only possibility for error would be that they are both in error in a manner that is exactly offsetting, which is quite unlikely. Comparison with the direct manipulation methods can alleviate this concern.

Optical Tweezers Compared with Other Approaches to Nanomanipulation

There are several alternatives to optical tweezers for working at the nanometer to micron scales and exerting piconewton forces. Most similar in application are magnetic tweezers, which use paramagnetic beads and an electromagnet to produce forces. The force profile of magnetic tweezers is constant on the size scale of microscopic experiments; the force felt by the bead is not dependent on displacement from a given point as with optical tweezers. This can be convenient in some circumstances, but is less desirable for holding form objects in specific locations.

A second option is the use of glass microneedles. These fine glass whiskers can be biochemically linked to a molecule of interest and their deflection provides a measure of forces and displacements. Stiffness must be measured for each needle with either fluid flow or methods relying on thermal forces similar to those described above. Glass needles can exert a broad range of forces but they only allow for force measurements along one axis, and are difficult for complex manipulations compared to optical tweezers devices.

Atomic force microscopy (AFM) is a third option for measuring small forces and displacements. Originally, this technique was used to image surface roughness by dragging a fine cantilever over a sample. A laser reflecting off the cantilever onto a photodiode detects cantilever deflection. To measure force, a cantilever of known stiffness can be biochemically linked to a structure of interest and deflections and forces measured with similar accuracy to optical tweezers. The AFM has the advantage that reliable AFMs can be purchased, while optical tweezers must still be custom built for most purposes. However, AFMs are unable to perform the complex manipulations that are simple with optical tweezers and typically are limited to forces >20 pN.

OPTICAL TWEEZERS RESEARCH

Within 4 years of the publication of the first demonstration of a single beam, three-dimensional (3D) trap, optical

tweezers were being applied to biological measurements (2,7). In the years that followed, optical tweezers became increasingly sophisticated, and their contributions to biology and biophysics in particular grew rapidly. Some important experimental considerations, and contributions to basic science made possible by optical tweezers, highlighted representative assays, and results are discussed in this section.

Practical Experimental Concerns

Beyond the design and calibration challenges, there are additional concerns that come into play preparing an experimental assay for use with optical tweezers. The most general of these attached is a trappable object to the system being studied, and accounting for series compliances when interpreting displacements of this object.

Probably the most popular attachment scheme currently in use is the biotin-streptavidin linkage. Microbeads are coated with streptavidin, and the structure to be studied, if a protein, can be easily functionalized with biotin via a succinimidyl ester or other chemical cross-linker. When mixed, the streptavidin on the bead tightly binds to biotin on the structure to be studied. Beads coated in this manner tend to stick to the surfaces in the experimental chamber, which is inconvenient for setting up an experiment, and recently developed neutravidin is an attractive alternative to streptavidin with decreased non-specific binding at close to neutral pH. Alternative attachment schemes usually involve coating the bead with a protein that specifically interacts with the structure to be studied. For example, a microtubule-associated protein might be attached to the bead; subsequently that bead sticks to microtubules, which can then be manipulated with the optical tweezers. Recombinant DNA technology can also be used; in this case the amino acid sequence of a protein is modified to add a particular residue (e.g., reactive cysteine), which serves as a target for specific cross-linking to the bead. This approach provides additional control over the binding orientation of the protein, but runs the risk that the recombinant protein may not behave as the wild type.

Interpreting displacements measured with optical tweezers is complicated by compliances in the system under study, or the linkage to the trapped bead; these must be accounted for to determine the actual displacement of specific elements. Figure 12 diagrams the compliances in a sample system. A filament to which the trapped bead is linked is pulled to the right by the force generating process under study (not shown). This causes the bead to be displaced to the right within the trap by an amount, ΔBead , which is directly measured. However, the other compliance in the system, κ_{linkage} , is also stretched and takes up some amount of the filament displacement, which can only be determined with knowledge of the link stiffness; thus the measured displacement is less than the actual displacement of the filament. In some situations it may be possible to measure the link stiffness directly, but generally this is not possible during an experiment. Furthermore, the link stiffness is usually nonlinear, and may be complicated by

Figure 12. Schematic diagram of series compliances in optical tweezers experiments. Both the optical trap and the linkage between the bead and hypothetical filament are shown as springs. The optical trap is a well characterized spring, having been carefully calibrated prior to beginning experiments. The stiffness of the linkage, however, is unknown. When the filament is pulled to the right by a hypothetical motor or other biological system, both springs are stretched. Therefore the displacement of the trapped bead is not necessarily equal to the displacement of the filament by the motor. Examination of the system shows that the force on the trapped bead is the same as the force on the filament once all elements have reached their equilibrium. Knowledge of κ_{linkage} would allow for displacements at the bead to be used to calculate filament displacements.

the bead rocking about the link under forces applied by the trap. When precision displacement measurements are desired these difficulties can be circumvented with a feedback system that maintains a constant force on the particle (force clamp). By maintaining constant force, the link is held at a fixed strain and the movements of the feedback controlled laser directly follow the positional changes of the filament.

Motor Proteins: Kinesin And Myosin

The kinesins and myosins are two large families of motor proteins that convert chemical energy released by adenosine triphosphate (ATP) hydrolysis into mechanical work. Kinesins move cargo along microtubules while myosins exert forces against actin filaments, most notably in muscle. Many of the mechanical and kinetic aspects of these molecules behaviors have been determined from measurements made with optical tweezers. These include the length of displacements during individual chemomechanical steps, single molecule force generation capabilities, and kinetic information about the enzymatic cycle that converts chemical into mechanical energy.

Due to the differences in the substrate along which myosin and kinesin motors move, and the nature of their movements, assays for studying them have significantly different geometries. In the case of kinesin (Fig. 13), generally a single bead coated with the motor is held in an optical trap (17,26). The motors are sparsely coated on the beads, so that only one motor interacts with the microtubule track, which has been immobilized onto a glass surface. The optical tweezers manipulate the coated bead onto the microtubule; bead movements ensue when a kinesin motor engages the microtubule lattice. If the

Figure 13. Schematic of an experiment to study kinesin. The motor protein kinesin is processive, meaning that the motor spends a large portion of its force generating cycle attached to the microtubule and is able to maintain movement when only a single motor is present. As a result, a single, sparsely coated bead held in an optical trap can be used to measure the force generating properties of kinesin.

optical tweezers are used in stationary mode, the records will indicate a fraction of the actual motor displacement, the remainder being taken up in the compliant link between the bead and the motor as described above. The actual displacements of the motor must then be inferred using estimates of the bead-motor link compliance, which is estimated in independent experiments (26).

Alternatively, a force clamp is applied to adjust the position of the trap to maintain a constant force on the bead as the kinesin motor travels along the microtubule. The movement of the motor is then inferred from the adjustments to the laser position, which directly reveal 8 nm steps, demonstrating that the kinesin molecule moves along the microtubule with the same periodicity as the microtubule lattice. Additional analysis of this data showed that kinesin stalls under loads of 5–8 pN, dependent on ATP concentration, and exhibits tight coupling between ATP hydrolysis and force generation (17,34).

Assays for studying myosin (Fig. 14) are somewhat more complicated, relying on two traps, each holding a microsphere, and a third large bead sparsely coated with myosin affixed to the surface of the microscope slide (35). An actin filament strung between the two smaller microspheres, each held by separate traps, is lowered into a

Figure 14. Schematic of an experiment to study muscle myosin. The motor protein myosin is not processive, meaning that a single copy of the motor cannot sustain movement along the actin filament. As a result an experimental arrangement that can keep the myosin in close proximity to the filament is necessary.

position where myosin on the large fixed bead can pull against it. Myosin is not processive; it spends only a small fraction of the force generating cycle attached to the actin filament, and an unrestrained filament will diffuse away from the motor during the detached portion of the cycle. Thus the filament is held in close contact with the motor to allow repeated force generating interactions to be observed.

The actin filament and attached beads will move back and forth due to Brownian motion, which is limited by the drag on the particle and the force provided by the trap. This has two important consequences: the myosin molecule on the large bead is exposed to a number of possible binding sites along the actin filament, and attachment of the myosin cross bridge elevates the stiffness of the system sufficiently to greatly reduce the extent of thermally induced bead motion. With bandwidth sufficient to detect the full extent of microsphere Brownian motion, myosin binding events are identified by the reduction in the amplitude of the thermal motion. The distribution of positions of the trapped microspheres and filament at the onset of binding events is expected to be Gaussian of the same width as if the myosin-coated bead was absent. However, shortly after binding, the myosin motor displaces the filament and this shifts the center of the Gaussian by the distance of a single myosin step. Analysis of high resolution, high bandwidth traces of bead position with the above understanding lead to determination of the step length for single myosin subfragment-1 and heavy meromyosin: 3.5 and 5 nm, respectively (28).

Other Motor Proteins

In addition to the classic motor proteins that generate forces against cytoskeletal filaments, proteins may exhibit motor activity, not as their *raison d'être*, but in order to achieve other enzymatic tasks. One such protein is ribonucleic acid (RNA) polymerase (RNAP), the enzyme responsible for transcription of genetic information from deoxyribonucleic acid (DNA) to RNA. The RNAP uses the energy of ATP hydrolysis to move along the DNA substrate, copying the genetic information at a rate of 10 base pairs per second. The movement is directed, and thus constitutes motor activity. The assay used to study RNAP powered movement along the DNA substrate is shown in Fig. 15. A piece of single-stranded DNA attached to the trapped glass microsphere is allowed to interact with an RNAP molecule affixed to the surface of the slide. Optical tweezers hold the bead so that the progress and force developed by RNAP can be monitored. As the RNAP molecule moves along the

Figure 15. Schematic of an experiment to study RNA polymerase.

DNA, the load opposing the motor movement increases until the molecule stalls (36,37). Details of the kinetics of RNAP can be inferred from the relation between the force and speed of movement.

Nonstandard Trapping

A number of research efforts have studied the trapping of nonspherical objects and/or applied them to study biological processes. For example, the stiffness of a microtubule was measured using optical tweezers to directly trap and bend the rod-like polymer. Image data of the induced microtubule shape were then used in conjunction with mechanical elastic theory to determine the stiffness of the microtubule (38). Recently, there has been significant interest in using optical traps to exert torques. Generally, these techniques rely on nonspherical particles, non-Gaussian beams, or birefringent particles to create the necessary asymmetry to develop torque. One approach relies on using an annular laser profile (donut mode) with an interfering reference beam to create a trapping beam that has rotating arms (39). With such an arrangement torque generation is not dependent on the particle shape, but the implementation is relatively complicated. Two closely located traps can also be used to rotate objects by trapping them in multiple locations and moving the traps relative to one another. Using a spatial light modulator, which splits the beam into an arbitrary number of individual beams, to create and move the two traps allows rotation about an axis of choice (40).

For experimental applications, it is generally desirable to calibrate the torque exerted on the particles. The above techniques are not easily calibrated. A more readily calibrated alternative uses birefringent particles such as quartz microspheres (41). The anisotropic polarizability of the particle causes it to align to the beam polarity vector. The primary advantage of this technique is that the drag coefficient of the spherical particle is easily calculated, allowing torques can be calibrated by following rotational thermal motion of the particle, similarly to the techniques described for thermal motion calibrations above.

Modulation of trap position along with laser power or beam profile can create a laser line trap (42–44). The scheme is similar to time sharing a single laser between several positions to create several traps. However, to form a line trap the laser focus is rapidly scanned through positions along a single line. With simultaneous power modulation a linear trapping region capable of applying a single constant force to a trapped particle along the entire length of the trap is created. This technique can be used to replace the conventional force clamp relying on electronic feedback.

Some Other Optical Tweezers Assays

Optical tweezers have made numerous contributions to other subfields. A number of groups have utilized optical tweezers to study DNA molecules. Stretching assays have produced force extension relations for purified DNA, and stretching of individual nucleosomes revealed sudden drops in force indicative of the opening of the coiled DNA structure (45). Optical trapping has also been used to directly study the forces involved in packaging DNA into

a viral capsid. Packaging was able to proceed against forces > 40 pN, and the force necessary to stall packaging was dependent on the how much of the DNA was already packaged into the capsid (46). Double-stranded DNA has also been melted (unzipped) by pulling the strands apart with optical tweezers: this established that lambda phage (a bacterial virus) DNA unzips and rezip in the range of 10–15 pN, dependent on the nucleotide sequence (47). Stretching RNA molecules to unfold loops and other secondary structures with a similar assay has been used to test a general statistical mechanics result known as the Jarzynski Inequality (48).

Similar stretching experiments have been performed on proteins. A good example is the large muscle protein titin, which mediates muscle elasticity. Optical tweezers were applied to repeatedly stretch the molecule, providing evidence of mechanical fatigue of the titin molecule that could be the source of mechanical fatigue in repeatedly stimulated muscles (49).

Experiments that study interactions in larger, more complex systems are increasing common. Microtubules associated to mitotic chromosome kinetochores have been studied with optical tweezers. Forces of 15 pN were generally found to be insufficient to detach kinetochore bound microtubules and kinetochore attachment was found to modify microtubule growth and shortening (21). A number of studies have also applied optical tweezers to study structures inside intact cells and the force generating ability of highly motile cells such as sperm (6,50).

Beyond biological measurements, optical tweezers have utility in assembling micron scale objects in desired positions. Weakly focused lasers operating similarly to optical tweezers have been used to directly pattern multiple cell types on a surface for tissue engineering (55). Optical trapping has also been used for assembly and organization of nonbiological devices, such as groups of particles (51) and 3D structures, such as a crystal lattice (52).

Additionally, optical tweezers have been applied to great advantage in material and physical sciences. A substantial body of work has applied optical tweezers to study colloidal solutions and microrheology (53).

INTRODUCTION

Musculoskeletal disorders are recognized as among the most significant human health problems that exist today, costing society an estimated \$254 billion every year, and afflicting one out of seven Americans. Musculoskeletal disorders account for nearly 70 million physician office visits in the United States annually and an estimated 130 million total healthcare encounters including outpatient, hospital, and emergency room visits. In 1999, nearly 1 million people took time away from work to treat and recover from work-related musculoskeletal pain or impairment of function in the low back or upper extremities (1). There is still an ongoing debate on cause, nature and degrees of musculoskeletal disorders particularly related to work and how to reduce it. However, it is agreed unanimously that the number of individuals with musculoskeletal disorders will only increase over the coming years, as our population ages. According to the World Health Organization (WHO), these factors are called “work-related conditions”, which may or may not be due to work exposures (1). Some of these factors include: (1) physical, organizational, and social aspects of work and the workplace, (2) physical and social aspects of life outside the workplace, including physical activities (e.g., household work, sports, exercise programs), economic incentives, and cultural values, and (3) the physical and psychological characteristics of the individual. The most important of the latter include age, gender, body mass index, personal habits including smoking, comorbidities, and probably some aspects of genetically determined predispositions (1). Among the various options to treat musculoskeletal disorders, use of orthopedic devices is becoming a routine,

with the number of annual procedures approaching five million in the United States alone (2). Some of the common orthopedic devices include joint replacement devices for hip and knee and bone fixation devices such as pins, plates and screws for restoring lost structure and function.

Materials and design issues of orthopedic devices are ongoing challenges for scientists and engineers. Total hip replacement (THR) is a good example to understand some of these challenges. Total hip replacements are being used for almost past 60 years with a basic design concept that was first proposed by Charnley et al. (3). A typical lifetime for a hip replacement orthopedic device is between 10 and 15 years, which remained constant for the last five decades. From design point of view, a total hip prosthesis is composed of two components: the femoral component and the cup component. The femoral component is a metal stem, which is placed into the marrow cavity of the femoral bone, ending up with a neck section to be connected to the ball or head. The neck is attached to the head, a ball component that replaces the damaged femoral head. The implant can be in one piece where the ball and the stem are prefabricated and joined at the manufacturing facility, this is called a monobloc construction. It can also be in multiple pieces, called modular construction, which the surgeon put together during the time of the surgery based on patient needs, such as the size of the ball in the cavity. An acetabular component, a cup, is also implanted into the acetabulum, which is the natural hip socket, in the pelvic bone. The femoral component is typically made of metallic materials such as Ti or its alloys. The balls of the total prostheses are made either from metallic alloys or ceramic materials. The hip cups are typically made from UHMWPE (ultrahigh molecular weight polyethylene). Some part of the stem can be coated with porous metals or ceramics, which is called cementless implant, or used as uncoated in presence of bone cement, which is called cemented implants. Bone cements, which is primarily poly (methyl methacrylate) (PMMA) based, stabilizes the metallic stem in the femoral bone for cemented implants. However, for cementless implants, the porous coating helps in tissue bonding with the implants surface and this biological bonding helps implants to stabilize (Fig. 1).

Figure 1. An example of a modern cemented hip prosthesis design and various components.

As it can be seen that THR by itself is a complex device that incorporates multiple materials and designs. However, all of these artificial materials mimic neither the composition nor the properties of natural bone. The inorganic part of natural bone consists of ~ 70 wt%, consists of calcium phosphate. Moreover, patient pool is different in terms of their age, bone density, physiological environment, and postoperative activities. To complicate matters further, surgical procedure and total surgery time can also be different for various patients. Because of these complications it is difficult, if not impossible, to point out the exact reason(s) for the low *in vivo* lifetime for these implants, which remained constant for the past 50 years. However, it is commonly believed that stress shielding is one of the key factors for limiting the lifetime of these implants. Because a metal stem is introduced into the bone, which has a complex architecture including an outer dense surface or cortical bone and an inner porous surface or cancellous bone, during the total hip surgery, the load distribution within the body shifts and the load transfer between tissue and implant does not match with normal physiological system. Typically, more load will be carried by the metal implants due to their high stiffness which will cause excess tissue growth in the neck regions. At the same time, upper part of the femoral bone will carry significantly less load and become weaker, which will make it prone to premature fracture. Both of these factors contribute to the loosening of hip implant that reduces the implant lifetime. This is also called stress-shielding effect, in general, which means the loss of bone that occurs adjacent to a prosthesis when stress is diverted from the area. To reduce stress-shielding, an ideal hip implant needs to be designed in a way that it has similar stiffness as natural femoral bone. However, current biomedical industries mostly use materials for load bearing implants that are typically designed and developed for aerospace or automotive applications, instead of developing new materials tailored specifically for orthopedic devices needs. But the time has come when materials need to be designed for specific biomedical applications to solve long-standing problems like stress-shielding in THR. Though THR is used as an example to show the complexity of materials and design issues in orthopedic devices but THR is not alone. Most orthopedic devices suffer from complex materials and design challenges to satisfy their performance needs.

FACTORS INFLUENCING ORTHOPEDIC DEVICES

There are several factors that need to be considered to design an orthopedic device. From the materials point of view, usually mechanical property requirement, such as strength, toughness, fatigue degradation becomes the most important issues as long as the materials are nontoxic and biocompatible. However, as the body tissue interacts with the surface of the device during *in vivo* lifetime, surface chemistry becomes one of the most important aspects for orthopedic devices. Most complex device functions cannot be accomplished using only one material, and require applications of structures made of multimaterials. As a result, compatibility of multimaterials in design and man-

Figure 2. Materials and design parameters for orthopedic devices.

ufacturing becomes another issue. Figure 2 summarizes various parameters that are important toward design and development of an orthopedic implants. Four main areas of orthopedic devices include materials issues, design issues, biocompatibility issues and patient specific information. All four of them are complex in nature and their interactions are even more difficult to appreciate. The following section offers some basic understanding of all of those issues.

MATERIALS ISSUES IN ORTHOPEDIC DEVICES

Selection of appropriate material is probably the most important issue in successful design and development of orthopedic devices. Among various materials related issues, (1) physical and chemical properties, (2) mechanical properties, (3) surface properties, and (4) *in vivo* degradation or corrosion behavior are some of the most important ones. In general, it is most widely accepted to use metallic materials for load bearing, and polymers and ceramic-polymer composites for nonload bearing applications. Some ceramic compositions and glasses are also used for nonload bearing coatings and defect filling applications. Development of biomaterials and materials processing for different orthopedic device applications is currently a very active research area (4–6) and new materials are constantly being developed to meet the current and future needs.

Physical and Chemical Properties

Physical properties include density, porosity, particle size, and surface area type of information. Composition or chemistry is probably the most important chemical property. It is important to realize that orthopedic devices cannot be built with materials that are carcinogenic. Nontoxic materials that do not leach harmful metal ions *in vivo* are ideal. Apart from dense structures, partially or completely porous materials are also used for orthopedic devices. If a porous material is used, then some of the properties, such as pore size, pore volume, and pore-pore interconnectivity

become important. Typically, for most porous materials, an optimum pore size between 100 and 500 μm are used in which cells can grow and stay healthy. Higher pore volume usually adds more space for cells to grow and naturally anchor the device. However, this also exposes higher surface area of the device material that can cause faster degradation or corrosion, which sometimes can be a concern depending on the materials used. For polymeric materials, chemistry, and structure are important because materials with the same chemistry, but different structure can show different *in vivo* response. This is particularly important for biodegradable polymers, such as poly lactic acids (PLA) and polyglycolic acids (PGA) and their copolymers. Trace element is another important factor in materials selection. Sometimes even a small amount of impurities can cause harmful effects *in vivo* (7). However, in calcium phosphate based ceramics, small addition of impurity elements actually proved to be beneficial for mechanical and biological response (8).

Mechanical Properties

Mechanical properties are important in selecting materials for orthopedic devices. Among various mechanical properties, uniaxial and multiaxial strength, elastic modulus, toughness, bending strength, wear resistance, fatigue resistance are some of the most important ones. Mechanical property requirements are tied to specific applications. For example, for the stem in THR, it should have high strength, low modulus, and very high fatigue resistance. As a result, due their low modulus, Ti and its alloys are usually preferred over high modulus metal alloys for the stem part of THR. However, for the acetabular component, high wear resistance requirement is the most important one and high-density polymers are preferred for the acetabular component. Mechanical properties are also linked on how they are processed. For example, casting devices in their near final shape can be a relatively inexpensive way to make complex shapes. However, material selection is critical in casting. The use of cast stainless steel for femoral hip stems is one experience that led to a high failure rate. This result generated significant debate in 1970s regarding processing of load bearing implants using casting and the options were considered by the ASTM Committee F04 on Medical and Surgical Materials and Devices to ban cast load bearing implants (8). For devices made of degradable polymers, strength loss due to degradation is an important factor. For example, materials compositions and structures in resorbable sutures are designed for different degradation times to achieve desired strength loss characteristics.

In vivo Degradation

Some orthopedic devices require materials to be bioresorbable or biodegradable, which will dissolve in body fluid as natural tissue repairs the site. Except for a few polymer and ceramic compositions, most materials are nondegradable in Nature. The degradation behavior is controlled by three basic mechanisms and they are (1) physiologic dissolution, which depends on pH and composition of calcium phosphate; (2) physical disintegration, which may be due to

biochemical attack at the grain boundaries or due to high porosity; and (3) biological factors, such as phagocytosis.

In most materials, not just one mechanism but a combination of all three mechanisms control biodegradation behavior. Among them, biological factors are probably the most interesting ones. Though the actual process is quite complex (9), a simplistic action sequence can be viewed as osteoclastic cells slowly eat away the top surface of the foreign material and stimulate osteoblast cells. Osteoblast cells then come and deposit new bone to repair the site. Such dynamic bone remodeling is a continuous process within every human body. The rate at which osteoblastic deposition and osteoclastic resorption are taking place changes with the age of the person. This process controls the overall bone density. In terms of materials, *in vivo* degradation of polymeric materials is probably the most well-characterized field. Numerous products are available in which degradation kinetics has been tailored for specific applications. However, the same is not true for ceramics. Controlled degradation ceramics are not commercially available though degradation behavior of some calcium phosphate based ceramics is well documented (10). For metallic implants, the most serious concern regarding *in vivo* degradation is metal ion leaching or corrosion of the implants, which can cause adverse biological reactions. Corrosion products of nickel, cobalt, and chromium can form metal-protein complexes and lead to allergic reactions (7,11). Early reports of allergic reactions were reported with metal on metal (MOM) total hips (12). The inflammatory response to metallic wear debris from these devices may have been enhanced due to the high corrosion rate of the small wear particles. However, there is a lack of a predictable relationship between corrosion and allergies except in a few cases, such as vitallium implants (13,14). The number of patients with allergic reactions is not large, and it remains to be proven whether corrosion of devices causes the allergy, or the reactions are only manifest in patients with preexisting allergies. Most materials that are currently used in load bearing dental and orthopedic devices are plates and screws and they show minimum long-term degradation and health related concerns such as allergies.

Surface Properties

Surface property of materials is another important parameter for orthopedic device design. Once implanted, it is the surface that the body tissue will see first and interact. As a result, surface chemistry and roughness both are important parameters for device design. Devices that are designed for different joints, where wear is a critical issue, smooth surface is preferred there. For example, in knee joints UHMWPE is used to reduce wear debris. But most other places, where tissue bonding is necessary, rough surface or surface with internal porosity is preferred primarily to enhance physical attachment. However, biomechanical and biochemical bonding to device surfaces are still subject of active scientific investigation (15). Tailoring internal porosity and chemistry of metallic implants is still an active research area. Either metal on metal or ceramic on metal coatings are used to achieve this goal. Different

Figure 3. Recent trends in orthopedic device design.

manufacturing techniques are used to modify surfaces of metal implants. Among them, partial sintering of metal powders on metallic implants is one approach (16). For example, Ti powders are sintered on cp-Ti or Ti6Al4V devices, where after sintering the sintered layers leave some porosity in the range of 100–500 μm for osteointegration by bone tissues. Similar techniques are also used for metal fibers to create a mesh with varying porosity for improved osteointegration (17). For ceramic coatings, such as calcium phosphate on Ti or Co–Cr based devices, plasma-spray technique is used. Typically, a direct current (DC) plasma gun is used under a controlled environment to coat metallic device with several hundred microns of calcium phosphate-based ceramics. Because of significantly better bioactivity of calcium phosphates, these coated devices show improved tissue–materials interaction and better long-term tissue bonding (18). In case of THR, ceramics coated cementless implants are placed without any bone cement during surgery. During healing, body tissue forms strong bonds with the coating and anchors the device. This biological fixation is believed to be equal or better than cemented implants in which bone cement is used during surgery to anchor the device. Though the idea of cementless implants is great, but lack of interfacial strength at the implant metal and ceramic coating interface is still a concern and subject of active research. Formation of amorphous calcium phosphate during processing of plasma-sprayed ceramic coatings increase potential biodegradation rate for the coating material, which is another major concern for these devices. In general, though coated implants are promising, a significant number of uncoated implants are still used in surgery every day that has worked for a long time. In fact there are more research data available today on uncoated implants than on the coated ones.

DESIGN ISSUES IN ORTHOPEDIC DEVICES

Design of orthopedic devices is focused on the needs for that particular problem. As a result, for the same device (spinal grafting cage or THR), different designs can be found from various device makers. These devices can be in single piece or multiple-piece, made from the same or different material(s). As a result challenges are significantly different for multiple piece multimaterial devices like THR than single piece ones like bone screws or plates. For multiple piece multimaterial devices, compatibility among different

materials/pieces and overall functionality becomes a more serious design issue.

Current practice in device design usually starts from biomechanical analysis of stress distribution and functionality of a particular device. If it is a joint related device, it is important that the patient can actually move the joint along multiple directions and planes to properly restore and recover functionality of that joint. Figure 3 shows some of the recent trends in orthopedic device designs. During the past 10 years, computer aided design (CAD) and rapid prototyping (RP) based technologies have played a significant role in orthopedic device design. Using this approach, real information from patients can be gathered using a computed tomography (CT) or magnetic resonance imaging (MRI) scans, which then can be visualized in three dimensions (3D). This 3D data can be transformed to a CAD file using different commercially available software.

The CAD file can be used to redesign or modify orthopedic devices that will be suitable to perform patient's need. If necessary, the device can also be tested in a virtual world using finite element analysis (FEA) to optimize its functionality. Optimized device can then be fabricated using mass manufacturing technologies such as machining and casting. If small production volume is needed, then RP technologies can be used. In RP, physical objects can be directly built from a CAD file without using any part specific tooling or dies. Rapid Prototyping is an additive or layer by layer manufacturing process in which each layer will have a small thickness, but the X and Y dimensions will be based on the part geometry. Because no tooling is required, batches as small as 1 or 2 parts can be economically manufactured. Most RP processes are capable of manufacturing polymer parts with thermoset or thermoplastic polymers. Some of the RP techniques can also be used to manufacture metal parts. Figure 4 shows a life-sized human femur made of Ti6Al4V alloy using laser engineered net shaping (LENS) process. The LENS technology uses metal powders to create functional parts that can be used in many demanding applications. The process uses up to 2 kW of Nd:YAG laser power focused onto a metal substrate to create a molten puddle on the substrate surface. Metal powder is then injected into the molten puddle to increase the material volume. The substrate is then scanned relative to the deposition apparatus to write lines of the metal with a finite width and thickness. Laser engineered net shaping is an exciting technology for orthopedic devices because it can directly build functional parts that can be used for different applications instead of

Figure 4. A life-sized human femur made of Ti6Al4V alloy using LENS.

other RP parts that are typically used for “touch and feel” applications. Commercial RP processes have also been modified to make ceramic parts for orthopedic devices. Figure 5 shows one such example in which reverse

engineering of horse’s-knuckle was used to show how fused deposition modeling (FDM), a commercial RP process, can be used to create tailored porosity bone implants in which pore size and pore volume can be varied simultaneously keeping the outside geometry constant (19,20). The FDM process was used to make polymer molds of to cast porous ceramic structures. The mold was designed from the CAD file of the horse’s knuckle. The CAD file was created from the 3D volumetric data received from the CT scan of the bone. Such examples demonstrate the feasibility of patient specific implants through novel design and manufacturing tools.

BIOCOMPATIBILITY ISSUES IN ORTHOPEDIC DEVICES

Biocompatibility issue is an important issue in orthopedic device design and development, but it is usually considered during materials selection and surface modification. From cell materials interaction point of view, materials can be divided into three broad categories: (1) toxic; (2) nontoxic and bioinert, and (3) nontoxic and bioactive. For any application in the physiological environment, a material must be nontoxic. A bioinert material is nontoxic, but biologically inactive such as Ti metal. A bioactive material is the one that elicits a specific biological response at the interface of the biological tissue and the material, which results in formation of bonding between tissue and material. An

Figure 5. (a) A real bone; (b) CT scans of the bone; (c) a CAD file from the CT scans; (d) FDM process. (e) a polymer mold processed via FDM of the desired bone; (f) alumina ceramic slurry infiltrated polymer mold; (g) controlled porosity alumina ceramic bone graft.

example of bioactive material will be hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, which is similar in composition to the inorganic part of natural bone. The terms biodegradable, bioresorbable, and bioabsorbable are often used interchangeably. For most orthopedic devices, bioactive surfaces are ideal for better cell-materials attachment.

In vivo cell-materials interaction is a fairly complex process. In simple terms, when orthopedic devices are placed inside, our body will try to isolate the device by forming a fibrous tissue around it, which is particularly true for devices made with bioinert materials. If the material is bioactive, bone cells will first attach to the implant surface and then grow or proliferate. A material shows good biocompatibility when cells will attach and grow quickly on the device surface. Growth factors, such as bone morphogenic proteins (BMP), are sometimes used to stimulate cell attachment and growth behavior *in vivo*. After proliferation, cells will differentiate or produce new bones, which will repair the site and anchor the device. All three stages, attachment, proliferation, and differentiation of bone cells are important for repair and reconstruction of musculoskeletal disorders.

PATIENT SPECIFIC ORTHOPEDIC DEVICE: A FUTURE TREND

Patient specific device is the future trend for repair and reconstruction of musculoskeletal disorders. Due to the advancement of CAD and RP based small volume manufacturing technologies, orthopedic devices for people with special needs will be designed to meet the specific requirements. Such activities are currently pursued in academic research and hope to translate into standard industrial practice in the next one or two decades. Three-dimensions (3D) visualization of disorders using computer images and physical models, and follow-up discussion between patients and physicians will help to better educate the patient population about their problems and possible options. These options can then be transformed to physical models for trials before placing them *in vivo*. The goal is to reduce revision surgeries and increase device lifetime while maintaining the quality of life for the patient population. Various innovative scientific and engineering advancements toward novel materials and design options are helping us to make significant developments to achieve this goal.

ORTHOPEDICS PROSTHESIS FIXATION FOR

PATRICK J. PRENDERGAST
Trinity Centre for
Bioengineering
Dublin, Ireland

INTRODUCTION

The fixation of an orthopedic implant should secure it rigidly to the underlying bone. The ideal fixation will sustain high forces, pain free, for the remaining lifetime of the patient. Difficulties in achieving this objective arise because (1)

1. The loads are often several times body weight in the lower extremity. The loads are fluctuating, or cyclic, and furthermore extremely high loads can occur occasionally (2).

2. The presence of the implant alters the stress transfer to the underlying bone leading to bone remodelling or fibrous tissue formation at the bone/implant interfaces. This can threaten the long-term mechanical integrity of the prosthetic replacement.
3. The range of materials that can be placed in contact with bone is limited by biocompatibility issues.

The fixation of an orthopedic implant may be categorized as either cemented fixation or biological fixation.

Cemented fixation involves securing the implant into the bone with a “bone cement.” By far the most common bone cement is based on the (polymer polymethylmethacrylate (PMMA)). PMMA bone cement is polymerized *in situ* during the surgery. It contains radiopacifiers in the form of particles of barium sulphate (BaSO₄) or zirconia (ZrO₂), which make it visible in radiographs (3). It also contains an inhibitor (hydroquinone) to prevent spontaneous polymerization and an initiator (benzoyl peroxide) to allow polymerization at room temperature. Antibiotics to prevent infection (e.g., gentamicin) may also be added. Table 1 lists typical components of bone cement and their roles. Polymerization begins when a powder of the PMMA polymer is mixed with the MMA monomer liquid. The mixing can either be done by hand in a mixing bowl just before to its use in the surgery or a mechanical mixing system may be used; these have the advantage of reducing the porosity of the bone cement and increasing its fatigue life. The cement is applied in a doughy state to the bone before placement of the implant.

In biological fixation, the implant is secured to the bone by a process known as “osseointegration.” Osseointegration occurs by bone ingrowth onto the surface of the implant. The surface of the implant must have a structure so that, when the bone grows in, sufficient tensile and shear strength is created. Bone ingrowth requires a mechanically stable environment and an osteoconductive surface. An osteoconductive surface can be achieved by various treatments, e.g., plasma spraying with hydroxyapatite. Ingrowth occurs over approximately 12 weeks, and during this period, implant stability is required: Initial stability can be achieved by press-fitting the implant into the bone, or by using screws.

Hybrid fixation refers to the use of both cemented and biological techniques for the fixation of a prosthesis. For example, a hip replacement femoral component may be

fixed using cement, whereas the acetabular cup may be fixed into the pelvic bone by osseointegration.

Failure of prosthesis fixation is observed as loosening and pain for the patient. If loosening occurs without infection it is called *aseptic* loosening. Loosening is a multifactorial process and does not have just one cause. Loosening of cemented fixation often occurs by fatigue failure of the bone cement, but loosening can have several root causes: fatigue from pores in the cement and stress concentrations at the implant/cement interface, debonding at the prosthesis/cement interface or cement/bone interface, or bone resorption causing stresses to rise in the cement. Loosening of biological fixation occurs if the relative micromotion between the bone and the implant is too high to allow osseointegration, i.e., if the initial stability of the implant is insufficient. Huiskes (4) proposed the concept of *failure scenarios* as a method for better understanding the multifactorial nature of aseptic loosening. The failure scenarios are

1. Damage accumulation failure scenario: the gradual cracking of bone cement, perhaps triggered by interface debonding, pores in the cement, or increased stresses due to peripheral bone loss.
2. Particulate reaction failure scenario: wear particles emanating from the articulating surfaces or from metal/metal interfaces in modular prostheses (fretting wear) can migrate into the interfaces causing bone death (osteolysis).
3. Failed ingrowth failure scenario: High micromotion of the implant relative to the bone can prevent bone ingrowth, as can large gaps (> 3 mm). If the area of ingrowth is insufficient, then the strength of the fixation will not be high enough to sustain loading when weight-bearing commences.
4. Stress shielding failure scenario: Parts of the bone can be “shielded” from the stresses they would normally experience because of the rigidity of the implant. This can lead to resorption of the bone and degeneration of the fixation.
5. Stress bypass failure scenario: In biological fixation, ingrowth can be patchy leading to stress transfer over localized areas. When this happens, some bone tissue is “bypassed,” and in these regions, bone atrophy can occur because the stress is low.

Table 1. Components of Bone Cement and Their Roles

Components	Role	Amount
Liquid		20 mL
Methyl methacrylate (monomer)	Wetting PMMA particles	97.4 v/o
N,N,-dimethyl-p-toluidine	Polymerization accelerator	2.6 v/o
Hydroquinone	Polymerization inhibitor	75 + 15 ppm
Solid powder		40 g
Polymethyl methacrylate	Matrix material	15.0 w/o
Methyl methacrylate-styrene-copolymer	Matrix material	75.0 w/o
Barium sulphate (BaSO ₄), USP	Radiopacifying agent	10.0 w/o
Dibenzoyl peroxide	Polymerization initiator	0.75 w/o

From Park (3).

Note: v/o: % by volume; w/o: % by weight.

6. Destructive wear failure scenario: In some joint replacement prostheses, e.g., hip and knee, wear can occur to such a degree that the component eventually disintegrates.

CEMENTED FIXATION

It is common to classify cementing techniques according to “generation”: The first generation involved hand-mixing and finger packing of the cement, and the second generation improved the procedure by using a cement gun and retrograde filling of the canal, with a bone-plug to contain the cement within the medullary canal. This allows pressurization of the cement and therefore better interdigitation of the cement into the bone. Third generation (called modern cementing) uses, in addition, mechanical mixing techniques for the cement to remove pores and pulsative lavage to clean the bone surface of debris. The most common mechanical mixing technique is “vacuum mixing,” where the powder and monomer are placed together in a mixing tube and the air is removed under pressure; often the tube can then be placed into an injection gun from which it can be extruded into the bone cavity. Another mechanical mixing technique is centrifugation (i.e., spinning the polymerizing bone cement in a machine), which is found to remove pores and increase the fracture strength (3). Precoating the implant with a PMMA layer or addition of a roughened surface strengthens the implant/bone cement interface.

Fixation strength using bone cement relies on an interdigitation of the bone cement with the bone; i.e., it is a mechanical interlock between the bone and the solidified cement that maintains the strength and not a chemical bond. Good interdigitation requires that the bone bed be rough. Creating a rough surface is done by appropriate broaching during preparation of the bony bed; it also requires lavage to clean the bed of loose debris and marrow tissue. Mann et al. (5) found the strength of the bone cement/bone interface to be positively correlated with the degree of interdigitation (Fig. 1). To achieve superior

Figure 1. Interdigitation of the bone cement into the bone increases the strength of the bone cement interface. q_{int} is the product of the average value of the thickness of the interdigitated region and the density of the interface region measured using a CT scan. See Mann et al. (5) for details.

Figure 2. A comparison of the fatigue strength of hand-mixed and vacuum-mixed bone cement. After Murphy and Prendergast (10).

interdigitation, it was thought useful to develop “low viscosity” cements, and although higher penetration was achieved, the clinical outcomes using low viscosity cements in hips were not superior (6).

PMMA bone cement undergoes an exothermic polymerization reaction. This means that heat is produced on polymerization and this can cause necrosis of the surrounding bone tissue. Another consequence of heating is that the cement expands and contracts on cooling. As solidification occurs before to full cooling, residual stresses are generated in the cement (7). This is one reason to minimize the thickness of the cement layer. Also, metallic stems, because they conduct heat, can minimize the peak temperature transmitted to the bone, cooling the metallic implant before implantation has also been suggested. Bioactive cements have also been proposed; see the review by Harper (8). These cements have filler particles added to create a bioactive surface on the cement; fillers can be hydroxyapatite powder or fibers, bone particles, or human growth hormone. Alternatives to PMMA are bisphenol- α -glycidyl methacrylate (BIS-GMA) or poly(ethylmethacrylate) (PEMA)/*n*-butylmethacrylate (*n*BMA) cement. However, these cements are not yet widely used.

The mechanical strength depends on the brand of cement used and on the mixing technique (9). To prevent the damage accumulation failure scenario (see above), sufficient fatigue strength is required. This has been measured as a function of mixing technique (Fig. 2) (10). Being a polymer operating close to its melting temperature, bone cement is also subject to creep, i.e., viscoplasticity, and the creep strain as a function of stress has been measured under dynamic loading (11). However, it is clear that the *in vitro* testing conditions may not account for many of the extremely complex *in vivo* conditions, so these results should be interpreted with caution (12).

OSSEOINTEGRATION (CEMENTLESS FIXATION)

There is no simple definition of osseointegration, although Albrektsson (13) advocates the following: Osseointegration means a *relatively soft-tissue-free contact between implant*

Figure 3. Bone ingrowth into a multilayer of a proximal part of a femoral hip prosthesis. After Eldridge and Learmonth (15).

and bone, leading to a clinically stable implant. Early in the study of the osseointegration concept, Skalak (14) found osseointegration was promoted by a micro-rough surface more so than a smooth one. Since then, many animal experiments investigating the effect of plasma spraying the surface and various methods of creating a porous surface have been reported. For orthopedic fixation, porous surfaces with beads in one or more layers have been used, as have wire meshes attached to surfaces, and plasma spraying the surface with hydroxyapatite.

Figure 3 shows bone ingrowth into a multilayer of a proximal part of a femoral hip prosthesis (15). It can be observed that ingrowth is patchy; this is what is commonly found, even with successful implants retrieved at autopsy (16); it is evident, therefore, that ingrowth is not required everywhere on the prosthesis for a successful fixation. Ingrowth is controlled by a combination of the mechanical environment and the size of the pores; the spacing between the pores should not be greater than the degree of micromotion or else the new bone ingrowth path will be continuously sheared as the tissue attempts to grow in. In experiments in dogs, Søballe (17) studied the relationship between implant coating and micromotion and found that hydroxyapatite coating increased the rate of bone ingrowth, and that a relative motion between implant and bone of 150 μm allowed osseointegration, whereas a relative motion of 500 μm inhibited it. The mechanobiolo-

gical consequences of these different shearing magnitudes was analyzed by Prendergast et al. (18). The depth of the porosity will also affect the strength, with multilayer beaded surfaces having the potential for greater tensile strength (1).

FIXATION OF PROSTHESIS DESIGNS

Each implant design has specialized fixation features. In the following sections, examples are provided of the fixation approaches used in the main orthopedic implant categories.

Hip Prostheses

Although hip arthroplasty may involve replacement of the femoral side only, *total* hip arthroplasty (THA) involves replacement of the proximal femur and the acetabular socket. Both cemented and cementless fixation is used for both the femoral component (the “stem”) and the acetabular component (the “cup”). Selection is a matter of surgeon choice, although there is some agreement that the cementless fixation is preferable in younger patients because cementless implants are easier to revise than cemented where complete removal of the cement mantle may be problematic.

Considering the femoral side first, cemented fixation takes two categories: stem designs in which a bond is encouraged between the stem and the cement (referred here as bonded stems) and designs that discourage a bond (referred here as unbonded stems). Stem bonding can be achieved through roughening of the stem surface to create a mechanical interlock between the metallic stem or cement or through use of a PMMA precoat to create a chemical bond between the precoat/cement interface. Bonded stems usually contain a collar that rests on the bone surface preventing subsidence and often containing ridges, dimples, and undercoats to provide additional interlock with the cement. As long as the bonded stems remain bonded, they have the theoretical benefit of reducing the stress levels in the cement. However, if the bonded stems fail, the roughened surface could generate debris particles and initiate a loosening process. In contrast to the bonded stems, unbonded stems discourage a bond between the stem and the cement through use of a smooth, polished stem surface in combination with a stem design that typically has no collar or macrofeatures to lock into the cement. With the lack of a bond, the polished stems facilitate some stem subsidence within the cement mantle and thereby allow wedging of the implant within the medullary canal. Lennon et al. (19) compared the damage accumulation around polished with matt stems and did not find a difference in the damage accumulated in their cement mantles. Another point of comparison between cemented and cementless fixation is that cementless stems will have a larger cross-sectional area than cemented stems because they must fill the medullary canal; this will make cementless hip prostheses stiffer and predispose them to the stress shielding failure scenario. Recognizing this, it is usual for the osseointegration surface to be on the proximal part of cementless stems to ensure proximal load transfer;

furthermore, patches of osseointegrative surface may be limited to the posterior and anterior faces of the stem.

Considering the acetabular side, the cup is either made from ultra-high-molecular-weight polyethylene (UHMWPE), ceramic, or metal. UHMWPE cups may be metal-backed. As the head can be either ceramic (a modular head can be connected to a metal femoral component using a Morse taper) or metal (modular or monobloc), this means that several combinations of bearing materials are possible. Polyethylene cups and metal heads are the most common, but the others, such as metal-on-metal, are advocated as well. The selection of bearing materials is important for the fixation because a high frictional torque predisposes to loosening of the cup or stem and because the wear particles produced can provoke the particulate reaction failure scenario. Polyethylene cups are cemented into the acetabulum using bone cement. Metal-backing of the cup is designed to decrease stresses in the polyethylene “liner,” which should lead to lower wear rates although it is also predicted to increase stress concentrations in the fixation at the periphery of the cup (20). Metal, ceramic, and metal-backed UHMWPE cups may be threaded on the outside so that they can be screwed into the acetabulum, or they may be fixated by osseointegration.

The interrelationship between design factors and fixation of hip implants is complicated and involves maximizing strength of the cement/metal interface, the cement itself, and the bone/cement interface. According to the design philosophy of polished stems, it is better to safeguard the vital bone/cement interface by allowing the cement/metal interface to fail first and facilitating subsidence (21). Not only should the interfaces have the required strength, but the stresses should be minimized to ensure the most durable fixation (22)—the measures to achieve this are listed in Table 2.

Knee Prostheses

Total knee replacement involves femoral and tibial components, and a component for patellar resurfacing (a patellar “button”) is also often used. Both cemented and cementless

Figure 4. A knee replacement prosthesis showing porous-coating for osseointegration and posts for fixation. From Robinson (23).

fixation is used in knee arthroplasty. The femoral component may be fixated with an intramedullary stem that may be cemented, or it may have a porous surface for osseointegration with medial and lateral “posts” to aid initial stability. The tibial component consists of a metal “tray” and a polyethylene insert; the tray may also be fixated with an intramedullary stem cemented into the tibia, perhaps accompanied by medial and lateral posts/pegs for rotational stability. Figure 4 shows a design fixated by osseointegration (23). Walker (24) gives a thorough description of the options available for knee prostheses.

Upper Extremity and IVD Prostheses

Upper extremity prostheses include the shoulder, elbow, and wrist (1). Total shoulder arthroplasty (TSA) consists of a humeral component with an intermedullary stem and a

Table 2. Measures that Maximize Strength and Minimize Stress in Total Hip Replacement Structures

glenoid component inserted into the glenoid cavity of the scapula. The glenoid component is either all-polyethylene; in which case, it is cemented; or metal-backed; in which case, it may be fixated by osseointegration. Glenoid components may have several pegs, or they may have one central "keel" for fixation (25). Elbow prostheses consist of humeral, ulnar, and radial components, all which may be fixated with or without cement. Wrist prostheses replaces the radial head and the scapoid and lunate bones of the wrist and may be cemented and uncemented (1). Intervertebral disk (IVD) prostheses replace the degenerated disk with a polymer; there are several strategies for fixation: The endplates may be porous coated and plasma sprayed for osseointegration to the cancellous bone with vertical fins to increase stability. IVD prostheses may also be fixed to adjacent vertebral bodies with screws (26).

EVALUATION OF FIXATION AND FUTURE STRATEGIES

One of the key issues in orthopedic implant fixation is whether to use cemented fixation or biological fixation, with surgeons on both sides of the debate (16,27). Cemented fixation has the advantage of immediate postoperative stability whereas concerns may be raised about the reliability of bone cement's fatigue strength; furthermore, there is a school of thought that the exothermic polymerization reaction should be avoided if at all possible. Biological fixation by osseointegration has the advantage of avoiding the use of the PMMA cement but runs the risk of the failed ingrowth failure scenario; furthermore, immediate postoperative weight-bearing is not possible. Finally cementless implants are easier to revise if they fail.

Another key issue in orthopedic implant fixation is that of preclinical testing and regulatory approval of new fixation technologies. Considerable challenges exist in achieving consensus around regulatory tests that safeguard patients against ineffective devices while still allowing innovation (4). Preclinical tests can use either (1) finite element models of the direct postoperative situation, e.g., for the hip (28), knee (29), or shoulder (25), or computer simulations of a failure scenario, e.g., damage accumulation (30); (2) physical model "bench" testing with simulators (24,31); or (3) animal testing. Animal testing is not ideal for testing the biomechanical efficacy of orthopedic implant fixation because the implant geometry must be modified to fit the animal skeleton. Furthermore, an important emerging concept is that of patient-specific implants based on computational analysis of a patient's medical images (32).

One useful clinical method to assess implant fixation is through the use of radiostereometric analysis (RSA). With this approach, the migration of the implant relative to the bone can be determined and is used to determine designs that may be at risk of early loosening. Retrospective and prospective clinical studies are also very useful to determine designs or materials that have promising or poor clinical results. On a larger scale, implant registries performed in many countries in Western Europe can provide information on how designs, materials, and surgical tech-

niques rank in terms of risk of failure. All of these clinical tools can aid in understanding the role of implant fixation in success of joint replacements.

A final issue is the degree to which broader technological innovations in surgery and medicine will affect orthopedics. For example, minimally invasive therapy (33) requires special implants and associated instrumentation. Tissue-engineering and regenerative medicine also has the potential to change the nature of orthopedics, not only by reducing the need for joint arthroplasty implants but by integrating tissue engineering concepts with conventional implant technologies, for example, cell seeding into implant surfaces to promote biological fixation.

OXYGEN ANALYZERS

SUSAN MCGRATH
SUZANNE WENDELKEN
Dartmouth College
Hanover, New Hampshire

INTRODUCTION

Oxygen is essential for all aerobic life on Earth. It is the most abundant element as it comprises a little more than one-fifth of the weight of air, nine-tenths of the weight of water, and almost one-half of the weight of the earth's crust (1).

Because of its role in supporting and sustaining life, it is often important to monitor the level of oxygen in the atmosphere. Too much oxygen can lead to a toxic atmosphere where as too little oxygen causes asphyxia and eventually death. A relatively constant level of oxygen is required for most aerobic processes.

Oxygen gas monitoring is used for a number of purposes: (1) **Medical:** anesthesia (drug delivery, airway monitoring), respiratory oxygen content monitoring (inhaled and exhaled), controlled environments, incubators. (2) **Physiological:** exercise (rate of oxygen consumption), aircraft, spacecraft, scuba diving, fire fighting, mountain climbing, spelunking. (3) **Biological:** metabolism (oxygen uptake and consumption), fermentation, beverage and food packing. (4) **Industrial:** combustion control, fuel and pollution management, safe operation of chemical plants, monitoring gas purity.

This article gives an overview of the analyzers used to measure gaseous oxygen in medicine, physiology, and biology. Measurement of dissolved or bound oxygen is also important in medicine and is discussed in detail elsewhere in this Encyclopedia.

History and Relevance

Oxygen was not known to exist until the 1770s when it was discovered by French scientist Antoine Lavoisier and English clergyman and scientist Joseph Priestly through experiments on combustion. Previously, air was considered to be an element composed of a single substance. Combustible materials were thought to have a substance called phlogiston, from the Greek word meaning to be set on fire, which escaped as a material was burned. Lavoisier, however, believed that combustion resulted from a combination of fuel and air. He conducted experiments where he burned a candle in a sealed jar and observed that only one-fifth of the air was consumed. He named this unconsumed portion of the air oxygen from the Greek word

meaning acid producing. Although his thoughts about oxygen being the corrosive agent in acidic compounds was wrong, the name stuck and the study of oxygen was born (2).

Oxygen is essential for most life on Earth as it plays a key role in aerobic metabolism as a final electron acceptor due to its high electron affinity. Metabolic rate can be indirectly measured by monitoring oxygen consumption as >95% of energy is produced by reactions of oxygen with other food (3). This method is called indirect calorimetry and is a much more cost effective and timely method for measuring metabolic rate as compared to direct calorimetry (the direct measure of heat energy produced).

Oxygen availability is a function of its partial pressure and the total pressure of the gas mixture in which it resides. At sea level, the partial pressure of oxygen is roughly 21%. With decreasing atmospheric pressure, as accompanies increasing altitude, the total amount of available oxygen decreases (Table 1). For example, at 18,000 ft. (5.48 km) above sea level, although the partial pressure of oxygen is still 21%, there is roughly half the amount of available oxygen. At ~29,000 ft. (8.33 km) above sea level on the top of Mt. Everest, there is less than a third the amount of total available oxygen compared to sea level. At such altitudes, most humans require the use of supplemental oxygen. In addition, the body will compensate for the reduced oxygen availability by increasing the heart and respiration rate to keep up with the metabolic demands (3). A climber's resting heart rate at this altitude is double to triple their normal resting heart rate. Long-term exposure to high altitude prompts the body to produce more red blood cells per unit blood volume thus increasing the number of oxygen carriers and making respiration easier. If the body does not properly adapt to such conditions, altitude sickness, pulmonary and cerebral edema, and potentially death may result (3).

Table 1. Atmospheric Pressure, the Fraction of Available Oxygen Compared to Sea Level, and Temperature All Decrease with Increasing Altitude^a.

Altitude, ft.	Barometric Pressure, mmHg	Fraction Available Oxygen	Temperature °C
0	760	1.00	15
1,000	733	0.96	13
5,000	632	0.83	5.1
10,000	523	0.69	-5.4
14,000	447	0.59	-12.7
16,000	412	0.54	-16.7
18,000	380	0.50	-20.7
20,000	349	0.46	-24.6
22,000	321	0.42	-28.6
24,000	295	0.39	-32.6
26,000	270	0.36	-36.5
28,000	247	0.33	-40.5
30,000	228	0.30	-44.4
32,000	206	0.27	-48.4
34,000	188	0.25	-52.4
36,000	171	0.23	-56.3

^aSee Ref. 4.

The partial pressure of oxygen remains a fairly constant 21% until very high altitudes [i.e., >50,000 ft. (15.24 km) (5)]. At these altitudes it is necessary to maintain a pressurized, enclosed environment, such as aircraft, spacecraft, or space suite, in order to sustain human life.

Oxygen availability can be decreased by displacement by other gases, such as nitrogen, carbon dioxide, methane, and anesthetics. Oxygen availability is also easily decreased by combustion and oxidation processes. Thus it is necessary to monitor the atmospheric oxygen level in situations where these gases or combustion is present such as in enclosed environments, closed breathing circuits, and fire fighting.

Each year ~20 deaths occur as a result of asphyxiation due to displacement of oxygen by another gas in air (6). Accidental asphyxia usually occurs in industry as a result of oxygen depletion by carbon dioxide, CO₂, methane (CH₄), or a hydrocarbon gas in a confined space, such as a tunnel, laboratory, sewer, mine, grain silo, storage tank, or well (7). For example, in 1992, a barge operator in Alaska died from asphyxiation and a rescuer lost consciousness during rescue efforts due to a low level of oxygen (6%) in a confined space (8). In anesthesia, accidental asphyxia has resulted from incorrectly connected gas delivery tubes (9).

In choosing an oxygen analyzer for a particular need, it is important to be acquainted with the properties of operation, characteristics, and limitations of these devices. The primary methods for oxygen detection are based on the paramagnetic susceptibility, electrochemical properties, and light absorption properties of oxygen.

PARAMAGNETIC OXYGEN ANALYZERS

All matter exhibits some form of magnetism when placed in a magnetic field. Magnetic susceptibility is the measure of the strength of a material's magnetic field when placed in an external magnetic field. Diamagnetic substances, such as gold and water, align perpendicularly to an external magnetic field causing them to be repelled slightly. This property arises from the orbital motion of electrons that produces a small magnetic moment. In substances with paired valence electrons, these moments cancel out. However, when an external magnetic field is applied it interferes with the motion of the electrons causing the atoms to internally oppose the field and be slightly repelled by it. Diamagnetism is a property of all materials, but is very weak and disappears as soon as the external magnetic field is withdrawn. In materials with unpaired valence electrons (e.g., nickel and iron) an external magnetic field aligns the small magnetic moments in the direction of the field, which increases the magnetic flux density. Materials with this behavior are weakly attracted to magnetic fields and are classified as paramagnetic. Ferromagnetism is a special case of paramagnetism where materials (e.g., iron and cobalt) are strongly attracted to magnetic fields. Paramagnetic materials have a high susceptibility (10).

Oxygen has a relatively high susceptibility when compared to other gases (see Table 2). This property is the key principle behind paramagnetic oxygen analyzers.

Table 2. Relative magnetic susceptibility values on a scale of Oxygen = 100 and Nitrogen \approx 0 at 20° C (11–13).

Gas	Relative Magnetic Susceptibility
Argon	-0.58
Acetylene	-0.38
Air (dry air)	21.00
Ammonia	-0.58
Carbon dioxide	-0.61
Carbon monoxide	0.06
Chlorine	-0.13
Ethane	-0.83
Helium	0.29
Hydrogen	-0.12
Methane	-0.37
Nitrogen	-0.42
Nitrous oxide	-0.58
Nitrogen monoxide	43.80
Nitrogen dioxide	28.00
Oxygen	100.00

The three main types of paramagnetic oxygen analyzers are (1) thermomagnetic (magnetic wind); (2) magnetodynamic (dumbbell or autobalance); (3) magnetopneumatic (differential pressure).

Paramagnetic analyzers are typically used for monitoring the quality of breathing air in open and enclosed environment, biological laboratory measurements, and in industrial combustion analysis (2,14).

Limitations of Paramagnetic Analyzers. Because the magnetic susceptibility of oxygen depends on temperature, it is necessary to operate at a constant temperature or to have some temperature compensation ability (1,15). The output of the sensor is also proportional to the absolute atmospheric pressure and thus pressure compensation is sometimes necessary (1,15).

Paramagnetic devices are typically delicate instruments with moving parts and are thus adversely influenced by vibrations. They generally are not used as portable devices (13).

Paramagnetic sensors work well for percent oxygen measurement, but are not recommended for trace oxygen measurements. In addition, these sensors should not be used when interference effects cannot be compensated for (i.e., sample gas containing other paramagnetic or diamagnetic gases, or varying background gas composition) (14). The effects of background gases used in anesthesia are small but not always negligible. These effects are summarized in Table 3.

Thermomagnetic (Magnetic Wind)

Thermomagnetic analyzers are based on the fact that magnetic susceptibility decreases inversely with the square of temperature.

Principles of Operation. A schematic diagram of a thermomagnetic analyzer can be seen in Fig. 1. A gas sample is admitted into the inlet that branches into equal

Table 3. Errors in Paramagnetic Analyzer measurements due to anesthesia gases^a.

Gas	Error in Instrument Reading in %O ₂ Due to 1% Vapor

segments and converges again at the outlet. These tubes are connected by another tube halfway between the inlet and outlet. This cross-tube is heated by a platinum coil that is separated in the center by a thermal resistance bridge. These two heater coil segments form two arms of a Wheatstone bridge with the third arm being the output of the sensor. A magnetic field is applied to one-half of the coil. Any oxygen in the gas is attracted to the magnetic field in the cross-section. These oxygen molecules are subsequently heated by the heater coil and immediately begin to lose their magnetic susceptibility. They are then displaced by cooler oxygen molecules with higher magnetic susceptibility. This flow of gas through the cross-tube, referred to as the magnetic wind, cools the magnetized heating coil and heats the unmagnetized coil causing an imbalance in the bridge resulting from the difference in resistance between the two coils. The bridge output is then calibrated by passing a gas with known oxygen concentration through the chamber (1,11,13).

Limitations of Thermomagnetic Analyzers. Measurement by thermomagnetic oxygen analyzers is affected by the magnetic susceptibility and thermal conductivity of the

**Figure 1.** Schematic diagram of a thermomagnetic oxygen analyzer (1).

carrier gas, the sample gas temperature, ambient temperature, tilt, sample flow, and pressure (1,16).

Magnetodynamic (Dumbbell or Autobalance)

Developed by Faraday in 1884, this is the most popular method of paramagnetic oxygen analyzers and the earliest developed oxygen analyzer (13). Magnetodynamic oxygen analyzers are based on property that oxygen will be drawn into a magnetic field because it is paramagnetic. These analyzers essentially measure the magnetic susceptibility of sample gas.

Principles of Operation. A simple form of this device consists of small, dumbbell shaped body made of quartz and filled with nitrogen or some gas with small or negative magnetic susceptibility, an optical lever system, and a nonuniform magnetic field (Fig. 2). The dumbbell is suspended in a closed chamber by a quartz or platinum wire between two permanent magnets that are specially shaped to have a nonuniform magnetic field. The dumbbell is free to rotate. Since the dumbbell is slightly diamagnetic, it will naturally rotate away from the highest magnetic field intensity. Oxygen in a sample gas will be attracted to the region of maximum field intensity and displace the dumbbell even further. This deflection is measured by an optical lever system in which a light source outside the test chamber shines a beam onto a mirror which is mounted in the center of the dumbbell. The beam is then reflected onto a scale outside the chamber. The amount of deflection is directly proportional to the partial pressure of oxygen in the sample (1,17).

Modern designs of this sensor are self-nulling and have temperature compensation capabilities. A single turn coil is wound around the dumbbell. The coil produces a magnetic field when current flows through it which will in turn cause the dumbbell to rotate in the external magnetic field. The deflection of the dumbbell is measured by an optical lever system that uses photocells to detect the light reflected from the mirror.

Figure 2. Schematic diagram of paramagnetic “dumbbell” sensor. Adapted from (1).

Figure 3. Self-nulling paramagnetic analyzer. Adapted from Refs. 1 and 17.

The photocells are connected to a feedback loop that controls the amount of current through the coil, keeping the dumbbell centered with respect to the photocell detectors. As the paramagnetic components of a gas sample move into the strongest part of the magnetic field, the dumbbell is displaced and begins to rotate. The photocells detect this motion and drive an amplifier to produce the necessary current in the coil to keep the dumbbell in the original zero position. The system is zeroed using a sample of pure nitrogen. In this case, the dumbbell is at an equilibrium position and there is no current flowing through the coil. The current is directly proportional to the magnetic susceptibility of the sample. The system is calibrated using a sample of known oxygen content. See Fig. 3 for a diagram of this design.

Limitations of Dumbbell Analyzers. The main limitation of the dumbbell design is its slow response time (~10 s) (15). Thus, the dumbbell analyzer is not recommended for uses where real-time oxygen analysis is needed. These analyzers also have moving parts and are extremely sensitive to tilt and vibrations.

Magnetopneumatic (Differential Pressure)

This sensor operates on the principle that a differential pressure will be generated when a sample containing oxygen is drawn into a nonuniform magnetic field with a reference gas of different oxygen content. Differential pressure sensors directly measure the magnetic susceptibility of sample gas and are thus not influenced by thermal properties of background gas.

Principles of Operation. A reference gas is admitted at a constant rate into a chamber like the one seen in Fig. 4. The

Figure 4. Schematic diagram of a differential pressure sensor. (Adapted from Ref. 1.)

reference gas is split into two paths with a flow equalizer to ensure equal flow in each path. Each path is joined at the midpoint by a connector pipe containing a differential pressure sensor (e.g., a capacitive differential pressure sensor or a microflow sensor). The two paths reconnect at an outlet where the sample gas is admitted. There is a strong nonuniform magnetic field placed over one of the reference gas outlets. The reference gas and the sample gas combine in the outlet. Oxygen or other paramagnetic gases in the sample gas will be drawn into the nonuniform magnetic field and cause a pressure build up on that side of the reference gas path.

The differential pressure is proportional to the magnetic susceptibility of the sample gas only. This imbalance is sensed by the differential pressure sensor in the cross-tube. The output of this sensor is calibrated in terms of oxygen

concentration by using a reference and sample gas of known oxygen content. The output is zeroed by using a sample gas that is the same as the reference gas. In this case, the output of the differential pressure sensor will be zero (1,15).

Limitations of Magnetopneumatic Analyzers. Differential pressure sensors are sensitive to tilt and vibrations. An alternating magnetic field reduces the effects of background flow and tilt on the sensor (1).

ELECTROCHEMICAL OXYGEN ANALYZERS

There are two main types of electrochemical oxygen analyzers: those with aqueous electrolytes, and those with solid electrolytes. These sensors use the chemical reactivity of oxygen to produce a measurable current that is proportional to the partial pressure of oxygen in a sample gas.

Aqueous Electrolyte Sensors

Galvanic Oxygen Analyzer. Galvanic oxygen analyzers are commonly called a Hersch cell after the inventor. They are essentially a battery that produces energy when it is exposed to oxygen. Fig. 5. Galvanic sensors are typically insensitive to vibration and tilt. They are usually packaged small and made out of inexpensive and sometimes disposable materials (14). Disposable capsules containing galvanic cells are fairly inexpensive (~\$85) and typically last 1–5 years (18). Recently, small, portable galvanic sensors have been manufactured and approved for medical breath analysis purposes (Fig. 6) (19).

Figure 5. Schematic diagram of a galvanic sensor. (Adapted from Ref. (14).)

Figure 6. A small, handheld galvanic oxygen sensor (model AII 2000, Analytical industries Inc.) (19).

Galvanic sensors are typically used for industrial purposes, such as validating the quality of semiconductor grade gases and for environmental monitoring (e.g., monitoring the quality of breathing air or monitoring the oxygen content in potentially hazardous or explosive environments) (14).

Principles of Operation. Basic cells consist of a cathode made of a precious metal (platinum, gold, silver, etc.) and an anode made of a base metal (lead, cadmium, antimony). These electrodes are in contact with a liquid or semisolid electrolyte, such as potassium hydroxide. A gas sample is admitted into the cell and diffuses through a membrane made of a thin material, such as Teflon or silicone, which is permeable to oxygen but not to the electrolyte. The oxygen in the solution is chemically reduced at the cathode to form hydroxyl ions that flow to the anode where an oxidation reaction occurs. This oxidation–reduction reaction results in an electromotive force (EMF), which is proportional to the oxygen concentration in the solution and the partial pressure of oxygen in the sample gas. The electron flow is measured by an external galvanometer connected to the electrodes.

Reactions at the cathode and anode are as follows (1, 20–22):

1. Cathode reaction:

2. Anode reaction:

3. Overall reaction:

Designs that allow for every oxygen molecule passing through the cell to react are called coulometers and are suitable for trace (parts per million, ppm) measurements (1,20–22).

Limitations of Galvanic Analyzers. Because the anode is consumed by oxidation, the cell has a limited life. These devices tend to lose sensitivity as they age resulting in falsely low readings (14).

There are some designs that lessen the rate of anode consumption by using a third inert electrode made of platinum that is kept at a constant positive potential. This results in the majority of the current to be conducted through this electrode instead of the consumable anode (1,4).

Acidic gases in the sample (i.e., SO_2 , CO_2 , Cl_2) react with the electrolyte and must be scrubbed out. There are some coulometric cell designs that overcome this problem by the use of additional electrodes (1,23).

Exposure to very high oxygen concentration can lead to oxygen shock where the sensor is saturated and does not recover for hours (14).

Polarographic Oxygen Analyzers. This sensor responds to changes in the partial pressure of oxygen in a sample

Figure 7. Schematic diagram of a polarographic sensor. (Adapted from Refs. 1,24,25.)

gas. Polarographic sensors can be used for measuring oxygen in dissolved liquid (14) or in a gas sample. They are often used in anesthesia gas delivery systems. Polarographic sensors are insensitive to shock, vibration, and tilt. The effects of flow are minimal because diffusion is controlled by a membrane (14).

Principles of Operation. A polarographic cell, as seen in Fig. 7, consists of two electrodes, usually a silver anode and a gold cathode, immersed in an electrolyte, such as potassium chloride (1). An EMF is applied across the electrodes inducing oxidation–reduction reactions when a sample containing oxygen is admitted into the cell. Like the galvanic cell, oxygen diffuses through a thin membrane that is preferentially permeable to oxygen and not to the electrolyte. This membrane is usually made from poly(tetrafluoroethylene) (PTFE) and controls the rate of oxygen flux to the cathode. The current flow in the cell is proportional to the applied EMF and the partial pressure of oxygen in the sample. As seen in Fig. 8, there are four main regions in the EMF–current curve of importance (1):

Figure 8. Diagram showing the operating regions of a polarographic sensor. (Adapted from Ref. 10.)

Region i: If the applied EMF is very low, then the presence of oxygen hardly has any effect on the current. There are very little reactions occurring at the electrodes.

Region ii: Oxygen molecules begin to react at the electrodes causing a measurable increase in current. For a given level of oxygen partial pressure, an increase in the EMF produces a sharp increase in the current.

Region iii: This region is the polarized or working region for the polarographic sensor. Here, the current plateaus and an increase in the EMF does not alter the current. In this region, all the oxygen molecules are reduced immediately at the cathode. A calibration curve is used in this region relating oxygen concentration to sensor current.

Region iv: In this region, an increase in EMF leads to a sharp, nonlinear increase in current as a result of the breakdown of the electrolyte solution.

The reactions at the cathode and anode are as follows (1,15):

1. Cathode reaction:

2. Anode reaction:

Limitations of Polarographic Analyzers. Polarographic sensors generally have slow response because oxygen must diffuse through membrane. They are also sensitive to pressure and temperature and compensation for these factors is sometimes required. In addition, these sensors lose sensitivity over time due to degradation of anode and electrolyte solution giving falsely low readings. Polarographic sensors that consume all the injected oxygen change the content of the sample gas and are not good for closed-loop systems, such as closed-circuit anesthesia systems (26).

Capacitive Coulometry. Capacitive coulometry (also referred to as coulometric microrespirometry) is another aqueous electrolytic method for oxygen analysis. This method is based on the replacement of oxygen consumed by an organism in a closed system with electrolytic oxygen produced by discharging a capacitor through a solution of CuSO_4 (27). Such analyzers can be used to monitor oxygen consumption and metabolism rate of tissues or microorganisms. However, this type of sensor is not used as frequently as other more common types of aqueous electrolyte sensors.

Solid Electrolyte Cells

Some ceramics conduct electricity at very high temperatures. This conductivity is largely a result of the oxygen

Figure 9. Schematic diagram of a solid electrolyte concentration cell. (Adapted from Refs. 1,15.)

mobility in this solid solution. Oxygen mobility is the principle behind solid electrolyte or concentration cells.

There exists a family of solid electrolytes, such as MgO or CaO in ZrO_2 (ceramic), whose electrical conductivity is mostly due to the mobility of O_2^- as opposed to electrons in the solid. At room temperature, the conductivity is low, but at high temperatures ($>600^\circ\text{C}$) the conductivity is comparable to that of an aqueous electrolyte and electron mobility can be neglected (1).

A solid electrolyte sensor is commonly referred to as a concentration cell. Solid electrolyte oxygen sensors are commonly used in anesthesia and patient monitoring for breath to breath analysis (15). Solid electrolyte cells typically have a fast response ($<150\text{ ms}$) (15) and are good for real-time oxygen analysis.

Principles of Operation. A concentration cell is made by separating a test chamber and a reference chamber by a solid, oxygen conducting electrolyte, such as ZrO_2 or Y_2O_3 with a porous electrode on either side (Fig. 9). When the temperature is increased by an external heater, the solid electrolyte begins to conduct O_2 and an EMF is established between the electrodes. The EMF is related to the partial pressure of oxygen in the test chamber by the Nernst equation:

$$\text{output EMF} = \frac{RT}{4F} \ln \left(\frac{P'_{\text{O}_2}}{P''_{\text{O}_2}} \right)$$

where R is the universal gas constant ($8.314\text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$), T is the operating temperature in kelvin, F is Faraday's constant ($9.6485 \times 10^4\text{ C} \cdot \text{mol}^{-1}$), P'_{O_2} is the reference partial pressure of oxygen, and P''_{O_2} is the sample partial pressure of oxygen.

Fuel cell: An alternative configuration of a concentration cell is a fuel cell. If a fuel gas such as hydrogen is admitted into one of the chambers, the cell converts

Figure 10. Schematic diagram of a flow through tube sensor. (Adapted from Refs. (1,28,29).)

the chemical energy of the fuel into electrical energy which may be delivered to a load placed across the electrodes (1,15).

Oxygen pump: A concentration cell may also be used as an oxygen pump. An EMF applied across the electrodes will pump oxygen from one chamber to another, the rate and direction depending on the strength and polarity of the applied EMF (1,15).

Sensor design: There are a number of different solid electrolyte sensor designs typically used: a flow through tube sensor, a test tube sensor, and a disk sensor.

Flow-through tube and test tube sensor: The flow-through tube sensor is made from a solid electrolyte tube with a porous platinum electrode on the outside and inside of the tube (Fig. 10). An external heater is used to raise the temperature of the solid electrolyte to its operating temperature where it conducts oxygen. Ambient air outside the tube is used as the reference gas. The sample gas is admitted into the central part of the tube. This simple design was one of the first forms used (15,30,31).

A common variation on this design is the miniature test tube sensor (Fig. 11), which uses a sealed tube containing a reference gas with known oxygen partial pressure (1,32).

Figure 11. Schematic diagram of a test tube sensor. (Adapted from Refs. 1,33.)

Figure 12. Schematic diagram of a miniature disk sensor. (Adapted from Refs. 1,34,35.)

Like the flow-through sensor, the test tube sensor is made of a solid electrolyte tube with porous electrodes on the inside and outside of the tube, but it is hermetically sealed at one end. The closed end of the tube is placed in an external heater. The inside of the tube is used as the reference chamber and ambient air is used for the reference gas. The sample gas is admitted into a chamber surrounding the tube and flows around the outer electrodes. Because of its simple design, it is the most common solid electrolyte cell (1).

Disk sensor: The disk sensor is made with a solid electrolyte disk with porous electrodes on each side. The disk is attached to a metal tube of equal thermal expansion coefficient. Sample gas is admitted into a chamber on one side of the disk and a reference gas on the other. A heater is placed inside the tube on the reference chamber side (1,15,34).

A miniature design of the disk sensor (Fig. 12) has symmetrically placed porous platinum electrodes on either side of a thin solid electrolyte disk. The disk divides a small ceramic cylinder into two hermetically sealed chambers: one for the reference gas and one for the sample gas. An electrical heater brings the cell to the operating temperature. A temperature sensor and feedback loop attached to the heater ensures that the electrodes are also heated to the same temperature as each other and to the disk. If there is a difference in oxygen concentration between the reference and sample chambers, a voltage is generated between the two electrodes. A thin metallic holder is used to suspend the ceramic cylinder and ensures that the ceramic will not crack due to sudden thermal expansion.

Limitations of Ceramic Analyzers. Because the electrode is catalytic, any combustible gas will react with oxygen on the electrode causing it to age and the sensor to give a falsely low reading.

The high operating temperature of these sensors precludes its use around combustible gases.

Ceramics fracture due to thermal shock. Miniaturization helps considerably. These sensors usually require a warm up time (1,15,34).

Pressure on both sides of the disk must be the same or the reading will be inaccurate. This can be accomplished by venting both sides to the ambient atmosphere (15).

OPTICAL SENSORS

Fluorescence Quenching

One of the more recent oxygen analyzer designs uses a technique known as fluorescence quenching. Fluorescence dyes, such as perylene dibutyrate fluoresce for a certain amount of time in an atmosphere without oxygen. The presence of oxygen quenches this fluorescence. The fluorescence time is thus inversely proportional to the partial pressure of oxygen. In addition to oxygen sensing, fluorescence sensing can be used to detect glucose, lactate, and pH in the laboratory setting (36).

Fiber optic sensors: Fiber optic sensors use fluorescence quenching to measure the partial pressure of oxygen. A fiber optic strand delivers an optical pulse (usually blue light) to the fluorescent dye. The dye molecules are held in place by small beads of clear plastic. The beads are enclosed by a porous polypropylene membrane that is gas permeable and hydrophobic. The fluorescence is sensed by a photodetector at the end of a second fiber optic strand. The configuration of this sensor can be seen in Fig. 13. The time of fluorescence is calibrated for oxygen concentration. Because the fiber optic is only used to deliver the optical pulse and the fluorescence quenching is used to sense oxygen, the term fiber optic sensor is somewhat of a misnomer.

Figure 13. Schematic diagram of a fiber optic sensor. (Adapted from Refs. 1,37.)

Figure 14. Schematic diagram of an integrated optic oxygen sensor chip. (From Ref. (38).)

Integrated optic oxygen sensor chip: Some sensors that can detect and identify multiple gases in a sample are called multianalyte sensors. One such sensor is an integrated optic multianalyte sensor. This recent development is a miniature optical sensor that has both biomedical and commercial applications. It is based on fluorescence quenching by oxygen.

This sensor, shown in Fig. 14, consists of a multimode ridge waveguide deposited on a dielectric substrate of a higher refractive index than the ridge. Spots of solgel, doped with an oxygen sensitive fluorescent dichlororuthenium dye complex, are deposited at the end of the waveguide and directly excited by a blue LED. Optical detectors at the other end of the waveguide detect emissions from the fluorescent spots. The fluorescence is efficiently coupled to the waveguide as the fluorescent spots are oriented to preferentially emit photons at an angle exceeding the critical angle defined by the two mediums. The theory of fluorescence emission at a dielectric interface is discussed further in (39).

The main limitation of this type of device is the response time. Typically, a 10 s integration period is used for each partial pressure oxygen measurement.

The main advantage of this device is its size and relative ease of fabrication (38). These chips have a very small foot print ($<1 \text{ cm}^2$). They can be quickly manufactured using soft lithography.

Polarization-based oxygen sensor: Another sensor based on fluorescence quenching is the polarization based oxygen sensor. This sensor uses an oxygen-sensitive film ($\text{Ru}(\text{dpp})_3\text{Cl}_2$) and an oxygen-insensitive film (Styrl7). A diagonally polarized source illuminates these films that fluoresce in different ways. The oxygen-insensitive film is stretched so that the molecules preferentially emit vertically polarized photons. The $\text{Ru}(\text{dpp})_3\text{Cl}_2$ film emits mostly unpolarized photons. Orthogonally oriented polarizers select for the vertical and horizontal components of the combined emitted light. The overall polarization of

Figure 15. The polarization of the combined film photon emission is proportional to the partial pressure of oxygen. (From Ref. (40).)

the combined emission is sensitive to the partial pressure of oxygen in a sample (Fig. 15). The theory of polarization sensing is discussed further in (40).

UV Absorption

Spectroscopy can also be used to detect oxygen. Oxygen has a maximum absorption coefficient around a wavelength of $0.147 \mu\text{m}$, which is in the ultraviolet (UV) range. Most other gases have a much smaller absorption coefficient at this wavelength (1).

A simple device uses an ultraviolet light source, such as a discharge lamp or UV laser as the light source. The beam is split into two paths by a vibrating mirror and directed into either a reference cell filled with nitrogen or a sample cell filled with the gas in question. A photomultiplier tube is used for detection at the end of each path. The ratio of energy received through the sample and reference cell is related to the partial pressure of oxygen in the sample.

Raman Spectroscopy

Raman spectroscopy can be used to monitor multiple gases in a sample. Raman spectroscopy is commonly used in medicine for real-time breath-to-breath analysis or for monitoring respiratory gas mixtures during anesthesia (41–44).

This technique uses the inelastic or Raman scattering, of monochromatic light. The frequencies of the returned

light give information about the vibrational, rotational, or other low frequency modes of atoms or molecules in a sample. This information is specific to given elements and compounds and can thus be used to identify and distinguish different gases in a mixture.

In Raman spectroscopy, a sample is illuminated with a laser beam, usually in the visible, near-IR, or near-UV range. Most of the light is scattered elastically or by Rayleigh scattering and is of the same frequency as the incident light. However, a small portion of the light is scattered in-elastically. Phonons, which are quanta of vibrational energy, are absorbed or emitted by the atom or molecule causing the energy of the incident photons to be shifted up or down. This shift in energy corresponds to a shift of frequency. Frequencies close to the laser line are filtered out and frequencies in a certain spectral window are dispersed on to a photomultiplier tube or CCD (charged couple device) camera.

OTHER GASEOUS OXYGEN SENSORS

Gas Chromatography–Mass Spectrometer

A gas chromatography–mass spectrometer (GCMS) combines GC and MS to identify substances in a gas sample. It can be used to detect a variety of compounds in a mixture or it can simply be used to detect the presence of oxygen. The GCMS analyzers are commonly used to measure gas composition in respiratory circuits (42).

Principles of Operation. The gas chromatograph separates compounds into the molecular constituents by retaining some molecules longer than others. These molecules are broken up into ionized fragments that are identified by the mass spectrometer based on the molecules' mass/charge ratio (m/z).

The GC consists of an injector port, an oven, a carrier gas supply, a separation column, and a detector. The injected sample is vaporized in a heated chamber and pushed through the separation column by an inert carrier gas. The separation column is typically a capillary column made of a long, small diameter (usually 1–10 m in length and 0.5 mm in diameter) tube of fused silica (high quality drawn glass) or stainless steel formed into a coil. The components of the sample are separated by two different mediums inside the column that control the speed of travel. These mediums are either coated on the inner surface of the column or packed in the column. Part of the media, known as the stationary phase, absorbs molecules for a certain amount of time before releasing them. The amount of time depends on the chemical properties of the molecule and thus certain molecules are detained longer than others. This, in effect, separates the molecules in the mixture in time. The molecules then travel to the detector. The output of the detector is processed by an integrator. The response of the detector over time is the chromatograph (Fig. 16).

The mass spectrometer separates ions from the gas chromatograph by their charge to mass ratio (m/z) by using an electric or magnetic field. Mass spectrometers usually consist of an ion source, a mass analyzer and a detector.

Figure 16. An example gas chromatograph and corresponding mass spectrograms.

The ion source ionizes the sample gas usually with an electron gun. The charged particles are accelerated with an electric field and are steered by the mass analyzer on to the detector by means of a varying electric or magnetic field. The speed and deflection of the particle depends on its mass and charge. When a charged particle comes near or strikes the surface of the detector, a current is induced and recorded. This current is typically amplified by an electron multiplier or Faraday cup. The resulting ionic current plot is the mass spectrum of the ions.

Limitations of Gas Chromatography–Mass Spectrometry. The main limitation of the GCMS is its extremely high price. Mass spectrometers alone run ~\$40 k. However, a GCMS may be used for any time of gas measurement.

The Warburg Apparatus

A much older method of oxygen analysis was pioneered by German biochemist Otto Heinrich Warburg (45). The Warburg apparatus was used for measuring cellular respiration and fermentation. This method is based on Boyle's law, which relates the pressure and volume of a gas, and Charles's law, which relates the pressure and temperature of a gas. Combining these laws yields the ideal gas law ($PV = nRT$, where P = pressure, V = volume, n = number moles, R = universal gas constant, T = temperature). At a constant temperature and volume, any change in the amount of gas can be measured as a change in pressure. A typical Warburg apparatus consists of a detachable flask, a waterbath, and a barometer. The sample is placed in a flask and immersed in a bath of water held at a constant temperature. Pressure is measured periodically to determine the amount of gas produced or absorbed by the sample. A variation of this device, used to measure gas production in plants directly from the stem, is the Scholander–Hemmel pressure bomb (46).

CONCLUDING REMARKS

There are three primary types of oxygen sensors available: paramagnetic, electrochemical and spectrographic. Each type of oxygen sensor has limitations and uses dependent on their design, cost and operational environment. Other

available oxygen sensors include semiconductor sensors, fluidic sensors, and electron capture oxygen sensors (1). These devices are typically not used in medicine or biology.

OXYGEN SENSORS

STEVEN J. BARKER
University of Arizona
Tucson, Arizona

INTRODUCTION

This article reviews recent advances in the monitoring of patient oxygenation. We summarize the transport of oxygen from the atmosphere to the cell, and describe monitors that function at four stages of the O₂ transport process. These four stages include respired gas, arterial blood, tissue, and venous blood. History and recent developments in pulse oximetry will be discussed. Continuous intraarterial blood-gas sensors will be described and contrasted with other oxygen monitors. Finally, tissue oxygen monitoring and mixed-venous oximetry are discussed.

OXYGEN TRANSPORT IN THE HUMAN BODY

At rest, we consume $\sim 10^{23}$ molecules of oxygen per second. Our complex cardiopulmonary system has developed to rapidly transport this large amount of oxygen from the atmosphere to every cell in the body (Fig. 1).

The equation for arterial blood oxygen content (CaO₂) shows that $\sim 99\%$ of the oxygen in arterial blood is in the form of hemoglobin-bound oxygen:

$$CaO_2 = 1.38(SaO_2/100)(Hb) + 0.003 PaO_2 \quad (1)$$

where CaO₂ is in units of milliliters per deciliter of blood (also called vols%); SaO₂ is the arterial hemoglobin saturation in percent; Hb is the total hemoglobin concentration in grams per deciliter; and PaO₂ is the arterial oxygen tension (partial pressure) in millimeters of mercury. Upon inserting typical arterial values [SaO₂ = 100%, Hb = 15 g·dL⁻¹, PaO₂ = 100 mmHg (13.33 kPa)], we find that normal CaO₂ is ~ 21 mL·dL⁻¹. The amount of oxygen delivered to the tissues in the arterial blood is then given by the cardiac output (CO) times the CaO₂ (neglecting the small dissolved oxygen term):

$$DO_2 = 13.8(CO)(Hb)(SaO_2/100) \quad (2)$$

(The factor 1.38 becomes 13.8 because Hb is normally measured in grams per deciliter, while CO is measured in liters per minute. There are 10 dL in 1 L.)

Finally, the oxygen consumption by the tissues (VO₂) is determined by the difference between arterial oxygen delivery and venous oxygen return:

$$VO_2 = 13.8(Hb)(CO)(SaO_2 - SvO_2)/100 \quad (3)$$

This Fick equation can be solved for any of the four oxygen variables involved.

If we substitute normal resting values into the equation, we predict a resting VO₂ of

$$\begin{aligned} VO_2 &= 13.8(15 \text{ g} \cdot \text{dL}^{-1})(5 \text{ L} \cdot \text{min}^{-1})(99 - 75)/100 \\ &= 248 \text{ mL} \cdot \text{min}^{-1} \end{aligned}$$

Figure 1. Schematic of the oxygen transport system. Arterial blood leaving the left ventricle (right side of figure) has an oxygen content of 21 mL·dL⁻¹, and the total oxygen delivery ($\dot{D}O_2$) is roughly 1000 mL·min⁻¹. At rest, 0.25 of this oxygen delivery is consumed ($\dot{V}O_2$), leaving a mixed venous saturation of 75%.

During exercise or stress we can rapidly increase cardiac output to at least 20 L·min⁻¹, and decrease venous saturation to ~ 40%, yielding a $\dot{V}O_2$ of

$$\begin{aligned}\dot{V}O_2 &= 13.8 (15 \text{ g} \cdot \text{dL}^{-1})(20 \text{ L} \cdot \text{min}^{-1})(99 - 40)/100 \\ &= 2029 \text{ mL} \cdot \text{min}^{-1}\end{aligned}$$

The human ability to rapidly adjust cardiac output (CO) and mixed-venous oxygen saturation ($S\bar{v}O_2$) can be used to compensate for disease processes that affect other transport variables, such as anemia (hemoglobin) or hypoxemia (SaO_2). For example, consider a severely anemic patient with Hb value of 2.5 g·dL⁻¹, who compensates by increasing cardiac output to 15 L·min⁻¹ and decreasing venous saturation to 50%:

$$\begin{aligned}\dot{V}O_2 &= 13.8 (2.5 \text{ g} \cdot \text{dL}^{-1})(15 \text{ L} \cdot \text{min}^{-1})(99 - 50)/100 \\ &= 254 \text{ mL} \cdot \text{min}^{-1}\end{aligned}$$

This extremely anemic patient can thus maintain a normal oxygen consumption by adaptations in CO and $S\bar{v}O_2$ that are milder than those we use during normal exercise.

OXYGEN IN THE ARTERIAL BLOOD: PULSE OXIMETRY

Physiologic Considerations

The normal relationship between SaO_2 and PaO_2 is the familiar oxyhemoglobin dissociation curve, shown in Fig. 2. Three convenient points on this curve to remember are $PaO_2 = 27$ mmHg (3.60 kPa), $SaO_2 = 50\%$; $PaO_2 = 40$ mmHg (5.33 kPa), $SaO_2 = 75\%$; and $PaO_2 = 60$ mmHg (8.00 kPa), $SaO_2 = 90\%$. The curve will be shifted toward the right by acidosis, hypercarbia, or increasing 2,3-DPG. At PaO_2 values greater than 80 mmHg (10.66 kPa), SaO_2 is almost 100% and thus becomes virtually independent of PaO_2 . It is important to remember this fact

during SaO_2 monitoring in the operating room, where elevated inspired oxygen fraction ($F_{I}O_2$) values will yield PaO_2 values much > 80 mmHg (10.66 kPa) most of the time.

A knowledge of the relationship between SaO_2 and PaO_2 allows us to predict the physiologic limitations of saturation monitoring by pulse oximetry. Specifically, the pulse oximeter will give no indication of downward trends in PaO_2 during anesthesia at elevated $F_{I}O_2$ until PaO_2 values < 80–90 mmHg (10.66–12.00 kPa) are reached. In an animal study, intentional endobronchial intubations at $F_{I}O_2$ values > 30% were not detected by the pulse oximeter (1). This results from the fact that the PaO_2 after endobronchial intubation did not decrease below ~ 80 mmHg (10.66 kPa) when $F_{I}O_2$ was elevated.

Technology

Oximetry, a subset of spectrophotometry, determines the concentrations of various hemoglobin species by measuring the absorbances of light at multiple wavelengths. The absorbance spectra of the four most common hemoglobin species are shown in Fig. 3. The number of oximeter light wavelengths used must be equal to or greater than the number of hemoglobin species present in the sample. A laboratory CO-oximeter, which uses four or more wavelengths, can measure the concentrations of reduced hemoglobin, oxyhemoglobin, methemoglobin, and carboxyhemoglobin. If all four hemoglobin species are present in significant concentrations, then an oximeter must have at least four light wavelengths to determine the concentration of any of the four species.

The conventional pulse oximeter is a two-wavelength oximeter that functions *in vivo*. Conventional pulse oximetry first determines the fluctuating or alternating current (ac) component of the light absorbance signal. At each of its two wavelengths the oximeter divides the ac signal by the

Figure 2. The oxyhemoglobin dissociation curve: a plot of hemoglobin oxygen saturation as a function of oxygen tension (PO_2). The curve is shifted to the right with decreasing pH or increasing temperature, PCO_2 , or 2,3-DPG.

corresponding fixed or direct current (dc) absorbance component, to obtain a pulse-added absorbance. It then calculates the ratio of the two pulse-added absorbances (one for each wavelength), and this ratio R is related to arterial hemoglobin saturation by a built-in calibration algorithm. The resulting pulse oximeter saturation estimate is called SpO_2 . The calibration curve of the pulse oximeter is empirical; that is, it is based on human volunteer experimental data.

Sources of Error

Dyshemoglobins. As previously noted, the pulse oximeter uses two wavelengths and can distinguish only two hemoglobin species: reduced hemoglobin and

oxyhemoglobin. If either carboxyhemoglobin (COHb) or methemoglobin (MetHb) is present, the pulse oximeter effectively has fewer equations than unknowns, and it cannot find any of the hemoglobin concentrations. It is thus unclear *a priori* how the pulse oximeter will behave in the presence of these dyshemoglobins.

Two animal experiments have characterized pulse oximeter behavior during methemoglobinemia and carboxyhemoglobinemia. In one of these, dogs were exposed to carbon monoxide (220 ppm) over a 3–4 h period (2). At a COHb level of 70% (meaning that 70% of the animal’s hemoglobin was in the COHb form), the SpO_2 values were $\sim 90\%$, whereas the actual SaO_2 was 30% (Fig. 4). The pulse oximeter thus “sees”

Figure 3. Extinction coefficient (or light absorbance) versus wavelength of light for four different hemoglobins: reduced Hb, O_2Hb , COHb, and MetHb. The two wavelengths used by most pulse oximeters (660 nm, 930 nm) are indicated by vertical lines.

Figure 4. The effect of carbon monoxide on pulse oximetry. Plots of Hb saturation measured by \blacksquare laboratory CO-oximeter, and \square conventional pulse oximeter, as functions of COHb level. As COHb increases, CO-oximeter shows linear decline in saturation, while pulse oximeter remains $> 90\%$ saturation (2).

carboxyhemoglobin as if it were composed mostly of oxy-hemoglobin.

In a similar animal experiment, increasing methemoglobin concentrations (up to 60%) produced SpO₂ readings that gradually decreased to ~ 85% (3). As these animals were further desaturated by lowering the FIO₂ during methemoglobinemia, the pulse oximeter SpO₂ reading failed to track either functional or fractional saturation. On the other hand, the presence of fetal hemoglobin has little effect on pulse oximeter accuracy, which is fortunate in the treatment of premature neonates. There are conflicting anecdotal reports on the influence of sickle hemoglobin, and it is impossible to perform volunteer hypoxia studies on patients with sickle-cell disease.

As of this date, no commercially available pulse oximeter can either measure dyshemoglobins or function accurately in the presence of substantial levels of COHb or MetHb. Masimo Inc. has very recently (March, 2005) announced the development of a new Rainbow Technology pulse oximeter that uses multiple light wavelengths to measure COHb and SaO₂ simultaneously. There are as yet no published data regarding the success of this approach, but it is a potentially important new advancement.

Intravenous Dyes. As abnormal hemoglobin species can adversely affect the accuracy of pulse oximetry, so can intravenous dyes injected during surgery or critical care. Two studies found that intravenous methylene blue causes large, rapid decreases in displayed SpO₂ without changes in actual saturation, and that indocyanine green causes smaller false decreases in SpO₂ (4,5). Intravenous fluorescein or indigo carmine appeared to have little effect.

Reductions in Peripheral Pulsation; Ambient Light. Several studies have examined the effects of low perfusion upon SpO₂ (6,7). In a clinical study of critically ill patients during a wide range of hemodynamic conditions, extremes in systemic vascular resistance were associated with loss of pulse oximeter signal or decreased accuracy. During reduced pulse amplitude, pulse oximeters may become more sensitive to external light sources, such as fluorescent room lights (8). Most modern pulse oximeters effectively measure and correct for ambient light intensity.

Motion Artifact. Patient motion, which causes a large fluctuating absorbance signal, is a very challenging artifact for pulse oximetry. Motion artifact rarely causes great difficulty in the operating room, but in the recovery room and intensive care unit it can make the pulse oximeter virtually useless. Design engineers have tried several approaches to this problem, beginning with increasing the signal averaging time. Most current pulse oximeters allow the user to select one of several time averaging modes. However, improving motion performance by simply increasing averaging time is potentially dangerous—it can cause the instrument to miss signifi-

cant, but short-lived hypoxemic events, which are very common in neonates.

Masimo, Inc. has developed a completely different approach to the analysis of the oximeter light absorbance signals, using adaptive digital filtering. This has led to improved accuracy and reliability during motion artifact, both in laboratory studies (9,10) and in the neonatal intensive care unit (11). The new technology has spurred other manufacturers (e.g., Nellcor, Philips, Datex-Ohmeda) to improve their signal analysis methods, so that today's generation of pulse oximeters has much improved performance during motion.

Venous Pulsations. Conventional pulse oximeter design is predicated on the assumption that the pulsatile component of tissue light absorbance is entirely caused by arterial blood. However, the light absorbance of venous blood can also have a pulsatile component, and this may affect SpO₂ values under some conditions (12). Conventional pulse oximeters may read falsely low values or may fail to give any reading in circumstances leading to venous congestion. This can occur, for example, when using an earlobe sensor on a patient who is undergoing mechanical ventilation, or who is in the Trendelenberg position.

Penumbra Effect. When a pulse oximeter sensor is not properly positioned on the finger or earlobe, the light traveling from the source to the detector may pass through the tissues at only grazing incidence. This penumbra effect reduces the signal/noise ratio, and may result in SpO₂ values in the low 1990s in a normoxemic subject. More importantly, a volunteer study has shown that in hypoxemic subjects, the penumbra effect can cause SpO₂ to either overestimate or underestimate actual SaO₂ values, depending on the instrument used (13). A pulse oximeter with a malpositioned sensor may therefore indicate that a patient is only mildly hypoxemic when in fact he or she is profoundly so.

OXYGEN IN THE ARTERIAL BLOOD: CONTINUOUS INTRAARTERIAL PO₂ MEASUREMENT

There have been a number of efforts to monitor intraarterial oxygen tension directly and continuously, using miniaturized sensors passed through arterial cannulas. The first practical approach to this problem employed the Clark electrode, the same oxygen electrode used in the conventional laboratory blood-gas analyzer. Although miniaturized Clark electrodes have been used in several clinical studies, the technique never achieved popularity because of problems with calibration drift and thrombogenicity (14). More recently, the principle of fluorescence quenching was used to develop fiberoptic "optodes" that can continuously monitor pH, PaCO₂, and PaO₂ through a 20 gauge radial artery cannula (Fig. 5).

Fluorescence quenching is a result of the ability of oxygen (or other substances to be measured) to absorb energy from the excited states of a fluorescent dye, thus preventing this energy from being radiated as light.

Figure 5. An intraarterial fiber-optic optode sensor. The optode is 0.6 mm in diameter and fits easily through a 20 gauge radial artery cannula, also shown.

Lubbers and Opitz (15) developed the first fluorescence quenching optode that simultaneously measured oxygen and carbon dioxide tensions in gases or liquids. In the 1980s, optodes were successfully miniaturized for intraarterial use, and several studies were reported in both animal and humans (16,17).

Clinical Studies

Several clinical studies suggested the usefulness of intraarterial optodes in the operating room (18). The scatter (random error) of optode oxygen tension values is lowest at low oxygen tensions, a characteristic of these sensors. The accuracy of the optode appeared to be within the clinically acceptable range when 18-gauge arterial cannulas were used. The optode can display complete blood-gas data continuously at the patient's bedside, with a time response measured in seconds. Nevertheless, the high costs of the disposable sensors (~\$300 each) and their inconsistent reliability have caused the intraarterial optodes to disappear from the clinical market. These devices have other potential applications in tissues and organs, which may be realized in the future. One manufacturer today is marketing an optode sensor for assessment of the viability of tissue grafts.

OXYGEN IN TISSUE: TRANSCUTANEOUS OXYGEN

Physiologic Considerations

The transcutaneous oxygen ($P_{tc}O_2$) sensor is a Clark electrode that measures oxygen diffusing through the surface of the skin from dermal capillaries (Fig. 6). The sensor must be heated to at least 43 °C (in adults) to facilitate diffusion through the stratum corneum. Surface heating also produces local hyperemia of the dermal capillaries, which tends to "arterialize" the blood and cause a rightward shift in the oxyhemoglobin dissociation curve. The effects above tend to increase $P_{tc}O_2$, and these are counterbalanced by other effects that decrease it, namely

Figure 6. Schematic of transcutaneous PO_2 sensor on skin surface. Heat from sensor "melts" the diffusion barrier of the stratum corneum layer, and "arterializes" the blood in the dermal capillaries beneath.

diffusion gradients and metabolic oxygen consumption by the skin. In neonates, these competing effects nearly cancel and $P_{tc}O_2$ is approximately equal to PaO_2 . In adults, the stratum corneum is thicker and hence the $P_{tc}O_2$ is usually lower than PaO_2 . The transcutaneous index, $P_{tc}O_2/PaO_2$, has average values of 1.0 in neonates, 0.9 in pediatric patients, 0.8 in adults, and 0.6–0.7 in the elderly.

The most serious challenges with the interpretation of $P_{tc}O_2$ values are their dependence upon cardiac output and skin perfusion. Several studies have shown that the transcutaneous index falls when the cardiac index decreases below its normal range (19). Animal shock studies have shown that $P_{tc}O_2$ decreases when either PaO_2 or cardiac index decreases, and that it closely follows trends in oxygen delivery (i.e., the product of CO and CaO_2). In other words, $P_{tc}O_2$ monitors oxygen delivery to the tissues rather than oxygen content of arterial blood.

Technical Problems

There are several practical problems associated with the use of $P_{tc}O_2$ sensors. The transcutaneous electrode must be gas calibrated before each application to the skin, and then the sensor requires a 10–15 min warm-up period. In children, the warm-up period is usually shorter. The sensor membrane and electrolyte must be replaced at least once a week. The heated $P_{tc}O_2$ electrode can cause small skin burns, particularly at temperatures of 44 °C or greater. Lower probe temperatures (43 or 43.5 °C) should be used on premature infants and neonates, and the sensor location should be changed every 2–3 h. In adults with a sensor temperature of 44 °C, we have used the same location for 6–8 h with no incidence of burns.

Summary

Transcutaneous oxygen sensors provide continuous, non-invasive monitoring of oxygen delivery to tissues. By contrast, pulse oximetry provides continuous monitoring of arterial hemoglobin saturation. The dependence of $P_{tc}O_2$ on blood flow as well as PaO_2 sometimes makes it difficult to interpret changing values. If $P_{tc}O_2$ is normal or high, we know that the tissues are well oxygenated. When $P_{tc}O_2$ is low, we must determine whether this is the result of low PaO_2 or a decrease in skin perfusion.

OXYGEN IN VENOUS BLOOD: PULMONARY ARTERY OXIMETRY

Physiology of Mixed-Venous Saturation

Oxygen saturation in venous blood is related to venous oxygen content CvO_2 by an equation similar to equation 1:

$$CvO_2 = 1.38(Hb)(SvO_2)/100 + 0.003(PvO_2) \quad (4)$$

The normal CvO_2 value [with $SvO_2 = 75\%$, $PvO_2 = 40$ mmHg (5.33 kPa)] is $15.6 \text{ mL}\cdot\text{dL}^{-1}$. If we solve equation 3 (the Fick equation) for the venous saturation (SvO_2), we obtain:

$$SvO_2 = SaO_2 - VO_2 / [(13.8)(Hb)(CO)] \quad (5)$$

Equation 8 shows how SvO_2 depends on the four oxygen transport variables: SaO_2 , VO_2 , Hb, and CO.

When VO_2 falls behind oxygen demand, lactic acidosis will result, eventually leading to death if the problem is

not corrected. When this begins to occur in disease (e.g., anemia), the patient's body will try to maintain normal VO_2 using the same two compensatory mechanisms described above during exercise: increasing CO and/or decreasing SvO_2 . In the case of anemia, we saw that such compensation can maintain normal VO_2 values even at hemoglobin levels $< 3 \text{ g}\cdot\text{dL}^{-1}$. Thus, a decrease in SvO_2 indicates that a patient is using oxygen reserves to compensate for a supply-demand imbalance. Decreasing oxygen supply may result from low CO (shock), low hemoglobin (anemia), abnormal hemoglobin (carboxyhemoglobinemia), or low PaO_2 (hypoxemia). On the other hand, increasing oxygen demand can result from fever, malignant hyperthermia, thyrotoxicosis, or shivering.

The aforementioned are possible clinical causes of a decrease in SvO_2 . There are also conditions that can increase SvO_2 above its normal range of 68–77%. High SvO_2 values can result from decreased tissue uptake of oxygen, peripheral arteriovenous shunting, and inappropriate increases in CO. Clinical conditions that produce elevated SvO_2 values include sepsis, Paget's disease of bone, excessive use of inotropes, cyanide poisoning, and hypothermia. A wedged pulmonary artery catheter will also cause a high SvO_2 reading, but this is a measurement artifact. This can actually be a useful artifact, since it warns the clinician of an inadvertently wedged catheter.

Technical Considerations

Pulmonary artery SvO_2 catheters use the technology of reflectance spectrophotometry; that is, they measure the color of the blood in a manner similar to pulse oximetry. The SvO_2 catheters use fiberoptic bundles to transmit and receive light from the catheter tip. Light-emitting diodes provide monochromatic light sources at two or three wave-

Figure 7. Effect of oxygen consumption (VO_2) upon mixed venous saturation (SvO_2). After weaning from cardiopulmonary bypass, the SvO_2 reaches a normal value of 75%, but then falls to 55%. Measured VO_2 at this time is $564 \text{ mL}\cdot\text{min}^{-1}$, or twice normal resting value. Patient noted to be shivering. Administration of muscle relaxant stops shivering, restores VO_2 to normal ($207 \text{ mL}\cdot\text{min}^{-1}$), and SvO_2 also returns to normal values.

lengths. (Currently, the Edwards system uses two wavelengths, while the Abbott instrument employs three.) A theoretical advantage of a three wavelength system is that its measurements should not depend on the total hemoglobin level (20). Another problem common to all SvO_2 catheters is the so-called wall artifact, whereby reflection from a vessel wall can produce a signal that is interpreted as an SvO_2 of 85–90%. This problem has been reduced by the addition of digital filtering to the processor, which effectively edits out sudden step increases in SvO_2 . However, a persistently high value of SvO_2 may alert the user that the catheter is in the wedged condition, as noted above.

Applications and Limitations

When interpreting continuous SvO_2 versus time tracings in the operating room and intensive care unit, we must always consider equation 5, the Fick equation solved for SvO_2 . When SvO_2 changes, we should ask which term(s) in equation 5 are responsible. In the operating room, the terms most likely to change significantly are cardiac output (CO) and hemoglobin (Hb). During general anesthesia with mechanical ventilation, SaO_2 and VO_2 are usually constant, with the exception that VO_2 will decrease during hypothermia. On the other hand, this is not the case in the intensive care unit. Patients in respiratory failure will have varying degrees of arterial desaturation (low SaO_2). Note that SvO_2 is directly related to SaO_2 ; if SaO_2 decreases by 20% and nothing else changes, then SvO_2 will decrease by 20%. Critical care unit patients may also have frequent changes in VO_2 , which can be increased by agitation, shivering, coughing, fever, pain, seizures, defecation, or eating, to name just a few (Fig. 7).

Continuous SvO_2 is a valuable adjunct in the treatment of ventilator-dependent patients. As positive end-expiratory pressure (PEEP) is slowly increased to improve oxygenation, SaO_2 will usually increase, but eventually the cardiac output will begin to decrease as venous return is compromised. At this point, oxygen delivery to tissue may begin to decrease (and SvO_2 begins to decrease) even though SaO_2 is still increasing. SvO_2 is a reflection of oxygen delivery in this situation, and can thus provide a means to optimize positive end-expiratory pressure without the need of serial blood gases and CO measurements.

In summary, continuous SvO_2 monitoring is a valuable technology for the operating room and the critical care unit. It reflects the overall health and functional state of the oxygen transport system. To realize the most benefit from this monitor, it is essential to thoroughly understand the physiology of SvO_2 and how it relates to the other oxygen transport variables.

CONCLUSIONS

Monitoring of oxygen in the respired gases and arterial blood is the standard of care during all anesthetics today.

None of us would consider administering general anesthesia without both an FiO_2 monitor and a pulse oximeter. New advances in pulse oximetry will make these instruments more reliable in moving or poorly perfused patients, but they will still be subject to the fundamental limitations of saturation monitoring. Further developments will include pulse oximeters that can function in the presence of COHb and MetHb. In the near future, noninvasive monitors of oxygenation in specific organs and tissues (heart, brain) will become available. Finally, mixed venous oxygen saturation indicates how much is “left over” at the end of the oxygen transport process, which gives an indication of the status of the transport system and the degree to which reserves are being used.

PACEMAKERS

ALAN MURRAY
Newcastle University
Medical Physics
Newcastle upon Tyne,
United Kingdom

INTRODUCTION

The primary function of a cardiac pacemaker is for the treatment of bradyarrhythmias, when the heart beat stops or responds too slowly. The clinical condition can be intermittent or permanent. If permanent, the pacemaker will control the heart continuously. If temporary, the pacemaker will respond only when necessary, avoiding competition with the heart's own natural response. As these devices are battery-powered, allowing the pacemaker to pace only when necessary also conserves pacemaker energy, extending its lifetime and reducing the frequency of replacement surgery.

Since their clinical introduction in the late 1950s and early 1960s, pacemakers have significantly improved the ability of many patients to lead normal lives. They also save lives by preventing the heart from suddenly stopping. The small size and long life of pacemakers allow patients to forget that they have one implanted in their chest. The first pacemakers were simple devices designed primarily to keep patients alive. Modern pacemakers respond to patients' needs and can regulate pacing function to enable the heart to optimize cardiac output and blood flow.

CLINICAL USE OF PACEMAKERS

The clinical problem with bradyarrhythmias is often associated with sick sinus syndrome. The heart's own natural pacing function originates from the sinus node in the right atrium. The rate of impulse formation at the sinus node is controlled by nerves feeding the node. Impulses arriving via the vagal nerve act to slow the heart down, as part of the body's parasympathetic response. When a higher heart rate is needed, the vagal nerve impulse rate to the sinus node is slowed down and the sinus node impulse rate increases.

Impulses propagating through the heart tissue are created via a series of action potential changes. Action potential changes can be triggered either naturally from one of the heart's pacing cells or by contact with a neighboring cell, causing the outside of the cell to produce a negative voltage with respect to the inside of the cell. These voltage changes are in the order of only 90 mV, but as we will see, an external voltage from a pacemaker has often to be several volts before depolarization is initiated.

Without pacemaker control, patients with bradyarrhythmias suffer from dizziness and can collapse without

warning and, hence, risk injuring themselves. Heart pauses of the order of 10 s will cause unconsciousness. Most patients who collapse will recover their normal heart rhythm. They can then subsequently be examined clinically, and, if necessary, a pacemaker can be implanted to prevent recurrence of a further collapse. Sometimes the heart will stop and not recover its normal pumping function and the patient will die, but usually there will have been preceding warning events allowing a pacemaker to be fitted to prevent death.

Many good texts exist that explain the clinical background to cardiac pacing, and these texts should be consulted (1–3). This text is primarily a description of the medical device itself.

Practical cardiac pacing started in the 1950s with the first clinical device, which was external to the body and required connection to a main power supply. This device was followed by an implantable pacemaker developed by Elmquist and surgically implanted by Senning in Sweden (4). The device only lasted a short time before failing, but it did show the potential for implanted pacemakers. This work was followed by Greatbatch and Chardack in the United States (5,6), first in an animal and then in a patient two years later. An interesting early review of this period has been given by Elmquist (7). These first pacemakers were very simple devices and paced only at a fixed rate, taking no account of the heart's natural rhythm. Although this approach was less than ideal, it did provide the necessary spur for both clinical expectations and technical and scientific developments by research bioengineers and industry.

The next major technical development allowed pacemakers to pace on demand, rather than only at a fixed rate. Other pacing functions developed, including pacemakers that could pace more than one heart chamber, and pacemakers that could change their response rate as a function of patient physiological requirements. Three- or four- chamber pacing was an extension of basic pacing. Pacing functions have also been included in implantable defibrillators. More complicated pacing algorithms have been developed for controlling tachyarrhythmias, including ventricular tachycardia and rhythms that can deteriorate to ventricular fibrillation.

With the evolution of smaller devices and leads, their use in pediatrics has grown, including for children with congenital heart problems. Devices as thin as 6 mm are available. Reduction in size has also aided the move from epicardial to endocardial fixation of the lead. When pacemakers are implanted in children, special consideration has to be given to the type of device as children are usually active, the lead length as children continue to grow, and lead fixation as future lead replacement must be considered.

No doubt exists that, with continuing experience, pacing techniques and pacemaker devices will continue to evolve.

PHYSIOLOGICAL FUNCTION

Understanding the physiological function of a pacemaker is more important than knowing the technical details of the pacemaker. The main functional characteristics are the ones that are important for the physician or cardiologist who will want to know how the device will operate when implanted in a patient. A series of clinical questions exist. The first question asks where you want the device to sense the heart’s rhythm, in the ventricle, the most common location, in the atrium, or in both. The second question asks in which chamber or chambers you would like the pacemaker to pace. This location is usually the ventricle, but can be the atrium or both. The third question relates to how you want the device to work when it encounters natural heartbeats. It can either be inhibited, which is by far the most common approach, or it can be triggered to enhance the natural beat. It is also possible to switch off the device’s ability to sense the heart’s natural rhythm, but is rarely done as there could then be competition between the pacemaker output and the heart’s natural rhythm.

The answers to these three questions provide the first three codes given to any pacemaker. This code is an international code developed by the Inter-Society Commission on Heart Disease (ICHHD) (8). It was subsequently expanded to a five-code system by the North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG) (9,10). The first version of the NASPE/BPEG codes allowed for programmability and communication, but as they became universal functions, the latest version of the codes simplified the codes in the fourth and fifth letter positions for use with rate modulation and multisite pacing only. These codes are used throughout the world. A summary of the coding is given in Table 1.

It is useful to give a few examples to illustrate how the codes are used. VVI pacemakers, which are in common use, allow the pacemaker to sense natural heartbeats in the ventricle (V), and, if they are absent, to pace in the ventricle (V), ensuring that the pacemaker inhibits (I) its output if a natural beat is detected. DDD pacemakers can sense in both the atrium and the ventricle (D), and, if required, pace in the atrium, ventricle, or both (D), with inhibiting and triggering (D). With programming techniques, the pacemaker’s mode can be changed after the device is implanted, and so a manufacturer may list a very large number of modes for some pacemakers.

The codes in Table 1 also show the fourth and fifth letters. The fourth tells the user if the device has an internal function for modulating its pacing rate, known

as a rate responsive (R) mode. If no code is quoted in the fourth position, it can be assumed that the device is not rate responsive. The fifth letter is for multisite pacing and is used if at least two atrial pacing sites or two ventricular pacing sites exist.

TEMPORARY EXTERNAL PACEMAKERS

This review primarily concerns implantable pacemakers, but the role of temporary external pacemakers must not be forgotten. These devices provide essential support after some cardiac surgery and after some myocardial infarctions, allowing time for the recovery of the heart’s own pacing function. The way these devices function is very similar to implantable pacemakers, but they are generally simpler and provide the clinician with access to controls such as for pacing rate and pacing voltage. The pacing leads do not have the tip features required for permanent fixation, and the connector to the temporary pacemaker is simpler. Also, the leads are bipolar with two electrode contacts.

CLINICAL IMPLANTATION

Briefly, pacemakers are implanted most commonly at one of three sites (Fig. 1). Implantation is undertaken by a surgeon or cardiologist using an aseptic technique. The pacemaker pulse generator and leads are delivered in sterile packages with clear use-by dates. Venous insertion of the lead allows it to be pushed through the right atrium and tricuspid valve, and into the right ventricle, where the electrode can be positioned in the apex where it is less likely to move or displace in comparison with other possible positions. If an atrial lead exists, it is positioned in the right atrium. Good contact with the atrial wall is harder to achieve, and active fixation such as with a screw contact can be used, in comparison with ventricular apex passive fixation.

Patients must be followed up at regular intervals to ensure that the device is working correctly, that its output pulse characteristics are appropriate, and that the end-of-life of the internal battery is estimated. This follow-up interval may be over a period of months initially, and then annually, with more frequent follow-up visits toward the end of the device’s life.

Most countries have national registration schemes, which enables information on specific patients to be obtained if, for example, a patient develops a problem while away from home. If, however, this information is not available, the device type can be recognized by a unique

Table 1. International Pacemaker Codes

1	2	3	4	5
Chamber sensed	Chamber paced	Response	Rate modulation	Multisite pacing
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	I = inhibited	R = rate modulation	A = atrium
V = ventricle	V = ventricle	T = triggered		V = ventricle
D = A+V	D = A+V			D = A+V

The following letters are used sequentially in 5 positions.

radiopaque code that can be obtained by X ray. There has been discussion on whether such codes could be retrieved by a standard external interrogating device without the need for an X ray, but no such device is as yet universally available for all pacemakers.

Another goal of pacemaker registration is to provide useful data on the range of device lifetimes for each pacemaker type and information on sudden pacemaker failures, which enables clinical staff to plan any necessary replacement, and manufacturers to act when it appears that failures are not random and may relate to their manufacturing process. This advance has enabled manufacturers to withdraw faulty or potentially faulty devices from the marketplace and correct production faults.

MARKET

Pacemakers have made a remarkable impact on clinical medicine. Over half a million new patients worldwide receive a pacemaker each year (11). In addition, approximately 100,000 patients worldwide receive a replacement pacemaker (11). Most implants are in the United States. When implants are related to the population size, the countries with the greatest new implant rates are Germany, the United States, and Belgium, with between approximately 700 and 800 implants per million population. Many countries with poor economies have very low implant rates. Within Europe, the implant rates are generally high, with, for example, the United Kingdom falling towards the bottom end of the implant rate, at approximately 300 per million population (12), where there are approximately 25,000 implants per year, and, of these, 75% are for new implants and 25% for replacements (12).

Table 2. Example Ranges of Pulse Generator Features

Volume	6–20 ml
Length/Width	30–60 mm
Depth	6–14 mm
Mass	13–50 g
Battery	0.8–2 Ah
Life	5–14 years
Sense threshold	0.1–15 mV
Refractory period	100–800 ms
Lower pulse rate	approximately 20/min
Upper pulse rate	approximately 185/min
Pulse amplitude	0–10 V
Pulse width	0.1–2 ms

FEATURES

Clinically, the most important pacemaker features relate to the device code, discussed above. Next in importance for both the clinician and patient is likely to be pacemaker size and lifetime. As a guide, example ranges of pacemaker features are included in Table 2. With continuous developments, these should be taken only as a guide. The shape and size of some pulse generators are shown in Fig. 2.

For a health-care system, the cost of devices is important. Costs vary significantly in different countries and also relate to the numbers purchased, so no specific figures can be given. It is, however, interesting to note the current relative costs of different types of devices. For guidance, approximate costs relative to a standard ventricular demand pacemaker type VVI are shown in Fig. 3, where the cost of the VVI pulse generator is given as unity. As the proportion of different types used will change, so will the relative costs.

The use of the unique radiopaque code for each pulse generator type is useful when a patient is referred to a medical center away from home, allowing that center to determine the pacemaker pulse generator being used.

Figure 2. Illustration of some pacemaker shapes and sizes.

Figure 3. Relative approximate costs of pulse generators and pacing leads. The demand pacemaker (VVI) is taken as the reference.

A unipolar device has only one electrode directly in contact with the heart. In this case, the electrode is at the distal end of the lead. To complete the pacing circuit, another electrode contact is required, and this is on the pacemaker case with current flowing via the muscle in contact with the case electrode to the heart. Bipolar electrodes are also common. Here, both electrode contacts are on the lead, one at the tip and another several centimeters away. The second electrode makes contact with the ventricular wall simply by lying against the wall with the tip firmly located at the apex of the ventricle.

PACEMAKER COMPONENTS

A pacemaker refers to all components necessary for a complete clinical pacing device. At least two components will always exist, the pulse generator and the lead (Fig. 4). More than one lead may exist, such as for dual-chamber pacing, in both the atrium and ventricle. Unusual pulse generator and lead combinations may require an adaptor, but extra components should be avoided whenever possible. Extra components add to the areas where failure might occur.

When a pacemaker has been implanted or is, subsequently, to be checked, external devices will be required. An ECG recorder will confirm correct pacing, and some pacemakers generate impulses that can be visualized on an ECG recorder for relaying pacing information. In addition, a magnet or other technique may be used to put the pacemaker into various test modes, which is now commonly achieved with a programmer that communicates with the pacemaker via an electromagnetic wand using communi-

Figure 4. Pulse generator and lead are the two main components of a pacemaker.

cation technology with coded sequences to prevent external interference such as from a radio telephone accidentally reprogramming the pacemaker. As well as controlling the pacing functions, the programmer can interrogate the pacemaker about the frequency of pacing, provided, of course, these features are available. Telemetry may also be available, where intracardiac waveforms can be relayed as they occur and selected pacing episodes can be recovered from the pacemaker memory.

Further useful technical information can be obtained from the books by Schaldach (13) and Webster (14).

PULSE GENERATOR

When pulse generators were first used in the early 1960s, they were simple devices with a battery power supply and a circuit to produce a regular pulse rate with a defined pulse voltage and pulse width output. Modern pulse generators are much more complex, with sensing and output control. Special electronic circuitry has been developed, often with sophisticated microprocessor control. Battery technology has also developed significantly. A block diagram of a complete pulse generator is shown in Fig. 5. Each major part is now described.

Power Supply

The first battery power supplies were made up from separate zinc-mercury cells. They could often be seen through the casing before implantation, after removal, or on the X ray. The voltage of these cells quickly fell to approximately 1.35 V, which was held until the cell reached the end of its life. Unfortunately, these cells could power the early pacemakers for only about two years.

These batteries encouraged the search for other power sources, including, for a short time, nuclear power, but safety concerns discouraged these developments. Rechargeable batteries, where the recharging energy was transmitted to the pulse generator via an external coil, were also employed, and had in fact been used in the first clinical pacemaker. However, reliability and frequency of charging inhibited their use.

Fortunately, a solution was found in the form of lithium-iodide cells. Their use in pacemakers was pioneered by Greatbatch (15) and introduced into clinical use in 1971. The cell has an initial open circuit voltage of 2.8 V, which falls slowly with use until its end of life is approached, when the voltage fall is more rapid. Although other types of lithium cells have been researched, they have not replaced the lithium-iodide cell for pacemakers. Some pacemakers

Figure 5. Block diagram of a complete pulse generator.

can now function for ten years, and, for low demand situations, 14 years can be achieved.

Ventricular and Atrial Sensing

All pacemakers sense natural cardiac impulses, which is achieved very reliably. However, the sensing circuitry needs to be able to differentiate between impulses coming from the heart and those due to external interference. The possibility of interference cannot be neglected, especially as the cardiac impulse is, at most, only a few tens of millivolts. In addition, in unipolar pacing, the sensing circuitry cannot differentiate between signals coming from the electrode at the end of the lead or the electrode on the pulse generator case, which is described more fully under leads below. It is not always possible to detect heart impulses reliably during periods of excessive interference, and in these cases, the device needs to be programmed to respond in a clearly defined way, such as by initiating fixed-rate pacing.

Pulse Interval Generator

At the heart of the pacemaker is the interval generator. As with other pulse generator functions, this is achieved with electronic circuitry or microprocessor control that generates the pacing interval measured in seconds or pacing rate measured in beats per minute. Without any means to detect patient activity or the need for a higher heart rate, this interval is fixed, other than for programmed changes that can be made at the clinic. The interval generator is connected to the sensing circuitry so that output from the interval generator can be synchronized or inhibited. Interactions for a VVI pulse generator are illustrated in Fig. 6. If a natural heartbeat is sensed, the pacemaker will time its pulse interval from that beat. If, however, the beat occurs in the refractory period set in the pacemaker, it will not respond to the beat, and the pulse interval timing will not be altered. For devices that can pace in both the atria and ventricle, such as a DDD device, the interval between atrial and ventricular pacing, known as the AV interval, will be set to optimize heart pumping function (Fig. 7).

Interval Modulator

The interval modulator, if it is available, simply attempts to change the response of the interval generator to that

Figure 6. Illustrative example of some pacemaker-heart interactions.

Figure 7. Atrioventricular pacing with the AV interval set within the pacemaker.

required by the patient. Electronic modulation of the interval is easy to achieve, and this function will usually be seen as part of the interval generator. However, determining how to modulate is difficult, and it requires a sensor to detect the patient's need for a higher or lower heart rate, usually in response to patient activity, whether determined directly or indirectly via physiological functions.

Activity Sensor

Many different sensors have been used. Some have been more successful than others. Changes in blood oxygen levels, through oxygen partial pressure or saturation levels, suggest the need for a higher heart rate when these levels fall, but this technique requires a sensor with continuous blood contact that will continue to work over many years, a difficult specification to achieve. Increased respiration rates also suggest the need for a higher rate. To detect respiration, some devices used a special lead to detect respiratory movement or electrical impedance changes but were not always successful. Special leads with inbuilt sensors add to the complexity of the pacemaker. Respiration can now be monitored using electrical impedance changes from a standard lead.

Other successful techniques used the intracardiac electrogram obtained from the sensing electrode or activity sensing from an inbuilt accelerometer. With careful analysis of the electrogram, it is possible to obtain a measure of the repolarization interval, which is known to change systematically with heart rate changes and, for this application, has been shown to shorten even without any increase in paced heart rate when the need for a higher rate is physiologically required. The use of a motion sensor using a piezoelectric sensor has been successful and is most widely applied because the technology is simple. The sensor can be built into the pulse generator housing with better reliability than for techniques requiring additional patient contacts. Movement of the sensor produces an output voltage proportional to acceleration. Algorithms have then been developed to relate changes in sensed activity to changes in pacing interval. They can also, to some extent, be programmed to individual patients. One drawback is that the sensor senses movement of the pacemaker that can be in a patient, for example, driving a car

where an increase in heart rate may not be appropriate. Improvements to deal with such situations are under continuous development, as is research into different sensor techniques.

Without doubt, rate-responsive pacemakers have made a great contribution, and patients welcome the ability of the pacemaker to adapt to their needs, even if the pacemaker response is not physiologically perfect (12).

Lead Connector

Leads and pulse generators are provided separately, which gives greater flexibility in their use and enables different lead lengths and lead types to be selected. However, a connector is then needed. Ideally, this connector should be able to connect any appropriate lead to any pulse generator, and international standards have gone a long way to achieving this. For single-chamber pacemakers, the connector takes one lead that can be either for a unipolar or bipolar lead with one or two electrode contacts.

It is important for the connector to make a good electrical contact, while preventing any body fluids penetrating into the pulse generator, which in the past, have caused pacemakers to fail. Connectors allow the electrical contact to be made easily and provide seals between leads and the pulse generator.

Case

The primary function of the case is to protect the inner electronics from mechanical damage and from penetration of blood or other fluids. It is essential for the case to be biocompatible so that the patient does not attempt to reject the pulse generator as a foreign body. Titanium has been a successful material.

For unipolar devices, the case must contain an electrode, which acts as the reference for the lead electrode. The sensed voltage is that between the case and the lead electrode. Also, when pacing, the stimulation voltage appears between the case and lead electrode. To minimize the possibility of muscle stimulation at the case electrode, this electrode has a large surface area, so reducing the current density in comparison with that at the lead electrode. Also, the output pulse is positive at the case electrode with respect to the negative voltage at the pacing electrode, which confers preference to stimulation at the negative site in the heart.

Telemetry Function and Programming

For programming and telemetry functions, the pacemaker needs to be able to communicate with an external device, usually with coded signals using electromagnetic transmission between the pacemaker and a wand of the programming unit. These devices use standard techniques, with only the coding being specific to pacemakers.

Computer Algorithms

Pulse generators usually can be seen as small microprocessor devices. As such they contain computer code or computer algorithms to control their function, delivering advantages to the patient and clinician, as the pacemaker's

Table 3. Example Ranges of Lead Features

Length	20–120 cm
Diameter	1.2–3.5 mm
Tip diameter	0.7–3.3 mm

mode of operation can be changed, and also to the manufacturer, as it is easier to develop new and improved devices. However, reliable software is notoriously difficult to develop and test. Manufacturers have discovered, to their cost-unusual errors in their software only after devices have been implanted, necessitating a recall of devices not yet implanted and careful follow-up of patients with devices already implanted. High quality software development is taken seriously by the manufacturers and cannot be stressed enough.

LEAD

The lead has four main features. It needs a connector to connect it to the pulse generator, a long flexible wire, a biocompatible sheath over the wire, and at least one electrode to make contact with the heart. Table 3 provides illustrative ranges of lead features.

Connector

The connector needs to be compatible with that on the pulse generator. As with the pulse generator, there should be no ingress of fluid, this time into the wire. Also, as the wire can move with each heartbeat, the construction needs to ensure that no extra stress exists on the lead wire near the connector.

Lead Wire

The most important characteristic of the lead wire is that it has to be flexible. Normal wire easily fractures when bent repeatedly. A pacing lead wire has to move with each heartbeat, which averages approximately 100,000 movements each day. Good flexibility is achieved by using a spiral construction. All wires have some impedance, which is taken into account by the pulse generator output.

Insulated Lead Sheath

The sheath covering the lead wire also needs to be flexible and must not become brittle with age. The sheath material must be biocompatible so as not to be rejected by the body. Materials used are silicone rubber or polyurethane.

Electrode

The design of the electrode is very important. In particular, the fixation, contact area, and contact material are essential features. Illustrative examples of basic features of lead-tip electrodes are shown in Fig. 8. Unipolar electrode leads have a single-electrode contact at the tip. Bipolar electrode leads have two contacts, one at the tip and the other a few centimeters distant from the tip.

When the lead is implanted and a suitable electrode site found, the electrode needs to stay in position, which is

Figure 8. Illustrative example of pacing electrodes.

achieved by mechanical features at the tip of the lead, which can be, for example, tines or a helical electrode construction. With time, tissue will grow over the tip holding it in place. One problem is that this fixation can become so good that the lead can be difficult to remove if a problem occurs and it needs to be replaced. Electrodes positioned in the ventricular apex are easy to locate and also tend to stay in position easily, and hence require only passive fixation, such as with tines at the end of the lead. Other tip locations may require active fixation such as with a screw tip.

The electrode area needs to be high enough to ensure good electrical contact. The greater the contact area, the lower the contact impedance, which in turn reduces the electrode-tissue interface impedance and ensures that most of the pulse generator voltage appears at the cardiac tissue.

As with any electrode, the electrode contact material is important. The aim in selecting the material is to reduce polarization effects. Many electrode-coating materials have been studied, including steroid-eluting electrodes to reduce inflammation. Changes in electrode polarization are the cause of the increase in stimulation voltage in the days and early months after implantation, to be subsequently followed by a lowering of the effect and also of the required stimulation voltage.

STIMULATION THRESHOLDS

Stimulation success is a function of both pulse amplitude and pulse width. A minimum voltage and energy is required. The voltage has to be greater than that required to initiate the approximate 90 mV change in action potential. However, because of polarization and other effects, the voltage required is usually in the order of several volts and can reach 10 V soon after implantation. After a few months, this voltage will have reduced to the level of a few volts.

The initial research on stimulation pulse energy was with stimulating nerves, but the results obtained have been shown generally to hold when stimulating or pacing cardiac tissue. The energy used should be the minimum possible to induce stimulation reliably, which is controlled by varying the pulse width. Early work on nerve stimulation showed that no matter how wide the pulse width was, a minimum pulse voltage existed, called the **rheobase** voltage. At about twice this voltage, with a lower pulse width, the minimum energy required is found. If the pulse width is reduced further, the greater voltage required results in increased energy requirements to induce pacing. The pulse width for lowest energy is called the chronaxie time, shown in Fig. 9.

Figure 9. Pulse energy as a function of pulse width.

As the pulse energy is only to initiate cardiac depolarization, and not for providing pumping energy, the energy levels required are low and on the order of only a few microjoules (16).

PROBLEMS IN USE

Interference

Interference is a well-understood problem. Muscle interference at the case electrode in a unipolar system can be a problem in active people, especially when the pulse generator is implanted beside the pectoral muscles. If this particular problem is anticipated, a bipolar system can be used.

Threshold Voltage Changes

Threshold voltages do change. If the pacing voltage is set too high, energy will be wasted, reducing the lifetime of the device. If set too low, changes in threshold voltage may result in the pacing voltage being below the pacing threshold. These factors have to be balanced. Some devices automate the selection of an appropriate voltage output.

Early Failure

Pacemakers are complex devices, and like all devices they can fail. Failure is not a common problem, but because pacemakers are implanted and are life supporting, failure can have fatal consequences. Reporting of individual problems is essential, allowing manufacturers and national health bodies to identify a common problem early and, if necessary, withdraw stocks before they are used in new patients and take action to review patients who already have the device implanted.

SPECIAL DEVICES

This review has concentrated on the main use of pacemakers for treatment of bradyarrhythmias. Other options

are used, but these options are based on the standard pacing approaches.

Implantable defibrillators can have an additional pacing function so that if the heart stops rather than developing ventricular fibrillation, pacing can be initiated. The pacing technology is exactly the same as for pacemakers described above, except that the electrode system will be different.

Devices are used for control of tachyarrhythmias. These devices, rather than using the regular pacing interval, usually use a series of pacing intervals at different rates to terminate the arrhythmia.

Some patients in heart failure were, in the past, often assumed to be untreatable unless by heart transplantation. Much can now be done for these patients, including pacing in all four cardiac chambers, which maximizes the pumping function of the heart by pacing the left as well as the right heart chambers, and pacing the atria and ventricles with an appropriate atrio-ventricular delay. This solution requires complex and multiple leads, and as these leads are used in sick patients, success is not always assured. Many of these patients may also require a defibrillation function.

FUTURE

Cardiac pacing had a small beginning but has grown at a steady rate each decade. With an aging population, the need for pacing will continue to grow. The development and production of pacemakers will remain a major medical device industry.

Of those devices currently available, increased use of physiological or rate responsive devices is likely as clinical studies prove their clinical value to patients, especially those who are active.

Technical advances will, to some extent, be dependent on the production of improved batteries, and then the decision will be either to make them smaller, last longer, or power more microprocessor technology. Improved electrode design to reduce energy requirements could also make a significant impact in reducing pacing pulse energy, and hence overall energy requirements. Improvements in setting the optimum AV delay will help many patients and, in particular, children who are active. Increased ability to store intracardiac data for review will ensure more research into effective use of pacing.

Pacing will continue as an essential therapeutic technique, saving lives and bringing some normality to patients with abnormal physiological heart rate control.

INTRODUCTION

In 2000, some 171 million people worldwide had diabetes. By 2030, a conservative forecast suggests that this number will increase to 366 million attaining epidemic proportions as the prevalence increases from 2.8 to 4.4% in all age groups (1) due to, primarily, a relative increase in developing countries (2).

Diabetes is a group of heterogeneous chronic disorders characterized by hyperglycemia due to relative

or absolute insulin deficiency. Two major categories of diabetes are recognized according to aetiology and clinical presentation, type 1 diabetes and type 2 diabetes. More than 90% cases are accounted for by type 2 diabetes. Regional and ethnic differences in diabetes incidence and prevalence exist.

Type 1 diabetes is one of the most common chronic childhood disease in developed nations (3), but occurs at all ages. Type 1 diabetes is caused by autoimmune destruction of pancreatic islet beta-cells resulting in the absolute loss of insulin production. Treatment demands the administration of exogenous insulin. Type 1 diabetes is associated with a high rate of complications normally occurring at young ages placing a considerable burden on the individual and the society.

Type 2 diabetes is caused by insulin resistance and relative insulin deficiency, both of which are normally present at the diagnosis of the disease. Environmental and polygenic factors contribute to these abnormalities (4), but specific reasons for their development are not known. A considerable number of subjects with type 2 diabetes progresses to insulin dependency.

The persistent hyperglycemia in diabetes is associated with long-term complications and dysfunction of various organs, especially the eyes, kidneys, nerves, heart, and blood vessels. The Diabetes Control and Complications Trial (DCCT) (5) and the United Kingdom Prospective Diabetes Study (UKPDS) (6) demonstrated that tight glycaemic control reduces the risk of long-term complications of type 1 and type 2 diabetes reducing the cost to the healthcare system (7). There is no threshold for the relationship between blood glucose, that is, glycosylated hemoglobin (HbA_{1c}) and reduced risk. This indicates that glucose levels in subjects with type 1 or 2 diabetes should be as close as possible to those observed in healthy subjects. However, tight glucose control is associated with an increased risk of hypoglycemia (8), which acts as a limiting factor to the effective diabetes management.

In health, insulin is secreted by the pancreas in a highly controlled fashion to maintain the plasma glucose concentration within a narrow physiological range. In type 1 diabetes, insulin is delivered exogenously to mimic the basal and postprandial insulin needs. The standard therapy is based on multiple insulin injections using a combination of short- and long-acting insulin analogs supported by blood glucose self-monitoring (9). Treatment by the continuous subcutaneous insulin infusion (CSII), that is, using insulin pumps, is on the rise (10).

The present review is limited to the artificial electro-mechanical endocrine pancreas, which has the potential to revolutionize diabetes management. The artificial pancreas replaces the glucose sensing and insulin delivery by beta-cells and is therefore sometimes called an "artificial beta-cell". It consists of three components, a glucose monitor to measure continuously glucose concentration, a titrating algorithm to compute the amount of insulin to be delivered, and an insulin pump to deliver the insulin. Only few prototypes have been developed and tested in a controlled clinical environment. Further progress depends on advancements of continuous glucose monitoring (11).

HISTORICAL BACKGROUND

The hormone insulin was discovered by Banting and Best in 1921. The first patient was treated a year later in 1922.

The first reported continuous *ex vivo* glucose measurement in humans was by Weller *et al.* in 1960 (12). In 1964, Kadish (13) was first to use continuous real-time glucose monitoring in a subject with diabetes to close the loop. The system employed an intravenous (iv) infusion of insulin and glucose, which could be switched on or off, denoted as an "on-off system". At that time, no suitable computational means were available.

In 1974, two groups developed a true "artificial endocrine pancreas". Albisser *et al.* (14,15) in Toronto and Pfeiffer *et al.* (16) in Ulm combined continuous glucose monitors with algorithms implemented on a microcomputer to automate iv delivery of insulin and glucose. The first commercial device, the Biostator (17) (Life Science Instruments, Miles, Elkhart, IN) was put into production in 1977 thanks to the determination by Clemens. The golden age of the Biostator was between late 1970s and early 1980s. It is still used for research purposes.

The last two decades have witnessed a considerable technological progress. Between 1999 and 2005, five continuous or semicontinuous monitors have received regulatory approval in the United States or Europe and further are under development (18). Since the introduction of continuous subcutaneous insulin infusion (CSII) (19), insulin pumps have been miniaturized and their reliability improved (20). Advanced titrating algorithms have been developed.

PHYSIOLOGICAL CONSIDERATIONS

Pancreas

The pancreas has digestive and hormonal functions. It is divided into the endocrine tissues secreting hormones insulin, glucagons, and somatostatin, and the exocrine tissues secreting digestive enzymes.

The endocrine tissues consist of many small clusters of cells called islets of Langerhans. Humans have roughly 1 million islets. Three major cell types are located in islets. Alpha-cells secrete the hormone glucagon. Beta-cells produce insulin and are the most abundant of the islet cells. Delta-cells secrete the hormone somatostatin.

Endogenous Insulin Secretion

Pancreatic beta-cells secrete insulin by sensing the levels of nutrients, such as glucose and certain amino acids. The beta-cells therefore integrate the sensing and secreting functions and are efficient in maintaining glucose homeostasis.

Four different phases of insulin secretion can be identified (21). Basal insulin secretion represents insulin released in the postabsorptive state. The cephalic phase of insulin secretion is evoked by the sight, smell, and taste of food before its digestion or absorption and is mediated by pancreatic innervations. The early-phase relates to the first 0–30 min postmeal insulin secretion, whereas the

late-phase relates to the secretion between 60 and 120 min. During all phases, insulin is secreted in a pulsatile fashion with rapid pulses occurring every 8–15 min superimposed on slower, ultradian oscillations occurring every 80–120 min.

Insulin secretion is induced by other energetic substrates besides glucose, such as amino acids and drugs. Incretin hormones, such as glucagon-like peptide-1 (GLP-1) and to a lesser extent, glucose-dependent insulinotropic polypeptide (GIP), are responsible, in part, for the higher insulin secretory response after oral compared to the intravenous glucose administration.

COMPONENTS

The artificial pancreas consists of three components, a glucose monitor to measure glucose concentration, an algorithm to decide the amount of insulin to be delivered, and a device delivering insulin. This is a minimum setup. Some argue that a safe system should include a device for the delivery of glucose but all existing prototypes, with the exception of the Biostator, avoid the delivery of glucose.

The glucose monitor could be an implantable or extracorporeal device and based on a minimally or noninvasive technology (22). Generally, the implantable sensors are projected to have several months to years lifetime whereas the nonimplantable devices have, at present, lifetime of one-half of a day to several days.

Similarly, the insulin pump can be implanted or extracorporeal. The implantable pump normally delivers insulin intraperitoneally whereas the extracorporeal insulin pump delivers insulin subcutaneously.

The control algorithm can be implemented on a separate device or on the same platform as the insulin pump. The communication between the devices can be achieved using wire or wireless technologies. The latter are becoming prevalent for the transfer of data from insulin pumps onto diabetes management systems. Integrated systems exist which allow wireless transfer of data between glucose meters and insulin pumps such as the “all-in-one” CozMore Insulin Technology System (Smiths Medical MD, Inc. MN).

TYPES OF ARTIFICIAL PANCREAS

Meal Time Insulin Delivery

Artificial pancreas can handle meal delivery in different ways. In a “fully closed-loop” setting, the artificial pancreas delivers insulin without information about the time or size of the meal. Insulin is administered purely by evaluating the glucose excursions and the system works autonomously.

Alternatively, the artificial pancreas is provided with information about the time and size of the meal. The controller generates an advice, in an open-loop manner, on prandial insulin bolus. This can be termed “closed-loop with meal announcement” or “semiclosed-loop” control.

Other ways exist to handle the meal-related insulin delivery, but most systems adopt a fully closed-loop or semiclosed-loop setting.

Body Interface

Depending on body interface, three major types of artificial pancreas are recognized, (i) the subcutaneous (sc) sensing and sc delivery (sc–sc) system, (ii) the iv sensing and intraperitoneal (ip) delivery (iv–ip) system, and (iii) the iv glucose sensing and iv insulin delivery (iv–iv) system. The approaches differ in their invasiveness and associated kinetic delays (11).

Subcutaneous: Subcutaneous Body Interface

As a minimally invasive solution, the sc–sc approach has the potential to achieve a widespread application. However, it is unlikely to be compatible with a fully closed-loop system due to considerable delays disallowing effective compensation of large disturbances, such as meals.

The overall delay from the time of insulin delivery to the peak of its detectable glucose lowering effect is 100 min (11). This consists of a 50 min delay due to insulin absorption with short-acting insulin analogs (23), 30 min and more due to insulin action (24), 10 min due to interstitial glucose kinetics (25), and 10–30 min due to the transport time for *ex vivo* based monitoring system, such as those based on the microdialysis technique (26).

It is likely that users of the sc–sc approach will have to enter nutritional information to assist in the delivery of the prandial insulin dose. Most present prototypes adopt the sc–sc approach.

Intravenous: Intraperitoneal Body Interface

The iv–ip can benefit from existing intraperitoneal insulin pumps. The delays in the system are about 70 min, which comprises a 40 min time-to-peak of plasma insulin following intraperitoneal administration and a 30 min delay due to insulin action (11). Additionally, a delay due to kinetic properties of the glucose sensor applies, such as a 16 min kinetic and transport delay introduced by the long-term sensor system (27). It is unclear whether a fully closed-loop system can be developed under such circumstances.

The drawback of the iv–ip route is considerable invasiveness and relative inexperience with intraperitoneal compared to subcutaneous insulin pumps. Only > 1000 intraperitoneal pumps have been implanted so far (28) compared to > 200,000 subcutaneous pump users (29). Intraperitoneal insulin can be delivered by an implantable insulin pump Minimed 2007 (28) or via an indwelling intraperitoneal catheter such as DiaPort by Disetronic.

Intravenous: Intravenous Body Interface

The iv–iv approach was the first to have been investigated. It is embodied by the Biostator device. At present, the iv–iv approach is usable at special situations, such as in critically ill patients, surgical operations, or for research investigations. The drawback of the approach is its invasiveness requiring vascular access for both glucose monitoring and insulin delivery and is associated with a high risk of complications arising from, for example, biocompatibility issues.

The benefit of the approach is that the kinetic delays, ~ 30 min due to the delay in insulin action, are minimized enabling the development of a fully closed-loop system.

PROTOTYPES

Biostator

Introduced in 1977, the Glucose-Controlled Insulin Infusion System (GCIIS), trademark name Biostator, is a modular, computerized, feedback control system for control of blood glucose concentrations (17), see Fig. 1. The Biostator is an example of an iv–iv system working in the fully closed-loop mode.

The Biostator was developed to normalise glucose in acute metabolic disturbances such as during diabetic ketoacidosis. However, its primary use has been in research investigating insulin sensitivity by the method of the glucose clamp and assessing insulin requirements and associated inter and intraindividual variability in subjects with type 1 diabetes and other conditions.

The rapid on-line glucose analyzer uses whole blood utilising a glucose oxidase sensor in the measurement process. The analyzer demonstrated both short- and long-range stability based on a two-point calibration.

The nonlinear proportional-derivative controller uses a five-point moving average smoothing and titrates insulin or dextrose intravenous infusion using a multichannel peristaltic infusion system to achieve user-defined glucose concentration. A printer records, on a minute-by-minute basis, the glucose value measured, the insulin and/or dextrose infusion rates, and the cumulative total of the insulin infused. A serial RS232 link allows these data to be downloaded to an external computer. The system response is < 90 s including transport of blood from the patient.

Although a pioneering device, the Biostator suffers from serious limitations. It needs constant technician's supervision. It discards continuously venous blood at a rate of 50 mL per 24 h. The control algorithm is oversimplistic. The original insulin titrating algorithm was linked to the rate of glucose change by Albisser *et al.* (14) with modifications, for example, by Botz (30), Marliss *et al.* (31), and Kraegen *et al.* (32) to reduce postprandial hyperglycemia and hyperinsulinemia. The algorithms require individualization by assigning values to constants. No formal adaptive approach was used to support the assignment, which is based on heuristics. These and similar algorithms were reviewed by Broekhuysen *et al.* (33), who concluded that none of the algorithms was superior and that further work was required to achieve normalization of the glucose concentration.

Over 200 devices have been sold worldwide. The Biostator contributed to the development and acceptance of the present gold standard in the diabetes management by multiple daily injections. At present, it is used for research purposes to evaluate diabetes drugs and technologies. The number of functioning prototypes counts in tens as spare parts run out. The Glucostator (mtb GmbH, Lonsee, Germany) is a CE-marked device recently marketed to replace the aging Biostator devices.

Shichiri's Group

Professor Shichiri and co-workers, Kumamoto, Japan, has developed as early as in 1975, a prototype of an iv–iv artificial endocrine pancreas (34) made later into a compact bedside version, STG-22 (Nikkiso Co. Ltd., Japan) (35) with a similar properties to the Biostator. The device is still marketed. STG-22 uses a glucose sensor for continuous glucose monitoring by combining the immobilised glucose oxidase membrane glucose enzyme sensor measuring hydrogen peroxide.

Following on, the group developed a prototype wearable artificial pancreas using the sc–sc route with the regular (36,37) and short acting insulin (38), and the sc–ip route (39). The latest versions use a microdialysis-type (40) or a ferrocene-mediated needle-type (39) glucose sensor working over a period of 7 days without any *in vivo* calibration (i.e., without using blood glucose measurement to calibrate the glucose sensor) followed by 14 days with one point calibration (41).

The results of the performance of their closed-loop system are even more impressive. With a fully closed sc–sc route using short acting insulin Lispro, the group claimed to have achieved “perfect” normalization of blood glucose over 24 h (38,42).

These results are surprising given that the control algorithm was a simple, nonadaptive PD controller in the form

$$IIR(t) = K_P G(t) + K_D \frac{dG(t)}{dt} + K_C$$

where $IIR(t)$ is insulin infusion rate, $G(t)$ is the monitored glucose concentration, and K_P , K_D , and K_C are constants, which are dependent on the type of insulin delivery, subcutaneous versus intravenous, and also on the type of insulin, regular versus short-acting insulin lispro (38,43).

These enviable groundbreaking results, however, failed to be confirmed by other groups. The achievements of the group are summarized in an edited monograph (34).

Minimed: Medtronic

The Continuous Glucose Monitoring System (CGMS; Medtronic MiniMed, Northridge CA) (44) is the first commercial continuous glucose monitor. Approved in 1999, CGMS adopts a Holter-style monitoring to store up to 3-day data for retrospective analysis.

The CGMS employs an electrochemical sensor inserted into the subcutaneous tissue adopting the hydrogen peroxide-based enzyme electrode (45), which provides signal every 10 s. Calibration is achieved using self-monitoring of blood glucose. The new “gold” sensor introduced in November 2002 is more accurate than the original sensor [the mean absolute deviation 0.83 vs 1.11 mmol·L⁻¹ (46)].

Employing the CGMS sensor, an external physiological insulin delivery (ePID) has been developed by Minimed–Medtronic. The system uses a PID controller (47), which was designed to reproduce the first phase insulin secretion by linking insulin administration to the rate of change in glucose concentration (the proportional component of the controller) and the second phase by linking insulin administration to the difference between the ambient and target glucose (the integrative component of the controller).

First studies with a fully closed loop were executed in dogs (48). The example presented in (49) shows peak post-meal glucose of 15 mmol·L⁻¹ with the set point reached in 11 h indicating a suboptimal performance of a fully closed loop with the sc–sc approach. The adaptation of the PID controller was achieved by assigning the proportional gain K_P a value resulting in a normal daily insulin dose of the dog at euglycemia (48).

An evaluation of the ePID system in six subjects with type 1 diabetes > 27.5 h resulted in preprandial and postprandial (2 h) glucose levels at 5.8 ± 1.2 and 9.8 ± 1.6 mmol·L⁻¹ (mean \pm SD) (50). Morning glucose after overnight control was 6.8 ± 1.0 mmol·L⁻¹.

Roche Diagnostics

The sc–sc closed-loop prototype with meal announcement (51,52) developed by Roche adopted the subcutaneous continuous glucose monitor (SCGM1; Roche Diagnostics GmbH, Mannheim, Germany), which has been designed to monitor glucose in the subcutaneous interstitial fluid for up to 4–5 days (53).

SCGM1 is based on the microdialysis technique with an *ex vivo* glucose measurement. The sensor produces a signal every second. This is reduced to one glucose measurement every 5 min. Calibration is required once every 24 h (26,53). SCGM1 has a low flow rate (0.3 μ L·min⁻¹), achieves a 100% recovery of the subcutaneous glucose in the dialysate, but has a 30 min technical lag. *In vitro* performance is excellent with a mean absolute difference of 0.2–3.8% in 10 sensor units (53).

An “empirical algorithm” (51) was developed to titrate sc insulin. A set of rules, derived from clinical observations, determine the insulin bolus administered every 10 min.

The closed-loop system with meal announcement was tested in 12 well-controlled (HbA_{1C} < 8.5%) subjects with type 1 diabetes (51). Control lasted over 32 h and included the digestion of breakfast, lunch, dinner, and a snack. The target glucose concentration for the algorithm was 6.7 mmol·L⁻¹. Prandial bolus was calculated from the carbohydrate content of the meal.

The algorithm achieved a near-target monitored glucose concentration (6.9 vs. 6.2 mmol·L⁻¹; mean, algorithm vs. self-directed therapy) and reduced the number of hypoglycemia interventions from 3.2 to 1.1 per day per subject. During the algorithm therapy, 60% of SCGM1 values were within the 5–8.3 mmol·L⁻¹ range compared to 45% with the self-directed therapy.

Adicol Project

The project Advanced Insulin Infusion using a Control Loop (Adicol) (54) was an EC funded project that completed at the end of 2002. The Adicol’s sc–sc closed loop with meal announcement consisted of a minimally invasive subcutaneous glucose system, a handheld PocketPC computer, and an insulin pump (Disetronic D-Tron) delivering subcutaneously insulin lispro, see Fig. 2.

As continuous sensor was developed in parallel with the control algorithm and was not sufficiently stable, throughout the Adicol project, the intravenous glucose measurement was used, delayed by 30 min to simulate the lag associated with sc glucose sampling.

Adicol adopted an adaptive nonlinear model predictive controller (MPC) (55), which included a model based on a two compartment representation of glucose kinetics (24)

Figure 2. Components used by the Adicol’s biomechanical artificial pancreas. Top left corner shows the microperfusion probe connected to the glucose monitor, which includes microfluidics components, Bluetooth communication, and the sensor. The handheld iPAQ PocketPC maintains wireless communication with the other two components, runs the MPC controller. Disetronic D-Tron insulin pump is equipped with a special sleeve visible on the left hand side of the pump which converts the Bluetooth radiofrequency signal to an infrared signal accepted by the pump (reprinted with permission from (54)).

extended by submodels representing the absorption of short acting insulin lispro, the insulin kinetics, the renal clearance of glucose, and the gut absorption. The MPC approach was combined with an adaptive Bayesian technique to individualize the gluco-regulatory model to represent the inter- and intrasubject variability. The individualization was integrated within the control algorithm and was executed at each 15 min control cycle.

The largest clinical study performed in the Adicol project assessed the efficacy of the MPC controller with 30 min delayed glucose sampling > 26 h in 11 subjects with type 1 diabetes. Glucose was normalized from 1400 to 1800. Dinner followed with an individually determined prandial bolus at 1800, and control by the MPC from 1930 to 2200 the following day.

One hypoglycemia event (touchdown at $3.3 \text{ mmol}\cdot\text{L}^{-1}$) due to the MPC control was recorded. The highest glucose concentration was $13.3 \text{ mmol}\cdot\text{L}^{-1}$ following breakfast; 84% of glucose measurements were between 3.5 and $9.5 \text{ mmol}\cdot\text{L}^{-1}$ (56).

Following the completion of the Adicol project, a visco-metric sensor (57) was tested with the MPC algorithm. Five subjects with type 1 diabetes treated by CSII were studied for 24 h (58). No hypoglycemia event ($< 3.3 \text{ mmol}\cdot\text{L}^{-1}$) due to the MPC control was observed. Overall, 87% sensor values were between 3.5 and $9.5 \text{ mmol}\cdot\text{L}^{-1}$. Outside the 3 h postmeal periods, 74% of sensor measurements were in the range 3.5 – $7.5 \text{ mmol}\cdot\text{L}^{-1}$.

Institute for Diabetes Technology, Ulm

Building on foundations laid by Professor Pfeiffer in the early 1970s, the work in Ulm continues (59).

The group used the amperometric–enzymatic approach in combination with the microdialysis technique. The continuous flow method uses a slow continuous flow through the tubing achieving nearly a 100% recovery with a 30 min lag (59). The comparative method does not require calibration (60). Saline with glucose ($5.5 \text{ mmol}\cdot\text{L}^{-1}$) is pumped through the probe in a stop-flow mode. During the stop mode, a nearly 100% equilibrium between the interstitial plasma glucose and the perfusate is achieved. In the flow mode, the dialysate is pumped rapidly to the sensor chamber. The technique facilitates sensor internal calibration for each measuring cycle and yields five glucose measurements per hour.

The group developed and tested an sc–sc closed-loop approach with meal announcement (61,62), see Fig. 3.

The algorithm uses the basal insulin need, determined from an individual insulin need, and a postprandial insulin need, expressed as an insulin/carbohydrate ratio. A model exploits these values and predicts future glucose excursions. The algorithm was tested in eight subjects with type 1 diabetes over a period of 24 h. The average glucose value was $7.8 \pm 0.7 \text{ mmol}\cdot\text{L}^{-1}$ (mean \pm SD). The postprandial increases were at $2.9 \pm 1.3 \text{ mmol}\cdot\text{L}^{-1}$ with largest excursions recorded after breakfast. One hypoglycemia ($< 3.3 \text{ mmol}\cdot\text{L}^{-1}$) was observed (62).

EVADIAC Group

Exploiting the progress made by the French group on implantable pumps “Evaluation dans le Diabete du Traite-

Figure 3. The system V4-IDT from the ULM group. The system uses a glucose monitor based on microdialysis integrated with a portable computer and an H-Tron pump, Disetronic. (Courtesy of Dr. Freckmann, Institute for Diabetes Technology, Ulm, Germany.)

ment par Implants Actifs” (EVADIAC), the work by Renard *et al.* is at the forefront of the fully closed-loop iv–ip approach. The group has developed the implantable physiologic insulin delivery (iPID) system, which uses a long-term sensor system (LTSS) (63,64).

Long-term sensor system, an intravenous enzymatic oxygen-based sensor developed by Medtronic MiniMed (Northridge CA), is implanted by direct jugular access in the superior vena cava. It is connected by a subcutaneous lead to an insulin pump delivering insulin intraperitoneally and implanted in the abdominal wall, see Fig. 4. The pump implements a PD controller similar to that used by the ePID system.

The system has been investigated in subjects with type 1 diabetes with collected data per sensor of ~ 280 days (65). Most investigations with LTSS have adopted the open-loop approach. The fully closed-loop system was tested > 48 h reducing % time spent at $< 3.9 \text{ mmol}\cdot\text{L}^{-1}$ from 18 to 6%, and % time spent at $> 13.3 \text{ mmol}\cdot\text{L}^{-1}$ from 17 to 2%. The addition of insulin bolus at meal time, all glucose values were inside the range 3.9 – $13.3 \text{ mmol}\cdot\text{L}^{-1}$.

Figure 4. Scheme of human implantation of the Long-Term Sensor System (LTSS, Medtronic-MiniMed), a prototype of artificial pancreas. (Courtesy of Dr. Renard, Lapeyronie Hospital, Montpellier, France.)

Recently, the iPID system was evaluated in four elderly lean subjects with type 1 diabetes over 48 h (66). During the second 24 h control period following empirical tuning of the algorithm, 4 and 7% of time was spent $< 4.4 \text{ mmol}\cdot\text{L}^{-1}$ in the postprandial (0–2 h) and outside meal conditions, respectively, 12 and 32% was spent in the region $4.4\text{--}6.7 \text{ mmol}\cdot\text{L}^{-1}$, 63 and 60% was spent in the region $6.7\text{--}13.3 \text{ mmol}\cdot\text{L}^{-1}$, and 20 and 2% was spent $> 13.3 \text{ mmol}\cdot\text{L}^{-1}$.

CLINICAL STUDIES

Clinical studies performed with prototypes of an artificial pancreas in subjects with type 1 diabetes are summarized in Table 1. All experiments were performed in hospital environment. No prototype has yet been studied in home settings.

Table 1 excludes numerous experiments carried out with the Biostator as the invasiveness and the setup adopted by the device does not permit development into a routinely used system.

Numerous experiments have been carried out in pancreatectomized dogs especially in the early phases of prototype development. This includes the ePID system (48), but some approaches such as that adopted by the Adicol project, did not use testing on animal models, but adopted testing on a simulation environment (82).

INDICATIONS

Artificial pancreas has the potential to be used in various disease conditions. For subjects with type 1 diabetes, the system offers “cure” especially if implemented as a fully closed-loop iv–ip system. Realistically, first prototypes for home setting are expected to adopt the sc–sc route with meal announcement and thus participation of the subjects with type 1 diabetes in the disease management process is required. Fail-safe procedures are needed for such a setup.

An increasing proportion of subjects with type 2 diabetes is treated by insulin. It has been reported that nearly 50% of subjects with type 2 diabetes require insulin treatment at some stage of their disease. The artificial pancreas could provide a solution for a subgroup of subjects with type 2 diabetes, but this has to be justified by a cost-benefit analysis.

The sc–sc route may require a continuing close subject involvement in the disease management. This would restrict the treatment group to those well motivated, who generally have good glucose control. The greatest treatment benefit would be for those with poor glucose control, but other aspects, such as psychological factors might impair or even prevent the system deployment.

A recent study in adult critically ill subjects revealed that glucose control $< 6.1 \text{ mmol}\cdot\text{L}^{-1}$ is associated with reduced mortality by 43%, overall inhospital mortality by 34%, newly developed kidney failure requiring dialysis by 41%, bacteremia by 46%, the number of red blood cell transfusions by 50%, and critical illness polyneuropathy by 44% (83). Although still awaiting confirmation by another

prospective study, the results indicate that artificial pancreas for critically ill is likely to bring about major improvements in therapeutic outcomes. Whether these results apply to a broader category of inpatients be it a general ward or pediatric population is yet to be determined. It is also unclear what is the most appropriate setup of a “hospital-based” artificial pancreas.

COST

The cost of the artificial pancreas can only be inferred from the cost of existing technology. The cost of the Biostator was $\sim \$70,000$ prohibiting its wider use.

Insulin pumps cost from \$5,000 to 6,000. The monthly cost of pump treatment is $\sim \$100$. The CGMS monitor costs $\sim \$4,000$ and the single-use 3 day sensors cost \$50 each. It is likely that the sc–sc artificial pancreas will be at least as expensive as the combined cost of the insulin pump and the glucose monitor.

The cost needs to be set against the total cost of diabetes which, in developed countries such as in the United States or the United Kingdom, is 10% of the total health care budget (84). Most of the direct expenditure is on treating diabetes complications, which could be delayed or prevented with tight glucose control.

OUTLOOK

Present technology has made considerable advances toward a truly personal wearable treatment system. The lack of availability of a glucose monitor with adequate properties appears to hinder further progress and the development of a commercially viable system. The algorithms need to be improved and subjected to rigorous clinical testing.

With regard to the existing glucose monitors, it is possible that their potential has not been fully exploited. The regulatory-driven research and development to achieve an equivalence between finger-prick glucose measurements and values provided by continuous glucose monitors in the interstitial fluid hinders the engagement of the industry and the academia in the development and testing of closed-loop systems.

In the first instance, the artificial pancreas is most likely to find its wider use in the supervised hospital environment, such as at the intensive care units. The application in home settings will most likely be gradual starting with a supervised system (by the treated subjects) and increasing its autonomous function following on from wider experience.

The regulatory bodies will play an important role in the introduction of the artificial pancreas into the clinical practice. Until recently, the perception of closed-loop systems was not overly positive by the regulatory authorities. Artificial pancreas with its potential to “cure” diabetes, but also to lead to life-threatening complications, if malfunctioned, will have to pave the way to a new generation of closed-loop home-based biomedical devices if it is ever to succeed.

INTRODUCTION

The primary task of the peripheral vasculature (PV) is to supply the organs and extremities with blood, which delivers oxygen and nutrients, and to remove metabolic waste products. In addition, peripheral perfusion provides the basis of local immune response, such as wound healing and inflammation, and furthermore plays an important role in the regulation of body temperature. To adequately serve its many purposes, blood flow in the PV needs to be under constant tight regulation, both on a systemic level through nervous and hormonal control, as well as by local factors, such as metabolic tissue demand and hydrodynamic parameters. As a matter of fact, the body does not retain sufficient blood volume to fill the entire vascular space, and only ~ 25% of the capillary bed is in use during resting state. The importance of microvascular control is clearly illustrated by the disastrous effects of uncontrolled blood pooling in the extremities, such as occurring during certain types of shock.

Peripheral vascular disease (PVD) is the general name for a host of pathologic conditions of disturbed PV function.

Peripheral vascular disease includes occlusive diseases of the arteries and the veins. An example is peripheral arterial occlusive disease (PAOD), which is the result of a buildup of plaque on the inside of the arterial walls, inhibiting proper blood supply to the organs. Symptoms include pain and cramping in extremities, as well as fatigue; ultimately, PAOD threatens limb vitality. The PAOD is often indicative of atherosclerosis of the heart and brain, and is therefore associated with an increased risk of myocardial infarction or cerebrovascular accident (stroke).

Venous occlusive disease is the forming of blood clots in the veins, usually in the legs. Clots pose a risk of breaking free and traveling toward the lungs, where they can cause pulmonary embolism. In the legs, thromboses interfere with the functioning of the venous valves, causing blood pooling in the leg (postthrombotic syndrome) that leads to swelling and pain.

Other causes of disturbances in peripheral perfusion include pathologies of the autoregulation of the microvasculature, such as in Reynaud's disease or as a result of diabetes.

To monitor vascular function, and to diagnose and monitor PVD, it is important to be able to measure and evaluate basic vascular parameters, such as arterial and venous blood flow, arterial blood pressure, and vascular compliance.

Many peripheral vascular parameters can be assessed with invasive or minimally invasive procedures. Examples are the use of arterial catheters for blood pressure monitoring and the use of contrast agents in vascular X ray imaging for the detection of blood clots. Although they are sensitive and accurate, invasive methods tend to be more cumbersome to use, and they generally bear a greater risk of adverse effects compared to noninvasive techniques. These factors, in combination with their usually higher cost, limit the use of invasive techniques as screening tools. Another drawback is their restricted use in clinical research because of ethical considerations. Although many of the drawbacks of invasive techniques are overcome by noninvasive methods, the latter typically are more challenging because they are indirect measures, that is, they rely on external measurements to deduce internal physiologic parameters. Noninvasive techniques often make use of physical and physiologic models, and one has to be mindful of imperfections in the measurements and the models, and their impact on the accuracy of results. Noninvasive methods therefore require careful validation and comparison to accepted, direct measures, which is the reason why these methods typically undergo long development cycles.

Even though the genesis of many noninvasive techniques reaches back as far as the late nineteenth century, it was the technological advances of the second half of the twentieth century in such fields as micromechanics, microelectronics, and computing technology that led to the development of practical implementations. The field of noninvasive vascular measurements has undergone a developmental explosion over the last two decades, and it is still very much a field of ongoing research and development.

This article describes the most important and most frequently used methods for noninvasive assessment of

the PV; with the exception of ultrasound techniques, these are not imaging-based modalities. The first part of this article, gives a background and introduction for each of these measuring techniques, followed by a technical description of the underlying measuring principles and technical implementation. Each section closes with examples of clinical applications and commercially available systems. The second part of the article briefly discusses applications of modern imaging methods in cardiovascular evaluation. Even though some of these methods are not strictly noninvasive because they require use of radioactive markers or contrast agents, the description is meant to provide the reader with a perspective of methods that are currently available or under development.

NONIMAGING METHODS

Arterial Blood Pressure Measurement
