

Figure 19. Example of a PIV particle image.

Similar to the multigrid method, the iterative method uses the obtained displacement from the first cross correlation to offset the second window for the next cross correlation. The difference is that it does not break down the interrogation areas into smaller windows, which is repeated until the difference between the displacements from successive cross correlations is less than one pixel. If the window B is shifted by the converged displacement, windows A and B should be virtually the same, as long as the gradient is sufficiently low. Iterative cross correlation is another way to increase accuracy.

A minimum number of particle pairs (on the order of 10) are required in PIV processing. The particle density in the flow will determine the minimum size subregion that can be used to obtain adequate vector maps. Thus, the spatial resolution is governed by the particle density. Near solid surfaces, the particle density is often lower in flows with strong wall gradients. Reducing the interrogation window size increases spatial resolution. However, an overly small window causes in-plane particle loss due to particles moving out of the interrogation spot. Several techniques exist to capture the particles moving out of the window without enlarging the interrogation spot. The first is simply to enlarge the second window to cover the expected displaced particle. The original interrogation window (frame A) is enlarged to the same size as window B and zero-padded at the extended part. The second technique is to offset the second window to the location of anticipated displacement.

Errors in PIV processing can occur from several sources. The spatial resolution for a velocity vector is the dimension of the interrogation volume. If the particles are evenly distributed, the center of an interrogation volume can be used as the vector location. The accuracy of the 'displacement depends on both the subpixel accuracy of the peak finding algorithm and the image quality. A one-tenth pixel is the most accurate (66). Time resolution for the velocity is the separation time between two pulses, as the information during this period is not recorded. The velocity error is composed of systematic and residual error. Systematic errors come from the algorithm and experiment setting or image quality, which can be minimized and uncertainty in the time separation. Residual errors are inherent in the processing, such as errors due to the peak finding algorithm. The residual errors are usually not a function of Δt . Therefore, a too small separation time increases the velocity error as this error is proportional to $1/\Delta t$.

The following discussion is relevant to the effect of image quality on PIV accuracy. Large particle images can result in wide cross-correlation peaks, which can reduce the accuracy of the peak finding algorithm. In addition, large particles require larger interrogation spots to contain an appropriate number of particles, which leads to a reduction in spatial resolution. Particle images smaller than 2 pixels in diameter, or particle displacements that are less than 2 pixels, can introduce a displacement bias, called "peak locking." The displacement peaks tend to be biased toward integer values. Peak locking presents itself as a "staircased" velocity pattern, in a region with a velocity gradient where the velocity distribution should be smooth. The calculation of spatial derivatives of this vector map then produces a mosaic pattern in the gradient map.

Figure 20 illustrates these patterns. Techniques, such as multigrid or continuous window-shifting or iterative image deformation, have been proposed to overcome peak locking. Image preconditioning, such as filtering, or defocusing can optimize the image diameter. The resolution of the CCD sensor, therefore, also limits the use of smaller particles to increase the velocity resolution.

The methods developed to increase displacement accuracy rely on the assumption of low displacement gradient. High gradient tends to bias the displacement toward low values because the particles with smaller displacements are more likely to remain in the interrogation volume longer than those with higher displacements. This bias can be minimized by reducing the size of the interrogation volume and separation time. For high distortion of the particle pattern in a high gradient spot, the centroid peak finding algorithm is more suitable than the Gaussian. However, PTV, as it follows an individual particle, is not affected by high gradient. Several research groups use the displacement results from PIV to guide the local search areas for PTV in a coupled PIV/PTV processing algorithm. These coupled techniques relieve the gradient limit in PIV and increases resolution of both velocity vectors and velocity fields.

The motion across the light sheet in highly 3D flows can bias the local velocity estimation due to perspective projection, if the particle has not left the light sheet. The effect of perspective projection velocity bias, illustrated in Fig. 21 (68), is usually more severe at the edges of the image, where the projection angle increases. At high image magnification, the focal length becomes shorter and the projection angle increases, which worsens the perspective projection. Strong perspective projection could vary the magnification factor through the image plane resulting in an image distortion.

In general, the light sheet thickness is smaller than the depth of focus, δ_z . The light sheet thickness, therefore, determines the thickness of the effective interrogation volume: All illuminated particles are well focused. Most commercial systems using standard-grade Yag lasers with appropriate optics can generate light sheets that have a thickness on the order of 100–200 μm , although light sheets can be as thick as a 1 mm. In high magnification imaging, the depth of focus can become smaller than the light sheet thickness. The thickness of the effective interrogation volume is then constrained to the depth of focus. In this case, particles located beyond the focal plane but within the illuminated plane are out-of-focus and appear as highly nonuniform background image noise and can affect the cross correlation. In addition, the thickness of the effective interrogation volume determines the tolerance to out-of-plane motion. A smaller effective volume thickness increases the probability for out-of-plane particle loss. In general, the estimated maximum out-of-plane motion should be less than one-fourth of the effective volume thickness.

Data validation is another source of uncertainty in PIV. Bad velocity vectors will ultimately appear within a vector map due to noise in the displacement estimation. Several filtering algorithms have been developed to remove these bad vectors. These filter routines operate on thresholding velocity at a particular location and use either the

Figure 20. (a) Staircased pattern in a velocity profile at a wall. (b) Gradient field calculation (bottom image) of a measured velocity field (top image) showing mosaic pattern (68).

magnitude of the velocity estimate, the mean, the median or the rms within a predefined subregion, or other more complicated thresholds to low pass filter the estimates. Improper application of a validation scheme can overfilter

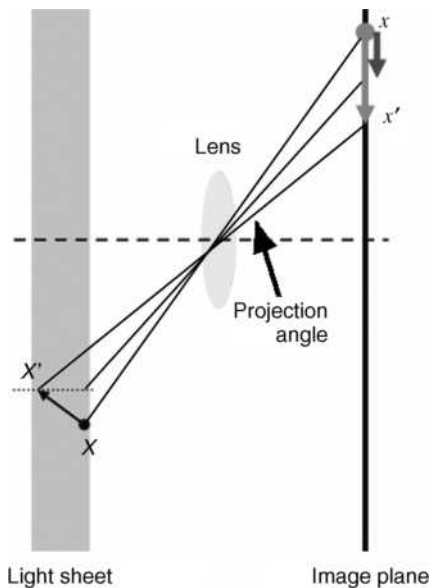

Figure 21. Illustration of the perspective projection; the red arrow is the vector obtained from perspective projection, the blue is the correct projection of displacement vector on the XY plane (68).

the velocity map and throw away good data. For example, rms validation techniques should be carefully used in turbulent shear layers where high rms values are normally encountered. It is possible to inadvertently filter good instantaneous turbulent velocity ensembles with a tight rms filter setting. In general, some knowledge of the flow under study is needed to accurately perform vector validation.

Commercial PIV systems can be two-component or three-component, planar or volume systems. A two-component, planar PIV system provides information on two components of the velocity vector. In two-component PIV, the measured displacement vector is the projection of the three-component velocity vector on the 2D plane of the light sheet. Flow information for highly three-component flows can be inaccurately represented by planar PIV images. Stereographic and holographic PIV systems have been developed for three-component measurement in a plane or volume, respectively. Although the instantaneous velocity field obtained by PIV has an advantage over LDV (or Doppler), two-exposure PIV only provides information on the particle motion during the two exposures and also suffers from poor temporal frequency response in the measurement of adjacent vector maps in time. Particle acceleration cannot be measured by direct two-exposure PIV. Four-exposure systems have been developed to permit calculation of the particle acceleration by Hassan and Phillip (73) and Lui and Katz (74), although the temporal resolution for the acceleration is not yet comparable with that of LDV.

INTRODUCTION

Following the absorption of light, fluorescent compounds release light at a less energetic wavelength. This phenomenon can be used to detect the presence of many compounds with exceedingly high sensitivity and selectivity.

The objective of this article is to acquaint the reader with the basic principles of fluorescence spectroscopy. For a more detailed analysis of this area, several reviews exist (1–5) that should be useful to readers with different levels of sophistication.

Most readers are probably familiar with the basic phenomenon involved in fluorescence measurements. For example, when certain minerals are irradiated with ultraviolet light, light in the visible region of the electromagnetic spectrum is released. In this case, absorption of high energy ultraviolet (UV) light excites electrons to leave their lowest energy state (the ground state); upon return to the ground state, energy is emitted as either light or heat. The energy emitted during fluorescence must be of a lower energy than the light that initially excited a compound and, hence, high energy ultraviolet light is emitted from a mineral as lower energy visible light.

When one deals with biological samples, one is always confronted with the problem of detecting extraordinarily small amounts of a compound mixed in an array of other compounds. As this article will show, fluorescence analysis provides a rather simple means to detect the existence of a compound within a complex mixture. For obvious

reasons, the ability of fluorescence spectroscopy to detect exceptionally small amounts of a compound in biological specimens has many applications of biomedical interest.

The analytical power of fluorescence measurements may be appreciated by consideration of the two following practical analogies. The sensitivity of fluorescence measurements is similar to the increased sensitivity with which one could measure the light output of a flashlight in a completely darkened room versus a sunlit room. In the case of the sunlit room, the light output of the flashlight would represent < 1% of the total light in the room; indeed, it would be difficult for an observer in a sunlit room to detect whether the flashlight was on or off. In contrast, in a darkened room, an observer would readily be able to sense whether a flashlight was turned on. In fluorescence measurements, light strikes a sensor only if the compound of interest is present and, thus, as in the case of the darkened room, the sensitivity of the fluorescence measurements is quite high.

The ability of fluorescence measurements to detect particular compounds in complex mixtures is due to the fact that several conditions must be met before a fluorescence signal is detected. Just as the location of a person would be precisely defined if one knew their street address, which consists of a city, state, street name, and house address, the selective ability of fluorescence measurements to detect the presence of only desired compounds arises from the fact that a compound will fluoresce only under a series of quite restrictive conditions. In the case of fluorescence spectroscopy, one observes light emanating from a compound if and only if the following conditions are met: (a) the compound must absorb light; (b) the compound must be capable of emitting light following excitation (the compound must be fluorescent); (c) the compound must be irradiated at a particular excitation wavelength; (d) a detector must be set to sense light at a different, less energetic emission wavelength; (e) a discrete time (in nanoseconds) must elapse between the time of excitation and emission; and (f) other conditions, such as type of solvent and pH, must be satisfactory. As a street address defines the location of a person, the parameters involved in the fluorescence of a compound can be used to determine the presence or absence of just a single compound. For example, the presence of the compound, fluorescein, can be accurately detected in a biological specimen because (a) fluorescein is a fluorescent compound; (b) fluorescein is excited to fluoresce only at wavelengths near 488 nm (nanometer) in aqueous solvents in the neutral to alkaline range; and (c) following excitation, fluorescein gives off light maximally at 514 nm (see Fig. 1). Hence, since only a very few compounds have fluorescence properties similar to that of fluorescein, selecting light with a wavelength of 488 nm to irradiate the sample and setting a detector to only respond to light with a 514 nm wavelength allows one to detect fluorescein in a complex mixture.

In addition to an overview of the theory involved in this area, a brief introduction into the instrumentation involved in fluorescence determinations will be presented. While there are numerous applications of fluorescence that are outside of the scope of this article (1–5), a few specific examples of the use of fluorescence measurements in biomedical studies will be presented and technical problems in interpretation of fluorescence data will be pointed out.

Figure 1. Excitation and emission spectra of the fluorescent compound, fluorescein. As described in the text, excitation and emission maxima are determined empirically and, then, spectra are obtained for the excitation and emission of fluorescein. Excitation of fluorescein at any wavelength in the excitation spectrum will produce emission at all wavelengths in the emission spectrum, with the exception of wavelengths of higher energy. Thus, fluorescence involves the conversion of high energy photons into photons of lower energy plus heat.

THEORY AND INSTRUMENTATION

After absorption of light energy, all compounds release some energy as heat; fluorescent compounds represent a special case in which some energy is also given off as light. Spectrofluorimeters are optical devices that measure the amount of light emitted by fluorescent compounds.

Spectrofluorimeters

While a complete description of the theory of fluorescence is quite involved (see Ref. 3, for a review), one can grasp the basic principles of the phenomenon from the following examples. If one were to aim a flashlight at a mirror, one would find that light would reflect off the surface of the mirror; in contrast, if one were to direct a flashlight beam at a black wall, one would see no light reflected from the wall. In this example, molecules in the black wall stop the transmission of light by absorbing the energy of the light and then converting the energy of light into heat energy. (Very precise measurements would reveal that the black wall was slightly warmer at the site at which the light beam struck it.) In the case of fluorescent compounds, light absorbed by a compound is converted into light (of a lower energy) as well as heat. The brighter the light that strikes a fluorescent compound, the stronger the fluorescent light emitted by the compound. The particular wavelength absorbed by a compound and the wavelength that is later emitted are characteristics of each fluorescent compound (Fig. 1).

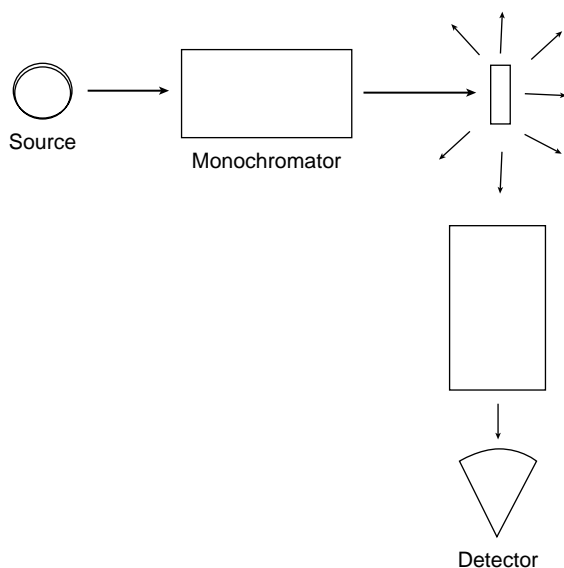

Figure 2. Design of a typical spectrofluorimeter. As described in the text, a desired wavelength is selected with the aid of a monochromator and is used to irradiate a sample (large arrows); light emitted by the fluorescent sample is released in all directions (small arrows). The detector is positioned at a right angle with respect to the excitation beam in order to avoid light from the exciting beam entering the detector.

While light reflection from a mirror occurs at an angle determined by the angle of the incident light, light emission by a fluorescent compound occurs in all directions. For example, if one observed a beam of light striking a mirror in a smoke filled room, one would see a beam of light reflected at a unique angle from the mirror. In contrast, if one observed a beam of light striking a solution of fluorescent compound, one would see the emitted light appear as if it originated from a glowing sphere (and, compared to the original beam of light, the emitted light would have a color that was shifted toward the red end of the spectrum, i.e., lower energy).

The above features of fluorescence dictate the design of instruments used in the measurement of fluorescence (see Fig. 2). First, an intense beam of light is passed through a filter (or monochromator) that permits only light of a desired band of wavelengths to proceed toward the sample. As indicated in Fig. 2, light not absorbed by the sample passes straight through the sample without change in angle while the light emitted by the fluorescent sample is released in all directions. By positioning the detector at a 90° angle with respect to the exciting beam, instrument designers can minimize the amount of stray light from the exciting beam that reaches the detector. As indicated above, the light emitted by the fluorescent sample is given off in all directions and, thus, the positioning of the detector with respect to the exciting beam does not affect the relative amount of the emitted fluorescent light received by the detector. Hence, as we have shown above, the design of a fluorimeter is predicated upon maximizing the signal/noise ratio.

The sensitivity of fluorescence measurements is inherent in the design of instruments used to make such measurements. Since only light that is emitted from a fluorescent compound reaches the detector, the sensitivity

of the measurement is equivalent to our analogy of measuring the light from a flashlight in a darkened room. The ability to selectively measure the presence of a given compound is determined by the appropriate selection of filters (or settings on monochromators) used to make the measurement. In contrast, analytical measurements based on absorption are inherently less sensitive (due to signal/noise problems).

Fluorescence Microscopy

The design of a fluorescence microscope is based on the same principles used in the construction of a spectrofluorimeter. In the technique of reflected fluorescence microscopy, light of a desired wavelength is used to irradiate a sample and, then, a dichroic mirror is used to separate light emitted by the fluorescent compounds in the sample from light in the original exciting beam (Fig. 3). A dichroic mirror is an optical device that reflects light of certain

Figure 3. Fluorescence microscope design. A fluorescence microscope employs optical components that allow one to irradiate a specimen at one wave length and then observe the fluorescence of a microscopic object at a second wavelength. The excitation beam (dashed line) is directed toward the specimen by the dichroic mirror and objective lens. Due to the fact that light emitted by a fluorescent object is released in all directions, one can observe the fluorescence of the specimen with the same objective lens that was used to irradiate the specimen. The emitted light (dotted line) is collected by the objective, passes through the dichroic mirror, and is observed via the eyepiece.

desired wavelengths and transmits light of other wavelengths.

Fluorescence microscopes can be used to detect fluorescence compounds in exceedingly small specimens. Via the technique of immunofluorescence, one can visualize the distribution of virtually any biological compound in living or fixed tissues by using antibodies tagged with fluorescent compounds.

PRACTICAL APPLICATIONS

The high sensitivity and selectivity of fluorescence methods permits the detection of exceedingly low amounts of many compounds of biological and biomedical interest.

In the preceding section, the basic methods that are used to detect fluorescent compounds were described. In the following section, the criteria that are used in establishing the presence or absence of particular chemical species are presented.

Detection of Fluorescent Compounds

It should be pointed out initially that only a small percentage of the known compounds are fluorescent. Thus, while most compounds cannot be studied by fluorescence techniques, the mere fact that an unknown compound is fluorescent can be used as a diagnostic means to positively identify it. In a following section, literature references are provided that list many fluorescent compounds and their properties (6,7).

Once it is established that a sample contains a fluorescent compound, one can use several criteria to establish the identity of the unknown compound. First, by trial-and-error, one establishes the wavelength(s) at which the compound is maximally stimulated to fluoresce (the excitation maxima). Second, again by trial-and-error, one determines the wavelength(s) at which the emission of light is highest (the emission maxima). Fluorescence emission spectra are then generated by holding the excitation monochromator at the excitation maximum wavelength and recording the intensity of light released from the sample as the wavelength of the emission monochromator is varied (Fig. 2). In this manner, a spectrum is produced that (a) describes the wavelengths at which a compound emits light and (b) establishes the relative efficiency with which light of different wavelengths is emitted (Fig. 1). The shape of the emission spectrum and the number of major and minor peaks are characteristics of each compound and are important parameters in establishing the identity of an unknown compound. The excitation spectrum, when appropriately corrected, is often identical to the absorption spectrum of the fluorescent compound. (In a similar fashion, the fluorescence excitation spectra are established by holding the emission monochromator at the emission maximum and varying the settings of the excitation monochromator.)

Strong evidence for the identity of an unknown compound is provided by (a) the establishment that a compound is fluorescent and (b) the shapes of the excitation and emission spectra. In addition, one could use other parameters involved in fluorescence to characterize a com-

pound, namely, (a) the fluorescent lifetime of a compound, (b) the quantum yield, and (c) the perturbation of fluorescence by various solvents. It is possible that two compounds could have identical excitation and emission spectra just as it is possible that two individuals could have the same blood groups. Other analytical methods may be required to establish the identity of a compound with certitude. If the sample under study is quite impure, it is possible to use high performance liquid chromatography (HPLC) in conjunction with a fluorescence detector to gain yet another parameter that is characteristic of a compound, namely, its elution time from a particular HPLC column. The nature of the sample and the reasons for interest in it will determine the rigor required in its characterization.

Biomedical Applications

As described above, fluorescence methods provide means to identify compounds in complex mixtures. The sensitivity of fluorescence methods coupled with their inherent selectivity provide valuable means for biomedical analysis; several examples are described below.

Identification of Compounds in Biological Samples. If a compound of interest proves to be fluorescent, several analytical methods for the detection and quantitation of this compound immediately become available. Many drugs and biological compounds can be detected by fluorescence analysis (6,7). Fluorescence can be used to identify these and many other biologically active compounds in complex pathological specimens.

Due to the sensitivity of fluorescence methods to detect compounds at the level of one part per billion, such methods can be used to determine the presence of environmental pollutants with great sensitivity. The presence of specific pesticides and potentially carcinogenic aromatic hydrocarbons from cigarette smoke can be easily detected. Leakage of industrial wastes into the environment can be proven by placing fluorescent compounds into waste containers and later detecting the fluorescent compound in streams and lakes.

Fluorescence spectra of many chemicals and pharmaceuticals have been obtained under well controlled conditions and are published as the Sadtler Standard Fluorescence Spectra (6). Passwater (7) published a three volume series that presents literature citations for the fluorescence properties of a wide variety of compounds.

Fluorescence Microscopy. Following staining with fluorescent dyes, the use of fluorescence at the microscopic level can be used to determine the sex of an individual from single hair follicle cells, teeth, or from blood smears (8). Sex determination is based upon the fact that male cells have a highly condensed Y chromosome that appears as an intense fluorescent spot in the nucleus of each male cell. Fluorescent dyes have found many applications in the biomedical sciences (1,5).

Immunofluorescence. Antibodies can be prepared that specifically recognize a wide variety of molecules and microbial organisms. By labeling such antibodies with fluorescein or other fluorescent probes, one can visualize

the presence of antigens at the subcellular level; this approach has been widely used in molecular biology (9). In addition, one can visualize specific molecules and organisms in pathological specimens. The identification of disease causing microorganisms in pathological specimens by immunofluorescence (10) can be used. Immunofluorescence microscopy can also be employed in the identification of bacteria in food products (11).

Fluorescence Imaging. In addition to localizing molecules in histological sections, fluorescence has found numerous novel applications in cell biology. The availability of highly sensitive optical detection systems has permitted the localization of specific molecules in living cells. By tagging recombinant proteins with the green fluorescent protein (GFP) of jellyfish origin, one can track the expression and translocation of specific proteins in living cells during hormonal responses (12). The rate at which molecules move within living cells can be determined by fluorescence recovery after photobleaching (FRAP), which involves the photobleaching of molecules in a small region of a cell and then monitoring of the recovery of fluorescence with time as unbleached molecules return to the bleached area (13). Fluorescence energy transfer and fluorescence polarization methods (14–16) can also be used to study the interaction of molecules within living cells (15,16).

Fluorescence Polarization. Fluorescence polarization is perhaps the only method in biology that is directly attributable to Albert Einstein. The principle of fluorescence polarization involves the fact that emission of a photon is delayed by a few nanoseconds following absorption of light. During the delay in emission of light, Brownian motion will result in the movement of a molecule and smaller molecules will move more than larger molecules. Thus, molecules excited by polarized light will emit progressively depolarized light as the size of the molecule increases. Hence, if a small fluorescent molecule binds to a large nonfluorescent molecule, the light emitted by the bound small fluorescent molecule will become more polarized. Thus, the method of fluorescence polarization permits one to measure the binding of ligands to large molecules in real time (14).

Forster Resonance Energy Transfer (FRET). This method involves the transfer of energy from a fluorophore, which absorbs light to a second molecule that emits light at a different wavelength. Since the efficiency of FRET depends on the distance between the absorbing and emitting molecules, FRET permits one to obtain information about the distance between two molecules. Thus, if the molecule that absorbs light binds to a molecule that emits light via FRET, one can measure the binding event via release of light.

Molecular Biology Applications of Fluorescence. The high sensitivity of Fluorescence has been used as the basis of several important methods in molecular biology. For example, real-time polymerase chain reaction (PCR) methods can be used to quantify the amount of a specific ribonucleic acid (RNA) species in a small sample of cells. In this method, fluorescence energy transfer is used to detect the increase in PCR product with time (16).

The jellyfish green fluorescent protein (GFP) has become an important tool in molecular biology because it is fluorescent without the necessity of binding or reacting with a second molecule. Mutant GFP and GFP-like molecules from various species have been described (17) that emit light at a variety of wavelengths. Thus, one can engineer the sequence of the GFP into a recombinant protein and have a fluorescently tagged protein (12). In contrast, the firefly luciferase protein must react with ATP and luciferin in order to release a photon (18).

The high sensitivity and specificity of fluorescence should find many new applications in the future.

GLOSSARY

Dichroic Mirror. An optical device that reflects light of a desired band of wavelengths yet permits the transmission of light of another band of wavelengths. Dichroic mirrors are used in fluorescence microscopes to separate the light that excites a sample from the light emitted from the sample.

Emission (Fluorescent). The release of light by a compound that follows the absorption of a photon.

Emission Wavelengths. Following absorption of light at a wavelength capable of inducing fluorescence, light is released by the compound at less energetic wavelengths, termed the emission wavelengths (Fig. 1).

Excitation (Fluorescent). Following the absorption of a photon, one or more electrons of a fluorescent compound are promoted to a more energetic, “excited” state of the compound.

Excitation Wavelengths. While light can be absorbed by fluorescent compounds at many wavelengths, only certain wavelengths, termed excitation wavelengths, are capable of inducing fluorescent emission of light. The wavelengths are often the same as those absorbed by the compound of interest.

Filter (Optical). Generally a colored piece of glass that transmits only certain wavelengths of light. Interference filters reflect light that is not transmitted while color glass filters absorb light and convert the absorbed energy into heat.

Fluorescence. The emission of light by certain compounds that is induced by the absorption of light at a more energetic wavelength.

Fluorescent Lifetime. The amount of time, generally in nanoseconds, that expires between the absorption of a photon and the emission of a photon.

Monochromator. An optical device that is used (a) to separate light into its component wavelengths and, then, (b) to isolate a desired group of wavelengths. Such devices employ either a prism or a diffraction grating.

Nanosecond. $0.000000001 \text{ s} = 10^{-9} \text{ s}$. (There are 1000 million ns in 1 s).

Quantum Yield. The percentage of excited compounds that release a photon of light during their return to the ground state. In most cases, the absorption of light by a compound is followed by the liberation of heat, rather than light.

Spectrofluorimeter. An optical device that is used to measure the amount of light that is emitted by fluorescent compounds.

INTRODUCTION

Functional electrical stimulation (FES) is a rehabilitative technique where low level electrical voltages and currents are applied to an individual in order to improve or restore function lost to injury or disease. In its broadest definition, FES includes electrical stimulation technologies that, for example, are aimed at restoration of a sense of hearing for the deaf, vision for the blind, or suppression of seizures in epilepsy or tremors for people with Parkinson's disease. Most FES devices and systems are known then as “neuroprostheses” because through electrical stimulation they artificially modulate the excitability of neural tissue in order to restore function. While sometimes used synonymously with FES, the term functional neuromuscular stimulation (FNS) is most commonly used to describe only those FES technologies that are applied to the neuromuscular system in order to improve quality of life for people disabled by stroke, spinal cord injury, or other neurological conditions that result in impaired motor function (e.g., the abilities to move or breathe). Another technology closely related to FES is that of therapeutic electrical stimulation (TES), wherein electrical stimulation is applied to provide healing or recovery of tissues (e.g., muscle conditioning and strengthening, wound healing). As will be seen, some FES and FNS technologies concurrently provide or rely upon such therapeutic effects in order to successfully restore lost function. For illustrative purposes, much of this article is centered on FNS and related TES devices and technologies. For a wider exposure to additional FES approaches and neural prosthetic devices, the reader is referred to this article's *Reading List*, which contains references to a number of general books, journal articles, and on-line resources.

An important consideration in most all FNS technologies is that significant neural tissue remains intact and functional below the level of injury or disease so that electrical stimulation can be applied effectively. Individuals exhibiting hemiplegia (i.e., paralysis on one side of the body) due to stroke, for example, will exhibit paralysis in an impaired limb due to loss of control from the central nervous system (CNS), not because the peripheral nervous system (PNS) innervation of skeletal muscles in the limb has been lost. Similarly, while spinal cord injury (SCI) destroys motor neurons at the level of injury either partially or completely, many motor neurons below the level of injury may be spared and remain intact. Therefore, in stroke or SCI the axons of these intact motor neurons can be artificially excited by introducing an appropriate

electrical field into the body using electrodes located on the skin surface, or implanted within the body. Artificial excitation of motor nerves by electrical excitation can generate action potentials (propagating excitation waves) along axons that, when they arrive at synaptic motor-endplate connections to skeletal muscle fibers, act to generate muscle force much as the intact nervous system would. Thus, lower extremity FNS systems often have the objective of restoring or improving mobility for stroke or SCI individuals. Upper extremity FNS systems often are designed to restore or augment reaching and grasping movements for SCI subjects. Both FNS and TES technologies are of course not a cure for stroke, spinal cord injury or diseases (e.g., cerebral palsy or multiple sclerosis where FNS also has been used). They are also not universally beneficial, and must be carefully matched by a clinician to an individual and their medical condition (1). On the other hand, as will be seen in the remainder of this article, FES and TES systems can provide greatly improved quality of life for many people who use them.

THEORY AND APPLICATION

In 1961, Liberson and co-workers proposed the usage of electrical stimulation in what was called functional electrotherapy to restore or augment movement capability that has been lost or compromised due to injury or disease (2). Specifically, Liberson's group developed the first electrical stimulation system for correction of hemiplegic drop foot: a gait disability occurring in some stroke survivors (for an excellent review of the history of development of neural orthoses for the correction of drop foot see Ref. 3). Moe and Post subsequently coined the term functional electrical stimulation to describe such techniques (4).

Electrical stimulation devices and systems now have been developed to activate paralyzed muscles in human subjects for a variety of applications in both the research lab and the clinic. Both FES and FNS systems have seen their greatest use as a tool for long-term rehabilitation of persons with neurological disorders (e.g., spinal cord injury, head injury, stroke) (5–10). For example, implanted electrical stimulation devices have been developed that can restore hand-grasp function to people with tetraplegia (11). Stimulation devices that utilize percutaneous electrodes (thin wires that cross the skin) have been developed to provide individuals with thoracic-level spinal cord injury with the ability to stand and step (12–14). Other devices that utilize electrodes placed on the surface of the skin can restore standing and locomotor function to individuals with spinal cord injury or other neuromuscular disorders (6,8,15,16). One system that uses surface electrodes (Parastep, Sigmedics Inc.) is FDA approved for use by people with thoracic level spinal cord injury and has been used at several rehabilitation centers worldwide. These efforts have clearly demonstrated that neuromuscular stimulation can be effectively used to activate paralyzed muscles for performing motor activities of daily living.

The basis by which all neuromuscular stimulation systems function is artificial electrical activation of muscle force, usually through excitation of the nerve fibers that innervate the skeletal muscle(s) of interest.

Excitation, Recruitment, and Rate Modulation

The nerve fibers that innervate skeletal muscle fibers are myelinated in nature, which means that they are regularly along their lengths ensheathed within layers of Schwann-cell derived myelin separating exposed axonal membrane at nodes of Ranvier. Myelination enables increased propagation velocities via saltatory conduction in such nerve fibers. The cell bodies of these alpha motor neurons lie within the ventral horn of the spinal cord. The efferent axons of these cells ($\sim 9\text{--}20\ \mu\text{m}$ in diameter) pass out from the spinal cord via the ventral roots and project then to muscle fibers within peripheral nerve trunks. When spared during damage or disease of the nervous system, alpha motor neurons and their axons usually form the substrate of electrical activation of skeletal muscle force in FNS applications. This may come as something of a surprise to the reader, in that skeletal muscle cells are themselves also excitable. Why then is indirect stimulation of the innervating nerve fiber generally the mechanism by which force is generated rather than direct stimulation of the muscle cells themselves? The reason is that large myelinated nerve fibers are usually excited at lower stimulus amplitudes (voltage or current) and with shorter stimulus pulse widths than are skeletal muscle cells (assuming similar spatial separations of electrodes to cells) (17). Electrical stimulation of myelinated nerves to threshold occurs when a critical extracellular potential distribution is created along or near the cell. At threshold, outward transmembrane currents are sufficient to depolarize the nerve cell membrane voltage to the level where an action potential is generated.

In normal physiology, there exist two natural control mechanisms to regulate the force a single muscle produces—recruitment and rate coding. Motor units are recruited naturally according to the Size Principle (18,19). Small alpha motor neurons innervating slow motor units have a low synaptic threshold for activation, and therefore are recruited first. As more force is demanded by an activity, progressively larger alpha motor neurons that innervate fast motor units are recruited. The second method of natural force regulation is called rate coding. Within a given motor unit there is a range of firing frequencies. Alpha motor neurons innervating fast-twitch motor units have firing rates that are higher than those that innervate slow-twitch units (20,21). Within that range, the force generated by a motor unit increases with increasing firing frequency. If an action potential reaches a muscle fiber before it has completely relaxed from a previous impulse, then force summation occurs. Twitches generated by the slow motor units have a fusion frequency of 5–10 Hz and reach a tetanic state at 25–30 Hz. The fast motor units may achieve fusion at 80–100 Hz (21,22).

The contractile properties of the muscle are largely dependent on the composition of the skeletal muscle (i.e., the muscle fiber types). The composition of muscle fibers varies across species. The composition of muscle fibers in the hindlimbs of the rat are predominantly fast fibers (23) whereas, human skeletal muscle is composed of a heterogeneous collection of muscle fiber types (24). This is also indicated in the differences in fusion frequencies observed

Table 1. Skeletal Muscle Fiber Types and Their Characteristics

Skeletal Muscle Fiber Types and Characteristics			
Fiber type	Type I	Type IIa	Type IIb
Other names	Slow red Slow oxidative (SO) Slow (S)	Fast red Fast oxidative (FOG) Fast resistant (FR)	Fast white Fast glycolytic (FG) Fast fatigable (FF)
Motor unit size	Smallest	Moderate	Largest
Firing order	1	2	3
Stimulation threshold	Lowest	Moderate	Highest
Force production	Lowest	Moderate	Highest
Resistance to fatigue	Highest	Moderate	Lowest
Contraction time	Slowest	Fast	Fastest
Mitochondrial density	High	High	Low
Capillary density	Highest	Moderate	Lowest

in the two species. The fusion frequency for muscles in the human is 25 Hz (25) and those for the muscles in the rat are higher (~ 75 Hz) (26). As summarized in Table 1, from various mammalian studies, skeletal muscle fibers have been grouped into many different types according to physiological, ultrastructural, and metabolic properties. Based on histochemical measurements of adenosinetriphosphatase (ATPase) reactivities, muscles were classified into type I, type IIA, and type IIB (27). A differentiation based on combination of physiological and metabolic properties categorized muscle fibers as SO-, FOG-, FG- (28). Based on twitch speed and fatigue resistance, muscle fiber types were identified as S, FR, and FF (29). There is also an intermediate type of fast muscle fiber in certain muscles denoted type IIAB or FI (Fast Intermediate resistance to fatigue). The different muscle fiber types vary in the amount of force generated, speed of contraction, and fatigability. The slow fiber types (SO, Type I, S) generate lower force, but for a prolonged duration. They are very fatigue resistant. The fast fiber types (FG, IIB, and FF) are on the other end of the spectrum with greater force generating capacity, but briefer intervals of time. Also, these fatigue very quickly compared to slow fibers. Therefore, there is a trade off between the ability to produce force quickly and powerfully or slowly and steadily. Though slow fibers are able to generate a steady force for long periods of time, their force output is less. Fast fibers on the other hand can generate quicker, greater forces, but they fatigue very fast. Some fibers are classified in between the two extremes of slow and fast and are termed intermediate fibers. These are fast fibers, but with fatigue resistant capability (FOG, IIA, FR, IIAB, FI). The properties of these intermediate fibers lie between those of slow fibers and fast fibers. The force generated by these fibers is less than those generated by fast fibers and greater than the force produced by slow fibers.

The heterogeneity of muscle fibers within the muscle is in part due to the hierarchy of motor unit recruitment order (the Size Principle, described above) (30) indicating the influence of motor neuron activity upon muscle fiber phenotypes. The fiber-type composition within a muscle can be altered by altering the excitation patterns delivered to the muscle (induced by various exercise regimes). The best documented effects of such transformations are those that

occur after chronic, low frequency stimulation (CLFS) of a predominantly fast muscle using implanted electrode systems. The fast skeletal muscles of a number of mammalian species have been shown to change to the slower phenotype in response to chronic electrical stimulation (31–39). The muscle phenotype can be manipulated to enhance fatigue resistance at the expense of contractile power and speed (40–45). Changes in metabolic activity, and muscle mass have been documented too (38,46). These transformations are also dose dependent. A continuous stimulation of rabbit fast muscle at 10 Hz completely transform the muscle fibers to the slow phenotype, but lower frequencies of stimulation produce an intermediate state of conversion. However, stimulation at 2.5 Hz for 12 weeks (47,48) or 10 months (49) results in a whole muscle consisting mainly of the fast phenotype.

CLFS has been shown to affect human muscle in a manner similar to that in animals (50–57). Electrical stimulation has shown to increase strength–force and build fatigue resistance in muscles in both healthy and SCI individuals (56,58–63). An increase in passive range of motion has also been observed (64). Electrical stimulation has been shown to prevent the shift and loss of fibers in patients with paralyzed muscles thereby increasing fatigue resistance (60,65–67). A well-defined progression of changes is observed, whereby the muscle changes first its metabolic and then its contractile properties to become slow muscle (68). This has been documented in different species and muscles suggesting that probably the effects observed are not species or muscle specific. Following transformation, the new slow fibers are indistinguishable from normal slow skeletal muscle fibers. Also, from time series studies (69) and single fiber biochemistry (70,71) it is clear that the changes that occur result from transformation at the level of the single fiber and not from fast-fiber degeneration with subsequent slow-fiber regeneration.

From the above sections, it is clear that skeletal muscle is very adaptive, and therefore provides an opportunity for conditioning and therapy after an injury. Electrical stimulation based exercise has gained much significance in toning and conditioning muscles. Even though electrical stimulation techniques are being used increasingly for rehabilitation and therapy, note that in general electrical stimulation systems generate activation patterns and

Figure 1. Typical force recruitment curves obtained from the ankle dorsiflexor muscle (Tibialis anterioralis) of a rat through intramuscular stimulation. The recruitment curves indicate two techniques of force–torque modulation (a) pulse width modulation (PWM) and (b) pulse amplitude modulation (PAM). Single, symmetric, charge balanced, biphasic (cathodic first) pulses at an interval of 60 s were delivered. The currents were chosen as multiples of the twitch threshold current at 40 μ s.

recruitment characteristics quite different from the normal physiological mechanisms. With electrical stimulation, physiological muscle force regulation is controlled either by spatial summation or by temporal summation (72). Spatial summation (or electrical recruitment) is achieved by increasing the pulse width (Fig. 1a) and/or the pulse amplitude (Fig. 1b) of the electrical stimulus—extending the excitatory extracellular potential distribution further out from the stimulating electrode(s) to greater numbers of nerve fibers, and/or longer in time. Force recruitment curves are in general quite nonlinear. The isometric recruitment curve (IRC) of a muscle can be defined as the static gain relation between stimulus level and output force/torque when the muscle is held at a fixed length. The features of a typical IRC are an initial dead-zone region, a high slope, monotonically increasing region, and a saturation region (73,74). These features can be explained by recognizing that the slope of the IRC is primarily a function of the electrode–nerve interface. The shape is dictated by the location and size distributions of the individual motor unit axons within the nerve with large diameter axons having a lower stimulus activation threshold than small diameter axons. The IRC depends on the past history of muscle activation and location of the electrode relative to the motor point. The motor point functionally is defined as the location (on the skin surface, or for implanted electrodes on the muscle overlying its innervation) where stimulation thresholds are lowest for the desired motor response. There is a drop in the maximum magnitude and slope of the monotonic region of the IRC on muscle fatigue (73,75). The IRC is also influenced by the muscle length tension curve (76) and, if muscle force is estimated by measuring joint torque, by the muscle nonlinear moment arm as it crosses the joint. Because of these factors, the IRC shape will be different for each muscle and set of experimental configurations and will also vary between subjects.

Temporal summation (also called rate modulation) varies the stimulus frequency or the rate of action potential firing on the nerve fiber(s). When electrodes are located

closer to the motor point for stimulation, enhanced spatial selectivity can be achieved because the electric field introduced can be focused closer to the α motor neuron fibers of interest. Another aspect of recruitment selectivity is fiber diameter, which relates to the tendency to stimulate sub-populations of nerve fibers based on their size. In electrical stimulation of myelinated fibers, there will be a tendency to recruit large axons at small stimulus magnitudes and then smaller axons with increased stimulus levels unlike during normal physiological recruitment—this is often dubbed reverse recruitment (77–79). Such reversed recruitment of motor units will inappropriately utilize fast, more readily fatigued muscle fibers for low force tasks. Slower fatigue resistant muscle fibers will only be recruited at higher stimulus levels. This also results in an undesirable steep relation between force output and stimulus magnitude. After injuries causing paralysis and disuse of muscle, many fatigue resistant muscle fibers tend to shift their metabolism toward less oxidative and more anaerobic, more readily fatigued mechanisms. Electrical stimulation therapy in such instances will recruit the faster muscle fibers first thereby inducing fatigue at a very early stage in the therapy.

FES DEVICES AND SYSTEMS

As illustrated in Fig. 2, all modern FES and FNS devices and systems incorporate (1) surface or implanted electrodes to generate an excitatory electric field within the body, (2) a regulated-current or regulated-voltage output stage that delivers stimulus pulses to the electrodes, (3) the stimulator pulse conditioning circuitry that creates the desired pulse shape, amplitude, timing, and pulse delivery (often within trains of pulses at set frequencies and for intended intervals), and (4) an open- or closed-loop stimulator controller unit. Systems may be completely or partially implanted and often incorporate a microcontroller or computer interface. Smith and colleagues at the Cleveland FES Center, for example, have developed an externally

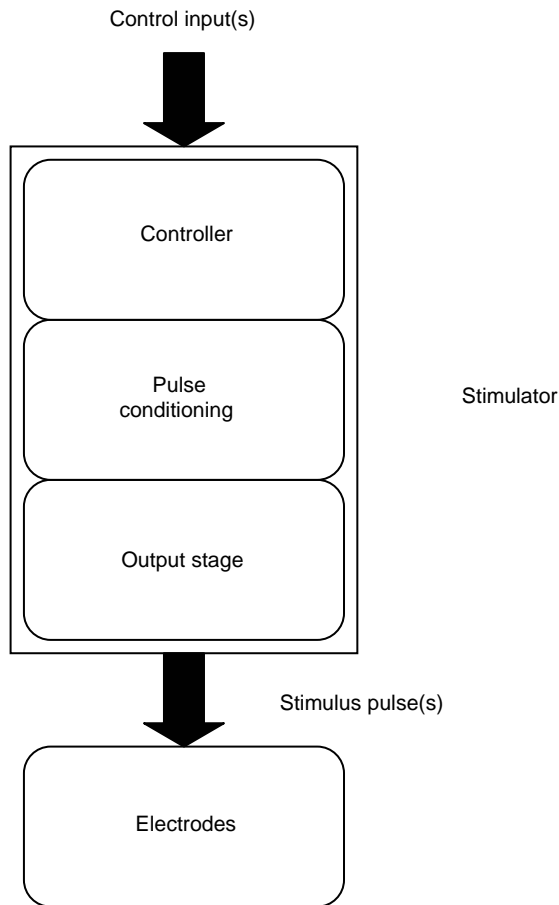

Figure 2. The FES systems typically incorporate control signals from the user that a Controller stage acts upon. Patterns of stimulation pulses are shaped with a pulse conditioning module that in turn feeds pulse information to an output stage that delivers regulated-current or regulated-voltage pulses of the desired amplitudes and timing to one or more channels of electrodes which are in contact with, or implanted within, the body.

powered, multichannel, implanted stimulator with telemetry for control of grasp and release functions in individuals with cervical level (C5 and C6) spinal cord injuries (80). Wu et al. designed a PC-based LabView controlled multichannel FES system with regulated-current or regulated-voltage arbitrary stimulation waveform pattern capability (81).

Commercialized FES systems include, for example, the Bioness, Inc. H200/Handmaster. This U.S. Food and Drug Administration (FDA) approved device incorporates microprocessor controlled surface stimulation into a portable, noninvasive hand-wrist orthosis for poststroke rehabilitation [see, e.g., (82)]. The FreeHand System, commercialized by NeuroControl Corporation in Cleveland, implements implanted receiver-stimulator, external controller, electrode, and sensor technologies (Fig. 3) developed through the Cleveland FES Center into a system for restoration of control of hand grasp and release for C5/C6 level spinal cord injured individuals. Compex Motion (Fig. 4), a programmable transcutaneous electrical stimulation product of Compex SA, is designed as a multipurpose FES system for incorporation into rehabilitation therapies (83). The Parastep System developed by Sigmedics, Inc. is designed

to enable independent, unbraced standing and walking for spinal cord injured people. Parastep is a noninvasive system that incorporates a battery-powered, microcomputer controlled stimulator unit (Fig. 5), surface electrodes, and a control and stability walker with finger activated control switches.

Electrode Designs for Electrical Stimulation

In the implementation of FES and FNS techniques, surface or implanted electrodes are used to create an excitatory electric field distribution within the targeted tissues. Researchers over the years have identified a number of important criteria for stimulation electrode selection and have developed a variety of electrode designs in order to meet specific application requirements (for an excellent recent review see Ref. 84).

Criteria for Electrode Selection. A few of the important factors identified for long-term applications are anatomical and surgical factors, mechanical and electrochemical characteristics, biocompatibility, long-term stability, and economics. Anatomical and surgical factors include ease of identification of stimulation site, either on the skin surface or through implantation. In the event of damage to the electrode, any implanted region should be easily accessible for retrieval and replacement. The mechanical properties of electrodes are important particularly with respect to implants whose lifetime is measured in years. Electrodes that are flexible, and consequently smaller in diameter, induce less trauma to muscles during movement. Instead of straight wires, coiled electrode wires provide for greater tension, and reduce the stress. The use of multistranded wires reduces breakage or provides redundancy if some wires should fail.

The electrical stability of the electrode is usually judged based upon reproducibility of muscle force recruitment curves. These depict some stimulation parameter (e.g., pulse width or current) against muscle force or torque output. As we have seen, the normal order of recruitment is generally reversed (larger motor units are activated before smaller ones). The threshold and the steepness of the curve are important properties that vary with electrode design, fiber size, and strength duration relations.

Another important criterion of consideration for choice of electrodes that are chronically implanted and tested over time is biocompatibility. The charge carriers in the electrode material (metal) are electrons unlike in our body wherein the charge carriers are ions. This results in a change of charge carriers when currents cross the metal-body interface. A capacitive double layer of charge arises at the metal-electrolyte interface; the single layer in the metal arises because of its connection to the battery, whereas that in the electrolyte is due to the attraction of ions in the electric field (85,86). These layers are separated by the molecular dimensions of the water molecule so the effective capacitance (being inversely proportional to charge separation) is quite high. At sufficiently low levels, the current will be primarily capacitive. But for high currents that exceed the capabilities of the capacitance channel, irreversible chemical reactions will take place

Functional electrical stimulation hand grasp system

Figure 3. (a) Diagram of components for the implanted stimulation system developed at the Cleveland FES Center and commercialized as the Freehand neuroprosthesis by NeuroControl Corp. In the hand-grasp example shown, shoulder position is transduced for use as the command input. (b) The external control unit (ECU) provides the transducer interface, user control algorithm, multichannel stimulus coordination, and power for the implanted receiver-stimulator system. (c) The implanted receiver-stimulator provides multiple channels of stimulus output via the leads seen in the figure. It also transmits implantable sensor data to the ECU, and is powered through an inductive link that forms a coreless bidirectional transformer. Intramuscular or epimysial electrodes implanted in the forearm or hand are attached to the stimulator leads (not shown). (Courtesy of the Cleveland FES Center.)

that are undesirable since they are detrimental to the tissue or electrode or both. Therefore, the electrode material must have little impact on the electrochemistry at the electrode–tissue interface. For biocompatibility and to avoid local tissue damage induced by high current levels, the electrode materials used are essentially inert (e.g., platinum, platinum–iridium, and 316LVM stainless steel).

The above mentioned criteria for electrode selection are a general guideline for either skin surface or chronically implanted electrode systems. However, the choice of electrode is also application dependent. For example, during stimulation of the brain, of particular concern is prevention of breakdown of the blood–brain barrier. For nerve stimulation circular (82) electrodes can be placed within an insulating cuff; consequently, smaller amounts of current are required because the field is greatly confined. Also, lower current tends to minimize unwanted excitation of surrounding tissue. Finally, intramuscular electrodes, because of the implant flexing that must be withstood, are usually of the coiled-wire variety discussed above.

Electrode Classification. In general, electrodes designed to deliver electrical pulses to excitable tissue are classified based on the site of stimulation or placement of electrodes. Motor nerves can be stimulated through electrodes

placed on the surface of the skin (surface electrodes) or implanted within the body. Implanted electrodes include those placed on or in the muscle (epimysial or intramuscular electrodes, respectively); as well as within or adjacent to a motor nerve (intranearal or extraneural electrodes). Electrodes that stimulate the spinal cord and BIONs (electrodes integrated with sensing and processing and packaged into a capsule) are recent additions to the family of implanted electrode technologies. The above classification of electrodes is further described below and summarized in Table 2.

Surface Electrodes. Surface electrodes as the name implies are placed on the surface of the skin and are the earliest of the electrodes to be used for applications in electrotherapy. These consist of conductive plates and are available in many types including conductive rubber patches coated with electrolyte gel, metal plates contacting the skin via thin, moist sponges and flexible, disposable, stainless steel mesh or rubber electrodes with self-adhesive conductive polymers (98–100). They do not need any implantation and are therefore noninvasive and relatively easy to apply and replace. An excellent description on the placements of these electrodes can be found in the Rancho Los Amigos Medical Center’s practical guide to neuromuscular electrical stimulation (101). Surface electrodes

Figure 4. The Compex Motion FES system, manufactured by the Swiss based company Compex SA, is a general purpose programmable transcutaneous electrical stimulation device. Seen are the stimulator unit, three memory chip-cards that are inserted into the stimulator and used to store all pertinent information for a specific protocol, two EMG sensors, and two surface electrodes. do have some disadvantages. They offer relatively poor selectivity for stimulation, have elevated threshold levels, may activate skin pain receptors, and do not have highly reproducible positioning capability. When higher currents are delivered to stimulate deeper muscles, spill over of charge to the nontargeted superficial muscles occurs. It is sometimes difficult to anchor surface electrodes in moving limbs and electrical properties at the skin–electrode interface can be variable.

Surface electrodes have been used for both lower limb and upper limb motor prosthesis, including the aforementioned Parastep system for ambulation (Fig. 6). WalkAid was designed for the management of foot drop to help toe clearance during the swing phase of walking (102). A single channel stimulator, the Odstock Dropped Foot Stimulator (ODFS) and later a two channel stimulator (O2CHS) designed for foot drop correction, used self-adhesive skin surface electrodes placed on the side of the leg (103,104). MikroFES was another orthotic stimulator for correction of foot drop in paralyzed patients (9). The Hybrid Assist System (HAS) (105) and the RGO system (106) use surface stimulation along with braces. Upper extremity applications include the Handmaster (107), the Belgrade Grasp System (BGS) (108), and the Bionic Glove (109) which focus on improving hand grasp.

Implanted Electrodes. Implanted electrodes can either be in direct contact with a muscle or peripheral nerve, within a muscle and only separated by muscle tissue from the motor nerves innervating the muscles, or within the spinal cord. Since peripheral electrodes are closer to the motor nerves than surface electrodes, they allow for better selectivity and more repeatable excitation. Their positioning and implantation is more permanent. Implanted electrodes have the advantage of place and forget by comparison to surface electrodes. That is, once the system is implanted, the user potentially can forget it is there. The chances of spill over are reduced since the electrodes can be placed close to the target muscle or nerve. The sensation to the user is usually much more comfortable as the implantation is away from the cutaneous pain receptors and the threshold current amplitude is lower. However, the implant procedure is invasive and in case of implant failure an invasive revision procedure can be required. Improper design and implantation can lead to tissue damage and infection. Insufficient tensile strength, high threshold levels, highly nonlinear recruitment curves, poor selectivity of activation and repeatability and adverse pain sensation (110–112) indicate failure. Excess encapsulation and infection (113); mechanical failures of electrode lead breakage and corrosion of electrodes and the insulator (114,115) can also impair the system.

Electrodes in or on the Muscle: Intramuscular and Epimysial Electrodes. Implanted electrodes that are placed on or in the muscle consist of intramuscular (87,88,116–121) and epimysial electrodes (89,122–125). Intramuscular electrodes (88,126) can, for example, be fabricated from multi-stranded Teflon coated stainless steel wires. This configuration provides good tensile strength and flexibility. They are implanted by injecting a hypodermic needle

Table 2. Electrical Stimulation Electrode Classifications and Types

Location/Type	Features and Advantages	Example	References
Surface	Metal plate with electrolyte gel, noninvasive	WalkAid, ODFS, MikroFES, HAS, RGO, Handmaster, BGS, Bionic Glove	
<i>In / On Muscle</i>	lower thresholds and better selectivity compared to surface electrodes		
Intramuscular	Implanted in the muscle, multistranded Teflon coated stainless steel wire, monopolar and bipolar configurations, good tensile strength, and flexibility		87,88
Epimysial	Implanted under the skin: on the muscle, monopolar and bipolar configurations, less prone to mechanical failure		89
BIONs	Injected into or near the muscle, hermetically sealed glass/ceramic capsule integrated with electronics		90
<i>Near / On Nerve</i>	Lower threshold levels and better selectivity than the above mentioned electrodes		
Nerve Cuffs	Monopolar, bipolar and tripolar configurations, good power efficiency, improved selectivity, comparatively stable		91,92
FINE	Reshape or maintain nerve geometry		93
<i>Intrafascicular</i>	Penetrate the epineurium and into the fascicle, selective stimulation, lower current and charge levels		
LIFE	Stable, suitable for stimulating and recording		94
SPINE	Reduced nerve damage		95
<i>Intraspinal</i>			
Microwires	Near to normal recruitment, reduced fatigue, highly selective stimulation		96,97

either nonsurgically or through an open incision. A fine needle probe used by itself or in conjunction with a surface probe is used to detect the motor point; the motor point for an intramuscular electrode is usually just below the muscle surface beneath the motor point position as defined by surface electrode. These electrodes can elicit a maximal muscular contraction with only $\sim 10\%$ of the stimulus charge required by equivalent surface electrodes (25). Figure 7 depicts a Peterson type intramuscular electrode developed at Case Western Reserve University (121).

Both monopolar and bipolar intramuscular electrodes have been used. Bipolar intramuscular electrodes that

Figure 7. A "Peterson" type intramuscular electrode design. This is a helically wound PFS insulated multistranded 316LVM stainless steel wire design that is attached to a barb-like anchoring structure constructed of polypropylene suture material. The wound section of the electrode is $\sim 800\ \mu\text{m}$ in diameter and is partially loaded into a hypodermic needle. (Courtesy of J.T. Mortimer and reproduced by permission of World Scientific Publishing Co.)

straddle the nerve entry point can be as effective at activating the muscles as a nerve cuff. If bipolar electrodes do not straddle the nerve entry point, full recruitment of the muscle can require large stimulation charge and stimulation cannot be achieved without activating the surrounding muscles. In contrast, monopolar stimulation is less position dependent, though it cannot match the selectivity obtained with good bipolar placement (127). The size of the

muscle will determine the limit of electrode size, although large electrodes are more efficacious.

A recent development in the intramuscular stimulating electrode world are BIONs (for BIONic Neurons), that can potentially provide precise and inexpensive interfaces between electronic controllers and muscles (90). The BIONs consist of a hermetically sealed glass–ceramic capsule with integral capacitor electrodes for safety and reliability (128). The internal electronics include an antenna coil wrapped around a sandwich of hemicylindrical ferrites over a ceramic microprinted circuit board carrying a custom integrated circuit chip. In animal studies, these electrodes have demonstrated long-term biocompatibility (129) and ability to achieve selective muscle stimulation (130). The first generation of BIONs, BION1, generates stimulation pulses of 0.2–30 mA at 4–512 μ s duration. This system is now in clinical trials to provide therapeutic electrical stimulation to patients with disabilities (131–135). The second generation BION, BION2, is under development. BION2s are expected to sense muscle length, limb acceleration and bioelectrical potentials for feedback control in FES (136–138).

Intramuscular electrodes have been used to activate paralyzed muscles that retain a functional motor neuron in the muscles of the upper extremity (139,140), lower extremity (118,140,141) and the diaphragm (142). Muscles also have been stimulated to correct spinal deformities in the treatment of scoliosis (143).

Epimysial electrodes (89,110) are positioned on the surface of a muscle below the skin but not within the muscle. They have a smooth circular disk on one side and a flat, insulating backing, reinforced with mesh. The motor point is usually identified by moving a stimulating electrode across the muscle surface to locate the surface position that requires the least amplitude to fully excite the muscle. Replacing this electrode in the event of failure is comparatively easier. The stimulation levels and impedance are also similar to that of intramuscular electrodes. A perceived advantage of epimysial electrodes over intramuscular electrodes is that they are less prone to mechanical failure and less likely to move in the hours and days immediately after implantation.

Epimysial electrodes also can be used either in the monopolar mode or the bipolar mode (89,108,119,120,123). Use of a monopolar epimysial electrode close to the motor nerves results in reduced threshold stimulus amplitude, higher gain and selectivity, and decrease in length dependent recruitment. When a bipolar epimysial electrode is used, the stimulus current is constrained to regions closer to the two electrodes. Compared to the results with monopolar electrodes, the threshold is increased, relative gain decreased, and though greater selectivity is found with stimulation current levels close to twitch threshold poorer selectivity is present in the stimulus range needed for maximum activation of the muscle (108).

Epimysial electrodes have been used for a number of years in the implementation of upper extremity assist devices for C5 or C6 adult subjects with tetraplegia (Fig. 8), including incorporation into the FDA approved FreeHand System (144) and more recently for providing the capability of standing after paraplegia (117).

Figure 8. An example implantable epimysial electrode (right) with intramuscular electrode (left), typical of those used with the Cleveland FES Center's implanted hand-grasp system. (Courtesy of the Cleveland FES Center.)

Implanted Nerve Electrodes. Electrodes that are placed in contact with the nerve include extraneural and intraneural electrodes. Extraneural electrodes do not penetrate the epineurium and include varying designs of nerve cuffs (91,92,145–149) and the recently investigated flat interface nerve electrodes (FINE) (93,150,152). Intraneural electrodes penetrate the epineurium and include intrafascicular and interfascicular electrodes (94,95,153–157). Nerve electrodes have several potential advantages over intramuscular electrodes—including, lower power requirements, the ability to control several muscles with a single implant, and the ability to place the electrodes far from contracting muscles (158).

Electrodes placed on the surface of the nerve, and housed in an insulative carrier that encompasses the nerve trunk, are cuff electrodes (91,151,159,160). The cuff material is often silicone rubber and sometimes reinforced with Dacron. Cuff-type electrodes hold the stimulating contacts in close proximity to the nerve trunk. Holding the target tissues close to the stimulating contacts offers opportunities for power efficiency and improved selectivity. Less power is spent on electrical conduction through space between the electrode and target tissues. Improved selectivity is possible because the electric potential gradient is larger when the spacing between the stimulating contact and the target tissue is least. Further, these electrodes are less likely to move in relationship to the target tissues after implantation (161–164). However, while nerve cuffs stimulate effectively and selectively they require invasive surgery for implantation. They may also damage the nerves they enclose unless carefully designed, sized, and implanted.

Figure 9. A self-sizing cuff electrode design fabricated using PMP (polymer–metal–polymer) technology and laser machining. (Courtesy of J.T. Mortimer and M. Tarler.)

To overcome potential problems with a fixed cuff-size, nerve cuff electrodes have been designed with different configuration. The Huntington nerve cuff (165), is a helix-type nerve electrode system that has exposed metal sections as stimulating contacts along the internal diameter of the helix. The open helix design can accommodate some swelling. Other self-sizing cuff electrode designs sometimes have a spiral configuration that enables opening or closing to accommodate a range of different diameter nerves (91). Figure 9, for example, is a photo of a self-sizing nerve cuff fabricated at Case Western Reserve University using PMP technology and laser machining. Both cuff and spiral electrode configurations can be used in various monopolar, bipolar or tripolar configurations (91,164). Cuff electrodes with multiple electrical contacts can produce selective activation of two antagonistic muscle groups innervated by that nerve trunk (166). Increased function and additional control of muscles with minimum number of electrodes can be achieved. Self-sizing nerve-cuff electrodes, with multiple contacts in a tripolar configuration, have been shown to produce controlled and selective recruitment of some motor nerves in a nerve trunk (145,158,167–170). A monopolar electrode with four radially placed contacts can work as well as a tripolar electrode with four radially placed tripoles (171,172). A four contact self-sizing spiral cuff electrode has been described as a tunable electrode that is capable of steering the excitation from an undesirable location to a preferred location (92).

The flat interface nerve electrode, or FINE system as seen in Fig. 10, has been introduced in an attempt to improve the stimulation selectivity of extraneural electrodes (151). The goal with the FINE is to create a geometry that optimizes stimulation selectivity. In contrast to cylindrical electrodes, the FINE either reshapes the nerve into, or maintains the nerve in, an ovoid geometry. Chronic studies in rats have demonstrated that nerves and fascicles can be safely reshaped (150,173). Also, acute experiments and finite element models have demonstrated that it is possible to selectively activate individual fascicles in the cat sciatic nerve using this electrode (151,152,174). This could be important in both reducing fatigue and selectively activating individual muscles (153,175). A potential disadvantage

Figure 10. The FINE nerve cuff design, intended to flatten peripheral nerve trunks into a layering of nerve fascicles. Electrode contacts are seen as small dots within the overall structure. (Courtesy of D. Durand.)

is that a fibrous capsule with electrical properties different from the surrounding tissues will envelope the electrode (176,177), potentially rendering the recruitment properties unstable, although a recent study has shown that both selectivity measurements and the recruitment curve characteristics can remain stable for a prolonged implant period (93).

Intraneural electrodes are positioned to penetrate the epineurium around the nerve trunks. Intraneural electrodes utilize a conductor that invades the epineurium. Maximal contraction is elicited at stimulation levels an order of magnitude lower than with nerve cuff electrodes (200 μ A, pulse duration 300 μ s). However, connectors, fixation, and neural damage are still not completely resolved to allow routine clinical usage. Intraneural multipolar sword type electrodes have been made out of solid silicon with golden contacts and can be very selective (178). Such electrodes could minimize the needs for using many electrodes for activation of different muscles that are innervated from a single nerve (179).

A subset of intraneural electrodes are meant to enter the perineurium around the fascicles and go between the nerve fibers: These are so-called intrafascicular electrodes. Intrafascicular electrodes place stimulating elements inside the fascicles, in close proximity to axons (126,153,160,175,178,180,181). They have been shown to produce axonal recruitment with almost no excitation of muscles that are not targeted (181). A variation of the intrafascicular electrode is the longitudinal intrafascicular electrode (LIFE) (94,153). Compared with extraneural electrodes, LIFEs have many advantages and can be implanted into any of the fascicles of peripheral nerves to selectively stimulate a single fascicle thereby offering highly selective stimulation. Also they serve as excellent recording electrodes. When LIFEs are used as recording electrodes, the amplitudes of motor evoked potentials (MEPs) recorded by LIFEs implanted in fascicles are much larger than those of EMGs recorded from the skin by surface electrodes and the signals recorded are not affected by external electrical fields (155,182). Therefore, the signals recorded by LIFE can be used to control a prosthetic limb more accurately than those controlled by EMGs (183). In addition, LIFEs have excellent biocompatibility with peripheral fascicles (156,184,185).

While intrafascicular electrodes can provide high degrees of selectivity, it remains unclear whether penetrating the perineurium will lead to long-term nerve injury (126,186). Interestingly, an intraneural electrode system dubbed the slowly penetrating interfascicular electrode (SPINE) has been developed, which has been reported to penetrate a peripheral nerve within 24 h without evidence of edema or damage of the perineurium and showed functional selectivity (95).

In general, compared to externally placed electrodes, the current and charge stimulation requirements for intraneural electrodes are low since they are positioned inside the nerve trunk to be excited. Also, the stimulation selectivity is high compared to extraneural electrodes where stimulation selectivity suffers from the relatively large amount of tissue interposed between the stimulating contacts and the target axons.

Micro wires: Electrodes for Intraspinal Stimulation

Spinal circuits that are shown to have the capacity of generating complex behaviors with coordinated muscle activity can be activated by intraspinal electrical stimulation (187–190). Microwires that are finer than a human hair have been used to stimulate the spinal cord neurons to control single muscles or small group of synergists (96,97,191–193). Stimulation through single wires in a few sites has been shown to have the ability to elicit whole-limb activation sufficient to support the animal's weight (191,192,194–196). The stimuli were not perceived but were able to produce strong coordinated movements. Near normal recruitment order, minimal changes in kinematics and little fatigue and functional, synergistic movements induced by stimulation in the lumbosacral cord (97,194,196) are some of the promising advantages of stimulating the spinal cord with microwires. However, the clinical and long-term feasibility of implanting many fine microwires into the spinal cord remains questionable. In addition, stimulating the spinal cord results in steep recruitment curves compared to muscle and nerve stimulation thereby limiting the degree of control achievable.

Controllers and Control Strategies

Besides stimulating the paralyzed muscles, it is also important to control and regulate the artificial movements produced. The control task refers to specification of the temporal patterns of muscle stimulation to produce the desired movements; and the regulation task is the mod-

ification of these patterns during use to correct for unanticipated changes (disturbances) in the stimulated muscles or in the environment. A major impediment to the development of satisfactory control systems for functional neuromuscular stimulation has been the nonlinear, time varying properties of electrically activated skeletal muscle that make control difficult to achieve (7,76,197). With FNS, the larger, fatigable muscle fibers are recruited at low levels of stimulation before the more fatigue-resistant fibers are activated thereby inducing rapid fatigue (56). It is important that the output of any FNS control system results in stable, repeatable, regulated muscle input-output properties over a wide range of conditions of muscle length, electrode movement, potentiation, and fatigue. To improve control strategies to provide near physiological control, inherent muscle characteristics (force-activation, force-length, and force-velocity), muscle modeling studies, studies on understanding how to model the patterns of neural prostheses and how neural prostheses respond to disturbances have been performed (197–200).

As depicted in Fig. 11 (201), FNS control methods include feedforward (open-loop), feedback, and adaptive control. Feedforward control requires a great deal of information about the biomechanical behavior of the limb. The control algorithms specify the stimulus parameters (musculoskeletal system inputs) that are expected to be needed to produce the desired movement (system outputs). In an open-loop control system these parameters are often identified by trial and error (6,13,202–205). The same stimulation pattern, which is often stored in the form of a lookup table, is delivered for each cycle of movement.

Three major problems exist with this form of fixed-parameters, open-loop control (204–206). First, the process of specifying the parameters for a single stimulation pattern for a single user often requires several extensive sessions involving the user, therapist, physician, and engineer. This process is often expensive, time consuming, and often only minimally successful in achieving adequate performance. Second, the fixed parameter stimulation pattern may not be suitable after muscles fatigue that is exacerbated by the stimulation paradigm itself. The third problem is that the open-loop stimulation pattern does not respond to changing environments (e.g., slope of walking surface) and external perturbations (e.g., muscle spasms).

To address the limitations of open-loop control systems feedback control was implemented (12,14,207,208). In a feedback control system, sensors monitor the output and corrections are made if the output does not behave as

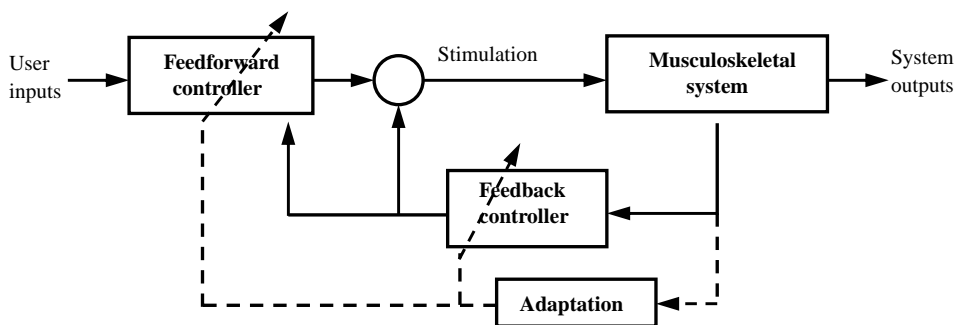

Figure 11. A representation of FNS control system components and strategies (feedforward, feedback and adaptive). (Reproduced by permission from *Neuromodulation* 2001;4: 187–195.)

desired. The corrections are made based on a control law, which is a mathematical prescription for how to change the input to reduce the difference (error) between the desired output and the actual output. Feedback control requires output sensors, and compensation is generally slower than in feedforward control since an output error must be present to generate a controller response. Thus feedback control might best be used for slow movements and for maintaining a steady posture. Since the output of the feedback controller is highly dependent on sensor signals, the quality of the control that is achieved will be compromised by the relatively low quality of sensors that are available. Feedback control has been successful in regulating hand grasp (209) and standing posture (12), but it appears that another strategy, adaptive feedforward control, is likely to be required for dynamic activities such as locomotion.

To improve performance of feedback control systems, adaptive control strategies were developed that automatically adjusted the overall system behavior (i.e., the combined response of the controller and the system) so that it is more linear, repeatable, and therefore predictable (75,210–213). These techniques adjust the parameters of the control system and attempt to self-fit the system to the user in order to make it easier to use and learn to use (206,212,214). The control system developed by Abbas and Chizeck has a pattern generator (PG) and a pattern shaper (PS) (211,215). The PG generates the basic rhythm for controlling a given movement. The PS adaptively filters those signals and sends its output to the muscles. The adaptive properties of the PS provide the control system with the ability to customize stimulation parameters for a particular individual and to adjust them on-line to account for fatigue. In some of the computer simulation experiments a proportional-derivative feedback controller was also active. Studies have shown that the pattern generator/pattern shaper (PG/PS) adaptive neural network controller is able to account for nonlinear and dynamic system properties and muscle fatigue (73,75,213). To summarize, adaptive control systems have replaced other developed control system strategies because this strategy can (1) provide the ability to automatically customize the stimulation pattern for a given user, (2) automatically adjust stimulation parameters to account for fatigue, and (3) automatically adjust to allow the voluntary motor commands to recover control of the movement pattern (in the case of partial recovery in a person with an incomplete spinal cord lesion).

Apart from the above other strategies, such as fuzzy logic (216) and proportional–integral–derivative (PID) controllers (217) have also been implemented to investigate automatic fatigue compensation. However, fatigue remains one of the major factors limiting utility of FES/FNS because such adaptive systems can adjust for fatigue only up to the contractile limits of the muscle.

Rather than initiating and modulating control of FES systems indirectly through residual motor function (e.g., as in the Freehand system for grasping, where paralyzed hand closure and opening were command controlled through sensing of opposite shoulder position), future FES devices might be controlled directly through thought—by tapping into the subject's remaining cortical

intent to move via a brain–machine interface (BMI) [or sometimes brain–computer interface (BCI)]. So-called direct brain–machine interfaces utilize arrays of intracortical recording electrodes to sense action potentials from a host of individual neurons in regions of the brain where cells code for movement and its intent. A number of research teams have in recent years demonstrated the feasibility of recording and processing movement related signals from cortex (in both animals and in humans), and then enabling the subject to control computers or devices directly through such processed thought (218–220). Ultimately, BMI technologies hold promise that paralyzed individuals might one day be able to control FES devices for movement restoration with little or no effort or learning other than forming the simple intent to move (221).

THERAPEUTIC EFFECTS OF ELECTRICAL STIMULATION

While this article is focused mainly on electrical stimulation therapies for restoring lost function, it is important to recognize that electrical stimulation techniques are used also for therapeutic reasons. A recent review summarizes the current state of therapeutic and neuroprosthetic applications of electrical stimulation after spinal cord injury and identifies some future directions of research and clinical and commercial development (222). Functional electrical stimulation therapy individually and in combination with other rehabilitation therapies also is being utilized after incomplete spinal cord injury to influence the plasticity within the nervous system for improved recovery (9,223–228).

Therapeutic electric stimulation (TES) can affect the restoration of muscle strength (229). Therapeutic electric stimulation in humans has been shown to prevent muscle atrophy thereby increasing muscle cross-sectional area, torque, and force (230–234). Such electrical therapy has been effective in reversing the increased fatigability associated with the change in fiber type in both animals (31–37) and humans (56,59–61,65–67) after spinal cord injury. Electrical stimulation has also been able to reduce spasticity among patients with neurological disorders (reference).

While osteoporosis has been prevented in the limbs of paralyzed individuals, in menopausal women, and in the elderly and fracture patients through electrical stimulation therapy (235–240), certain other studies have shown little or no change in bone density (235,241–244). These contradictory results suggest the importance of other characteristics, such as the stimulation patterns, specifications for training (intensity, duration, loading), and the time postinjury. Enhancing fracture–wound healing is another therapeutic application of electrical stimulation (245–249). The theory here is to attract negatively or positively charged cells into the wound area, such as neutrophils, macrophages, epidermal cells, and fibroblasts that in turn will contribute to wound healing processes by way of their individual cellular activities (250). Electrical stimulation may also play a role in wound healing through improved blood flow (251,252), prevent occurrence of pressure sores thereby improving general tissue health (253). A recent

review details all the theories suggested and experimental studies and clinical trials performed on wound healing through electrical stimulation (254).

Recent applications of electrical stimulation have also been successful in altering neural function. For example, deep brain stimulation (DBS) is being used to treat a variety of disabling neurological symptoms, most commonly the debilitating symptoms of Parkinson's disease (PD), such as tremor, rigidity, stiffness, slowed movement, and walking problems [for a review, see (255,256)]. Deep brain stimulation uses a surgically implanted, neurostimulator approximately the size of a stopwatch. The implanted device delivers electrical stimulation to targeted areas in the brain that control movement, blocking the abnormal nerve signals that cause tremor and PD symptoms. Vagal nerve stimulator (VNS), approved by the FDA in 1997 are used to treat patients with intractable epilepsy. These devices controls seizures by sending electrical pulses to the vagus nerve (257,258). Transcutaneous electrical nerve stimulation (TENS), wherein electrical signals are sent to underlying nerves, can relieve a wide range of chronic and acute pain (259). The TENS devices are small battery-powered stimulators that produce low intensity electrical signals through electrodes on or near a painful area, producing a tingling sensation that reduces pain. Chronic electrical stimulation of the GI tract has been found to be a potential therapy for the treatment of obesity (260–262). It is clear that in future development of electrical stimulation technologies many devices will be designed to achieve both therapeutic and functional outcomes.

GAMMA KNIFE

STEVEN J. GOETSCH
San Diego Gamma Knife Center
La Jolla, California

INTRODUCTION

The Leksell Gamma Knife is one of the most massive and costliest medical products ever created (see Fig. 1). It is also one of the most clinically and commercially successful medical products in history, with > 180 units installed worldwide at this writing. The device is used exclusively for the treatment of brain tumors and other brain abnormalities. The Gamma Knife, also known as the Leksell Gamma Unit, contains 201 sources of radioactive cobalt-60, each of which emits an intense beam of highly penetrating gamma radiation (see Cobalt-60 units for radiotherapy). Due to the penetrating nature of the gamma rays emitted by these radiation sources, the device must be heavily shielded, and therefore it weighs ~ 22 tons. The Gamma Knife must also be placed in a vault with concrete shielding walls 2–4-ft thick.

This remarkable device is used in the following way: A patient known from prior medical diagnosis to have a brain tumor or other treatable brain lesion, is brought to a Gamma Knife Center on the selected day of treatment. Gamma Knife treatment is thus intended for elective surgery and is never used for emergency purposes. The patient is prepared for treatment, which normally occurs with the patient alert and awake, by a nurse. Then, a neurosurgeon injects local anesthetic under the skin of

Figure 1. The Leksell Gamma Unit Model U for treatment of patients with brain tumors and other brain abnormalities.

Figure 2. Patient with Leksell Model G stereotactic frame affixed to their head. This frame restricts patient motion during imaging and treatment and also allows placement of fiducial markers to localize the volume to be treated.

the forehead and posterior of the skull. He/she then affixes a stereotactic head frame (see Fig. 2) with sharp pins to the patient's head (much like a halo fixation device for patients with a broken neck). The patient is transported by wheelchair or gurney to a nearby imaging center where a Computed Tomography (CT) X-ray scan or a Magnetic Resonance Imaging (MRI) scan of the brain (with the stereotactic head frame on) is obtained (see articles on Computed Tomography and Magnetic Resonance Imaging). Specially constructed boxes consisting of panels containing geometric localization markers are attached to the stereotactic frame and surround the patient's head during imaging. The markers contained in the localization boxes are visible on the brain scan, just outside the skull (see Fig. 3). All imaging studies are then exported via a PACS computer network or DAT tape (see the article on Picture Archiving and Communication Systems) into a powerful computer, where a treatment plan is created. A neurosurgeon, a radiation oncologist, and a medical physicist participate in the planning process. When the plan is satisfactorily completed, the patient (still wearing the stereotactic frame) is brought into the treatment room. The patient is then placed on the couch of the treatment unit and the stereotactic frame is docked with the trunnions affixed to the helmet (see Fig. 4). After the staff members leave the room and the room shielding doors are closed, the Gamma Knife vault door automatically opens and the patient couch is pushed forward into the body of the device, so that the holes in the collimating helmet line up with the radiation source pattern inside the central body of the device. The treatment begins at that point. Any given patient may be treated in this manner with a single "shot" (e.g., treatment) or with

Figure 3. Axial MRI scan of patients brain, with external fiducial markers filled with copper sulfate solution to enable localization of target volumes.

many shots (30 or more in some cases). The collimating helmet may be changed to use one or more of the available helmet sizes, corresponding to a roughly spherical volume 4, 8, 14, or 18 mm in diameter. At the conclusion of treatment, the stereotactic frame is removed and most patients are then discharged. Thus Gamma Knife radiosurgery is most commonly performed on an outpatient basis.

Gamma Knife radiosurgery has shown rapidly increasing acceptance, since the first commercial unit was introduced at the University of Pittsburgh in 1987 (1). Despite the high purchase price (a little >\$3 million) and single purpose, Gamma Knife units are widely available in the

Figure 4. Supine patient in position for treatment in Gamma Knife. Stereotactic head frame is carefully docked with trunnions, which slide in precise channels in the secondary collimator helmet.

United States, Europe, Asia, and other parts of the world. All units are manufactured by Elekta Instruments, of Stockholm, Sweden. Use of this device can eliminate the need for open surgery of the brain. Modern surgical techniques and nursing follow-up have reduced the death rate due to brain surgery from as much as 50% in the 1930s to <1% in the United States in 2002. However, Gamma Knife patients most commonly do not have to remain overnight in the hospital at all (an important consideration in a very cost conscious healthcare environment), while craniotomy patients typically have a 2–5 day stay. Conventional brain surgery patients sometimes require 30 days or more of hospitalization if extremely adverse effects occur. Thus, the cost of the Gamma Knife outpatient procedure is typically far less than that for inpatient open brain surgery. Recovery of the patient is much more rapid for Gamma Knife patients, with most patients going home immediately and returning to work or other normal routines in 1–2 days.

EARLY HISTORY OF THE DEVICE

Gamma Knife radiosurgery was an outgrowth of several prior inventions. Dr. Lars Leksell, a Swedish neurosurgeon, was one of the pioneers in the field of stereotaxis (see the article on Stereotactic Surgery). Dr. Leksell was motivated to find minimally invasive ways to treat brain abnormalities by the appalling death rate for early twentieth century brain surgery, which could be as high as 50% (2). Leksell was one of the first surgeons to create a workable stereotactic frame (in 1949) that could be affixed to a patient's skull, together with a set of indexed external markers (called fiducials) that were visible on an X-ray of the patient's head. Only primitive brain imaging procedures were available in 1950 to the late 1970s, so stereotactic surgery patients had to undergo a painful procedure called pneumoencephalography. A lumbar puncture was used to introduce air into the spinal canal while the patient (strapped into a special harness) was manipulated upside down, back and forth, while air was injected under positive pressure to displace the cerebro-spinal fluid in the ventricles of the brain. A pair of plane orthogonal X-ray images (anterior–posterior and lateral) were then taken. Since the air-filled ventricles were well imaged by this technique, standard atlases of the human brain such as Schaltenbrand and Wahren (3) were then used to compute the location of the desired target relative to these landmarks. The imaging procedure alone was considered extremely painful and typically required hospitalization. The early stereotactic frames were applied by drilling into the patient's skull and driving screws into the calvarium (outer table of the skull), which was then topped with a Plaster of Paris cap that could be rigidly fixed. A twist drill could then be guided to create a small hole (a few millimeters in diameter) in the patient's skull, through which a catheter could be passed to a designated target, such as the globus pallidum for treatment of Parkinsons disease. A radio frequency transmitter was passed through the catheter and a small volume of tissue was heated to high

temperature, creating a deliberate, controlled brain lesion. This procedure, though rigorous, was far less invasive and dangerous than open brain surgery, called craniotomy.

Leksell then attached an X-ray treatment unit to his stereotactic frame and used it in 1951 to treat brain structures without opening of the skull. He called this procedure “radiosurgery”, which he defined as “a single high dose of radiation stereotactically directed to an intracranial region of interest” (4). Leksell was successful in treating previously intractable cases of trigeminal neuralgia, an extremely painful facial nerve disease, by stereotactically irradiating the very narrow ($\sim 2\text{--}4$ mm diameter) nerve as it enters the brainstem. Only a few patients were treated with this X-ray unit.

Leksell then collaborated with physicist Borge Larsson in treating patients at a cyclotron located at Uppsala University near Stockholm beginning in 1957. Tobias and others had just begun treating patients with proton therapy (see article on Proton Beam Radiotherapy) at the University of California Berkeley in 1954. The proton is a positively charged subatomic particle, a basic building block of matter, which has extremely useful properties for treatment of human patients. The charged particles, accelerated to very high energies by a massive cyclotron (typically located at a high energy physics research laboratory) are directed at a patient, where they begin to interact through the Coulomb force while passing through tissue. At the end of the proton range, however, the particles give off a large burst of energy (the Bragg peak) and then stop abruptly. Leksell and Larsson utilized these properties with well-collimated beams of protons directed at intracranial targets. A few other centers in the United States and Russia also began proton therapy in the 1950s and 1960s.

The Gamma Knife was invented in Stockholm, Sweden by Leksell and Larsson and was manufactured (as a prototype) by the Swedish shipbuilding firm Mottola. The first unit had 179 radioactive cobalt-60 sources and was installed in 1968 at Sophiahemmet Hospital in Stockholm, Sweden (5). This original unit had three interchangeable helmets with elliptically shaped collimators of maximum diameter 4, 8, or 14 mm. Despite the lack of good brain imaging techniques at that time, the Gamma Knife was used to successfully treat Parkinson’s disease (a movement disorder), trigeminal neuralgia (extreme facial pain), and arteriovenous malformations (AVMs), which are a tangle of congenitally malformed arteries and veins inside the brain. Several years later a second nearly identical unit was manufactured for Leksell when he became a faculty member at Karolinska Hospital in Stockholm. The original unit lay idle for a number of years, until it was donated to UCLA Medical Center in Los Angeles, where it was moved in 1982 (Fig. 5). It was used in animal research and treated a limited number of human patients before it was retired permanently in 1988 (6). The two original, custom-made Gamma Knife units were unique in the world and did not immediately enjoy widespread acceptance or gain much notice. A large number of patients with AVMs began to be treated at the Gamma Knife Center in Karolinska, by Dr. Ladislau Steiner, a neurosurgical colleague of Lars

Figure 5. Original Gamma Knife, after being moved from Stockholm to UCLA Medical Center in Los Angeles.

Leksell. Arteriovenous malformations are prone to spontaneous hemorrhage that can cause sudden coma or death. Open surgical techniques for removal of these life-threatening vascular anomalies were extremely difficult and dangerous in the 1970s. Patients came from all over the world to be treated for these AVMs at the Gamma Knife Center in Stockholm.

In 1984 and 1985, two new Gamma Knife units were manufactured using Dr. Leksell’s specifications by Nucletec SA of Switzerland (a subsidiary of Scanditronix AB, Sweden) for installation in hospitals in Buenos Aires, Argentina and Sheffield, England, respectively (7,8). These units also had three sets of collimators, which were now circular in shape, of 4, 8, and 14 mm diameter, but the number of cobalt-60 sources was increased to 201. The mechanical tolerance was exquisite: The convergence of all 201 beams at the focal point was specified as ± 0.1 mm. The total radioactivity was 209 TBq (5500 Ci) and the sources were distributed evenly over a $160 \times 60^\circ$ sector of the hemispherical secondary collimators (Fig. 6). An ionization chamber (a type of radiation detector) placed at the center of a spherical phantom 16 cm in diameter was used to measure an absorbed dose rate of ~ 2.5 gray \cdot min $^{-1}$ for the Sheffield unit. This was adequate to treat patients to a large radiation dose in a reasonable period of time. Both Gamma Knife units were successfully used for many years to treat patients in their respective countries.

A new corporation, called Elekta Instruments, AB, of Stockholm was created in 1972 by Laurent and Dan Leksell, sons of Lars Leksell, to manufacture neurosurgical products, including the Gamma Knife, which is now a trademark of this firm. Elekta created the first commercial Gamma Knife product, the Model U, and has manufactured all Gamma Knife units worldwide since that time. This new 201 source unit was installed at the University of Pittsburgh in 1987 and expanded the available beam diameters to include a fourth secondary collimator with a nominal diameter of 18 mm (1). The trunnions, which connect the secondary collimator helmets to the patient, were now configured to dock with connecting points located

Figure 6. (Upper panel) Collimator helmets for Leksell Gamma Unit Model U. (Lower panel) Collimator helmet for Leksell Gamma Unit Models B and C.

on removable *Y-Z* positioning bars on the patients headframe. The earliest versions of the Gamma Knife had required implantation of screws into the patients skull and covering with Plaster of Paris to achieve this docking. The unit (like the two previous units) utilized a hydraulic drive to open the shielding door in the central body and propel the patient couch into treatment position.

Elekta also introduced a radiation therapy treatment plan called KULA to calculate the size and shape of the radiation volume to be treated for each patient and compute the necessary duration of the treatment. The Sophiahemmet and Karolinska Gamma Knife Centers had relied on manual calculations until this time. The KULA plan could calculate isodose lines (lines of equal radiation dose) in a two-dimensional (2D) plane, which could then be manually traced onto an axial brain image. The advent of stereotactic imaging with computed tomography also eliminated the need for the difficult and painful pneumoencephalograms and was capable of localizing brain tumors as well as anatomical targets. The University of Pittsburgh Gamma Knife Center enjoyed a relatively high degree of acceptance from the time of installation, and was soon joined by other Leksell Gamma Units in the United States, Europe, and Asia.

One drawback of the Leksell Gamma Unit Model U, which is no longer manufactured, is that it was shipped to the hospital unloaded and then loaded with cobalt-60 sources on site. This necessitated the shipment of many tons of shielding materials to create a temporary hot cell, complete with remote manipulating arms (Fig. 7). A further difficulty with Gamma Units is that the radioactive cobalt-60 is constantly being depleted by radioactive decay. The half-life of cobalt-60 is ~ 5.26 years, which means that the radiation dose rate decreases $\sim 1\%$ /month. The Sheffield Gamma Unit (manufactured by Nucletec) was reloaded after a number of years of use by British contractors who had not been involved in designing or building the unit and it therefore took ~ 12 months to complete the task. The University of Virginia Leksell Model U Gamma Unit was the first to be reloaded (in 1995) and it was out of service for only 3 weeks. Nevertheless, the necessity of having the treatment unit down for a period of weeks after 5–6 years of operation, at a cost approaching \$500,000 with a very elaborate construction scenario inhibited the early acceptance of these units. A compensating advantage of the Gamma Unit Model U was the extremely high reliability of these devices. Routine maintenance is required once every 6 months and mechanical or electrical breakdowns preventing use of the device are very rare.

Leksell introduced the Gamma Unit Model B in Europe in 1988, although it was not licensed in the United States until 5 years later. The new unit, which strongly resembles the later Model C (Fig. 8), departed from the unique spherical shape of the earlier unit and more closely resembled the appearance of a CT scanner. The source configuration was changed to five concentric rings (Fig. 6b), although the number and activity of the cobalt-60 sources remained the same as in the Model U. The new Gamma Unit Model B was designed so that the radioactive cobalt-60 sources could be loaded and unloaded by means of a special

Figure 7. Loading cobalt-60 sources into Gamma Unit with remote manipulating arms.

11 ton loading device (Fig. 9), without the necessity for creating a large and costly hot cell. This significantly reduced installation and source replenishment costs and speeded up these operations as well. The hydraulic operating system used to open the shielding doors and to move the patient treatment couch was replaced with a very quiet electrically powered system.

Extensive innovations were introduced with the Leksell Gamma Unit Model C with optional Automatic Positioning System (APS) in calendar year 2000. This unit was

Figure 8. Leksell Gamma Unit Model C, which strongly resembles the previous Leksell Gamma Unit Model B.

Figure 9. Special loading device for insertion and removal of cobalt-60 sources with the Leksell Gamma Units Models B and C.

awarded three American patents and one Swedish patent. The new unit provided several upgrades at once: a new computer control system operates the shielding door and patient transport mechanism and is networked via RS232C protocol with the Leksell GammaPlan treatment planning computer. All previous models required manual setting (and verification) of helmet size, stereotactic coordinates and treatment time for each shot. An optional APS system (Fig. 10) has motorized trunnions that permit the patient to be moved from one treatment isocenter to another without human intervention. This automated system can only be utilized if the secondary helmet, gamma angle (angle of patients stereotactic frame Z axis with respect to the longitudinal axis of symmetry of the Gamma Unit helmet) and patient position (prone or supine) are identical to the values for these respective treatment parameters as provided in the final approved treatment plan. In addition, the isocenters (or shots) are grouped into “runs” having stereotactic coordinates within a predefined distance of each other (typically ± 2 cm) so as not to introduce unacceptable strain on the patient’s neck while their head is being moved

Figure 10. Close-up view of trunnions and helmet of Leksell Gamma Unit model C with Automatic Positioning System in place.

Figure 11. Geometry of sources installed in Leksell Gamma Units.

to a new position relative to the immobile body. Within these limitations the efficiency of a complex treatment plan can be greatly increased. Additionally, two independent electromechanical devices verify the positioning of the patient's stereotactic coordinates to within $50\ \mu\text{m}$ (below the resolution of the unaided human eye).

THEORY

The invention of the Gamma Knife built on seven decades of previous experience with radiation therapy (see related articles). Early external beam radiation treatments used X-ray sets with low energies, in the range of 100–300 kV, which have the disadvantage of depositing a maximum dose at the surface of the skin. This physical characteristic makes it difficult to treat deep seated tumors without causing unacceptable damage to the overlying skin and tissue. Lars Leksell used a 200 kV X-ray set to treat his first radiosurgery patient in 1951, but abandoned that technique after only a few patients to work with far more penetrating proton beam radiotherapy (see article Proton beam radiotherapy). The disadvantage of proton beam therapy was that the patient had to be brought to a high energy physics laboratory, which was not otherwise equipped to treat sick or infirm patients and was often located at a great distance from the surgeon's hospital. This made treatments somewhat difficult and awkward, and the cyclotron was not always available. An important breakthrough came when two Canadian cancer centers introduced cobalt-60 teletherapy (see article Cobalt-60 units for radiotherapy) in the early 1950s. Leksell and Larsson realized that this new, more powerful radiation source could be utilized in a hospital setting. They also realized that rotational therapy, where a radiation source is revolved around a patient's tumor to spread out the surface dose, could be mimicked in this new device by creating a static hemispherical array of smaller radiation sources. Since Leksell was interested only in treating intracranial disease, where the maximum patient dimension is only $\sim 16\ \text{cm}$, the device could place radiation sources relatively close to the center of focus. The Leksell Gamma Knife uses a 40 cm Source to Surface Distance (SSD), far shorter than modern linear accelerators (see article Medical linear accelerator), which typically rotate around an isocenter at a distance of 100 cm (see Fig. 11). This short SSD allows the manufacturer to take advantage of the inverse square principle, which implies that a nominal 30-curie source at 40 cm achieves the same dose rate at the focus as a 187.5

curie source would achieve at 100 cm. This makes loading and shielding a Gamma Knife practical.

The Gamma Knife treats intracranial tumors or other targets by linear superposition of 201 radiation beams. The convergence accuracy of these sources is remarkable: The radiation focus of the beams converge at the center point of stereotactic space (e.g., 100, 100, 100 in Leksell coordinates) to within $< 0.3\ \text{mm}$. Thus the targeting accuracy of treatment of brain tumors is essentially not limited at all by mechanical factors, and is primarily limited by the inaccuracy of imaging techniques and by target definition. Each cobalt-60 beam interacts by ionization and excitation (primarily by Compton scattering) as it passes through the skull of the patient. The intensity of each beam is diminished by $\sim 65\%$ while passing through 16 cm of tissue (a typical skull width, approximated as water for purposes of calculation). At the mechanical intersection of all 201 radiation sources, which are collimated to be 18, 14, 8, or 4 mm in diameter, the useful treatment volume is formed (see Fig. 12). Outside this volume the radiation dose rate drops off precipitously (90% of Full Maximum to 50% in 1 mm for the 4 mm beam) thereby mimicking the behavior of protons at the end of their range. The mathematics of this 3D convergent therapeutic beam irradiation

Figure 12. Illustration of convergence of 201 radiation beams to create treatment volume.

is relatively simple: The radiation absorbed dose adds up in linear superposition.

$$D(P) = D_{fi} / \sum D_{fi} \times [d_{fs} / (d_{fs} - dz)]^2 \times \mu dz$$

where $D(P)$ is the total dose at arbitrary point P , D_{fi} is the relative contribution from source i to the total dose at the point of focus, d_{fs} is the distance from the source to the focus (40 cm), dz is the distance along the beam axis from the focal point to intersection with the perpendicular from point P , and μ is the linear attenuation coefficient for Co-60 gamma radiation in tissue.

A radiation therapy treatment planning code (see article Radiation Therapy Treatment Planning) called Leksell GammaPlan is provided by the manufacturer for the purpose of preparing treatment plans for the Leksell Gamma Unit for use with human patients. An early treatment plan called KULA calculated treatment time and created a 2D plot of lines of equal radiation dose (or isodose lines), but with severe limitations. The early code could only calculate plans with a single center of irradiation (called an isocenter in general radiosurgery applications, or a “shot” in Gamma Knife usage). Calculated isodose lines had to be transferred by hand from a plot to a single CT slice in the axial plane. In 1991 the Leksell GammaPlan software was introduced (and premarket clearance by the FDA was obtained), which permitted on-screen visualization of isodose lines in multiple CT slices. The improved code could calculate and display the results of multiple shots and could model the effect of “plugging” some of the 201 source channels with thick steel plugs to “turn off” certain radiation sources. The software was written for UNIX workstations and has rapidly become increasingly powerful and much more rapid as processing speed and computer memory increased in the last decade. Leksell GammaPlan utilizes a matrix of > 27,000 equally spaced points (in the shape of a cube), which can be varied from 2.5 cm on a side to 7.5 cm on a side. Within this cube a maximum radiation dose is computed from the linear superposition of all 201 radiation beams (some of which may be plugged), from collimator helmets of 18, 14, 8, or 4 mm diameter, and this calculation is integrated over each “shot”. More than 30 different shots (each with a discrete X, Y, and Z stereotactic coordinate, in 0.1 mm increments) can be computed and integrated, with user selectable relative weighting of each shot. Whereas the original KULA plan required ~ 15 min for one single shot calculation, modern workstations with Leksell GammaPlan can now compute 30 shot plans in up to 36 axial slices in < 1 min. Leksell GammaPlan can now utilize stereotactic CT, MRI, and Angiographic studies in the planning process. Each study must be acquired with the stereotactic frame in place and registered separately. Image fusion is now available. Figures 13 and 14 give two of the many possible screen presentations possible with a very sophisticated Graphical User Interface.

CLINICAL USE OF GAMMA KNIFE

The Gamma Knife has gained widespread acceptance in the neurosurgical and radiation oncology community as an

Figure 13. Screen from Leksell GammaPlan illustrating multiple MRI slices with superimposed isodose display.

effective treatment for many different pathologies of brain tumors, neurovascular abnormalities and functional disorders. Gamma Knife radiosurgery may in some cases be used as an alternative to open craniotomy while for other patients it may be used after previous surgeries have been attempted. Since Gamma Knife radiosurgery infrequently requires overnight hospitalization, and generally has a very low probability of adverse side effects, it may in many cases be much less costly, with lower chance of complication and much less arduous recovery.

A typical Gamma Knife procedure is performed after a patient has been carefully screened by a neurosurgeon, a radiation oncologist, and a neuroradiologist. The procedure is scheduled as an elective outpatient procedure and typically lasts from 3 to 8 h. The first critical step is placement of a stereotactic frame (see article Stereotactic Surgery) to provide rigid patient fixation and to allow stereotactic imaging to be performed with special fiducial attachments. The exact position of the frame (offset to left or right, anterior or posterior) is crucial, since the tumor must be well centered in stereotactic space to permit

Figure 14. Screen from Leksell GammaPlan illustrating angiographic study and three-dimensional display of AVM nidus.

accommodation of the patient's skull (with the frame attached) inside the small volume of the secondary collimator helmet. The Leksell Model G frame encloses $\sim 2900 \text{ cm}^3$ of accessible stereotactic space, significantly less than other stereotactic frames which do not have to fit inside the Gamma Knife helmet. A stereotactic localization study is immediately performed, using one or more modalities such as computed tomography, and magnetic resonance imaging. Patients with vascular abnormalities may also undergo an angiographic study: A radiologist inserts a thin catheter (wire) into a vein in the patient's groin and then carefully advances the wire up through one of the major arteries leading to the brain, then into the area of interest. The catheter is then used to inject X-ray opaque dye, which reveals the extent of the vascular lesion (see Fig. 14). These imaging studies must then be promptly networked (via a hospital PACS system) to the planning computer. There the images are registered from couch coordinates (left-right, in-out, up-down) to stereotactic space (X , Y , and Z). At that point, each individual point in the brain corresponds to a specific stereotactic coordinate, which can be identified from outside the brain.

Gamma Knife radiosurgery, both in the United States and worldwide, has enjoyed a very rapid acceptance since the first commercial unit was produced in 1987. The number of procedures performed annually, subdivided by indication, is compiled by the nonprofit Leksell Society. Only results voluntarily reported by Gamma Knife centers are tallied, with no allowance for nonreporting centers, so their statistics are conservative. The growth in use of this device has been explosive, with < 7000 patients treated worldwide by 1991 and $> 297,000$ patients reported treated through December, 2004 (see Fig. 15). This parallels the increase in number of installed Leksell Gamma units, going from 17 in 1994 in the United States to 96 centers by the end of 2004. The number of Gamma Knife cases reported performed in the United States has increased by an average of 17%/year for the last 10 years, a remarkable increase. Table 1 indicates the cumulative number of patients treated with Gamma Knife radiosurgery in the western hemisphere and worldwide through December, 2004, subdivided by diagnosis.

Treatment objectives for Gamma Knife patients vary with the diagnosis. The most common indication for treatment is metastatic cancer to the brain. An estimated

Figure 15. Cumulative number of Gamma Knife patients treated worldwide from 1991 through December, 2004.

Table 1. Cumulative Reported Gamma Knife Radiosurgery Procedures through December, 2004

Indication	Western Hemisphere Procedures	Worldwide Procedures
AVM and other vascular	9,793	43,789
Acoustic neuroma	7,719	28,306
Meningioma	11,016	36,602
Pituitary adenoma	3,577	24,604
Other benign tumors	3,137	14,884
Metastatic brain tumors	29,285	100,098
Glial tumors	7,727	20,614
Other malignant tumors	1,501	6,492
Trigeminal neuralgia	11,609	17,799
Other functional disease	1,135	4,441
TOTAL INDICATIONS:	67,336	297,529

1,334,000 cancers (not including skin cancers) were diagnosed in the United States in calendar year 2004. Approximately 20–30% of those patients will ultimately develop metastatic tumors in the brain, which spread from the primary site. These patients have a survival time (if not treated) of 6–8 weeks. The treatment objective with such patients is to palliate their symptoms and stop the growth of known brain tumors, thereby extending lifespan. A recent analysis (9) reported a median survival of patients treated with radiosurgery of 10.7 months, a substantial improvement. Approximately 18,000 patients were diagnosed with primary malignant brain tumors in the United States in calendar year 2004, with 13,000 deaths from this cause. Patients with primary malignant brain tumors (i.e., those originating in the brain) have a lifespan prognosis varying from 6 months to many years, depending on the grade of the pathology. Many glioma patients are offered cytoreductive brain surgery to debulk the tumor and may have an extended period of recovery and significant loss of quality of life afterwards. At time of tumor recurrence for these patients, the noninvasive Gamma Knife procedure may accomplish as much as a second surgery, while sparing the patient the debilitation of such a procedure. Recent reports in the clinical literature indicate that Gamma Knife radiosurgery is effective in improving survival for glioma patients.

Many patients with nonmalignant brain tumors are also treated with Gamma Knife radiosurgery. Meningiomas are the most common nonmalignant brain tumor, arising from the meninges (lining of the brain) as pathologically altered cells and causing neurological impairment or even death. Approximately 7000 new meningiomas are diagnosed in the United States each year. Most grow very slowly ($\sim 1 \text{ mm} \cdot \text{year}^{-1}$) while the most aggressive tumors may grow rapidly to as much as 12–15 cm in length and may even invade the bone. Gamma Knife radiosurgery has been reported for treatment of meningioma as far back as 1987 and is considered a well-established treatment for this extremely persistent disease, with > 1000 Gamma Knife treatments reported for meningioma in the United States during calendar year 2001. Another common nonmalignant tumor is the acoustic neuroma (also called vestibular schwannoma), which arises from the auditory nerve

(cranial nerve VIII). It can cause deafness and imbalance, and in severe cases motor impairment as it compresses the brainstem. The incidence of newly diagnosed acoustic neuromas is 2500–3000/year in the United States. Craniotomy for acoustic neuroma is among the most challenging brain operations, typically requiring 8–24 h on the operating table. Potential complications range from loss of residual hearing to devastating facial palsy to cerebrospinal fluid leak requiring as much as 30 days of hospitalization. Extremely high control rates of up to 97% (no additional tumor growth or moderate shrinkage) have been reported for Gamma Knife radiosurgery of these tumors with extremely low complication rates (10). This may explain why >1000 acoustic neuromas were treated with Gamma Knife radiosurgery in the United States during Calendar Year 2003, nearly one-third of all such tumors diagnosed that year.

Arteriovenous malformations are a rare genetic disorder of the vascular system of the brain and spinal cord. Estimates of incidence ranges from 5 to > 600/100,000 people. The lesion consists of a tangle of abnormal arteries and veins that may not be detected until late in life. The AVMs can cause debilitating headaches, epileptic seizures, coma, and even sudden death due to cerebral hemorrhage. Arteriovenous malformations were first described in the 1800s and the first surgical resection was credited to Olivecrona in Stockholm in 1932. The AVMs were categorized by Spetzler and Martin into five distinct surgical categories in order of increasing surgical risk and one additional category for inoperable lesions (11). Surgery for these lesions remained extremely challenging until late in the twentieth Century. Therefore, when angiography became available in the 1960s, Ladislau Steiner (a neurosurgical colleague of Lars Leksell at Karolinska Hospital) began to treat AVMs with the Gamma Knife as early as 1970 (12). A large number of AVMs were treated in the early days of Gamma Knife radiosurgery both because of the extreme risk of open surgery and the early success with this technique in obliterating these lesions. Recent clinical studies report an obliteration rate for these lesions of 75–85% within 3 years of Gamma Knife radiosurgery, with similar obliteration rates if a second Gamma Knife treatment is necessary. Over 33,000 AVMs have been treated with Gamma Knife radiosurgery worldwide, making it the second most common indication after metastatic brain tumors.

Trigeminal neuralgia is a neurological condition marked by excruciating pain of the fifth cranial nerve that innervates the face in three branches between the eyebrows and the jawline. The pain may be caused by a blood vessel pressing on a nerve, by a tumor, by multiple sclerosis, or for unknown reasons. This is the first condition ever treated by Lars Leksell, using a 200 kVp X-ray unit affixed to a stereotactic frame in a treatment performed in 1951. The root entry zone of the nerve as it enters the brainstem is the target volume. The nerve diameter at that point is only 2–4 mm and the consequences of a geometric miss with the radiosurgery treatment volume accidentally being directed to the brainstem could be quite severe. Alternative treatments include injection of glycerol into the cistern under radiographic guidance, radio frequency “burn” of

the nerve under radiographic guidance and microvascular decompression which is a fairly major brain surgery. Physicians at the University of Pittsburgh recently reviewed their first 10 years of treatments on 202 trigeminal neuralgia patients and found that > 85% had complete or partial relief of pain at 12 months after Gamma Knife radiosurgery (13). Over 12,500 patients with trigeminal neuralgia have been treated with Gamma Knife radiosurgery at this writing.

QUALITY CONTROL/QUALITY ASSURANCE

Quality Control and Quality Assurance for Gamma Knife radiosurgery is of critical importance. Unlike fractionated radiation therapy, Gamma Knife treatments are administered at one time, with the full therapeutic effect expected to occur in weeks, months, or years. Errors in any part of the radiosurgery process, from imaging to planning to the treatment itself could potentially have severe or even fatal consequences to the patient. An international group of medical physicists published a special task group report on Quality Assurance in stereotactic radiosurgery in 1995 (14) and the American Association of Physicists in Medicine discussed Quality Assurance for Gamma Knife radiosurgery in a task group report in that same year (15). Each group stressed the need for both routine Quality Control on a monthly basis, examining all physical aspects of the device, and calibration of radiation absorbed dose measurements with traceability to national standards. Both groups also emphasized detailed documentation and independent verification of all treatment parameters for each proposed isocenter before the patient is treated. An Information Notice was published by the U.S. Nuclear Regulatory Commission (NRC) on December 18, 2000 that documented 16 misadministrations in Leksell Gamma Knife radiosurgery cases in the United States over a 10-year period (16). The Nuclear Regulatory Commission defines a misadministration as “A gamma stereotactic radiosurgery radiation dose: (1) Involving the wrong individual, or wrong treatment site; or (2) When the calculated total administered dose differs from the total prescribed dose by > 10% of the total prescribed dose.” Fifteen of the 16 incidences were ascribed to human error while utilizing the Leksell Gamma Knife models U, B, and B2. Six of the reported errors involved setting incorrect stereotactic coordinates (often interchanging Y and Z coordinates). Two errors occurred when the same shot was inadvertently treated twice. One error involved interchanging left and right side of the brain. One error involved using the wrong helmet. No consequences to patients were reported, but would be expected to be minor in most of the reported cases.

It is important to note in this respect that the new Leksell Gamma Unit Model C with (optional) Automatic Positioning System has the potential to eliminate many of the reported misadministrations. The older Leksell Gamma Unit Models U and B are manual systems in which the treatment plan is printed out and hand carried to the treatment unit. Stereotactic coordinates for each of the isocenters (shots) are set manually by one clinician and checked by a second person. It is thus possible to treat the

patient with the wrong helmet, prone instead of supine, wrong gamma angle, incorrect plugged shot pattern, wrong time, or to repeat or omit shots. The operation of the new Model C Gamma Unit is computer controlled. The Leksell GammaPlan workstation is networked via an RS232C protocol with full error checking, thus transferring the treatment plan electronically. The shots may be treated in any order, but no shot may be repeated and the screen will indicate shots remaining to be treated. The helmet size is remotely sensed and treatment cannot commence if an incorrect helmet is selected. If the optional Automatic Positioning System is used, the X, Y, and Z stereotactic coordinates are automatically sensed to within 0.05 mm. The device will not permit treatment until the X, Y, and Z coordinates sensed by the APS system match those indicated on the treatment plan. Thus, it appears that all of the 15 misadministrations due to human error as reported by the Nuclear Regulatory Commission would have been prevented by use of the Model C with APS.

RISK ANALYSIS

The concept of misadministration should be placed in the larger concept of risk analysis. All medical procedures have potential adverse effects and, under state laws, patients must be counseled about potential consequences and sign an informed consent before a medical procedure (even a very minor procedure) may be performed. The relative risk of misadministration of Gamma Knife misadministration may be computed, utilizing the NRC report and data from the Leksell society on number of patients treated per year in the United States. Since ~ 28,000 patients received Gamma Knife radiosurgery between 1987 and 1999, while 16 misadministrations were reported during the same interval, a relative risk of misadministration of 0.00057 per treatment may be computed for that period. Using the most recent year (1999) for which both NRC and patient treatment data are available, the relative risk drops to 0.0001/patient treatment.

These risks may be compared with other risks for patients undergoing an alternative procedure to Gamma Knife radiosurgery, namely, open craniotomy with hospital stay (17). A report by the National Institute of Medicine estimates that medical errors kill between 44,000 and 98,000 patients/year in the United States (18). These deaths reportedly occur in hospitals, day-surgery centers, outpatient clinics, retail pharmacies, nursing homes, and home care settings. The committee report states that the majority of medical errors do not result from individual recklessness, but from basic flaws in the way the health system is organized. A total of 33.6 million hospital admissions occur in the United States each year, which yields a crude risk estimate range of 0.0013–0.0029 death per admission to hospital or outpatient facility.

A second source of inadvertent risk of injury or death must also be considered. The National Center for Infectious Diseases reported in December, 2000 that an estimated 2.1 million nosocomial (hospital based) infections occur in the United States annually (19). These infections are often

drug resistant and require extremely powerful antibiotics with additional adverse effects. Given that there are 31 million acute care hospital admissions annually in the United States, the relative risk of a hospital based infection may be computed as 0.063/patient admission, or roughly one chance in 16. The risk of infection from craniotomy was given by the same report as 0.82/100 operations for the time period January, 1992–April, 2000.

The Leksell Gamma Knife Model C system is one example of a computer-controlled irradiation device. The rapidly developing field of Intensity Modulated Radiation Therapy (IMRT) is the subject of a separate article in this work. These complex treatments require extraordinary care on the part of treatment personnel to minimize the possibility of misadministration. Only rigorous Quality Assurance and Continuing Quality Improvement in radiation oncology can make such treatments safe, reliable and effective. Leveson has studied the use of computers to control machinery which could potentially cause human death or injury, such as linear accelerators, nuclear reactors, modern jet aircraft and the space shuttle (20).

EVALUATION

The Leksell Gamma Knife, after a long period as a unique invention of limited applicability, has enjoyed explosive growth in medical application in the last 10 years. It is one of a number of medical instruments specifically created to promote minimally invasive surgery. Such instruments subject human patients to less invasive, painful, and risky procedures, while often enhancing the probability of success or in fact treating surgically inoperable patients. Over 297,000 Gamma Knife treatments have been performed worldwide as of the last tally. Most treatments are successful in achieving treatment objectives in 85–90% of patients treated. Although the Gamma Knife is the most massive and probably the costliest single medical product ever introduced, it has enjoyed widespread commercial and clinical success in 31 countries. The simplicity and reliability of operation of the unit make its use an effective treatment strategy in lesser developed countries where difficult craniotomies may not be as successful as in more developed countries. The newest version of the unit addresses the issues of automation, efficiency, treatment verification, and increased accuracy. The instrument appears to be well established as an important neurosurgical and radiological tool.

GAS AND VACUUM SYSTEMS, CENTRALLY PIPED MEDICAL

BURTON KLEIN
Burton Klein Associates
Newton, Massachusetts

INTRODUCTION

Terminal gas outlets or vacuum inlets are as common a fixture today in hospital rooms as stethoscopes. Even clinics, outpatient surgery facilities, and some nursing homes utilize them. But how did they get there? And have they helped medical and nursing staff give better patient care?

This article is intended to give readers a brief look at how and why these systems were developed, how they operate, what hazards they pose, what standards have been developed to mitigate hazards as well as to standardize operation, and why maintenance of these systems is very important. In a sense, medical gas and vacuum systems are a reflection, in part, of how the practice of medicine has changed over the past 60–70 years: Both systems have become more complex and sophisticated in order to meet and treat more serious illnesses.

The systems discussed below are those involving the distribution of pressurized gases (or suctioning of air) or the creation of a vacuum via rigid metal pipes, with the source of gas or suction *not* in the same room as the end-use terminals of the system. Further, the description of these systems is a generalized one; specific systems may have different operating characteristics to meet a particular need. The authority(ies) having jurisdiction (AHJ) should be consulted for specific locations (e.g., hospital, clinic, nursing home) and application purpose (medical surgical, dental, laboratory, veterinary).

Finally, the limited bibliography provided at the end of this article has been included (1) for readers who wish to pursue this subject further, and (2) to show the various standards organizations involved in setting standards that are used in designing, installing and using these systems.

GAS SYSTEMS (PRESSURIZED)

To understand how and why the piping of medical gases to operating rooms and other patient care areas came into practice, it is necessary to briefly review how the practice of medicine, and in particular the practice of anesthesiology, changed from the mid-1800s to the early 1900s, for it was advances in administering anesthesia that led to the piping of gases into operating rooms, and from there to many other patient care areas.

Some History

The first public demonstration of inhalation anesthetics took place on October 16, 1846 at the Massachusetts General Hospital in Boston. There had been some experimentation prior to this date, but this publicized demonstration by Dr. John W. Collins clearly showed that patients could

be kept unconscious as long as necessary and have surgery performed without their sensing pain. A giant step forward in the practice of medicine had been achieved.

These first years of anesthesiology were relatively simple in that only a sponge soaked in ether and placed over the nose and mouth of patients was used to induce anesthesia. In 1868, Andrews introduced oxygen mixed with nitrous oxide as an adjunct to inhalation anesthesia. In 1871, cylinders of nitrous oxide became available. In 1882, cyclopropane was discovered, though it was not until the 1930s that it was found useful for anesthesia. And in 1887, Hewitt developed the first gas anesthesia machine that used compressed gases in cylinders.

This controlled unconsciousness sparked a dramatic increase and change in medical practice and hospital activities. No longer did patients enter a hospital only for terminal care or to feel the cutting edge of a scalpel. Problems occurring inside the body could now be exposed for examination and possible correction. And, as anesthesia systems became more available and sophisticated, the volume and type of operations increased dramatically. Finally, the discovery that oxygen enrichment helped patients during anesthesia and operations increased the use of oxygen in operating rooms tremendously.

By the 1920s, cylinders of oxygen and nitrous oxide were constantly in motion about hospitals, from loading docks to storage rooms to operating rooms and back again. But, occasionally, cylinders did not make the entire circuit in one piece. Thus, the question occurred to healthcare staff: Was there another, better way to provide gas in operating rooms?

Some sources credit the late Albert E. McKee, who was working with a Dr. Waters at the University of Wisconsin Medical Center in the 1920s, with installing the first medical piped gas system that used high pressure cylinders of oxygen connected by pipes to outlets in nearby operating rooms. He (and his counterparts) saw this as a better method of providing gases to operating rooms. Their installation had some very positive effects (it also had some negative ones that will be discussed shortly):

1. There was an immediate reduction in operating costs. Instead of many small cylinders, fewer but larger cylinders could be utilized, with concurrent reduction in the unit cost per cubic foot of gas. (It has been reported to this author that the amount saved after McKee installed his system was sufficient to pay the salaries of the University of Wisconsin anesthesiology departmental staff.) Fewer cylinders also meant less loss of residual gas that remained in empty cylinders. When individual cylinders were used, they would be replaced when the pressure inside the cylinder dropped down to ~ 500 psi ($\text{lb} \cdot \text{in}^{-2}$ or 3448 kPa); when two or more cylinders were manifolded together as a source, however, individual cylinders could be allowed to go down to ~ 40 psi (276 kPa), since there were other cylinders in the system from which gas could be drawn.
2. This method provided immediate access to gases. Operating room staff only needed to connect hoses to gas outlets to obtain gas. The large supply at the

central dispersion point could be monitored by one person (instead of each anesthesiologist worrying about their own individual small cylinders). Since several large cylinders were grouped together, when one became empty, or nearly empty, others could be switched on line and the empty one replaced. Thus, operating room staff were assured of a constant supply of gas.

3. Safety was improved. No longer were cylinders, with their inherent hazards, inside the operating room. Cylinder movement around the hospital was dramatically reduced.

Industry had been using gas under pressure in pipes since the late 1800s (e.g., street lamps). Piping gases around a hospital was, thus, a natural extension of this methodology, though components had to be modified to meet medical needs. These new installations were not without problems, however. The system had to be leak-free, since an escape and buildup of gases (flammable or oxidizing) within a building was dangerous. Also, having these gases carried in pipes around a healthcare facility meant that an incident in one place now had a means of becoming an incident in another place. Finally, if more than one gas were piped, the possibility of cross-connection and mixing of gases existed (and cross-connecting of some gases can create explosive possibilities).

This last problem was of particular concern since initially there was no restriction on the piping of flammable anesthetic gases. Several institutions, including the University of Wisconsin, installed systems to pipe ethylene gas. Even though the standardization of terminal connectors began in the late 1940s, explosions in operating rooms continued to occur. While the number of such incidents was not large, the occurrence was always devastating, almost always killing the patient, and sometimes maiming medical–surgical–nursing staff. In 1950, the National Fire Protection Association (NFPA) Committee on Hospital Operating Rooms proposed a number of changes, including prohibiting the piping of flammable anesthetic gases. The proposal, adopted by the NFPA membership, eliminated one possible source of explosions and fire.

The relatively recent introduction (late-1940s) of storing a large volume of oxygen on-site in a liquid state presented a new host of concerns. While large-volume storage replaced the use of many cylinders, it vastly increased the amount of oxygen in one location and introduced the hazard associated with gas in a cryogenic state (i.e., gas at an extremely low temperature).

System Components

The following is a general description of components used in piped gas systems today (Fig. 1). An actual system may not utilize all these components. However, all systems have certain minimum safety features, as discussed below. In addition, standardization of some components (e.g., threaded station outlet connections) and practices (e.g., operating pressures) has evolved over the years, which will be discussed later as well.

Figure 1. Components of a medical gas (pressurized) central piping system (simplified). Standards have been developed for component and total-system performance and safety.

Gases. The most common nonflammable medical gases piped under pressure today include medical air, oxygen, nitrogen, and nitrous oxide. These gases are available from manufacturers in cylinders into which a large volume of the gas has been compressed. The pressure of the gas in these cylinders can be > 2000 psig (13.8 GPa). Some of these gases are also available in a liquefied state, through a refrigeration process, and are supplied in portable containers or in large stationary bulk units (tanks). (When the gas is used, it is allowed to evaporate and return to its gaseous state.) The gas in the liquefied state is placed under relatively low pressure [~ 75 psig (520 kPa)]. One gas (air) can also be obtained on-site using compressors. Whichever method is used to obtain a specific gas, it must interface with the piping portion of the system; that is, the mechanical parts must interconnect. It also means that the pressure of the source gas needs to be regulated to pressure at which the system is operating. Gas in the liquid state must be transformed to the gaseous state. For all gases, except nitrogen, a pressure between 50 and 55 psig (344 and 379 kPa) at station outlets has become the standard. For nitrogen, which is used to power nonelectric surgical tools, such as drills, bone saws, and dermatomes, a pressure between 160 and 185 psig (1103 and 1379 kPa) is used. This regulation can be likened to electricity and the use of transformers that are installed between the power generators of utility companies (where voltages upward of 10,000 V are generated) and buildings where the voltage

is regulated down to 208 or 110 V. In gas systems, these transformers are called pressure regulators.

In the last few years, other nonpatient medical gases (called support gases in NFPA 99, *Standard for Health Care Facilities*) have begun to be piped. These gases are used for powering equipment that use pressurized gas in order to function (e.g., pneumatically operated utility columns). Gases in this category include nitrogen and instrument air.

Source Equipment

Other devices used at the source portion of the piped gas system include (1) shutoff valves at prescribed locations so that a complete or partial shutdown of a source can be accomplished; (2) check valves to control the direction of gas flow (i.e., one direction only); (3) pressure-relief valves, which are preset to vent gas to the atmosphere if the pressure in a cylinder, container, or pipeline becomes excessive enough to cause a rupture or explosion if allowed to continue to increase; and (4) signals to alarm panels to indicate such conditions as low and high pressure.

A separate reserve supply of the gas is also included in some piped systems. This reserve serves as a backup if the main (normal) source is interrupted or requires repair. This reserve can be adjacent to, or remote from, the main source. Its remote location precludes both sources from damage should an accident occur to one source. Such separation, however, may not always be possible.

A requirement added in NFPA 99 in the early 1990s called for a piped bulk-oxygen system that has its source sources located outside the building to have a separate connection to the piping system, also located outside of the building and accessible to a bulk oxygen delivery truck (ODT). Thus, if both the main and reserve supplies of oxygen were to fail or become damaged or depleted, the ODT could be used as the source. This emergency connection is required only for the oxygen supply because it is a life-support gas.

Finally, if extra cylinders or containers of gases are kept stored within a facility or within close proximity to a healthcare facility, a safe means of storing the gas must be provided. These storage requirements are intended to provide safety for occupants should an incident occur outside the storage room (i.e., in order to protect the cylinders from adding to the incident), or should an incident occur inside the storage room (i.e., in order to protect occupants in the building from the incident in the storage room).

Piping (Distribution) System. From the source piping is installed to distribute the gas to patient care areas. (Standards require gases piped to laboratory areas to be supplied from a separate system from gases piped to patient care areas. This is to prevent any backfeeding of gas from laboratory systems into patient care systems, and to allow for different pressures where required or desired for laboratory purposes.) Sizes and locations of main, riser, and lateral pipes should take into consideration both present and future needs or plans. As with the source, shutoff valves and flow-control devices (check valves) are required by standards at certain locations in the piping (distribution) system.

Terminal Units (Station Outlets). The endpoints (called outlets) of the piped gas system are very important since it must be very clear what gas is flowing to each outlet. To eliminate any chance of mix-up, noninterchangeable mechanical connectors have been designed for each type of gas. These different connectors are similar to the different configurations of electrical outlets for 110, 220–208 (single-phase), 220–208 V (three-phase), and so on. Labeling of gas outlets and piping is also required. Color coding of new piping became a requirement in NFPA 99 in 2005. However, it requires staff to remember the color coding scheme. It also poses problems for persons who are color-blind.

Alarm Panels/Monitoring. Because gases are relied upon for life support, system monitoring is essential and has become standard practice. Sensors and alarms are required to be installed in all critical care areas to detect if the pressure decreases or increases beyond specified limits (e.g., should someone inadvertently or deliberately close a shutoff valve). Other sensors are required to detect when the normal source and/or reserve supply are low and when the reserve supply has been switched in.

All signals are fed to one or more master alarm panels, one of which is required to be constantly monitored by facility staff. The electrical power for these alarms is to

be connected to the facility's emergency power system so that alarms will continue to function if normal electrical power is interrupted. This constant surveillance is required because of fire hazards that could develop should something in the system malfunction, and for patient safety should gas delivery be interrupted. Immediate action (corrective, responsive) is necessary in either situation.

Installation of Systems. In the early 1990s, concern about the quality of the installation of medical piped gas (and vacuum) systems resulted in the technical committee responsible for piping system requirements listed in NFPA 99, *Standard for Health Care Facilities*, to revise and expand requirements for their installation. To assure the system has been installed according to the design drawings, extensive requirements were included not only for the installer, but also for a verifier who is to be totally independent of the installer, and who tested the system after everything was connected and readied for operation (i.e., for patient use).

Performance Criteria and Standards

When first installed, medical piped gas systems generally followed the practices then in use for the piping of nonmedical gases. These practices were considered adequate at the time. In 1932, the subject came to the attention of the NFPA Committee on Gases, which noted the following hazards that the installation of these systems posed for hospitals:

1. Pipes, running through an extensive portion of a building into operating rooms, carried gases that were of the flammable type (those that burn or explode if ignited) or of the oxidizing type (those that support and intensify the burning of combustibles that have been ignited).
2. A large quantity of gas in cylinders was being concentrated and stored in one area.
3. The possible buildup of potentially hazardous gas concentrations existed should the pipes leak.
4. A possible explosion in an operating room was possible if a hose on an anesthesia machine were connected to the wrong gas.
5. A compromising of patient safety existed in that a mix-up of gases could be injurious or even fatal.

This notification came in the form of identification of hazards resulted in a request by the National Board of Fire Underwriters that this Committee develop a set of guidelines on the subject. The Committee studied the subject and, in 1933, proposed "Recommended Good Practice Requirements for the Construction and Installation of Piping Systems for the Distribution of Anesthetic Gases and Oxygen in Hospitals and Similar Occupancies, and for the Construction and Operation of Oxygen Chambers." The proposed document contained guidance on acceptable types of piping, the length of pipe runs, the identification of piping, the kind of manifolds that were acceptable, and the number and location of shutoff valves. As noted

in the title, it permitted the distribution of anesthetic gases, which were flammable. The NFPA did not formally adopt the proposed Recommended Good Practice until 1934. Over the years, as more knowledge was gained from the hazards, installation, and use of piped gas systems, the NFPA standard also changed. In addition, other organizations prepared standards addressing other aspects of piped gas systems (1–10). A brief summary of these efforts follows.

National Fire Protection Association Standards. The original NFPA document, first designated NFPA 565 and later, NFPA 56F, which in turn was incorporated into NFPA 99 (11) remained unchanged until 1950 when the NFPA Hospital Operating Room Committee, working with the NFPA Gas Committee, recommended that piping of flammable anesthetic gases be prohibited. Later, specific safety requirements were added, such as for the storage of gases, shutoff valve locations, check valves, line-pressure gages, pressure switches and alarm panels, and installation and testing criteria. Performance criteria, in the form of operating pressure limits for different gases, were added because no other organization had included them in their documents, and uniformity of systems operations was helpful to both medical staff, designers, and the industry producing the equipment for these piped systems.

Other NFPA documents have been developed over the years that impact on medical piped gas systems. These include documents on the subjects of emergency electric power, bulk oxygen supplies, and building construction (11–16).

Compressed Gas Association (CGA) Standards. The CGA, an organization of manufacturers of gases and gas equipment, publishes many documents on the subject of gases. Some of these apply directly to medical gas piping systems; others are generic and affect any closed gas system. Topics addressed include gas cylinder criteria; noninterchangeable connectors for cylinders and terminal outlets; liquefied gas transfer connections; compressed gas-transfer connections; and commodity specifications for nitrogen, air, nitrous oxide, and oxygen (1–6).

Other Organizations. (7–10).

VACUUM SYSTEMS

Some History

The development of vacuum central piped vacuum systems, in place of portable suction machines, occurred over a period of time from the late-1940s to the early-1950s. These systems did not have to face the same unknowns and problems that the development of piped gases faced 20 years earlier. While they did not pose as great a threat as piped gases [i.e., they were not carrying oxidizing gases at 50 psig (344.8 kPa)], they did have their own hazards (e.g., they carried flammable and/or nonflammable oxidizing gases around a facility; created patient risks should the system stop; created possible restrictive contamination of

orifices and low vacuum levels if orifices became clogged or contaminated; and created excessive loading on emergency electrical power systems if not properly provided for in the system). Since many vacuum systems were and still are installed simultaneously with central piping systems for gases, they added to the problems associated with installing two or more systems simultaneously (e.g., cross-connections, incorrect labeling).

Until vacuum central piping systems were installed, medicine utilized small portable suction pumps that created a vacuum much the same way an ordinary vacuum cleaner creates suction (Fig. 2). A major difference, however, is the type of collection container used. For a home vacuum cleaner, a semiporous bag collects dirt; for a medical vacuum machine, a nonporous “trap” is necessary because of the products collected (e.g., body fluids of all kinds, semiliquid bulk material). In addition, a major problem with portable suction machines is the airborne bacteria it can spread as it operates. Since vacuum pumps operate on the principle of moving air from one place to another, this movement can be unhealthy in a healthcare setting where airborne bacteria can be infectious. Another problem with individual suction pumps was their need to be safe when flammable anesthetics were in use. (This ceased to be a problem as flammable anesthetics were replaced by nonflammable anesthetics in the 1960s and 1970s.) A central vacuum system eliminated these two problems, since it exhausted contaminated air outdoors and no electric motor was needed in the patient area in order to provide the vacuum. (It should *not* be concluded that portable suction pumps are no longer used. With bacteria filters now available and used on suction pumps,

Figure 2. Home vacuum cleaner (high volume, low degree of vacuum) versus portable medical vacuum pump [low volume, low-to-high (adjustable) level of vacuum].

these devices are still quite suitable, in the same fashion that individual gas cylinders are still used.) It is necessary, however, that a trap unit be used between the patient and the vacuum control regulator and station inlet, so that nothing but air is drawn into the piping system.

The other reason central (add) vacuum systems began to be installed was the result of studies by the late David A. McWhinnie, Jr., in the early 1950s that showed the economic viability of these systems. Initially, vacuum central piped vacuum systems served only operating rooms and specialty areas, such as postanesthesia recovery rooms and emergency rooms. General patient care areas were added as demand for suction increased and economics made their installation viable. The reduction in the spread of airborne bacteria that central piped vacuum systems provided also contributed to their installation in general patient care areas as hospitals become more aware and concerned about this hazard. Pediatric and neonatal areas were last to install piped vacuum systems because of concern over what high degrees of vacuum and flow rates might do to babies (e.g., damage to very delicate tissues, possible collapse of newly functioning lungs). With improvements in the regulation of the degree of vacuum and more staff education, this concern abated, and piped vacuum systems were installed in these areas as well.

System Components

A medical piped vacuum system can be diagrammed, as shown in Fig. 3, in a fashion similar to the piped gas system described above. However, remember that the flow of subatmospheric air is opposite to the flow of pressurized gases in centrally piped gas systems. Note that piped vacuum systems require much larger orifices at

inlet terminals than those at outlet terminals for gas systems because of (1) the pressures involved [i.e., 12 in. (30.5 cm) of Hg (40.6 kPa) (negative pressure) as opposed to 50 psi (344.8 kPa)]; and (2) the need for high flow. As noted previously for piped gas systems, the following description for piped vacuum systems includes the major components of a large system. Of course, individual systems will vary.

Sources for Vacuum. Pumps provide the means by which suction is created. They draw in the air that exists within the piped system, and exhaust it via a vent discharge located on the outside of the building (generally on a roof) and away from any intake vents. This configuration allows exhausted air, which may be infectious, to dissipate into the atmosphere.

At least two pumps are required to be installed, each with either one capable of providing adequate vacuum to the entire system. This redundancy is necessary to keep the vacuum system functioning in case one pump fails or needs maintenance. To smooth out pump impulses and provide a constant vacuum, a receiver (surge tank) is required to be installed at the source site between the pumps and the rest of the system. Shutoff valves and check valves are to be installed for maintenance, and efficiency, and to shut down the system (or portions of the system) in the event of an emergency.

Piping (Distribution) System. Like piped gas systems, the first standard on piped vacuum systems required metal pipes to be used to connect the various patient care areas to the receiver. And like gas systems, there were and still are prescribed locations for shutoff valves, check valves, vacuum switches, and vacuum-level gages.

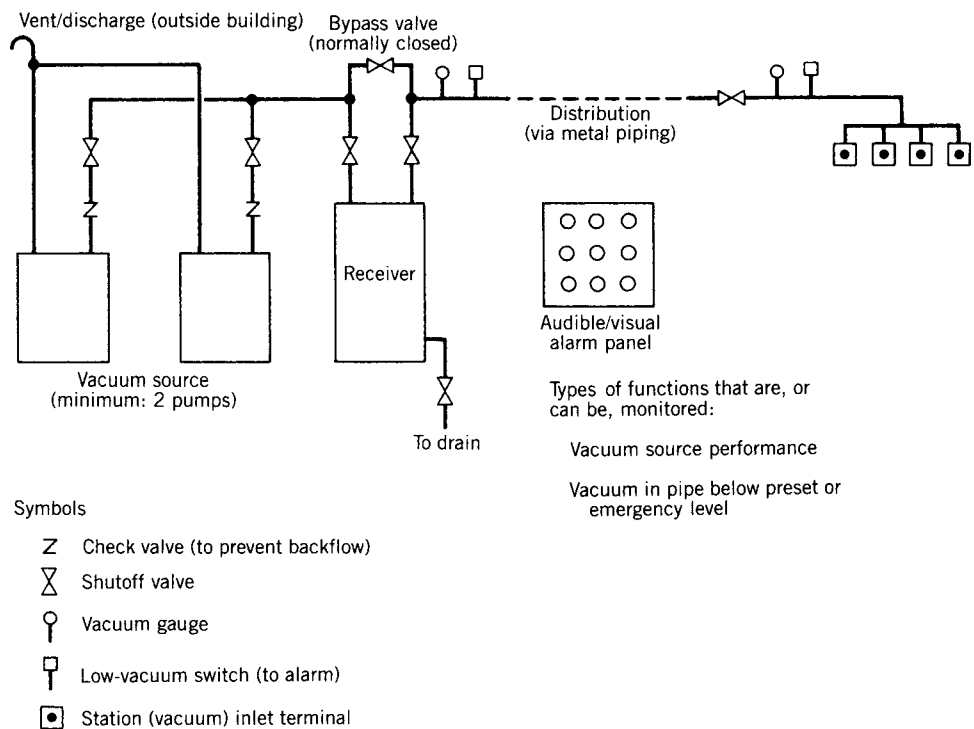

Figure 3. Components of a medical piped vacuum central piping system (simplified). Standards have been developed for component and total-system performance and safety. A collection unit and a trap are required between the inlet terminal and the patient.

However, because of the subatmospheric operating pressures and lower concentration of oxidizing gases in a piped vacuum system as opposed to a piped gas system, more types of metal pipes are allowed in the first standard on these vacuum systems. Piping for vacuum systems may have to be larger than piping for gas systems because of the level of airflow (vacuum) required by medical staff. Also, originally, the melting point allowed for joints can be lower for piped vacuum systems was permitted to be lower than the 1000° withstand-temperature required for piped gas systems. However, it is recognized that vacuum systems are sometimes installed at the same time as gas systems; as such, it may be prudent in those situations to use one type of piping throughout in order to reduce the chance of using the wrong piping and/or brazing on the piped gas system. In recent years, the committee responsible for piped vacuum system requirements has gradually required the type of piping for vacuum systems to be closer to that required for piped gas systems.

A significant difference of piped vacuum systems from piped gas systems permits connection of medical laboratories into patient care vacuum systems, though with the stipulation that the connection be made directly into the receiver and not via the pipes serving patient areas, so that a fluid trap and manual shut off valve are included. Separate systems, however, are encouraged.

Terminal Units (Station Inlets). The terminals for vacuum systems (called inlets), resemble the outlets of gas systems. Thus, it is required that they be clearly labeled vacuum or suction. To preclude problems (since piped vacuum systems sometimes are installed along at the same time with piped gas systems), the connector used for vacuum inlets is to be mechanically different from all gas outlet connectors, thereby reducing the chance of interconnection of gas and vacuum equipment.

Alarm Panels/Monitoring. Because vacuum is now a critical tool in the practice of medicine, it, too, requires constant monitoring. An audible/visual alarm panel (integrated with one for a piped gas system if also installed) alerts staff to problems similar to those of gas systems (e.g., pump malfunction, a drop in vacuum below a prescribed level).

Performance Criteria and Standards

With no vacuum standards in existence, the first piped vacuum systems installed were based on prevailing engineering expertise. While vacuum systems may seem similar to gas systems (e.g., piping, the movement of gas, although in the opposite direction), the design criteria for them are very different technically. With a piped gas system, after the source gas has been connected, the whole system reaches and stabilizes at a narrow range of pressure. In a piped vacuum system, a pump is trying to evacuate a space and provide a degree of vacuum [measured in inches of Hg (negative) *and* in volume displacement (flow)] at each inlet. In the former, the gas itself within the system provides a positive pressure and flow; in the latter, a pump is required to create a subatmospheric pressure and flow.

In the early 1950s, ineffective performance plagued many piped vacuum systems. Staff techniques, the lack of appropriate check valves, and widely divergent pump sizing contributed to the problems. One city known to have been investigating the problem was Detroit. During the 1950s, the city attempted to establish a municipal standard for the piped vacuum systems in city hospitals. Several of the major manufacturers of vacuum pumps became involved in the effort. Because general agreement could not be reached, the manufacturers suggested that industry try to develop a standard. This led to Compressed Gas Association (CGA) involvement, since many of its members were by the late 1950s supplying vacuum pumps and inlet connectors. In 1961, the CGA released a document (designated P-2.1) that included recommendations on pumps, warning systems, piping, installation, and labeling. It also included recommendations on pump sizing.

During the 1960s, staff practices were improved or standardized. This included the location of collection bottles (below patient level) and the use of regulator bypasses. This helped system performance as well. Because there continued to be differences of opinion in the engineering world regarding piped vacuum system design, the CGA approached the NFPA in the early-1970s about the NFPA developing a medical-surgical vacuum system standard. The NFPA agreed to the idea and a subcommittee of the then Committee on Hospitals was established. After tests of various pumps and suction-therapy equipment, and surveys of actual systems in hospitals, a recommended practice (designated NFPA 56K) was adopted by NFPA in 1980. After 3 years, it was revised and changed to a standard (being incorporated into NFPA 99, Standard for Health Care Facilities, at the same time) (11). The NFPA recommended practice (and then standard) generally contained the same topics as the CGA document. Other standards that impact piped vacuum systems have been developed. Most have already been mentioned or listed for piped gas systems and cover such subjects as cleaning and purging, pressure testing, and connection for emergency electrical power.

As noted, the initial criteria for installing vacuum central piped vacuum systems differed from piped gas systems. Of late, the major document on the subject (NFPA 99) has gradually revised piped vacuum system requirements, particularly on piping material, to that required for piped gas systems. But if they a piped vacuum system is are installed alongside a piped gas system at the same time the gas system is installed, the installation standards of the gas system should be considered to avoid possible degradation of the gas system, which requires more stringent standards.

Requirements on piped vacuum system design have also been deleted from the NFPA 99 document as it was seen to be outside the scope of the document (NFPA 99 is a minimum performance safety standard), as well as not changed in the document for > 20 years.

MAINTENANCE OF SYSTEMS

A separate note on maintenance is deemed warranted because of the inherent hazards posed by piped gas and

vacuum systems, as well as the high reliance now placed on these systems by medical–surgical–nursing staff. In the former, everyone is affected by the hazards; in the latter, failure of these systems can place patients at considerable medical risk.

Like any system, periodic maintenance is necessary in order to assure continuous, and optimum and safe level of operation. For piped gas or vacuum systems, this includes visual inspection of exposed pipes and outlets–inlets, sampling of gases (gas systems), measurement of pressures (gas systems), measurement of flow rates (vacuum systems), and testing of alarms. Guidance on this subject is included in such documents as NFPA 99, *Standard for Health Care Facilities* (11).

While today's standards assure a high probability of a safe and reliable system, mechanical failures can and do occur, and human error or abuse still remain. Thus, should a fault of some kind occur, or a wrong connection be made, periodic maintenance should detect the condition so that corrective action can be taken before a serious incident occurs. This maintenance is particularly necessary whenever either system is breached for upgrading, component maintenance occurs, or system expansion purposes made. The value of these systems in the treatment of patients demands no less.

GASTROINTESTINAL HEMORRHAGE

R.C. BRITT

INTRODUCTION

Gastrointestinal (GI) hemorrhage is a common medical problem, with significant morbidity and mortality. Traditionally, GI hemorrhage was managed by medically supporting the patient until the bleeding stopped or surgical intervention was undertaken. The modern day management of GI hemorrhage involves a multidisciplinary approach, including gastroenterologists, surgeons, interventional radiologists, primary care physicians, and intensivists. Despite the evolution in management of GI hemorrhage, the mortality rate has remained fairly constant, concentrated in the elderly with greater comorbidity (1). Additionally,

medical advances, e.g., proton pump inhibitors, H₂ blockers, antimicrobial treatment of *Helicobacter pylori*, and endoscopic management have led to a decrease in the number of operations for hemorrhage, but not in the actual number of hemorrhages (2). The incidence of upper GI bleeding has remained relatively constant at 100–150/100,000 people (3), with an estimated 300,000–350,000 admissions annually and a mortality rate of 7–10% (4). Lower GI hemorrhage accounts for 20–30% of GI hemorrhage, and typically has a lower mortality rate than upper GI bleeding.

There are three major categories of GI hemorrhage, including esophageal variceal bleeding, nonvariceal upper GI bleeding, and lower GI bleeding. Typically, upper GI bleeding is classified as that bleeding occurring from a source proximal to the ligament of Treitz, with lower GI bleeding occurring distally. When bleeding occurs in the upper GI tract, it can be vomited as bright red blood, referred to as hematemesis. Slower bleeding from the upper GI tract is often referred to as “coffee-ground emesis”, which refers to the vomiting of partially digested blood. Black, tarry stool is referred to as melena, and usually originates from an upper GI source, with the black color due to the action of acid on hemoglobin. Visible blood in the stool, or bright red blood per rectum, is referred to as hematochezia. Hematochezia is usually indicative of lower GI bleeding, although brisk upper GI bleeding may also present as hematochezia. The stool may also be maroon, suggesting the blood has mixed with liquid feces, usually in the right colon.

INITIAL EVALUATION AND RESUSCITATION

Upon presentation with GI hemorrhage, two large-bore (16 gauge or larger) peripheral IVs should be placed and intravascular volume resuscitation initiated with an isotonic solution. Lactated Ringers is frequently preferred to 0.9% Normal Saline because the sodium and chloride concentrations more closely approximate whole blood. The ABCs of resuscitation are a priority in the initial evaluation of the massive GI bleed, with careful attention given to the airway because of the high incidence of aspiration. The patient must be carefully monitored to ensure the adequacy of resuscitation. In the presence of continued rapid bleeding or failure of the vital signs to improve following 2 L of crystalloid solution, the patient should also begin receiving blood. If type-specific blood is not yet available, the patient may receive O negative blood.

On presentation, blood is drawn for hematocrit, platelets, coagulation profile, electrolytes, liver function tests, and a type and cross. Caution must be used when evaluating the initial hematocrit, as this does not accurately reflect the true blood volume with ongoing hemorrhage. A foley catheter should be inserted to monitor for adequate urine output as a marker for adequate resuscitation. An NG tube should be inserted to evaluate for the presence of upper GI bleeding, as bright red blood per NG tube indicates recent or active bleeding. While clear, bilious aspirate usually indicates that the source of bleeding is not upper GI, this is not a definite as absence of blood on

nasogastric aspirate is associated with a 16% rate of actively bleeding lesions found on upper endoscopy (5).

A thorough history is paramount when evaluating a patient presenting with GI hemorrhage. The clinical history may suggest the etiology of hemorrhage, as well as offer prognostic indicators. Important features in the history include a history of previous bleeding, history of peptic ulcer disease, history of cirrhosis or hepatitis, and a history of alcohol abuse. Also important is a history of medication use, particularly aspirin, nonsteroidals, and anticoagulants. Symptoms the patient experiences prior to the onset of bleeding, such as, the presence or absence of abdominal pain, can also be useful in the diagnosis.

A comprehensive physical exam must be done to evaluate the severity of the hemorrhage, as well as to assess for potential etiology. Massive hemorrhage is associated with signs and symptoms of shock, including tachycardia, narrow pulse pressure, hypotension, and cool, clammy extremities. The rectal exam may reveal the presence of bright red blood or melena, as well as evidence of bleeding hemorrhoids in a patient with bright red blood per rectum. Physical exam is also useful to evaluate for stigmata of liver failure and portal hypertension, such as, jaundice, ascites, telangiectasia, hepatosplenomegaly, dilated abdominal wall veins, and large hemorrhoidal veins.

When faced with a patient presenting with GI hemorrhage, the complete history and physical exam will help direct further management by assessing the likely source of bleed. The initial questions that must be answered to determine management priorities include whether the likely source of hemorrhage is from the upper or lower GI tract, and if the bleeding is from an upper source, whether the bleed is likely variceal or nonvariceal (Table 1).

UPPER GASTROINTESTINAL BLEEDING

Upper gastrointestinal bleeding is shown in Table 2.

Gastroesophageal Varices

Portal hypertension, defined as an increase in pressure > 5 mmHg (0.666 kPa) in the portal venous system (6), can lead to acute variceal hemorrhage. Cirrhosis, related to either chronic alcohol abuse or hepatitis, is the most common cause of portal hypertension, and leads to an increased outflow resistance, which results in the formation of a collateral portosystemic circulation. Collaterals form most commonly in the gastroesophageal junction and form submucosal variceal veins. Patients with isolated splenic vein thrombosis often form submucosal varices in the fundus of the stomach. Some 30–60% of all cirrhotic patients will have varices at the time of diagnosis, and 5–8% develop new varices each year (7). One-third of patients with varices will experience variceal hemorrhage, with mortality from the first variceal bleed as high as 50% (8). Rebleeding occurs frequently, especially in the first 6 weeks. Risk factors for early rebleeding, within the first 6 weeks, include renal failure, large varices, and severe initial bleeding with hemoglobin < 8 g·dL⁻¹ at admission (6). The risk of late rebleeding is related to the severity of liver

Table 1. Localization of Gastrointestinal Hemorrhage

Diagnosis	History	Physical Examination
<i>Esophagus</i>		
Nasopharyngeal bleeding	Epistaxis	Blood in nares, blood dripping down pharynx, evidence for telangiectasias
Esophagogastric varices	Alcoholism, lived in area where schistosomiasis is endemic, history of blood transfusions or hepatitis B	Stigmata of chronic liver disease, (e.g., gynecomastia, testicular atrophy, parotid enlargement Cachexia, Kaposi's sarcoma, oral candidiasis)
Esophagitis	Dysphagia, odynophagia; immunosuppressed, (e.g., AIDS); diabetes mellitus, lymphoma, elderly	
Esophageal neoplasm	Progressive dysphagia for solids	Cachexia
Mallory–Weiss tear	Retching or vomiting prior to hematemesis	Not specific
<i>Stomach</i>		
Acute gastric ulcer	Intensive care unit setting	Comatose, multiple burns, on respirator
Chronic gastric ulcer	Peak between 55 and 65 years old	Not specific
Acute hemorrhagic gastritis	History of aspirin use, intensive care unit setting	Similar to acute gastric ulcer
Gastric neoplasm	Weight loss, early satiety; obstructive symptoms	Cachexia, Virchow's node; abdominal mass
Gastric angiodysplasia	Elderly	Aortic stenosis murmur
Gastric telangiectasia	Epistaxis, family history of Osler-Weber-Rendu disease or history of renal failure	Telangiectasias on lips, buccal mucosa, palate
<i>Duodenum</i>		
Duodenal ulcer	Epigastric pain	Not specific
Aortoenteric fistula	History of abdominal aortic aneurysm repair	Laparotomy scar
<i>Colon</i>		
Colonic neoplasm	Often occult; if located in rectosigmoid then may have obstructive symptoms	Mass on rectal examination
Cecal angiodysplasia	Elderly, recurrent bleeding, low grade	Aortic stenosis murmur
Colonic diverticuloses	Severe, single episode of bright red blood per rectum	Not specific

failure, ongoing alcohol abuse, variceal size, and renal failure (6).

Variceal bleeding classically presents as massive, painless upper GI hemorrhage in a patient with known cirrhosis. The management of acute variceal bleeding requires attention to adequate resuscitation as well as control of the active bleeding and minimization of complications related to the bleed (Fig. 1). Early endoscopy is imperative for the successful management of variceal bleeding. Frequently,

endoscopy is performed in conjunction with pharmacologic therapy. Endoscopy is essential to confirm the diagnosis of bleeding varices, as many patients with cirrhosis bleed from a source other than varices. Endoscopic sclerotherapy is effective in managing active variceal hemorrhage 70–90% of the time, and is superior to balloon tamponade or vasopressin (6). Intravariceal and paravariceal injections are equally efficacious. Sclerotherapy should be repeated at 1 week, and then at 1–3 week intervals until the varices are obliterated. Endoscopic variceal band ligation achieves hemostasis 90% of the time, and is felt to have a lower rebleeding and complication rate than sclerotherapy (9).

Pharmacologic therapy is used in conjunction with early endoscopy in massive variceal bleeding. Vasopressin, which works to cause splanchnic and systemic vasoconstriction and thus decrease portal venous flow, was traditionally used to control hemorrhage, but its use is limited by systemic side effects in 20–30% of patients (10). Vasopressin causes systemic vasoconstriction, which is particularly problematic in patients with coronary artery disease, in which vasoconstriction may induce myocardial infarction. Simultaneous administration of intravenous nitroglycerine will minimize the cardiac complications

Table 2. Upper Gastrointestinal Bleeding**Differential Diagnosis of Upper GI Hemorrhage**

Gastroesophageal varices

associated with vasopressin. Somatostatin, and its long-acting analog Octreotide, work via inhibition of various vasodilatory hormones, and therefore inhibit splanchnic vasodilatation and decrease portal pressure. Somatostatin is as effective as vasopressin, but without the systemic side effects (11), and is currently the medication of choice to reduce portal pressure.

Occasionally, a patient presents with massive variceal hemorrhage not amenable to endoscopic or pharmacologic

therapy. Balloon tamponade, generally done with the Sengstaken–Blakemore tube, can be used to achieve short-term hemostasis, which is successful 60–90% of the time (12). Caution must be taken to secure the airway with endotracheal intubation prior to placement of the tamponade balloon because of the high risk of aspiration. Care must be used to ensure that the gastric balloon is in the stomach prior to full insufflation, as migration or inflation of the gastric balloon in the esophagus can lead to esophageal rupture. The balloon can be left in place for 24 h, at which time endoscopic band ligation or sclerotherapy can be performed.

Bleeding that cannot be controlled by endoscopic therapy or that recurs should be managed with portal pressure reduction. The initial approach currently used is the transjugular intrahepatic portosystemic shunt (TIPS), which can be done with or without general anesthesia. Potential benefits to the use of general anesthesia include advanced management of fluid dynamics by the anesthesiologist and pain management for the patient. The TIPS method works by creating a channel between the hepatic and portal veins, which is kept patent by a metal stent, which achieves

hemostasis in 90% of patients (13). The downside of TIPS is related to shunt thrombosis, which can occur early or late and may result in recurrent variceal bleeding. Approximately 20% of patients by 1 year and 30% by 2 years experience recurrent bleeding related to shunt thrombosis (14,15). Complications related to TIPS procedures include a 30% rate of encephalopathy, procedure related complications including inadvertent puncture of the portal vein leading to massive hemorrhage, stent stenosis and malfunction, and TIPS-associated hemolysis.

Traditionally, reduction of portal pressure was achieved by surgical shunt procedures or devascularization. Surgical shunt procedures include nonselective shunts, which divert all the portal flow away from the liver, and selective shunts. Nonselective shunts include the portacaval end-to-side and side-to-side shunts, the central spleno-renal shunt, and the interposition portacaval shunt. Nonselective shunts are successful in achieving hemostasis in the actively bleeding patient, but frequently lead to hepatic encephalopathy as well as acceleration of liver failure. Selective shunts include the distal splenorenal shunt and the small-diameter mesocaval shunt. The selective shunts have a lower rate of encephalopathy, but are frequently complicated by uncontrollable ascites given the continued portal flow. Nonshunt operations, including esophageal transection and devascularization of the gastroesophageal junction are rarely used today. In the setting of emergent operation for ongoing hemorrhage, a nonselective portacaval shunt is most frequently employed. The distal splenorenal shunt is the most common shunt used for elective control.

Once control of active bleeding is achieved, the focus shifts to prevention of future bleeding. Endoscopic band

ligation is the treatment of choice for long-term management of variceal hemorrhage (16). Beta-blockers in combination with nitrates have been shown to synergistically lower portal pressures and thus decrease the risk of rebleeding. Surgical shunting is an option in patients refractory to endoscopic or pharmacologic therapy, with the distal splenorenal shunt the most frequently used for this indication. For patients with liver failure, liver transplantation is effective for both long-term prevention of bleeding as well as hepatic decompensation and death.

NONVARICEAL UPPER GI BLEEDS

Peptic Ulcer Disease

Peptic ulcer disease is the most common cause of upper GI hemorrhage; accounting for between 40 and 50% of all acute upper GI bleeds. Major complications related to peptic ulcer disease include perforation, obstruction, and hemorrhage and occur in ~25% of patients, with hemorrhage the most common complication. Risk factors for peptic ulcer disease include infection with *H. pylori*, nonsteroidal antiinflammatory use, and physiologic stress related to critical illness. Medical advances including proton pump inhibitors and H₂ blockers have led to a decreased need for operation for hemorrhage, but no decrease in the actual number of hemorrhages (17).

Hemorrhage related to peptic ulcer will classically present as hematemesis. In the setting of massive bleeding, the patient may also present with hematochezia. The patient may give a history of midepigastic abdominal pain preceding the bleeding. Important elements in the history include a history of peptic ulcer disease and recent usage of aspirin or nonsteroidal medications. Adverse clinical prognostic factors include age > 60 years, comorbid medical conditions, hemodynamic instability, hematemesis, or hematochezia, the need for emergency surgical interventions, and continued or recurrent bleeding (18).

The initial diagnostic test on all patients presenting with an upper GI bleed should be endoscopy. Endoscopy is the best test for determining the location and nature of the bleeding lesion, provides information regarding the risk of further bleeding, and allows for therapeutic interventions. Endoscopy should be performed urgently in all high-risk patients, and within 12–24 h for patients with acute, self-limited episodes of bleeding. The goal of endoscopy is to stop the active hemorrhage and reduce the risk of recurrent bleeding. Stigmata of recent hemorrhage (SRH) are endoscopically identified features that help determine which patients should receive endoscopic therapy. The SRH include active bleeding visible on endoscopy, visualization of a nonbleeding visible vessel, adherent clot, and a flat, pigmented spot (18). Certainly, patients with the major SRH including active bleeding or a visible vessel should undergo endoscopic therapy, as meta-analysis has shown a significant reduction in rates of continued or recurrent bleeding, emergency surgery, and mortality in those who received endoscopic therapy versus those who did not (19).

A variety of modalities exist for endoscopic therapy, including injection, thermal, and mechanical therapy. Epinephrine diluted 1:10,000 is the most frequently used

Figure 3. Management of acute lower gastrointestinal bleeding.

injection therapy, with injection into and adjacent to the bleeding point until hemostasis is achieved. Other agents used for injection therapy include ethanol, ethanolamine, thrombin, and fibrin. Thermal therapy is generally delivered by coaptive techniques, including bipolar electrocoagulation or heater probe. With coaptive coagulation, the probe is used to physically compress the vessel prior to delivery of heat to seal the vessel. Laser photocoagulation and argon beam plasma coagulation are noncoaptive techniques that are used less frequently. Mechanical therapy with hemoclips can also be used in bleeding, although the efficacy may be limited by ulcer location or a firm, scarred ulcer base preventing adequate application of the clips. A combination of injection therapy with epinephrine and bipolar thermal therapy is the most common endoscopic management of an acute bleed.

Despite initial success with endoscopic therapy, 15–20% of patients will rebleed, generally within the initial 72 h (18). While this was traditionally considered a surgical indication, endoscopic retreatment is now recommended for most patients. Repeat endoscopy rather than surgery was found in a prospective, randomized study to be associated with less complications and similar mortality (20). Surgical indications include massive hemorrhage

unresponsive to resuscitation and continued bleeding unresponsive to nonoperative management. For bleeding gastric ulcers, the operation of choice is a wedge resection to include the portion of the stomach containing the ulcer with or without vagotomy. For duodenal ulcers, truncal vagotomy, pyloroplasty, and direct oversewing of the bleeding ulcer via duodenotomy is the most common operation. Care must be taken to incorporate the proximal and distal gastroduodenal artery as well as the transverse pancreatic artery.

Therapeutic angiography is an option when therapeutic endoscopy is unsuccessful and may be performed prior to surgical intervention, as is effective, less invasive than surgery, and does not impact on the ability to surgically manage the bleeding if the intervention is unsuccessful. Angiographic options include selective intra-arterial vasopressin infusion or embolotherapy with microcoils, poly(vinyl alcohol) (PVA) particles, or gelatin sponge. Embolization is considered the first line angiographic therapy, with success rates as high as 88% (21). Vasopressin is selectively infused after bleeding has been identified by contrast extravasation at an initial rate of 0.2 units per minute, with an increase to 0.4 units per minute then 0.6 units per minute if hemostasis is not achieved. The infusion

is continued for 12–24 h, and then gradually tapered. Efficacy of vasopressin infusion ranges from 60 to 90% (22). Side effects related to selective infusion of vasopressin include abdominal cramping, fluid retention, hyponatremia, cardiac arrhythmias, and systemic hypertension. Vasopressin should not be used in patients with coronary artery disease because of the risk for myocardial ischemia.

Pharmacologic therapy to reduce gastric acidity is generally started as an adjunct to endoscopic therapy. The H₂ blockers were found in meta-analysis to reduce the rate of continued bleeding, surgery, and death (23); however, a subsequent multicenter randomized trial found no difference in rebleeding rates in patients randomized to famotidine infusion versus placebo (24). Intravenous proton pump inhibitors have been shown to reduce rebleeding rates, length of hospital stay, and need for blood transfusion (25). Treatment with a proton pump inhibitor is generally started on admission for upper GI bleed, and continued as an adjunct to endoscopic therapy.

Mallory–Weiss Tear

The Mallory–Weiss syndrome describes acute upper GI bleeding that occurs after retching or vomiting, and was first described by Kenneth Mallory and Soma Weiss in 1929 (26). The increased intragastric pressure caused by vomiting causes mucosal lacerations, which are usually longitudinal. The typical presentation is a patient who initially vomits gastric material, followed by hematemesis and melena. Mallory–Weiss tears can also occur after anything that raises intragastric pressure, such as blunt abdominal trauma, severe coughing, childbirth, seizures, and closed chest cardiac compression. Mallory–Weiss tears classically occur at the gastroesophageal junction, but can occur in the distal esophagus. The lesion is common, occurring in 5–15% of patients presenting with upper GI bleeding. The majority of Mallory–Weiss tears will stop bleeding spontaneously, although some patients will require emergency treatment for ongoing hemorrhage. Endoscopic options for Mallory–Weiss bleeding include band ligation, epinephrine injection, and hemoclip application. In cases not amenable to endoscopic management, operative therapy involves oversewing the laceration via a gastrotomy.

Gastritis

Stress gastritis is associated with multiple superficial gastric ulcerations and is typically seen in the critically ill patient. Mechanical ventilation and coagulopathy increase the risk for hemorrhage in the critically ill. Prophylaxis with H₂ blockers and proton pump inhibitors has led to a decrease in the incidence of stress gastritis in the critically ill. Bleeding from gastritis usually is self-limited, not requiring intervention. Early endoscopy is essential to establish the diagnosis and rule out other sources of upper GI bleeding. The patient should be started on pharmacologic therapy with either proton pump inhibitors or H₂ blockers at a therapeutic dose. Endoscopic laser anticoagulation has been used for bleeding gastritis. Intraarterial infusion of vasopressin or selective embolization may also be used to arrest hemorrhage in gastritis. Ongoing hemorrhage not amenable to nonsurgical management is

operatively managed with vagotomy, pyloroplasty, and oversewing of the bleeding sites versus total gastrectomy. The mortality for a patient requiring surgical management of bleeding gastritis remains quite high.

Esophagitis

Esophagitis is an unusual cause of acute gastrointestinal bleeding, and only rarely occurs in association with severe reflux esophagitis. The history would be suggestive of gastroesophageal reflux, with symptoms, such as, heartburn, cough, and hoarseness. Rare causes of esophagitis associated with bleeding in the immunocompromised patient include infection with candida, herpes, or cytomegalovirus (27).

Neoplasm

Acute upper GI bleeding is a rare manifestation of esophageal neoplasms, with <5% of esophageal malignancies presenting with an acute bleed. Occult, slow GI bleeding is much more common with esophageal neoplasms. Benign tumors of the esophagus include leiomyomas and polyps, and are very unlikely to present with GI bleeding. Esophageal hemangiomas, which constitute only 2–3% of benign esophageal tumors, may present with potentially massive GI hemorrhage. Leiomyosarcomas are more likely to bleed than benign leiomyomas. When brisk bleeding occurs in the setting of esophageal cancer, one also must consider the erosion of the tumor into a major thoracic vessel.

Dieulafoy Vascular Malformation

Dieulafoy lesions are the result of arterioles of large diameter (1–3 mm) running through the submucosa, with erosion of the overlying mucosa resulting in bleeding. The mucosal defect is usually small, without evidence of chronic inflammation. Dieulafoy lesions generally present with brisk hemorrhage, due to their arterial nature. Diagnosis is made by upper endoscopy, with visualization of a small mucosal defect with brisk bleeding. Management is initially endoscopic with epinephrine injection and bipolar thermal therapy. Catheter embolization is generally successful in patients who fail endoscopic management. For patients requiring surgical management, the operation involves a wedge resection of the lesser curve of the stomach at the site of the lesion.

AORTOENTERIC FISTULA

Aortoenteric fistula classically occurs as a communication between a prosthetic aortic graft and the distal duodenum, and the diagnosis should be entertained in any patient presenting with an upper GI bleed who has undergone aortic reconstruction. The time period from aortic surgery to presentation is varied, and many patients present years down the road. The patient will frequently present initially with a sentinel bleed, which may be followed by massive upper GI hemorrhage. Upper endoscopy is paramount to making the diagnosis, as well as ruling out other sources of upper GI bleeding. Upon making the diagnosis of aortoenteric fistula, the optimal management is surgical, with removal of the aortic prosthesis, extra-anatomic bypass, and repair of the duodenum.

HEMOBILIA

Hemobilia classically presents as upper GI bleeding, melena, and biliary colic. Diagnosis is established by upper endoscopy, with visualization of blood from the ampulla. Endoscopic retrograde cholangiopancreatography can more clearly delineate the source of hemobilia. A variety of disease processes can lead to hemobilia, including hepatobiliary trauma, chronic cholelithiasis, pancreatic cancer, cholangiocarcinoma, and manipulation of the hepatobiliary tree. While hemobilia remains a rare cause of upper GI bleeding, the frequency is increasing related to increased manipulation of the hepatobiliary system and improved diagnostic modalities. Many cases of hemobilia will resolve without intervention. In the setting of ongoing hemorrhage, angiography with selective embolization of the bleeding vessel is the primary treatment modality. Surgery is reserved for failure of angiographic management.

LOWER GI BLEEDING

The passage of bright red or maroon blood via the rectum suggests a bleeding source distal to the ligament of Treitz, although blood can originate from any portion of the GI tract, depending on the rate of bleeding. Some 80–90% of lower GI bleeding will stop spontaneously. Initial resuscitation is similar to the patient presenting with upper GI bleeding, with hemodynamic assessment, establishment of appropriate access, and thorough history and physical exam. Visual inspection of the anorectal region, followed by anoscopy is essential to rule out a local anorectal condition such as hemorrhoids as the source of bleeding. A variety of modalities are available to further define the etiology of the bleeding, including endoscopy, nuclear medicine, angiography, and intraoperative localization.

The timing of colonoscopy for acute lower GI bleeding is controversial, with early (within 24 h of admission) colonoscopy increasingly advocated. Certainly, visualization may be difficult in a massively bleeding patient. Aggressive bowel prep can be given for 6–12 h prior to endoscopy, with the benefit of improved visualization. The benefit of early colonoscopy, similar to early upper endoscopy for upper GI bleed, is the opportunity for endoscopic diagnosis and therapy, using injection therapy and thermal modalities. Colonoscopy can directly visualize the bleeding source, which is beneficial in directing the surgeon in resection if the patient has continued or recurrent hemorrhage. Additionally, early colonoscopy may shorten hospital length of stay (28).

Nuclear scans can localize the site of lower GI bleeding and confirm active bleeding, with sensitivity to a rate of bleeding as low as 0.05–0.1 mL·min⁻¹. Bleeding scans use either ^{99m}Tc sulfur colloid or ^{99m}Tc-labeled erythrocytes, with radioactivity detected by a gamma camera, analyzed by computer, and recorded onto photographic film. The ^{99m}Tc sulfur colloid has the advantage of detection of bleeding as slow as 0.05 mL·min⁻¹, is inexpensive, and easy to prepare, but only will detect bleeding within 10 min of injection as it disappears quickly from the bloodstream (21). ^{99m}Tc-labeled erythrocytes detect bleeding as

slow as 0.1 mL·min⁻¹, and circulate within the bloodstream for 24 h. The ^{99m}Tc-labeled erythrocyte technique is generally considered the test of choice because of an increased sensitivity and specificity when compared with the ^{99m}Tc sulfur colloid (21). When a bleeding scan is positive, angiography or endoscopy is recommended to confirm the location of bleeding, to diagnose the specific cause, and to possibly apply either endoscopic or angiographic therapy.

Angiography is advantageous because of the potential for both localization and treatment. Angiographic control can permit elective rather than emergent surgery in patients who are good surgical candidates, and can provide definitive treatment for poor surgical candidates. Bleeding can be detected at a rate as low as 0.5 mL·min⁻¹. The SMA is cannulated initially, with cannulation of the IMA if the SMA study is nondiagnostic. When bleeding is localized, either vasopressin infusion or superselective catheter embolization may be used. Vasopressin is used in a method similar to upper GI bleeding, with an infusion rate of 0.2–0.4 units·min⁻¹. Efficacy varies from 47–92%, with rebleeding in up to 40% of patients (21). Vasopressin is particularly effective for bleeding from diverticula.

Angiographic embolization may be done with a variety of agents, including coil springs, gelatin sponge, cellulose, and (PVA). There is less collateral blood supply in the lower G tract than in the upper, so embolization was initially thought to be a salvage therapy for those patients who would not tolerate an operation. Recent innovations in catheter and guidewire design, however, have enabled the interventional radiologist to superselectively embolize the bleeding vasa recta, sparing the collateral vessels and thus minimizing ischemia. Several small studies have reported successful embolization without intestinal infarction (21), with combined results showing successful hemostasis in 34 of 37 patients. Superselective embolization with coaxial microcatheters is currently considered the optimal angiographic therapy.

Traditionally, emergency operations for lower GI bleeding were required in 10–25% of patients presenting with bleeding (29). Surgical indications traditionally include hemodynamic instability, ongoing transfusion requirements, and persistent or recurrence of hemorrhage. If the bleeding has not been localized, a total abdominal colectomy with ileorectal anastomosis or end ileostomy is performed. If the lesion has been localized to either the right or left side of the colon, a hemicolectomy may be performed. With the advances in angiography available, the surgical indications are evolving. If an angiographer is readily available, angiographic localization and therapy is a viable option even for the hemodynamically unstable or persistently bleeding patient, thus avoiding the high morbidity and mortality associated with emergent total colectomy in this patient population.

Diverticulosis

The most common cause of lower GI bleeding is diverticular disease. Diverticular disease increases with age and is present in 50% of people > 80 years. Less than 5% of these patients, however, will hemorrhage. While most diverticula are found distal to the splenic flexure, bleeding

diverticula more frequently occur proximal to the splenic flexure. Classically, the patient will present with sudden onset of mild lower abdominal pain and the passage of maroon or bright red bloody stool per rectum. The majority of diverticular bleeds will stop spontaneously, with a recent study showing spontaneous resolution in 76% of patients (1). About 20–30% of patients will have a recurrent bleeding episode, of which the majority will again stop without intervention. Patients that have persistent or recurrent bleeding should be considered for surgical therapy, particularly if the site of bleeding has been localized. High risk surgical patients can be treated with angiographic or endoscopic therapy.

Angiodysplasia

Angiodysplasia arises from age-related degeneration of submucosal veins and overlying mucosal capillaries, with frequency increasing with age. The bleeding tends to be less severe than with diverticular bleeds, and frequently resolves spontaneously, although recurrence is common. Diagnosis can be made by colonoscopy, with electrocoagulation as definitive therapy. Angiography may also be used for diagnosis, with the angiographic hallmarks a vascular tuft from an irregular vessel, an early and intensely filling vein resulting from arteriovenous communication, and persistent venous filling (30). Angiographic therapy with vasopressin can be used for treatment.

Neoplasm

While polyps and cancers frequently present with blood per rectum, they rarely cause massive hemorrhage as the presenting symptom. Diagnosis is made with colonoscopy. Management of a polyp is via colonoscopic polypectomy, while cancer requires surgical resection. Occasionally, a patient will present up to 1 month following a polypectomy with lower GI bleeding, which should prompt colonoscopy and thermal or injection therapy to the bleeding polypectomy site.

Meckel's Diverticulum

Meckel's diverticulum is an unusual cause of GI bleeding, and usually occurs in the first decade of life. The etiology of the bleeding is ectopic gastric mucosa in the diverticulum with resultant ulceration of adjacent bowel. Diagnosis is usually demonstrated by nuclear scanning demonstrating the ectopic gastric mucosa. Management is with surgical resection of the diverticulum as well as the adjacent bowel.

Ischemic Colitis

Ischemic colitis generally presents with bloody diarrhea, and massive lower GI bleeding is rare in this population. The bloody diarrhea is due to mucosal sloughing. Ischemic colitis should be suspected in patients with a history of vascular disease and in critically ill, hypotensive patients with a low flow state. Diagnosis is made by flexible endoscopy showing evidence of ischemia. Management for early ischemia is resuscitation and improvement of blood flow. Advanced ischemia requires surgical resection of the necrotic portion of the bowel.

Inflammatory Bowel Disease

GI bleeding characterizes both Crohn's disease and ulcerative colitis; however, massive bleeding is quite uncommon. The bleeding from inflammatory bowel disease is usually self-limited, and rarely acutely requires surgical attention. Diagnosis is made by colonoscopy, with identification of features unique to these entities and biopsy for pathology. Occasionally, ulcerative colitis will present fulminantly with massive hemorrhage and require surgical resection, consisting of total colectomy, end ileostomy, and Hartman's pouch, leaving the possibility for future conversion to an ileo-pouch anal anastomosis. Both entities are managed with immunosuppressive medications.

GLUCOSE SENSORS

FARBOD N. RAHAGHI
DAVID A. GOUGH
University of California,
La Jolla, California

INTRODUCTION

Glucose assay is arguably the most common of all medical measurements. Billions of glucose determinations are performed each year by laypeople with diabetes based on

“fingersticking” and by healthcare professionals based on blood samples. In fingersticking, sample collection involves the use of a lancet to puncture the skin of the fingertip or forearm to produce a small volume of blood and tissue fluid, followed by collection of the fluid on a reagent-containing strip and analysis by a handheld meter. Glucose measurements coupled to discrete sample collection continue to be the most common method of glucose monitoring. However, new types of sensors capable of continuous glucose monitoring are nearing clinical introduction. Continuous or near-continuous glucose sensors may make possible new and fundamentally different approaches to the therapy of the disease. This article reviews recent progress in the development of new glucose sensors and describes the potential roles for these sensors in the improved treatment of diabetes.

THE CASE FOR NEW GLUCOSE SENSORS

The objective of all forms of therapy for diabetes is the maintenance of blood glucose near normal levels (1). The Diabetes Control and Complications Trial (or DCCT) and counterpart studies such as the United Kingdom Prevention of Diabetes Study (UKPDS) have clearly demonstrated (Fig. 1) that lower mean blood glucose levels resulting from aggressive treatment can lead to a reduced incidence and progression of retinopathy, nephropathy, and other complications of the disease (2,3). These prospective studies showed definitively that there exists a cause-and-effect relationship between poor blood glucose control and the complications of diabetes. As convenient means for frequent glucose assay were not available at the time, glucose control was assessed in these trials by glycosylated hemoglobin levels (Hb_{A1c}), which indicate blood glucose concentrations averaged over the previous 3 month period. Although Hb_{A1c} levels are useful for assessment of longitudinal blood glucose control, the values indicate only *averaged* blood glucose, rather than blood glucose *dynamics* (i.e., how blood

Figure 1. The results of the DCCT (2). Results show that improved glucose control, measured by a reduction in the fraction of glycosylated hemoglobin, leads to reduced long-term complications of diabetes. (Copyright © 1993, Massachusetts Medical Society.)

glucose changes with time), and cannot be used for immediate adjustment of therapy (4). There is general agreement that frequent determination of glucose by a sensing method that is convenient and widely acceptable to people with diabetes would allow a finer degree of control. Normalization of blood glucose dynamics may be of equal or greater importance than normalization of average blood glucose. The results of the DCCT and related studies point to the need for practical new approaches to achieve control.

The primary need for a new type of glucose sensor is to facilitate improved treatment of type 1 diabetes. In this case, the insulin producing ability of the pancreas has been partially or fully destroyed due to a misdirected autoimmune process, making insulin replacement essential. The sensor would help avoid the long-term complications associated with hyperglycemia (i.e., above-normal blood glucose) by providing information to specify more timely and appropriate insulin administration. It is now becoming widely appreciated that a new sensor could also be beneficial for people with the more common type 2 diabetes, where a progressive resistance of peripheral tissues to insulin develops, leading to glucose imbalances that can eventually produce long-term clinical consequences similar to type 1 diabetes. Type 2 diabetes is related to obesity, lifestyle, and inherited traits. In recent years, the incidence of type 2 diabetes has increased at extraordinary rates in many populations, to the point of becoming a worldwide epidemic (5). It is estimated that within 10 years, the prevalence of diabetes may approach 210 million cases worldwide (6). This places increased urgency on developing new approaches to managing or preventing the disease where possible, and a meliorating its consequences.

In addition, an automatic or continuous sensor may also have an important role in preventing hypoglycemia (i.e., below-normal blood glucose). Hypoglycemia is caused primarily by a mismatch between the insulin dosage used and the amount of insulin actually needed to return the blood glucose level to normal. Many people with diabetes can reduce the mean blood glucose by adjustment of diet, insulin, and exercise, but when aggressively attempted, this has led to a documented increase in the incidence of hypoglycemia (7). Below-normal glucose values can rapidly lead to cognitive lapses, loss of consciousness, and life-threatening metabolic crises. In children, there is concern that severe hypoglycemic events may lead to neurologic sequelae (8). A significant percentage of deaths of people under 40 with type 1 diabetes is due to the "dead-in-bed" syndrome (9), which may be linked to nocturnal hypoglycemia. Some experts claim that "... the threat of severe hypoglycemia remains the single most important barrier to maintaining normal mean blood glucose" (10). A continuous glucose sensor that does not depend on user initiative could be part of an automatic alarm system to warn of hypoglycemia and provide more confidence to the user to lower mean blood glucose, in addition to preventing hypoglycemia by providing improved insulin dosages. Hypoglycemia detection may be the most important application of a continuous glucose sensor. Ultimately, a glucose sensor may also be useful in the prediabetic state to indicate

behavior modification for reduction of metabolic stress on the pancreas.

Beyond applications in diabetes, it has recently been shown that stricter glycemic control during surgery and intensive care can reduce mortality in non-diabetic patients and significantly shorten the hospital stay (11). The exact mechanism of this effect has not been elucidated, but the benefit is closely tied to the extent of glucose control and not simply insulin dosage (12). This is another important application for new glucose sensors.

Alternatives to sensor-based therapies for diabetes are more distant. Several biological approaches to diabetes treatment have been proposed, including pancreatic transplantation, islet transplantation, genetic therapies, stem cell-based therapies, new pharmaceutical strategies, islet preservation, and others. Whole or partial organ and islet transplantation requires discovery of methods for assuring immuno-tolerance that do not rely on anti-rejection drugs and approaches for overcoming the shortage of transplantable pancreatic tissue. Potential therapies based on stem cells, if feasible, require basic research on growth, regulation, and implementation of the cells, and share the immuno-intolerance problem. Genetic therapies are limited by incomplete understanding of the complex genetic basis of diabetes, as well as progress in developing site-specific gene delivery, activation, and inactivation. Although transplantation, stem cell, and genetic approaches are based wholly on biological materials, it is not certain that the glucose and insulin dynamics resulting from their use will necessarily be near-normal or readily adjustable. Immunotherapeutic approaches for *in situ* preservation of islets are also being studied but, if eventually feasible, are far off and may require lifetime immune system modulation. The possibility of prevention of type 1 diabetes relies on development of timely methods for early detection of the disease and discovery of an acceptable approach to avoid or interrupt the islet destruction process. Furthermore, prevention will have little value for people who already have diabetes. These alternatives require substantial basic research and discovery, and while often highly publicized, are not likely to be available until far into the future, if eventually feasible.

Although new glucose sensors have the advantage of being closer to clinical introduction, there are certain other advantages as well. First, no anti-rejection medication will be needed. Second, the sensor will provide real-time information about blood glucose dynamics that is not available from other technologies. Third, in addition to real-time monitoring, continuous sensor information may be useful to *predict* blood glucose ahead of the present (13), a capability not feasible with the other approaches. Real-time monitoring and predictive capabilities may lead to entirely new applications of present therapies. Fourth, the sensor could operate in parallel with various other therapies, should they become available. The glucose sensor will likely have broad application, regardless of whether or when other technologies are introduced.

The sensor is also key to the implementation of the mechanical artificial beta cell. In the ideal configuration, this device would have an automatic glucose sensor, a refillable insulin pump, and a controller containing an

algorithm to direct automatic pumping of insulin based on information provided by the sensor. There has been progress on development of several of the components of this system, including: (1) external insulin pumps, which operate in a substantially preprogrammed mode with minor adjustments by the user based on fingerstick glucose information; (2) long-term implantable insulin pumps that operate in a similar way; (3) models of glucose and insulin distribution in the body that may eventually be useful in conjunction with control systems; and (4) controllers to direct insulin pumping based on sensor information. In contrast to other approaches to insulin delivery, the mechanical artificial beta cell has the advantage that the insulin response can be reprogrammed to meet the changing needs of the user. Development of an acceptable glucose sensor has thus far been the most difficult obstacle to implementation of the mechanical artificial beta cell.

THE IDEAL GLUCOSE SENSOR

The likelihood that glucose monitoring will reach its full potential as a tool for the therapy of diabetes depends on the technical capabilities of candidate sensors and the general acceptance of sensors by people with diabetes. Technical requirements of the sensor system include: specificity for glucose in the presence of interfering biochemicals or physiological phenomena that may affect the signal; sensitivity to glucose and adequate concentration resolution over the relevant range; accuracy as compared to a “gold standard” blood glucose assay; a sufficiently short response lag to follow the full dynamic range of blood glucose variations; reliability to detect mild hypoglycemia without false positives or negatives; and sufficient stability

that recalibration is rarely needed. The specific criteria for sensor performance remain a matter of consensus and may become better defined as sensors are introduced. The general acceptance of new sensors by people with diabetes will be based on such factors as safety, convenience, reliability, automatic or initiative-independent operation, infrequent need for recalibration, and independence from fingersticking.

For the glucose sensor to be a widely accepted innovation, the user must have full confidence in its accuracy and reliability, yet remain uninvolved in its operation and maintenance. Sensor systems under development have yet to reach this ideal, but some promising aspirants are described below. Short of the ideal, several intermediate sensing technologies with limited capabilities may find some degree of clinical application and, if used effectively, may lead to substantial improvements in blood glucose control. Nevertheless, the most complete capabilities will lead to the broadest adoption by users.

GLUCOSE SENSORS AND SENSING METHODOLOGIES

Several hundred physical principles for monitoring glucose have been proposed since the 1960s. Many are capable of glucose measurement in simple solutions, but have encountered limitations when used with blood, employed as implants, or tested in clinically relevant applications. Certain others have progressed toward clinical application. A brief summary of the history of events related to glucose sensor development is shown in Figure 2.

Present Home Glucose Monitoring

A major innovation leading to improved blood glucose management was the widespread use of home glucose

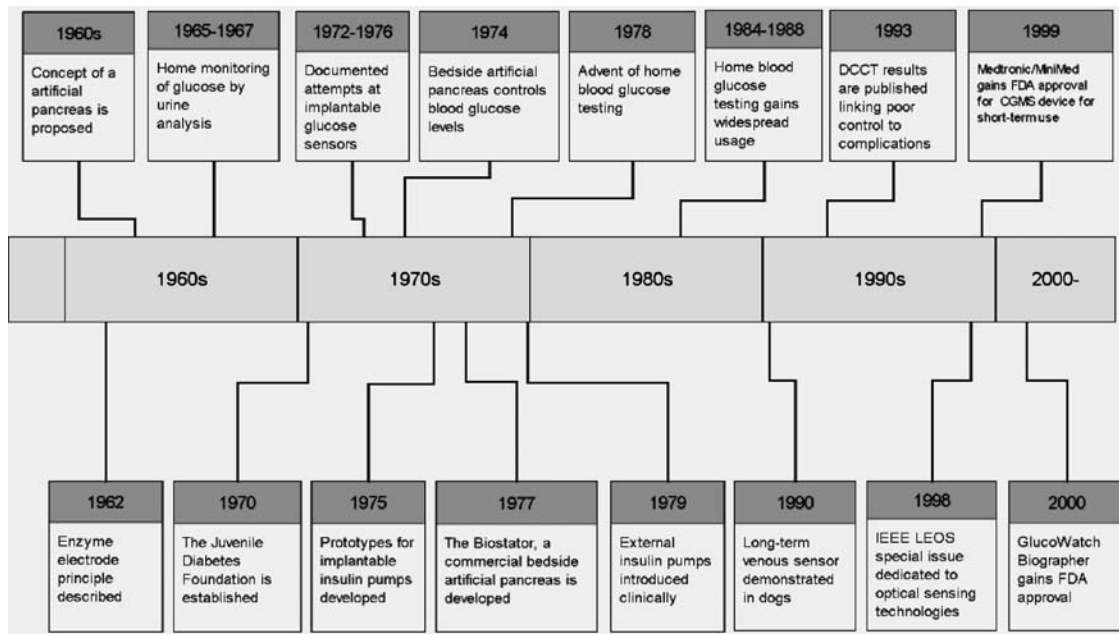

Figure 2. A time-line of some important developments relating to glucose sensors (2,14–24).

Figure 3. A small collection of home glucose monitoring equipment developed over the past decade. At either end (above) are devices used to puncture the skin for sample collection. Examples of commercial glucose meter (above, center) are also shown. Strips (below) contain immobilized glucose oxidase and are discarded after a single measurement.

monitoring in the 1980s (22). Present commercial versions of this technology are available with respective methods for glucose assay, data presentation and storage, sample volume requirements, and various convenience features (Fig. 3). These devices employ single-use strips based on enzyme methods discussed below. The widespread application of home glucose monitoring has permitted laypeople with diabetes to assume a newfound role in the management of their disease. The present standard-of-care recommends glucose measurement three or more times a day for insulin-dependent individuals (25), but a small number of individuals samples 10 or more times daily. It is generally suspected that the average sampling rate is inadequate and a recent publication noted that only 56% of diabetic individuals sampled their blood glucose once or more daily (26). The general resistance to more frequent sampling may be related to several factors, including: the pain associated with finger puncture, the requirement for user initiative, the general inconvenience of the assay, and unwillingness to carry out nocturnal testing (27).

When sampling is not sufficiently frequent, undetected blood glucose excursions can occur between samples. It has been shown that blood glucose measurements must be obtained every 10 min to detect all blood glucose excursions in the most severe diabetic subjects (28), although slower blood glucose excursions in the majority of people with diabetes may not require sampling at this frequency. The fact that the sample frequency required to detect all glycemic excursions is not clinically feasible with present technology indicates that the dynamic control of blood glucose is currently not practiced in diabetes management.

To compensate for infrequent monitoring, users typically adopt various strategies to estimate blood glucose concentration using subjective *ad hoc* models. These strategies rely on the most recent reported values of glucose, in conjunction with the timing and content of recent or upcoming meals, insulin therapy, and exercise. The effectiveness of these strategies is limited and the constant attention required to make such estimates represent a

substantial intrusion in lifestyle. Although glucose monitoring by fingersticking is likely to become more acceptable as the sample volume and the pain associated with sample collection are reduced, the problem of infrequent sampling and the requirement for user initiative will continue to be the major obstacles to the improvement of glucose control based on this technology.

Noninvasive Optical Sensing Concepts

Noninvasive optical methods are based on directing a beam of light onto the skin or through superficial tissues, and recording the reflected, transmitted, polarized, or absorbed components of the light (29). A key requirement for success of these methods is a specific spectral region that is sufficiently sensitive to glucose, but insensitive to other similar optically active interfering molecules and tissue structures. Several optical methods allow straightforward glucose measurement in simple aqueous solutions, but are ineffective at detecting glucose in tissue fluid, plasma, or blood. If an optical approach can be validated, a non-invasive sensor might be possible. For this reason, an intensive research effort and substantial industrial investment over the past two decades have gone into investigation of these concepts.

Infrared (IR) absorption spectroscopy is based on excitation of molecular motions that are characteristic of the molecular structure. The near-infrared (NIR) region of the spectrum (750–2500 nm) is relatively insensitive to water content so that the beam penetration depth in tissues can be substantial (30). Trials to identify a clinical correlation between NIR signals and blood glucose have employed various computational methods for analyzing the absorption spectrum. Basic studies have focused on identifying the absorbing species and tissue structures responsible for optical signals. However, after much effort the operating conditions that provide selectivity for glucose have yet to be established, leading one investigator to conclude that "... signals can be attributed to chance" (31).

Raman spectroscopy relies on detecting scattered emissions associated with vibrational molecular energy of the chemical species (as opposed to transmitted, rotational, or translational energy). Early studies compared the measurement in water of three different analytes (urea, glucose, lactic acid) and found that glucose levels could be determined with limited accuracy (32). Raman spectroscopy has been applied in the aqueous humor of the eye (33), which is thought to reflect delayed blood glucose levels over certain ranges (34). As with other optical methods, adequate specificity for glucose in the presence of other molecules remains to be demonstrated.

Measurement of the concentration using *polarimetry* is based on ability of asymmetric molecules such as glucose to rotate the plane of polarized light (35). This method is limited by the presence of other interfering asymmetric molecules, as well as the thickness and light scattering by tissues in the region of interest (30). Considerable development of polarimetry has centered on measurements in the anterior chamber of the eye (36), but there is yet to be a demonstration of sufficient selectivity under biological conditions.

Attempts at validation of optical sensor concepts have involved two general approaches. One approach endeavors to establish selectivity for glucose by identification of the components of tissues besides glucose that contribute to the optical signal, and determine if the effects of these interfering substances can be eliminated or the observed signals can be reconstructed based on all contributions. This has not yet been successful, in spite of intensive efforts. The impediment is the large number of optically active components in tissues, many of which produce much stronger effects than glucose. A second approach to validation involves identifying an empirical relationship between the observed optical signal *in vivo* and simultaneously recorded blood glucose concentration. Noninvasive optical approaches have been the premise of several human clinical trials, all of which have been unsuccessful. The prospects for a non-invasive optical glucose sensor are distant.

Implantable Optical Sensor Concepts

Implanted optical sensors offer the prospect of a less congested optical path, at the expense of requiring a more complicated device and confronting the foreign body response. One promising optical concept is based on chemical interaction between glucose and an optically active chemical species that is immobilized in an implanted, glucose-permeable chamber. The interaction creates a change in the optical signal which, under ideal conditions, may indicate glucose concentration. An example is the "affinity sensor" (37), in which glucose competes with a fluorescent substrate for binding with a macromolecule, Con A, resulting in a change in the optical signature. A similar detection strategy has been proposed as part of an implantable intraocular lens (38). There are difficulties with biocompatibility of the implant, design of the chamber, specificity of the optical detector, as well as toxicity and photobleaching of the indicator molecules (38). These systems have yet to be extensively tested.

Tissue Fluid Extraction Techniques

The interstitial fluid that irrigates tissues contains glucose derived from the blood in local capillaries. Several strategies have been devised to extract this fluid for glucose assay.

Microdialysis is based on a probe consisting of a fine hairpin loop of glucose-permeable dialysis tubing in a probe that is inserted into subcutaneous tissues (39). A fluid perfusate is continuously circulated through this tubing by a pump contained in an external apparatus (40), collected, and assayed for glucose concentration using an enzyme electrode sensor (Fig. 4). This methodology relies on the exchange of glucose between the microvascular circulation and the local interstitial compartment, transfer into the dialysis tube, and appropriate adjustment of the pumping pressure and perfusion rate (41). The advantage of the system is that a foreign body response of the tissue and local mass transfer resistance are slow to develop due to the sustained tissue irrigation, but drawbacks include the requirement for percutaneous access, the need for frequent relocation of the probe to minimize the chance

Figure 4. Diagram of a microdialysis probe (39). The semipermeable membrane at the probe tip allows exchange of soluble molecules between the probe and surrounding tissue. Samples are continuously collected and analyzed. (Used with permission of BMJ Publishing Group.)

of infection, and management of the external apparatus by the user. This device may find clinical applications for short-term monitoring.

Reverse iontophoresis employs passage of electrical current between two electrodes placed on the surface of the body to extract tissue fluid directly through the intact skin (42). Glucose in the fluid has been measured by an enzyme electrode-type sensor as part of a wristwatch-like apparatus (43) (Fig. 5). With a 2 h equilibration process after placing the device and a fingerstick calibration, the sensor can take measurements as often as every 10 min for 12 h, at which time sensor components must be replaced and the sensor recalibrated (44). This sensor was approved by the Food and Drug Administration (FDA) for indicating glucose trends, but users are instructed to revert to more reliable conventional assays for insulin dosing decisions. Minor skin irritation has been reported as a side effect (45). Although this sensor was briefly available commercially, it

Figure 5. The Glucowatch Biographer (43). An integrated system for sample extraction by reverse iontophoresis and glucose sensing. (Used with permission from John Wiley & Sons, Inc.)

was not successful as a product due to its limited capabilities and inconvenience.

Implantable Enzyme Electrode Sensors

The most promising approaches have been various configurations of the enzyme electrode sensor based on immobilized glucose oxidase coupled to electrochemical detectors. The enzyme catalyzes the reaction:

Monitoring of glucose can be based on detection of hydrogen peroxide production, oxygen depletion, or electron transfer via a conductive polymer link, as described below. Enzyme electrode sensors must contact the sample fluid to be assayed, and therefore require either sensor implantation or sample extraction (as in the case of reverse iontophoresis, microdialysis sensors and finger-stick devices). By employing the enzyme, sensors can have a significant advantage over non-enzymatic sensors of being *specific* for glucose rather than just selective. However, the benefits of enzyme specificity may not be fully realized unless the sensor is properly designed. To achieve the best performance, enzyme electrode sensors must include design features to address enzyme inactivation, biological oxygen variability, mass transfer dependence, generation of peroxide, electrochemical interference, and other effects.

From the perspective of biocompatibility, sensors can be implanted either in direct contact with blood or with tissues. Biocompatibility in contact with blood depends on the surface properties of the sensor as well flow characteristics at the implant site. Implantation in an arterial site, where the pressure and fluid shear rates are high, poses the threat of blood clotting and embolization, and is rarely justified. Central venous implantation is considerably safer, and there are several examples of successful long-term implants in this site.

Implantation of the sensor in a tissue site is safer, but involves other challenges. The sensing objective is to infer blood glucose concentration from the tissue sensor signal, and factors that affect glucose mass transfer from nearby capillaries to the implanted sensor must be taken into account. These factors include: the pattern and extent of perfusion of the local microvasculature; regional perfusion of the implant site, the heterogeneous distribution of substrates within tissues, and the availability of oxygen. There are also substantial differences in performance between short- and long-term implant applications. In the short term, a dominant wound healing response prevails, whereas in the long term, encapsulation may occur. Definitive studies are needed to establish the real-time accuracy of implanted sensors and determine when recalibration is necessary. Studies should be designed to ascertain whether signal decay is due to enzyme inactivation, electrochemical interference, or tissue encapsulation. More information is needed about the effect of these processes on the sensor signals.

There are $>10^4$ technical publications and several thousand patents related to glucose measurement by glucose oxidase-based enzyme electrodes, although only a fraction

of these address implant applications. Rather than an attempt to be comprehensive, comments here are limited to examples of the most advanced approaches intended for implant applications.

Enzyme Electrode Sensors Based on Peroxide Detection.

Detection of hydrogen peroxide, the enzyme reaction product, is achieved by electrochemical oxidation of peroxide at a metal anode resulting in a signal current that passes between the anode and a counterelectrode (46). A membrane containing immobilized glucose oxidase is attached to the anode and, in the presence of glucose and oxygen under certain conditions, the current can reflect glucose concentration.

The peroxide-based sensor design is used in several home glucose monitoring devices and has been highly successful for glucose assay on an individual sample basis. However, it is not easily adapted as an implant, especially for long-term applications. The peroxide-based sensor is subject to electrochemical interference by oxidation of small molecules due to its requirement of a porous membrane and an aqueous pathway to the electrode surface for transport of the peroxide molecule. This factor partially accounts for a documented decay in sensitivity to glucose during sensor use. In addition, this sensor design can incorporate only a limited excess of immobilized glucose oxidase to counter enzyme inactivation, as high enzyme loading reduces peroxide transport to the electrode (47). Coimmobilization of catalase to avoid peroxide-mediated enzyme inactivation is not an option because it would prevent peroxide from reacting with the anode. There are also no means to account for the effects of physiologic variation in oxygen concentration and local tissue perfusion on the sensor response.

There have, nevertheless, been proposals to address some of these challenges. Composite membranes with reduced pore size have markedly reduced electrochemical interference from a variety of species over the short-term (48). A "rechargeable" enzyme system has been devised for periodically replenishing enzyme activity (49), in which a slurry of carbon particles with immobilized glucose oxidase is pumped between membrane layers of a peroxide electrode from a refillable reservoir. A gas-containing chamber has been proposed (50) to address the "oxygen deficit" (51), or stoichiometric limitation of the enzyme reaction by the relatively low tissue oxygen concentration. Certain other challenges of the peroxide sensor principle remain to be addressed. As a result of the inherent features of this sensor principle, the peroxide-based sensor may be best suited to short-term implant applications and where frequent sensor recalibration is acceptable.

Small, needle-like *short-term peroxide-based sensors* connected by wire to a belt-mounted monitor have been developed for percutaneous implantation (52) (Fig. 6). The sensor was ultimately intended for insertion by the user for operation up to 3 days at a given tissue site before relocation. Sensors based on peroxide detection have been tested extensively in animals and humans (52–55) and, in some cases have functioned remarkably well, although frequent recalibration was required. In

Figure 6. Components of the MiniMed CGMS system (62). This sensor, based on the peroxide-based sensing principle, is FDA approved for short-term monitoring. (Copyright © 1999, Elsevier.)

some cases, difficulties of two types have been identified (56–61). First, the sensors themselves have not been specific for glucose, sufficiently sensitive, or stable. In some cases where the sensor response in simple buffer solutions was acceptable, ambiguous signals have sometimes resulted when used as an implant. Examples of such responses are: sensor signals that decay over the short term while blood concentrations remain constant, signals that apparently follow blood concentrations during some periods, but not at other times; and identical sensors implanted in different tissue sites in a given subject that sometimes produce opposite signals (55). The peroxide-based subcutaneous sensor was the first commercially available near continuous sensor. In small controlled studies, use of the sensor was shown to lower Hb_{A1c} levels (62). Latter versions of this sensor have been approved by the FDA to be used as monitors to alarm for hyper- and hypoglycemia in real time. Although there are reservations about its accuracy, the needle sensor has been used in clinical research settings (Figs. 7, 8). A recent study found substantial error in values produced by a prominent commercial needle sensor and concluded that this sensor "... cannot be recommended in the workup of hypoglycemia in nondiabetic youth" (66) and, by extension, to other diabetic subjects. Reasons for these signal deviations are not fully understood.

Figure 7. An approach to sensor validation. Comparison of 2477 glucose values determined by a CGMS sensor system and a standard meter (63). Data pairs were collected during home use from 135 patients. The plot, known as the Clarke Error Grid, has zones with differing clinical implications. This type of plot is widely used to describe glucose sensor performance, but has limited ability to discriminate ineffective sensors (64). (Copyright © 1999, Elsevier.)

Although the needle sensor may be acceptable only to a relatively small group of the most motivated individuals, it represents an advance in glucose sensor technology. Perhaps the most important contribution of the short-term needle sensor has been the revelation to users and clinicians that blood glucose excursions generally occur much more frequently and in a greater number of people than previously thought. This heightened awareness of blood glucose dynamics may lead to a greater appreciation of the need for dynamic control in improved metabolic management.

Long-term peroxide-based sensors have been implanted in the peritoneal cavity of dogs and in humans in conjunction with battery-operated telemetry units (67,68). Although the sensors remained implanted in humans for up to 160 days, the sensitivity to glucose decayed during the study and frequent recalibration was required.

Peroxide-based sensors with telemetry systems have also been implanted in the subcutaneous tissues of human type 1 diabetic subjects to determine if the mere presence of a nonreporting sensor can improve metabolic control (69). Glucose was monitored in parallel by finger-stick throughout the study as a basis for insulin dosage. Study subjects were able to reduce the time spent in hyperglycemia, increase the time spent in normoglycemia and modest hypoglycemia, and markedly reduce the time spent in severe hypoglycemia, but reductions in Hb_{A1c} values were not observed. The study was not specifically designed to validate sensor function and a more straightforward and informative study design is needed.

Short-Term Enzyme Electrodes Based on Conductive Polymers. Another principle for glucose monitoring is based on

Figure 8. An example of the CGMS sensor response (65). Squares are reference values utilized in sensor calibration. Circles are additional reference blood glucose values. Reference values were obtained from a standard glucose meter. Values are in $\text{mmol} \cdot \text{L}^{-1}$. (Used with permission.)

immobilization of glucose oxidase to electron-conducting polymers that can act as “chemical wires”, providing a means for direct electron transport between glucose oxidase and the electrode (70). This principle eliminates the need for oxygen as a coreactant and, although a porous membrane that can allow passage of ionic current and interferants is still required, the electrode can be operated at lower anodic potentials to reduce electrochemical interference (71). A short-term needle-like version of this sensor for 3 day operation is under development.

Long-Term Enzyme Electrode Sensors Based on Oxygen Detection. Glucose can also be monitored by detecting differential oxygen consumption from the glucose oxidase reaction. In this case, the process is based either on glucose oxidase alone (reaction 1), or a two-enzyme reaction including catalase in excess, which produces the following overall process:

The enzymes are immobilized within a gel membrane in contact with the electrochemical oxygen sensor. Excess oxygen not consumed by the enzymatic process is detected by an oxygen sensor and, after comparison with a similar background oxygen sensor without enzymes, produces a differential signal current that is related to glucose concentration.

This approach has several unique features (23). Electrochemical interference and electrode poisoning from endogenous biochemicals are prevented by a pore-free silicone rubber membrane between the electrode and the enzyme layer. This material is permeable to oxygen but completely impermeable to polar molecules

that cause electrochemical interference. Appropriate design of the sensor results in sufficient supply of oxygen to the enzyme region to avoid a stoichiometric oxygen deficit (51), a problem that has not been addressed in the peroxide-based sensor system. The differential oxygen measurement system can also readily account for variations in oxygen concentration and local perfusion, which may be particularly important for accurate function of the implant in tissues. Vast excesses of immobilized glucose oxidase can be incorporated to extend the effective enzyme lifetime of this sensor, a feature not feasible with peroxide- and conductive polymer-based sensors. Co-immobilization of catalase can further prolong the lifetime of glucose oxidase by preventing peroxide-mediated enzyme inactivation, the main cause of reduced enzyme lifetime (72). This sensor design also avoids current passage through the body and hydrogen peroxide release into the tissues.

A long-term oxygen-based sensor has been developed as a central venous implant (23) (Fig. 9). The sensor functioned with implanted telemetry (73) in dogs for >100 days and did not require recalibration during this period (Fig. 10). The central venous site permitted direct exposure of the sensor to blood, which allowed simple verification of the sensor function without mass transfer complications. This was particularly beneficial for assessing sensor stability. In clinical trials, this system has been reported (74) to function continuously for >500 days in humans with <25% change in sensitivity to glucose over that period. This achievement represents a world record for long-term, stable, implanted glucose sensor operation, although there may still exist hurdles to commercialization.

Figure 9. Animal prototype long-term central venous glucose sensor with implanted telemetry (73). Glucose and oxygen sensors are at the end of the catheters. Telemetry antenna emerges from the top, left. The telemetry body is 2×2.5 in.

These results have led to several unanticipated conclusions. Although native glucose oxidase is intrinsically unstable, with appropriate sensor design the apparent catalytic lifetime of the immobilized enzyme can be substantially extended (75). The potentiostatic oxygen sensor is remarkably stable (76) and the oxygen deficit, once thought to be an insurmountable barrier, can be easily overcome (51). The central venous implant site, which is uniquely characterized by slow, steady flow of blood, allows for sufficient long-term biocompatibility with blood that the sensor stability can be documented (23). Nevertheless, the

Figure 10. Response of an implanted intravenous sensor to glucose challenges on day 108 after implantation in a dog (23). The solid line is the sensor signal and triangles are venous blood glucose assays. Blood glucose excursions with initial rates of $0.2\text{--}0.8\text{ mM}\cdot\text{min}^{-1}$ were produced by infusions of sterile glucose solutions through an intravenous catheter in a foreleg vein. (Note: $90\text{ mg}\cdot\text{dL}^{-1}$ glucose = 5.0 mM .) (Copyright © 1990, American Diabetes Association.)

Figure 11. Close-up view of tissue glucose and oxygen sensor array (77). Sensor array with small ($125\text{ }\mu\text{m}$ diameter) independent platinum working electrodes, large ($875\text{ }\mu\text{m}$ diameter) common platinum counterelectrodes, and a curved common Ag/AgCl reference electrode. The membrane is not present. (Copyright 2003, American Physiological Society.)

potential for thromboembolic events, anticipated to be rare but potentially significant over many years of sensor use, suggests reservations that may limit clinical acceptance and provides motivation for development of a potentially safer long-term sensor implant in tissues.

Long-term oxygen-based sensors have also been implanted in tissues. The successful central venous sensor cannot be simply adopted for use in the safer tissue site, but certain design features of that sensor which promote long-term function, such as immobilized enzyme design, the stable potentiostatic oxygen sensor, and membrane design to eliminate the oxygen deficit, can be incorporated (Fig. 11).

A systematic approach is required to validate sensor function, based on quantitative experimentation, mass transfer analysis, and accounting for properties of tissues that modulate glucose signals. Several new tools and methods have been developed. A tissue window chamber has been developed that allows direct optical visualization of implanted sensors in rodents, with surrounding tissue and microvasculature, while recording sensor signals (77) (Fig. 12). This facilitates determination of the effects of microvascular architecture and perfusion on the sensor signal. A method has been devised for sensor characterization in the absence of mass transfer boundary layers (78) that can be carried out before implantation and after explantation to infer stability of the implanted sensor. This allows quantitative assessment of mass transfer resistance within the tissue and the effects of long-term tissue changes. A sensor array having multiple glucose and oxygen sensors has also been developed that shows the range of variation of sensor responses within a given tissue (77). This provides a basis for averaging

sensor signals for quantitative correlation to blood glucose concentration.

REMAINING CHALLENGES FOR SENSOR DEVELOPMENT

Although there has been recent progress in sensor development and implementation, certain challenges remain. In many cases, there is need for improvement in data presentation and sensor validation. Standard glucose measurements for validation of sensor signals are often either not reported or are not obtained frequently enough to validate sensor responses. Requirements for sensor recalibration are not always given. Published results are often selected to show what may be ideally possible for a particular sensor rather than what is typical, sometimes conveying the impression that sensors are more accurate than may be the case.

There is a need to understand the effects of physiologic phenomena such as local perfusion, tissue variability, temperature and movement, that modulate sensor responses to glucose and affect measurement accuracy. A detailed understanding of these effects and their dynamics is needed for a full description of the glucose sensing mechanism. Robust sensor designs and modes of operation are required that assure reliable determination of glucose during exercise, sleeping and other daily life conditions.

A complete explanation for the response of every sensor should be sought, whether it is producing “good” or “bad” results, as more can often be learned for sensor improvement from sensors that produce equivocal results than from those that produce highly predictable signals (56). Present definitions as to what constitutes an acceptable sensor are based on narrow technical criteria proposed by sponsors of individual sensors that apply under specific conditions and lead to limited-

Figure 13. Blood glucose prediction based on recently sampled values (13). A 10 min prediction in a non-diabetic, average rms error = 0.2 mM. (Copyright © 1999, American Diabetes Association.)

use approvals by the FDA. There is a need to establish rational criteria for sensor validation and performance specific for the intended use (80). As sensors must be useful for hypoglycemia detection, sensor function must be validated in the hypoglycemic state. Correlation with HbA_{1c} levels may not be useful for sensor validation, as the detailed information from sensors is likely to supplant HbA_{1c} as a more comprehensive index of control.

BLOOD GLUCOSE PREDICTION

The ability to monitor blood glucose in real-time has major advantages over present methods based on sample collection that provide only sparse, historical information. There exists, however an additional possibility of using sensor information to *predict* future blood glucose values. It been demonstrated that blood glucose dynamics are not random and that blood glucose values can be predicted using autoregressive moving average (ARMA) methods, at least for the near future, from frequently sampled previous values (13) (Fig. 13). Prediction based only on recent blood glucose history is particularly advantageous because there is no need to involve models of glucose and insulin distribution, with their inherent requirements for detailed accounting of glucose loads and vascular insulin availability. This capability may be especially beneficial to children. Glucose prediction can potentially amplify the considerable benefits of continuous glucose sensing, and may represent an even further substantial advance in blood glucose management.

CLOSING THE LOOP

Glucose control is an example of a classical control system (Fig. 14). To fully implement this system, there is a need to establish a programmable controller based on continuous glucose sensing, having control laws or algorithms to counter hyper- and hypoglycemic excursions, identify performance targets for optimal insulin administration, and employ insulin pumps. The objective is restore optimal blood glucose control while avoiding over-insulinization by adjusting the program, a goal that may not be possible to achieve with alternative cell- or tissue-based insulin replacement strategies.

Figure 14. A simple control system for blood glucose. $y(out)$ is the blood glucose concentration, $y(sp)$ is the desired blood glucose, the natural sensor is in the pancreatic beta cell, the plant is the body over which glucose is distributed, and the disturbance is absorption of glucose from the gut via digestion. The control element can be an insulin pump. The control law is an algorithm that directs the pump in response to the difference between measured and target blood glucose.

Programmable external pumps that deliver insulin to the subcutaneous tissue are now widely used and implanted insulin pumps may soon become similarly available. At present, these devices operate mainly in a preprogrammed or *open-loop* mode, with occasional adjustment of the delivery rate based on fingerstick glucose information. However, experimental studies in humans have been reported utilizing *closed-loop* systems based on implanted central venous sensors and intra-abdominal insulin pumps in which automatic control strategies were

employed over periods of several hundred days (81) (Fig. 15). Initial inpatient trials using subcutaneous peroxide sensors to close the loop with an external insulin pump are also underway. There is a need to expand development of such systems for broad acceptance. Extensive reviews of pump development can be found elsewhere (82–84).

These results demonstrate that an implantable artificial beta cell is potentially feasible, but more effort is required to incorporate a generally acceptable glucose sensor, validate the system extensively, and demonstrate its robust response.

CONCLUSIONS

The need for new glucose sensors in diabetes is now greater than ever. Although development of an acceptable, continuous and automatic glucose sensor has proven to be a substantial challenge, progress over the past several decades has defined sensor performance requirements and has focused development efforts on a limited group of promising candidates. The advent of new glucose sensing technologies could facilitate fundamentally new approaches to the therapy of diabetes.

Iowa City, Iowa

INTRODUCTION

The human circulatory system provides adequate blood flow without interruption to the various organs and tissues and regulates blood supply to the demands of the body. The contracting heart supplies the energy required to maintain the blood flow through the vessels. The human heart consists of two pumps in series. The right side of the heart, a low pressure pump, consisting of the right atrium and the right ventricle supplies blood to the pulmonary circulation. The left side consisting of the left atrium and the left ventricle is the high pressure pump circulating blood through the systemic circulation. Figure 1 is a schematic representation of the four chambers of the heart and the arrows indicate the direction of blood flow. The pressure gradients developed between the main arteries supplying blood to the systemic and pulmonary circulation and the respective venous ends are the driving forces causing the blood flow and the energy is dissipated in the form of heat due to frictional resistance.

The four valves in the heart ensure that the blood flows only in one direction. The blood from the systemic circula-

tion supplies nutrients and oxygen to the cells for the various tissues and organs and removes carbon dioxide at the level of capillaries. The oxygen depleted blood returns through the systemic veins to the right atrium. During the ventricular relaxation or diastole, the blood passes through the tricuspid valve into the right ventricle. In the ventricular contraction phase of the cardiac cycle or systole, the tricuspid valve closes and the pulmonic valve opens to pump the blood to the lungs through the pulmonary arteries. Carbon dioxide is removed and oxygen is absorbed by the blood in the capillaries of the lungs that is surrounded by the alveolar sac with the air we breathe. The oxygen-rich blood returns to the left atrium via the pulmonary veins and passes through the mitral (bicuspid) valve into the left ventricle during the ventricular diastole. During the ventricular contraction, the mitral valve closes and the aortic valve opens to pump the blood through the systemic circulation. The main function of the heart valves is to control the direction of blood flow permitting flow in the forward direction and preventing regurgitation or back flow through the closed valves.

Anatomy of the Native Valves

The aortic valve (Fig. 2) consists of three semicircular (semilunar) leaflets or cusps within a connective tissue sleeve (1) attached to a fibrous ring. The cusps meet at three commissures that are equally spaced along the circumference at the supraaortic ridge. This ridge is thickening of the aorta at which the cusps insert and there is no continuity of tissue from one cusp to the other across the commissure. The leaflet consists of three layers as shown in Fig. 3: the aortic side layer is termed the fibrosa and is the

major fibrous layer within the body of the leaflet; layer on the ventricular side termed ventricularis is composed of both collagen and elastin; and the central portion of the valve termed the spongiosa consisting of loose connective tissue, proteins, and glycosaminoglycans (GAG). The leaflet length is larger than the radius of the annulus, and hence a small overlap of the tissue from each leaflet protrudes and forms a coaptation surface when the valve is closed to ensure that the valve is sealed in the closed position. The sinus of Valsalva is attached to the fibrous annular ring on the aortic side and is comprised of three

bulges at the root of the aorta. Each bulge is aligned with the belly or the central part of the valve leaflet. The left and the right sinuses contain the coronary ostia (openings) giving rise to the left and right coronary arteries, respectively, providing blood flow and nutrients to the cardiac muscles. When the valve is fully open, the leaflets extend to the upper edges of the sinuses. The anatomy of the pulmonic valve is similar to that of the aortic valve, but the sinuses in the pulmonary artery are smaller than the aortic sinuses, and the pulmonic valve orifice is slightly larger. The average aortic valve orifice area is $\sim 4.6 \text{ cm}^2$ and is $\sim 4.7 \text{ cm}^2$ for the pulmonic valve (2). In the closed position, the pulmonic valve is subject to a pressure of $\sim 30 \text{ mmHg}$ (3.99 kPa) while the load on the aortic valve is $\sim 100 \text{ mmHg}$ (13.30 kPa).

The mitral and tricuspid valves are also anatomically similar with the mitral valve consisting of two main leaflets (cusps) compared to three for the valve in the right side of the heart. The valves consist of the annulus, leaflets, papillary muscles, and the chordae tendinae (Fig. 4). The average mitral and tricuspid valve orifice areas are 7.8 and 10.6 cm^2 , respectively (2). The atrial and ventricular walls are attached to the mitral annulus, consisting of dense collagenous tissue surrounded by muscle, at the base of the leaflets. The chordae tendinae are attached to the free edge of the leaflets at multiple locations and extend to the tip of the papillary muscles. Anterior and posterior leaflets of the mitral valve are actually one continuous tissue with two regularly spaced indentations called the commissures. The combined surface area of both the leaflets is approximately twice the area of the valve orifice and thus the leaflets coaptate during the valve closure. The posterior leaflet encircles two-thirds of the annulus and is quadrangular shaped, while the anterior leaflet is semi-lunar shaped. The left ventricle has two papillary muscles that attach to the ventricular free wall and tether the mitral valve in place via the chordae tendinae. This tethering prevents the leaflets from prolapsing into the left atrium during ventricular ejection. Improper tethering will result in the leaflets extending into the atrium and incomplete apposition of the leaflets will permit blood to

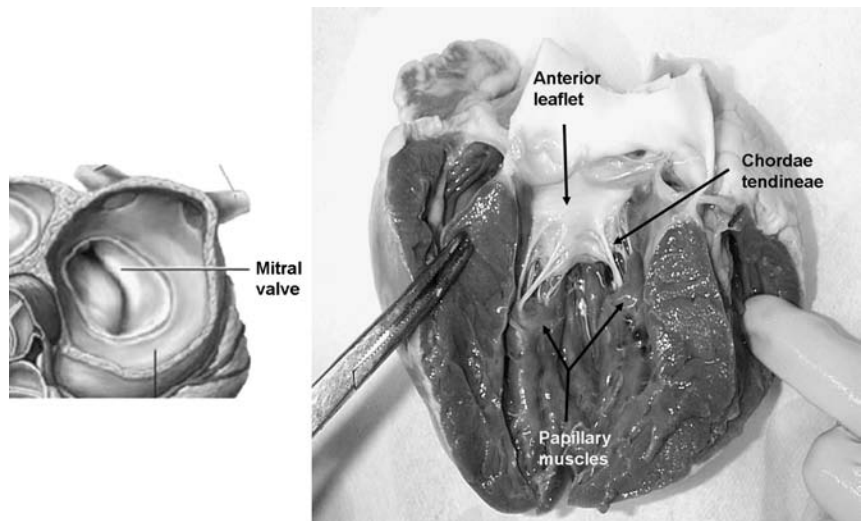

Figure 4. Schematic of the human mitral (bicuspid) valve and a photograph showing the anterior leaflet with the chordae tendinae attachment with papillary muscles. (Courtesy of Prof. Ajit Yoganathan from Georgia Institute of Technology.)

regurgitate back to the atrium. The tricuspid valve has three leaflets, a septal leaflet along with the anterior and posterior leaflets, and is larger and structurally more complicated than the mitral valve.

Valve Dynamics

At the beginning of systole, the left ventricle starts to contract and with the increase in pressure, the mitral valve closes preventing regurgitation of blood to the left atrium. During the isovolumic contraction with both the mitral and aortic valves closed, the ventricular pressure rises rapidly. The aortic valve opens when the left ventricular pressure exceeds the aortic pressure. The blood accelerates rapidly through the open valve and peak velocity of flow occurs during the first third of systole. The pressure difference between the left ventricle and the aorta required to open the valve is of the order of 1–2 mmHg (0.13–0.26 kPa). During the forward flow phase, vortices develop in the three sinuses behind the open leaflets and the formation of such vortices was first described by Leonardo da Vinci in 1513. Several studies have suggested that the vortices and the difference in pressure between the sinuses and the center of the aortic orifice pushes the leaflets toward closure even during the second third of systole when forward flow of blood continues. With the ventricular relaxation and rapid drop in the ventricular pressure, an adverse pressure gradient between the ventricle and the aorta moves the leaflets toward full closure with negligible regurgitation of blood from the aorta to the ventricle. Systole lasts for about one-third of the cardiac cycle and the peak pressure reached in the aorta during systole in healthy humans is ~120 mmHg (15.96 kPa) and the diastolic pressure in the aorta with the aortic valve closed is ~80 mmHg (10.64 kPa).

At the beginning of diastole, the aortic valve closes and the ventricular pressure decreases rapidly during the isovolumic relaxation. As the ventricular pressure falls below the atrial pressure, the mitral valve opens and the blood flows from the atrium to the ventricle. The pressure difference between the left atrium and the ventricle required to open the mitral valve and drive the blood to fill the ventricle is smaller than that required with the aortic valve (<1 mmHg or 0.13 kPa). As the blood fills the ventricle, vortical flow is established in the ventricle, and it has been suggested that the leaflets move toward closure due to the same. The atrial contraction induces additional flow of blood from the atrium into the ventricle during the second half of diastole and the adverse pressure gradient at the beginning of ventricular contraction forces the mitral valve to close and isovolumic contraction takes place. The chordae tendinae prevents the prolapse of the leaflets into the left atrium when the mitral valve is in the closed position. The dynamics of the mitral valve opening and closing is a complex process involving the leaflets, mitral orifice, chordae tendinae, and the papillary muscles. During systole, the closed mitral valve is subjected to pressures of ~120 mmHg (15.96 kPa).

The dynamics of opening and closing of the pulmonic and the tricuspid valves are similar to the aortic and mitral valve, respectively, even though the pressures generated in

the right ventricle and the pulmonary artery are generally about a one-third of the corresponding magnitudes in the left side of the heart. From the description of the valve dynamics, one can observe several important features on the normal functioning of the heart valves. These include opening efficiently with minimal difference in pressure between the upstream and downstream sides of the valve, and efficient closure to ensure minimal regurgitation. In addition, the flow past the valves are laminar with minimal disturbances in flow and the fluid induced stresses do not activate or destroy the formed elements in blood such as the platelets and red blood cells. As the valves open and close, the leaflets undergo complex motion that includes large deformation, as well as bending. The leaflet material is also subjected to relatively high normal and shear stresses during these motions. The valves open and close at about once every second, and hence functions over several million cycles during the normal life of a human. These are some of the important considerations in the design and functional evaluation of heart valve prostheses that we consider in detail below.

Valvular Diseases and Replacement of the Diseased Valves

Valvular diseases are more common on the left heart due to the high pressure environment for the aortic and mitral valves and also with the tricuspid valve on the right side of the heart. Valvular diseases include stenosis and incompetence. Stenosis of the leaflets is due to calcification resulting in stiffer leaflets that will require higher pressures to open the valves. Rheumatic fever is known to affect the leaflets resulting in stenosed valves (3). Premature calcification of the bicuspid valve, as well as significant obstruction of the left ventricular outflow in congenital aortic valve stenosis, also affects the valves of the left heart (3). Aortic sclerosis due to aging can also advance to valvular stenosis in some patients. Mitral stenosis may be the result of commissural fusion in younger patients and may also be due to cusp fibrosis. In the case of valvular stenosis, higher pressure needs to be generated to force the stiffer leaflets to open and the valvular orifice area in the fully open position may be significantly reduced. Effective orifice area (EOA) can be computed by the application of the Gorlin equation (4) based on the fluid mechanic principles and is given by the following relationship:

$$EOA(\text{cm}^2) = \frac{Q_{\text{rms}}}{C\sqrt{\Delta\bar{p}}} \quad (1)$$

In this equation, Q_{rms} is the root-mean-square (rms) flow rate (mL/s) during the forward flow through the valve and $\Delta\bar{p}$ is the mean pressure drop (mmHg) across the open valve. The measurement of mean pressure drop *in vivo* is described later, and the flow rate across the valve during the forward flow phase is computed from the measurement of cardiac output and the heart rate. The parameter C represents a constant that is based on the discharge coefficient used for the aortic or mitral valve, and the unit conversion factors to result in the computed area in terms of square centimeter. A more direct technique to estimate the effective orifice area is the application of conservation of mass principle. The systolic volume flow through the left

ventricular outflow tract is determined as the product of the outflow tract cross-sectional area and the flow velocity–time integral. Since the same blood volume must also pass through the valve orifice, the valve orifice area is computed by dividing the volume flow with the measured aortic valve velocity–time integral (5). Replacement of the aortic valve is generally considered when the measured valvular orifice area is $< 0.4 \text{ cm}^2 \cdot \text{m}^{-2}$ of body surface area (6). The corresponding value for the mitral stenosis is $1.0 \text{ cm}^2 \cdot \text{m}^{-2}$.

Valvular incompetence results from incomplete closure of the leaflets resulting in significant regurgitation of blood. Incompetence could be the result of decrease in leaflet area due to rheumatic disease or perforations in the leaflets due to bacterial endocarditis. Structural alterations due to loss of commissural support or aortic root dilatation can result in aortic valve incompetence. Rupture of chordae tendinae, leaflet perforation, and papillary muscle abnormality may also affect the mitral valve closure and increase in regurgitation. Optimal timing for valvular replacement in the case of native valve incompetence is not clearly defined.

Various methods for valvular reconstruction or repair are also being developed instead of replacement with prostheses since these techniques are associated with lower risk of mortality and lower risk of recurrence (7). Valvular repair rather than replacement is generally preferred for regurgitation due to segmental prolapse of the posterior mitral leaflet. Implantation of a prosthetic ring to reduce the size of the mitral orifice and improve leaflet coaptation is performed in the case of mitral regurgitation due to ring dilatation. Mitral endocarditis with valvular or chordal lesions is also repaired rather than replacing the whole valve. Dilatation of the root and prolapse of the cusps are also the most important causes for regurgitation of the aortic valves and several techniques have also been developed to correct these pathologies (7).

The cardiopulmonary bypass technique to reroute the blood from the vena cava to the ascending aorta, and the introduction of cold potassium cardioplegia to arrest the heart to perform open heart surgery introduced in the 1950s enabled the replacement of diseased valves. Replacement of severely stenosed and/or incompetent valves with prostheses is a common treatment modality today and patients with prosthetic valves lead a relatively normal life. Yet, significant problems are also encountered with implanted prosthetic valves and efforts are continuing to improve the design of the valves for enhanced functionality and minimizing the problems encountered with implantation.

PROSTHETIC HEART VALVES

Ideal Valve Design

An ideal valve to be used as replacement for a diseased valve should mimic the functional characteristics of the native human heart valves with the following characteristics (adapted from Ref. 8). The prosthetic valve should open efficiently with a minimal transvalvular pressure drop. The blood should flow through the orifice with central and undisturbed flow as is observed with healthy native

heart valves. The valve should close efficiently with minimal amount of regurgitation. The material used for the valve should be biocompatible, durable, nontoxic, and nonthrombogenic. The valve will be anticipated to open and close for > 40 million cycles/year for many years and must maintain the structural integrity throughout the lifetime of the implant. Blood is a corrosive and chemically unstable fluid that tends to form thrombus in the presence of foreign bodies. To avoid thrombus formation, the valve surfaces must be smooth, and the flow past the valve should avoid regions of stagnation and recirculation as well as minimize flow-induced stresses that are factors related to thrombus initiation. The prosthetic valve should be surgically implantable with ease and should not interfere with the normal anatomy and function of the cardiac structures and the aorta. The valve should be easily manufactured in a range of sizes, inexpensive, and sterilizable.

Transplanting freshly explanted human heart valves from donors who died of noncardiovascular diseases is probably the most ideal replacement and such homograft valves have been successfully used as replacements. These are the only valves entirely consisting of fresh biological tissue and sewn into place resulting in an unobstructed central flow. The transplanted homograft valves are no longer living tissue, and hence lack the cellular regeneration capability of the normal valve leaflets. Thus, the transplanted valves are vulnerable to deterioration on a long-term use. Moreover, homograft valves are difficult to obtain except in trauma centers in large population areas, and hence not a viable option generally.

Numerous prosthetic valves have been developed over the past 40 years and most of the design and development of valvular prostheses have been empirical. The currently available heart valve prostheses can be broadly classified into two categories: mechanical heart valves (MHV) and bioprosthetic heart valves (BHV). Even though valves from both categories are routinely implanted in patients with valvular disease and the patients with prosthetic implants lead a relatively normal life, several major problems are encountered with the mechanical and biological prosthetic valves (9). These problems include: (1) thromboembolic complications; (2) mechanical failure due to fatigue or chemical changes; (3) mechanical damage to the formed elements in blood including hemolysis, activation, and destruction of platelets and protein denaturation; (4) perivalvular leak due to healing defects; (5) infection; and (6) tissue overgrowth. The first three problems with implanted valves can be directly attributed to the design of the mechanical and biological prostheses and the fluid and solid mechanics during valve function. Thrombus deposition on the valvular surface and subsequent breakage of the thrombus to form emboli that can result in stroke or heart failure is still a major problem with MHV implants. Hence, patients with MHV implants need a long-term anticoagulant therapy that can lead to complications with bleeding. On the other hand, patients implanted with bioprostheses do not generally require anticoagulant therapy except immediately after surgery. Yet, leaflet tearing with structural disintegration results in the need for BHV implants to be replaced at about 10–12 years after implantation on the average. Due to the necessity of multiple

surgeries during a lifetime, the tissue valves are generally not implanted in younger patients. Patients who cannot tolerate or cannot be on long-term anticoagulant therapy are also candidates for the BHV.

Mortality is higher among patients after prosthetic valve replacement than among age-matched controls. Mortality rate is not significantly different between MHV and BHV implantation. In addition to the mortality rate and valve related morbidity, quality of life for the patient must be an important consideration in the choice of valve implantation and the quality of life is difficult to quantify. Individual patients may place different emphasis on mortality, freedom from reoperation, risk of thromboembolism and stroke, risk of anticoagulation-related hemorrhage, and lifestyle modification required with chronic anticoagulation. Patients may choose to accept the high probability of reoperation within 10–12 years with BHV in order to avoid long-term anticoagulation with MHV, whereas others may want to avoid the likelihood of reoperation (10).

We will review the historical development of heart valve prostheses, functional evaluation of these valves in order to understand the relationship between the dynamics of the valve and the problems associated with the valve implants and our continuing efforts on the understanding of the problem and improvements in design.

Mechanical Heart Valves

Mechanical valves are made of blood compatible, nonbiological material, such as metals, ceramics, or polymers. The initial designs of mechanical valve prostheses were of the centrally occluding type with either a ball or disk employed as the moving occluder. The occluder passively responds to the difference in pressure in opening and closing of the valves. Starr-Edwards caged ball valve (Fig. 5a) was the first mechanical valve to be implanted in 1960 in the correct anatomical position as replacement for the diseased native mitral valve (11–14). The caged disk prostheses (Fig. 5b), in which a flat disk was employed as the occluder, were of a lower profile than the ball valves, and hence were thought to be advantageous especially as a replacement in the mitral position in order to minimize interference with the cardiac structures. However, increased flow separation and turbulence in the flow past the flat disk compared to that for the spherical ball occluder in the caged ball prostheses resulted in larger pressure drop across the valve with the caged disk design. An increased propensity for thrombus deposition in the recirculation region was also observed, and hence this design was not successful in spite of the low profile. The cage in the caged ball prostheses is made of a polished cobalt–chromium alloy and the ball is made of a silicone rubber that contains 2% by weight barium sulfate for radiopacity. The sewing ring contains silicone rubber insert under knitted composite polytetrafluoroethylene (PTFE: Teflon) and polypropylene cloth. With the centrally occluding design, the flow dynamics past the caged ball prostheses is vastly different from that of flow past native aortic or mitral valves.

Within the next two decades of 1970s and 1980s, valve prostheses with a tilting disk or bileaflet designs were introduced with significantly improved flow characteris-

(a)

(b)

tics. The first tilting disk valve that was clinically used was a notched Teflon occluder that engaged in another pair of notches in the housing (15). The stepped occluder with the notches was not free to rotate. Clinical data soon indicated severe thrombus formation around the notches and wear of the Teflon disk leading to severe valvular regurgitation or disk embolization (16). A major improvement to this design was the introduction of hinge-less free-floating tilting disk valves in the Bjork–Shiley (17) and the Lillehei–Kaster valves. The Bjork–Shiley valve had a depression in the disk and two welded wire struts in the valve housing to retain the disk. The occluder tilted to the open and closed position and it was free to rotate around its center. The Bjork–Shiley valve housing was made from Stellite-21 with a Teflon sewing ring and a Delrin disk. Compared to the

Figure 6. Tilting disk mechanical valve prostheses: (a) Bjork–Shiley valve; (b) Medtronic Hall valve (Medtronic, Inc., Minneapolis, MN); (c) Omni Carbon valve (MedicalCV Inc., Minneapolis, MN); (d) Sorin valve (Sorin Biomedica Cardio S.p.A., Via Crescentino, Italy).

centrally occluding caged ball valves, a large annulus diameter compared to the tissue annulus diameter in the tilting disk valve resulted in a very low pressure drop and thus energy loss in the flow across the valve in the open position. The disk opened to an angle of 60° or more, and hence the flow was more central. The free floating disk that rotated during the opening and closing phases prevented any build up of thrombus. However, the Delrin disk had a propensity for swelling during autoclaving that may compromise the proper functioning of the leaflets (18,19). The disk for the Lillehei–Kaster valve consisted of a graphite substrate coated with a $250\ \mu\text{m}$ thick layer of a carbon–silicon alloy (Pyrolite). The pyrolytic carbon has proven to be a very durable and blood-compatible material for use in prosthetic heart valves and is the preferred material for the MHVs currently available for implants. The Bjork–Shiley valve also had the Delrin disk replaced with pyrolytic carbon disk shortly thereafter (Fig. 6a). The Medtronic Hall tilting disk valve (Fig. 6b) has a central, disk control strut. An aperture in the flat pyrolytic carbon disk affixes it to this central guiding strut and allows it to move downstream by $\sim 2.0\ \text{mm}$. This translation improves the flow velocity between the orifice ring and the rim of the disk. The ring and strut combination is machined from a single piece of titanium for durability and the housing can be rotated within the knitted Teflon sewing ring for optimal orientation of the valve within the tissue annulus. The Omniscience valve was an evolution of the Lillehei–Kaster valve and the Omnicarbon valve (Fig. 6c) is the only tilting disk valve with the occluder and housing made of pyrolytic carbon. Sorin Carbocast tilting disk valve (Fig. 6d), made in Italy and available in countries outside United States, has the struts and the housing made in a single piece by a microcast process and thus eliminates the need for welding the struts to the housing. The cage for this valve is made of a chrome–cobalt alloy and coated with a carbon film. The

tilting disk valves of the various manufacturers open to a range of angles varying from 60 to 85° and in the fully open position, the flow passes through the major and minor orifices. Some of the valve designs, such as the Bjork–Shiley valve, encountered unforeseen problems with structural failure due to further design modifications, and hence are currently not used for replacement of diseased native heart valves. However, some of these designs are still being used in the development of artificial heart and positive displacement left ventricular assist devices.

Another major change in the MHV design was the introduction of a bileaflet valve in the late 1970s. The St. Jude Medical bileaflet valve (Fig. 7a) incorporates two semicircular hinged pyrolytic carbon leaflets that open to an angle of 85° and the design is intended to provide minimal disturbance to flow. The housing and the leaflets of the bileaflet valve is made of pyrolytic carbon. Numerous other bileaflet designs have since been introduced into the market. Several design improvements have also been incorporated in the bileaflet valve models in order to improve their hemodynamic performance. The design improvements have included a decrease in thickness of the sewing cuff that allows the placement of a larger

Figure 7. Bileaflet mechanical valve prostheses: (a) St. Jude valve (St. Jude Medical, Inc., St. Paul, MN); (b) Carbomedics valve (Carbomedics Inc., Austin Texas); (c) ATS valve (ATS Medical Inc., Minneapolis, MN); (d) On-X valve (Medical Carbon Research Institute, LLC, Austin, Texas); and (e) Sorin valve (Sorin Biomedica Cardio S.p.A., Via Crescentino, Italy).

housing within the cuff for a given tissue annulus diameter with the resulting hemodynamic improvement. Structural reinforcement of the housing has also allowed reducing its thickness that increases the internal orifice area for improved hemodynamics. The Carbomedics bileaflet valve (Fig. 7b) was introduced into the market in the 1990s with a recessed pivot design. The aortic version of this valve is designed to be implanted in the supraannular position enabling a larger size valve to be implanted with respect to the aortic annulus. More recent bileaflet valve designs available in the market include the ATS valve (Fig. 7c) with an open leaflet stop rather than the recessed hinges and the On-X bileaflet valve (Fig. 7d) that has a length to diameter ratio close to the native heart valves, a smoothed pivot recess allowing for the leaflet to open to 90° , a flared inlet for reducing flow disturbances, and a two point landing mechanism for smoother closing of the leaflets. The Sorin Bicarbon valve (Fig. 7e), marketed outside the United States, has curved leaflets, and hence increases the area of the central orifice. The pivots of this valve with two spherical surfaces enable the leaflet projections to roll against the surfaces rather than with the sliding action between the leaflet and the housing at the hinges.

Studies have shown that the bileaflet valves generally have a smaller pressure drop compared to the tilting disk valves, especially in the smaller sizes. However, there are several characteristic differences between the bileaflet and tilting disk valve designs that must be noted. The bileaflet valve designs include a hinge mechanism generally by introducing a recess in the housing in which a protrusion from the leaflets interacts during the opening and closing of the leaflets, or open pivots for the retention of the leaflets. On the other hand, the tilting disk valve designs do not have a hinge mechanism for retaining the occluder and the occluder is freefloating. The free-floating disk rotates as the valve opens and closes, and hence the stresses are distributed around the leaflets as opposed to the bileaflet designs. In spite of the advances in the MHV valves by the introduction of the tilting disk and bileaflet designs, design improvements aimed at enhancing the flow dynamics, and material selection, problems with thromboembolic complications and associated problems with bleeding (20) are still significant with the implanted valves and the possible relationship between the flow dynamics and initiation of thrombus will be discussed in detail later. An example of thrombus deposition and tissue ingrowth with an explanted MHV is shown in Fig. 8.

Bioprosthetic Valves

With the lack of availability of homograft valves as replacement of diseased valves, and as alternative to MHV that required long-term anticoagulant therapy, numerous attempts have been made in the use of various biological tissues as valvular replacement material. BHV made out of fascia lata (a layer of membrane that encases the thigh muscles) as well as human duramater tissue has been attempted. Fascia lata tissue was prone to deterioration, and hence unsuitable while the duramater tissue suffered from lack of availability for commercial manufacture in sufficient quantities. Harvested and preserved porcine

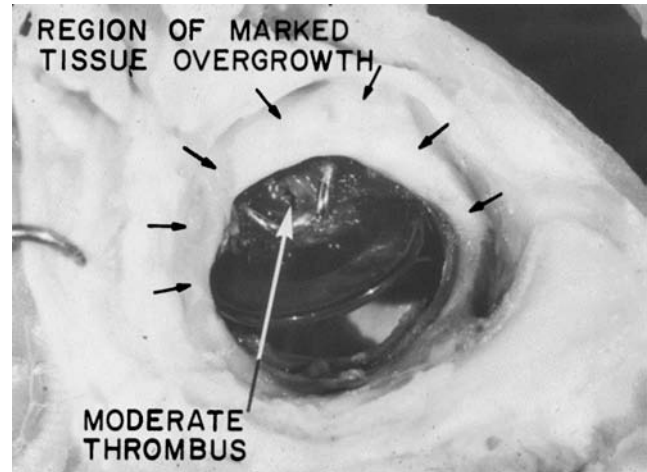

Figure 8. Photograph of an explanted mechanical heart valve prosthesis with thrombus deposition on the leaflet surface and tissue ingrowth (Courtesy of Prof. Ajit Yoganathan of Georgia Institute of Technology, Atlanta, GA.)

aortic valve as well as BHV made of bovine pericardial tissue have been employed as replacement and have been available commercially for >30 years. The early clinical use of a xenograft (valve made from animal tissue) employed treatment of the leaflets with organic mercurial salts (21) or formaldehyde (22) to overcome the problems of rejection of foreign tissue by the body. Formaldehyde is used to fix and preserve the tissue in the excised state by histologists and results in shrinkage as well as stiffening of the tissue. Formaldehyde treated valves suffered from durability problems with 60% failure rates at 2 years after implantation. Subsequently, it was determined that the durability of the tissue cross-links was important in maintaining the structural integrity of the leaflets and glutaraldehyde was employed as the preservation fluid (23). Glutaraldehyde also reduces the antigenicity of the foreign tissue, and hence can be implanted without significant immunological reaction.

Porcine aortic valves are excised from pigs with the aortic root and shipped to the manufacturer in chilled saline solution. Support stents, configured as three upright wide posts with a circular base, is manufactured out of metal or plastic material in various sizes and covered in a fabric. A sewing flange or ring is attached to the base of the covered stent and used to suture the prostheses in place during implantation. The valve is cleaned, trimmed, fitted, and sewn to the appropriate size cloth covered stent. The stented valve is fixed in glutaraldehyde with the valve in the closed position. Glutaraldehyde solution with concentrations ranging from 0.2 to 0.625% is used in the fixation process at pressures of < 4 mmHg (0.53 kPa) to maintain the valve in the closed position. The low pressure fixation maintains the microstructure of collagen. The first glutaraldehyde-treated porcine aortic valve prosthesis mounted on metallic stent was implanted in 1969 (24). The metallic frame was soon replaced by a flexible stent on a rigid base ring; the Hancock Porcine Xenograft was commercially introduced in 1970. The stent in this valve is made of polypropylene with stainless steel radiopaque marker,

sewing ring made of silicone rubber foam fiber and polyester used as the cloth covering. Hancock Modified Orifice valve (Fig. 9a) was introduced in 1977 as a refinement of the earlier valve. The right coronary cusp of the pig's aortic valve is a continuation of the septal muscle, and hence stiffer. In the modified orifice valve, the right coronary cusp is replaced with a non-coronary cusp of comparable size from another valve. The Carpentier-Edwards Porcine valve (Fig. 9b) also employs a totally flexible support frame. The Hancock II and the Carpentier-Edwards supra-annular porcine bioprostheses employed modified preservation techniques in which the porcine tissue is initially fixed at 1.5 mmHg (0.2 kPa), and then at high pressure in order to improve the preservation of the valve geometry. The supra-annular valve is designed to be implanted on top of the aortic annulus while aligning the internal diameter of the valve to the patient's annulus and this technique allows implantation of a larger valve for any given annular size. These valves are also treated with antimicrobialization

solution such as sodium dodecyl sulfate (SDS) in order to reduce calcification.

Another major innovation in the bioprosthetic valve design was the introduction of stentless bioprostheses. In the stented bioprostheses, the regions of stress concentration are observed at the leaflet-stent junction and the stentless valve design is intended to avoid such regions prone to failure. The absence of the supporting stents also results in less obstruction to flow, and hence should improve the hemodynamics across the valves. Due to the lack of stents, larger size valve can be implanted for a given aortic orifice to improve the hemodynamics. Stentless porcine bioprostheses are only approved for aortic valve replacement in the United States. *In vitro* studies have shown improved hemodynamic performance with the stentless designs in the mitral position, but questions remain about the durability of these valves, and the implantation techniques are also complex in the mitral position. Examples of stentless bioprostheses currently available in the United States include: St. Jude Medical Toronto SPV (Fig. 9c); Medtronic Freestyle (Fig. 9d); and Edwards Prima (Fig. 9e) valves. The Edwards Prima prosthesis is the pig's aortic valve with a preserved aortic root, with a woven polyester cloth sewn around the inflow opening to provide additional support and with features that make it easier to implant. The other stentless valve designs are also porcine aortic valves with the intact aortic root and specific preservation techniques in order to improve the hemodynamic characteristics and durability after implantation. In the Toronto SPV valve, a polyester cloth covering around the prosthesis separates the xenograft from the aortic wall of the host, making it easier for handling and suturing, and also promotes tissue ingrowth.

Both stented and stentless porcine tissue valves are from the pig's native aortic valve, and hence individual leaflets need not be manufactured. In order to have sufficient quantities of these valves in various sizes available for implant, a facility to harvest adequate quantities of these valves become necessary. As an alternative, pericardial valves are made by forming the three leaflets from the bovine pericardial tissue, and hence valves of various sizes can be made. In the pericardial valves, bovine pericardial sac is harvested and shipped in chilled saline solution. At the manufacturing site, the tissue is debrided of fatty deposits and trimmed to remove nonusable areas before the tissue is fixed in glutaraldehyde. After fixation, leaflets are cut out from the selected areas of the pericardial tissue and sewn to the cloth-covered stent in such a fashion to obtain coapting and fully sealing cusps. Since the valve is made in the shape of the native human aortic valve, the hemodynamic characteristics were also superior to the porcine valves in comparable sizes. The Ionescu-Shiley pericardial valve introduced into the market in the 1970s was discontinued within a decade due to problems associated with calcification and decreased durability. For this reason, pericardial valve were not marketed by the valve companies for several years. With advances in tissue processing and valve manufacturing technology, pericardial valves were reintroduced into the commercial market in the 1990s. The Edwards Lifesciences introduced the Carpentier-Edwards PERIMOUNT Bioprostheses

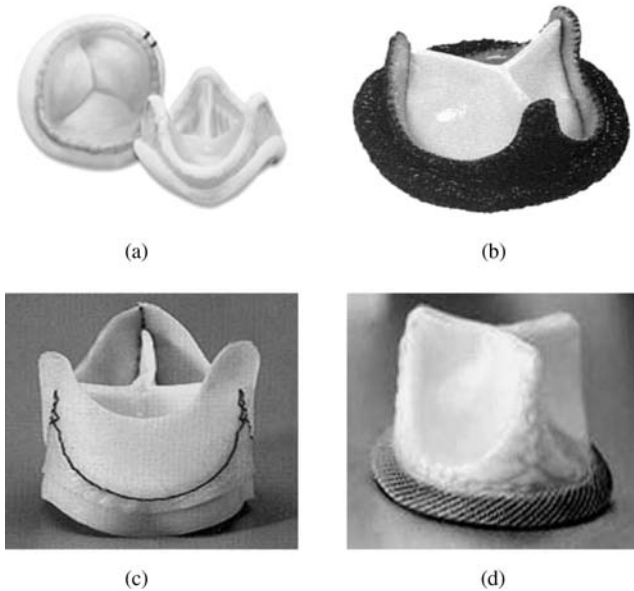

Figure 10. Pericardial bioprosthesis valve prostheses: (a) Carpentier-Edwards valve (Edwards Lifesciences, LLC, Irvine, CA), (b) Sorin Pericarbon valve (Sorin Biomedica Cardio S.p.A., Via Crescentino, Italy); (c) Sorin Pericarbon stentless valve (Sorin Biomedica Cardio S.p.A., Via Crescentino, Italy); and (d) Mitroflow Aortic pericardial valve (Sorin Group Canada, Inc., Mitroflow Division, Burnaby, B.C., Canada.)

(Fig. 10a) in the early 1990s. The pericardial tissue in this valve is mounted on a lightweight frame that is covered with porous, knitted PTFE material. A sewing ring made of molded silicone rubber covered with PTFE cloth is incorporated to suture the valve in place. Sorin pericardial valve (Fig. 10b), Sorin stentless pericardial valve (Fig. 10c) and the Mitroflow aortic pericardial valve (Fig. 10d) are available in markets outside the United States.

FUNCTIONAL CHARACTERISTICS

From the functional point of view, the implanted valve prostheses should open with minimal transvalvular pressure drop and have minimal energy loss in blood flow across the valve, and the valve must close efficiently with minimal regurgitation. The valve should mimic the central flow characteristics that are observed with native human heart valves with minimally induced fluid dynamic stresses on the formed elements in blood. The flow characteristics across the implants should also avoid regions of stasis or flow stagnation where thrombus deposition and growth can be enhanced. *In vivo* measurements, *in vitro* experimental studies, and computational simulations have been used over the past 40 years in order to assess the functional characteristics of the mechanical and bioprosthesis heart valves. The information gained from such studies have been exploited to improve the design of the valves in order to improve the performance characteristics of the valves and also increase the durability in order to provide a “normal” life style for the patient with prosthetic valve implants.

Pressure Drop and Effective Orifice Area

In vivo measurement of pressure drop requires placing pressure transducers inserted via a catheter both on the inflow and outflow side of the valve, and computing the pressure drop during the phase when the valve is open. For the aortic valve, the pressure transducers are placed in the left ventricular outflow tract and in the ascending aorta. The peak or the average pressure drop during the forward flow phase is computed from the recorded data. To avoid the invasive technique of catheterization, the fluid mechanics principle can also be applied to estimate the pressure drop across the valve in the aortic position. The average velocity, V in $\text{m} \cdot \text{s}^{-1}$, in the ascending aortic cross-section is measured noninvasively and the pressure drop, Δp expressed in millimeters of mercury can be computed using the equation

$$\Delta p \cong 4V^2 \quad (2)$$

Using this simplified equation and noninvasive measurement of the aortic root velocity using the Doppler technique, the pressure drop across the aortic valve can be computed. With the availability of several designs of MHV and BHV, it is desirable to compare the pressure drop and regurgitation for the various valve designs. In the case of development of a new valve design, United States Federal Drug Administration (FDA) requires that these quantities measured *in vitro* for the new designs are compared with currently approved valves in the market. *In vitro* comparisons are performed in pulse duplicators that mimic the physiological pulsatile flow in the human circulation. One of the initial designs of a pulse duplicator for valve testing was that of Wieting (25) that consisted of a closed-loop flow system that is actuated by a pneumatic pump to initiate pulsatile flow through the mitral and aortic valves in their respective flow chambers. Pressure transducers were inserted through taps in the flow chambers on the inflow and outflow sides to measure the pressure drop across the valves. The fluid used in such *in vitro* experimental studies, referred to as the blood-analogue fluid, is designed to replicate the density ($1060 \text{ kg} \cdot \text{m}^{-3}$) and viscosity coefficient (0.035 P or $35 \times 10^{-4} \text{ Pa} \cdot \text{s}$) of whole human blood. A glycerol solution (35–40% glycerin in water) has been generally used as the blood analog fluid in these studies. Prosthetic valves are made in various sizes (specified in sewing ring diameter magnitude). In comparing the pressure drop data for the various valve designs, proper comparison can be made on data only with comparable valve sizes. Since the flow across the valve during the forward flow phase is not laminar, the pressure drop has a nonlinear relationship with flow rate. Hence, pressure drop is measured for a range of flow rates and the pressure drop data is presented as a function of flow rate. Numerous studies comparing the pressure drop data for the various mechanical and bioprosthesis valves have been reported in the literature. Typical pressure drop comparisons for MHV and BHV (of nominal size of 25 mm) are shown in Fig. 11 (14). As can be observed, stented porcine tissue valves have the higher pressure drop, and hence are considered to be stenotic, especially in smaller valve sizes. The advantage of the stentless bioprosthesis design is

Figure 11. Typical plots for the pressure drop as a function of flow rate for the various mechanical and bioprosthetic valve prostheses (Courtesy of Prof. Ajit Yoganathan of Georgia Institute of Technology, Atlanta, GA.)

obvious especially in smaller sizes since the flow orifice will be larger due to the absence of supporting stents. Supra-annular design also permits the implantation of a larger sized valve for a given annulus orifice, thus providing a smaller pressure drop and energy loss. Smaller pressure drops across the valve prostheses will result in a reduced workload of the left ventricle as the pump. Gorlin equation, described in Eq. 1, has also been employed to compute the effective orifice area for the various valve designs (14). Generally, the pericardial and bileaflet valve designs have the largest effective orifice area, followed by the tilting disk, and porcine valves, with the caged ball valve exhibiting the smallest effective orifice area for a given sewing ring diameter. Valves with the larger EOA correspond to a smaller pressure drop and energy loss in flow across the valve. Performance index (PI), computed as the ratio of effective orifice area to the sewing ring area is also used for comparison of the various valve designs. Table 1 includes data on the EOA and PI for the various MHV and BHV with a 27 mm tissue annulus diameter from *in vitro* experimental studies. It can be observed that the centrally occluding caged ball valve and stented porcine valves have lower values of PI where as the tilting disk, bileaflet, pericardial valves, and stentless tissue valves have higher values indicating improved hemodynamics for the same values of the tissue annulus diameter.

Regurgitation

In discussing the flow dynamics with native heart valves, it was observed that the anatomy and the fluid dynamics enable the leaflets to close efficiently with minimal amount

Figure 12. Flow rate across mechanical valve prosthesis in the aortic position obtained in a pulse duplicator *in vitro* measured with an electromagnetic flow meter.

of regurgitation. On the other hand, the adverse pressure gradient at the end of the forward flow motion induces the occluders to move toward closure and all prosthetic valves exhibit a finite amount of regurgitation. Figure 12 shows a typical flow rate versus time curve obtained from an electromagnetic flow meter recording obtained *in vitro* in a pulse duplicator with a mechanical valve in the aortic position. As can be observed, a certain volume of reverse flow is observed as the valve closes and is termed as closing leakage. The closing leakage is related to the geometry of the valve and the closing dynamics. The rigid occluders in the mechanical valves also prevent the formation of a tight seal between the occluder and the seating ring when the valve is closed. With the tilting disk and bileaflet valves, a small gap between the leaflet edge and the valve housing is also introduced in order to provide a continuous wash-out of blood in the hope of preventing any thrombus deposition. Hence, even when the valve is fully closed, a small volume of blood is continuously leaking and is termed the static leakage. Percent regurgitation is defined as the ratio of the leakage volume over the net forward flow volume expressed as a percentage. Percent regurgitation can be computed by recording the flow rate versus time curve in an *in vitro* experimental set up and measuring the area under the forward and reverse flow phases from the data. These can be compared for the various size valves of the same model and also for comparison across the various valve models. Table 1 shows typical data of regurgitant volumes measured *in vitro* under physiological pulsatile flow in a pulse duplicator. The BHV designs result in more efficient leaflet closure with relatively small regurgitant volumes followed by the caged ball valve design. The magnitudes of the regurgitant volumes for the tilting disk and bileaflet valves are relatively larger and comparable to each other.

Quantitative measurement of percent regurgitation *in vivo* with both incompetent native valves or with prostheses has not been successful, even though attempts have

Table 1. Comparison of Effective Orifice Area (EOA)^a, Performance Index (PI), Regurgitation Volume, and Peak Turbulent Shear Stresses for the Various Models of Commercially Available Valve Prostheses

been made to employ fluid mechanical theories for regurgitant flow in order to estimate the leakage volume. Turbulent jet theory and proximal flow convergence theory have been employed in an attempt to measure the regurgitant glow volume quantitatively (26,27). However, *in vivo* application has not been successful due to the restrictive assumptions of steady flow and alterations due to impingement of the jet on the ventricular wall in the theoretical considerations as well as lack of *in vivo* validation.

Dynamics of Valve Function

As discussed earlier, significant problems still exist with the implantation of heart valve prostheses in patients with disease of native heart valves. These include thrombus initiation and subsequent embolic complications with MHV implantation. The thromboembolic rates with MHV have been estimated at 2%/patient year (28). Structural disintegration and tearing of leaflets are the major complications with BHV requiring reoperation in ~10–12 years after implantation. Flow past healthy native valves are central with minimal flow disturbances and fluid induced stresses and it can be anticipated that the fluid dynamics past the mechanical valve prostheses will be drastically different from those of native heart valves. Flow induced stresses with MHV function have long been implicated with hemolysis and activation of platelets that may trigger thrombus initiation. Regions of stress concentration on the leaflets during the opening and closing phases have been implicated on structural alterations of collagen fibers resulting in leaflet tears with BHV. Detailed functional analysis of implanted valve prostheses *in vivo* is impractical. Limited attempts have been made in the measurement of velocity profiles distal to the valve prostheses in the aortic position with hot film anemometry (29). Doppler and MR phased velocity mapping techniques have also been used to measure the velocity profiles distal to heart valves (30–32). However, detailed velocity measurements very close to the leaflets and housing of prosthetic valves are not possible *in vivo*, and hence *in vitro* experimental studies and computational fluid dynamic simulation are necessary for the same. Limited *in vivo* studies in animal models have also been employed to describe the complex leaflet motion with native aortic valves (33–37). *In vitro* studies and computer simulations are also necessary for a

detailed analysis of stress distribution in the leaflets of native valves and bioprostheses during the opening and closing phases of the valve function and to determine its relationship with failure of the leaflets.

Flow Dynamics Past Mechanical Valves

With the assumption that the deposition of thrombi in MHV implants is related to the flow induced stresses, studies are continuing to date on the deterministic relationship between fluid induced stresses and damage to formed elements in blood. Subjecting blood cells to precise flow fields and assessing the destruction or activation (of platelets), magnitudes of turbulent stresses beyond which damage can be expected has been established. In addition to the magnitude of the flow induced stresses, the time for which the blood elements are exposed to the stresses also need to be considered in assessing the destruction or activation of the platelets. Nevaril et al. (38) reported that blood cells can be hemolyzed with shear stresses of the order of 150–400 Pa. In the presence of foreign surfaces, the threshold for red blood cell damage reduces to ~1–10 Pa (39). Sublethal damage to red blood cells have also been reported at turbulent shear stress levels of about 50 Pa (40). Shear induced platelet activation and aggregation is observed to be a function of both magnitude and duration of shear stresses. The larger the magnitude of the shear stress, the shorter is the duration to which platelets are subjected to the shear before they get activated. Platelets have been shown to be activated with 10–50 Pa of shear stresses with a duration of the order of 300 ms (41). Platelet damage also increases linearly with time of exposure when subjected to constant magnitudes of shear (42).

Hence, it is of interest to determine the level of wall shear and turbulent shear stresses in flow past valve prostheses as factors causing initiation and deposition of thrombus.

For the first two to three decades after the implantation of the first mechanical valve, investigations concentrated on the flow dynamics past the valves during the forward flow phase and measurements of velocity profiles, regions of stasis and recirculation, high wall shear and bulk turbulent shear stresses. Wieting (25) employed a pulse duplicator and flow visualization studies using illuminated neutrally buoyant particles in order to qualitatively describe the nature of flow past the prosthetic valves.

Figure 13. Velocity profile measured distal to a caged ball valve in the aortic position *in vitro* in a pulse duplicator using laser Doppler anemometry technique.

Yoganathan (43) employed laser Doppler velocimetry (LDV) technique to measure the velocity profiles and turbulent shear stresses under steady flow past the valve prostheses. Since then numerous detailed studies have

been reported in the literature on the detailed measurement of velocity profiles and turbulent shear stresses distal to the prostheses under physiological pulsatile flow (13,14).

Figure 13 shows the velocity profile distal to a caged ball valve during the peak forward flow phase measured under physiological pulsatile flow *in vitro* (44). Jet-like flow is observed around the circumference that is separated by the ball and high turbulent stresses were measured at the edge of the jet. A wake is observed behind the ball with slow moving fluid. With the caged ball valve, higher incidences of thrombus deposition have been observed at the top of the cage and correspond to the slow moving fluid in this region behind the wake of the ball. With the tilting disk valves in the fully open position, the blood flows through the major and minor orifices as shown in Fig. 14 where the velocity profile during peak forward flow phase is once again depicted (44). Two jets are formed corresponding to the two orifices with the major orifice jet having larger velocity magnitudes. The amount of blood flow through the major and minor orifices will depend on the angle of opening of the occluder as well as the geometry. A region of reverse flow is also observed adjacent to the valve housing in the minor orifice. The velocity profile measured distal to the leaflet along the major flow orifice in the perpendicular orientation is also included in the figure.

Velocity profiles with three jets corresponding to the central orifice and two peripheral orifices are observed with the bileaflet valve as shown in Fig. 15 (45). The velocity profile along the central orifice in the perpendicular orientation is also included in this figure. Regions of flow reversals near the valve housing are also observed in the figure. Typical magnitudes of turbulent shear stresses measured in the various positions distal to the MHV under pulsatile flow conditions are also included in Table 1. It can be

Figure 14. Velocity profile measured distal to a tilting disk valve in the aortic position *in vitro* in a pulse duplicator using laser Doppler anemometry technique.

Figure 15. Velocity profile measured distal to a bileaflet valve in the aortic position *in vitro* in a pulse duplicator using laser Doppler anemometry technique.

observed that the measured bulk turbulent stresses are large enough to cause hemolysis and platelet activation that can be related to thrombus deposition with MHV. Thrombus deposition is generally observed on the leaflets and the valve housing with the tilting disk valves and also in the hinge region in the case of bileaflet valves.

More recently, it has been suggested that the relatively high turbulent stresses observed during the forward flow phase may not necessarily be the only reason for problems associated with MHV implantation. High turbulent stresses that may damage the formed elements occur in bulk flow distal to and moving away from the valve during the forward flow phase. The activated platelets will need to go through the systemic and pulmonic circulation before it will get deposited once again in the vicinity of the housing in the case of tilting disk and bileaflet valves. Several other experiences with mechanical valve prostheses designs have also indicated the importance of the valve dynamics during the closing phase to be more important for structural integrity and also in the initiation of thrombus. Medtronic Parallel valve design was introduced in the European market in the 1990s with the two leaflets opening to 90° in the fully open position. *In vitro* studies suggested that the fluid dynamics past this valve in the forward flow phase is superior or at least comparable to the currently available bileaflet valves. However, soon after human implantation trials in Europe, increased incidences of thrombus deposition was observed with this valve model, and hence it was withdrawn from clinical trials.

Another example is a design change in the tilting disk valve resulting in major changes in valve dynamics that

resulted in structural failure in a small percentage of implanted valves. In an effort to increase the flow through the minor orifice with an aim of preventing thrombus deposition, the flat disk geometry of the original Bjork–Shiley valve was changed to a curved geometry in the Bjork–Shiley convexo-concave valve. Even though this design change resulted in improved forward flow hemodynamics, this change resulted in alterations in the dynamics of valve closure with the leaflet overrotating and subjecting the outlet strut to additional loading (46). In a small percentage of valves particularly in the mitral position, single leg separation followed by outlet strut fracture resulted in leaflet escape, and hence this valve was withdrawn from the market. These developments also suggest the importance of understanding the mechanics of valve function throughout the cardiac cycle with any mechanical valve designs. In addition, structural failure and leaflet escape was reported with the implantation of a newly introduced bileaflet valve (Edwards-Duromedics) that resulted in the withdrawal of the valve from the market (47,48). The structural failure was thought to be due to pitting and erosion of the valve structures due to cavitation damage on the pyrolytic carbon (49). These reports also spurred a number of investigations on the closing dynamics and the potential for the mechanical valves to cavitate during the closing phase.

The occluders in the mechanical valves move toward closure with the onset of adverse pressure gradients, and the time taken to move from the fully open to the fully closed position is ~ 30 ms. Toward the end of the leaflet closure, the leaflet edge moves with a velocity of $\sim 3\text{--}4\text{ m}\cdot\text{s}^{-1}$

Figure 16. Typical negative pressure transients recorded at the instant of mechanical heart valve closure (in the mitral position) with the pressure transducer placed very close to the leaflet on the inflow side (atrial side) from *in vitro* experiments.

(50–53) and comes to a sudden stop as it impacts the seating lip. This produces a water hammer effect with large positive pressure transient on the outflow side (left ventricle in the mitral position and aorta in the aortic position) and a large negative pressure transient on the inflow side (left atrium in the mitral position and the left ventricular outflow tract in the aortic position). Several *in vitro* studies have recorded negative pressure transients (54) with magnitudes below that of the vapor pressure for blood (ca. -713 mmHg or -94.8 kPa) and cavitation bubbles have also been visualized at the edge of the leaflets (53–58) in the region corresponding to large negative pressure transients and where the linear velocity of the leaflet edge will be the largest. Figure 16 depicts measured negative pressure transients with the pressure transducer placed near the leaflet edge on the inflow side (atrial side) of the leaflet of a tilting disk valve at the instant of valve closure from *in vitro* experiments. Note that structural failure due to cavitation type of damage has been reported with only one model of the bileaflet valve and there are no other reports of pitting and erosion on the valve material reported with implanted mechanical valves. It is also not possible to visualize cavitation bubbles *in vivo* with implanted mechanical valves. However, *potential* for mechanical valves to cavitate has been demonstrated in an animal model with the recording of negative pressure transients, similar to those measured *in vitro*, in the left atrium in the vicinity of the implanted mechanical valves in the mitral position (59,60). The actual mechanism of cavitation bubble formation, whether due to the negative pressure magnitudes below the vapor pressure for blood or due to strong vortices forming in the atrial chamber providing additional pressure reductions, is still being debated. It has also been suggested that vortex cavitation

bubbles forming away from the valve surfaces, can trap the dissolved gas from blood and form stable gas bubbles that travel with blood to the circulation and induce neurological deficit due to the gas emboli (61). Number of attempts has also been reported on the detection of the induced cavitation *in vivo* with implanted mechanical valves from acoustic signals (62–64). Another aspect of MHV cavitation that has been neither fully understood nor fully investigated is the development of stable bubbles, found by microembolic signals (MES) or high intensity transient signals (HITS) during and post-MHV implantation. *In vitro* studies have shown the development of stable bubbles (HITS) in an artificial heart and closing dynamics experimental models, and are affected by the concentration of CO_2 (65–67). *In vivo*, HITS have been visualized during and post-MHV implantation through transcranial Doppler ultrasound (68,69). These events have been implicated as a cause of strokes and neurological deficits. Further evidence has shown that these HITS are in fact, gaseous, and not solid. Patients placed on pure O_2 after MHV implantation showed a large decrease in the number of HITS recorded, when compared to patients on normal air (70). These stable bubbles are believed to develop when gaseous nuclei that are present in blood, flow into low pressure regions associated with valve closure. As the valve closes and rebounds inducing vaporous cavitation, gas diffuses into the nuclei enlarging the bubble. When the pressure recovers and the vapor collapses, the bubble dynamics and local fluid mechanics prevent the gas from diffusing back into solution causing the bubble to stabilize and allowing it to flow freely in the vasculature. There is some discussion as to which gas stabilizes the nuclei. Both N_2 and CO_2 have been suggested as the link to MES/HITS/stable bubble formation (71), but there has yet to be concrete proof indicating which one does.

Large negative pressure transients occur due to the rigidity of the occluder and negative pressures do not occur at the instant of valve closure in the case of bioprosthetic valves (59). *In vitro* measurements with a tilting disk valve design employing a flexible occluder being implanted in India has also demonstrated that large negative pressures do not develop in such designs because the leaflets deform at the instant of valve closure and absorb part of the energy (12,59).

Irrespective of the formation of cavitation bubbles and subsequent collapse with implanted mechanical valves, the flow induced stresses during the valve closing phase has been suggested as of sufficient magnitude to induce platelet activation and initiation of thrombus. Even if the negative pressure transients do not reach magnitudes below the vapor pressure for blood, the large positive and negative pressure transients on the outflow and inflow sides of the valve at the instant of valve closure can induce high velocity flows through the gap between the leaflet and the housing, in the central gap between the two leaflets in the bileaflet valve, and also through the hinge region. The wall shear stress in the clearance region have been computed to be relatively high, even though present only for a fraction of a second. They induce platelet activation in the region where thrombus deposition is observed with mechanical valves (72). Relatively

high turbulent shear stresses have also been reported from *in vitro* studies distal to the hinge region of bileaflet valves during the valve closing phase (73,74) indicating the presence of high fluid induced regions near the leaflet edges during the valve closing phase that may be a significant contributor for thrombus initiation.

Most of the studies described above for the measurement of velocity profiles and turbulent stresses employed the laser Doppler velocimetry (LDV) technique. This is a point-velocity measurement technique, and hence measurement of the complete three-dimensional (3D) velocity profile distal to the valve under unsteady flows is tedious and time consuming. On the other hand, particle image velocimetry (PIV) technique has the ability to capture the whole flow field information in a relatively shorter time. Lim et al. employed the PIV technique to study the flow field distal to prosthetic heart valves in steady (75) and pulsatile (76) flow conditions. Along with the description of the flow field at the aortic root that was employed to identify the regions of flow disturbances, they also presented the results of turbulent Reynolds stress and turbulent intensity distributions. Under pulsatile flow conditions distal to a BHV, the velocity vector fields and Reynolds stress mappings at different time steps were used to estimate the damage of shear induced damage to formed elements of blood (76). Browne et al. (77) and Castellini et al. (78) compared the LDV and PIV techniques for the measurement of flow past MHV. Both these works conclude that PIV has the advantage of describing the detailed flow field distal to the valve prostheses in a relatively short time, but LDV technique affords more accurate results in the measurement of turbulent stresses. Regurgitant flow fields and the details of the vortical flow, a potential low pressure field for cavitation initiation have also been measured employing PIV techniques (79,80) and with a combination of PIV and LDV techniques (81).

Bioprosthetic Valve Dynamics

Measurement of velocity profiles and turbulent stresses from *in vitro* tests in pulse duplicators past BHV have also been reported in the literature (82). Figure 17 depicts typical velocity profiles past a porcine bioprosthesis under normal physiological flow simulation (82). With the porcine valve, a jet-like flow is observed during the peak forward flow phase with high turbulent shear stresses at the edge of the jet. With the pericardial valves (82), the peak velocity magnitudes in the jet-like flow during the peak forward flow phase were smaller than those for the porcine valves in comparable sizes (Fig. 18). It can be observed from Table 1 that the peak turbulent stresses are also smaller in the pericardial valves with geometry closer to the native aortic valves compared to that of the porcine prostheses. It should be noted that the magnitudes of turbulent stresses with the BHV also exceed those values suggested for activation of platelets. However, the leaflets of the BHV are treated biological tissue rather than artificial surfaces. Long-term anticoagulant therapy is generally not required with the implantation of bioprostheses since thrombus initiation is not a significant problem with these valves.

Figure 17. Velocity profile measured distal to a porcine bioprosthetic valve in the aortic position *in vitro* in a pulse duplicator using laser Doppler anemometry technique.

On the other hand, these valves fail after an average of 10–12 years of implantation and replacement surgery is required with leaflet failure. A number of studies have been reported on the analysis of the complex leaflet motion during the valve function in order to determine a causative relationship between regions of high stress concentration

Figure 18. Velocity profile measured distal to a pericardial bioprosthetic valve in the aortic position *in vitro* in a pulse duplicator using laser Doppler anemometry technique.

on the leaflets and its attachment sites and structural failure. Based on the analysis of native aortic leaflet motion *in vivo* with the use of radiopaque markers, it has been reported that the design of the native aortic leaflets affords minimal stresses on the leaflets (33,35). On the other hand, stress analysis on the BHV valve leaflets *in vivo* suggests that mechanical stresses play a role in calcification of the leaflets (33,34,83). A number of studies has been reported on a finite element stress analysis on the BHV valve leaflets in the closed position in order to correlate regions of high stresses with calcification and tissue failure (84,85). Recent studies have indicated that damage to the valvular structural matrix occurs as the result of mechanical stresses and that the structural damage occurs in spatially distinct sites from those of cuspal mineralization (86). Hence, there is a renewed interest in analyzing the stresses on the leaflets during the opening and closing phases of the leaflet function since loss in flexural rigidity has been demonstrated after the valves undergo 50 million cycles of loading *in vitro* (87). Detailed analysis on the mechanism of structural failure under cyclic loading requires experimental quantification of the complex motion and also detailed description of the nonlinear anisotropic material property description of the BHV leaflets (88). Leaflet motion quantification by the application of ink markers on the leaflet surface (89), laser profiling technique (90), and noncontacting structured laser light projection technique (91) have been employed for the BHV leaflets. Several studies have been reported on the material characterization of chemically treated BHV leaflet tissue (92–94). Even though these studies have yielded valuable information about the nonlinear material characterization of the leaflets, true physiological characterization requires biaxial loading tests. Recently, constitutive models for the BHV leaflets under biaxial loading have been reported (95,96), which takes into consideration the local architecture of the valve fibers. Since the treated aortic valve leaflet consists of three layers, it can also be anticipated that the behavior of each layer will be different under the physiological loading during the valve opening and closing phases. Recent studies have included separating the fibrosa and ventricularis layers by dissecting microscope and each layer being subjected to biaxial testing (97). Incorporating such detailed material description in the computational analysis in order to determine the flexural and shear stresses on the multilayered tissue leaflets may yield valuable information on the nature of the effect of mechanical stresses on structural disintegration and limited durability with implanted BHV.

Computational Simulation of Heart Valve Function

With the advent of high speed computing capabilities, advances in computational fluid dynamic and finite element numerical analyses algorithms, simulations to determine the mechanical stresses on the blood elements and leaflets during the valve function, is being increasingly employed to understand the mechanics of valve function. In the case of MHV, recent studies have focused on the mechanical stresses developed during the closing phase of valve function. Wall shear stresses of the order of 1000 Pa

have been reported through a numerical simulation in the central clearance of a bileaflet valve with the leaflets in the fully closed position (98). Since the simulation was with the leaflets in the closed position, this simulation did not incorporate the effects of a large pressure gradient across the leaflet at the instant of valve closure (54). A quasistatic simulation in which the leaflets were in the fully closed position and with the application of the measured transient pressures at the instant of valve closure indicated the presence of shear stresses of ~ 2200 Pa (99,100). Employing moving boundaries for the mechanical valve leaflet very near the time of valve closure, simulations of the flow dynamics in the clearance region between the edge of the leaflet and the seat stop have demonstrated fluid velocities of the order of $28 \text{ m} \cdot \text{s}^{-1}$ with large negative pressure regions on the inflow side of the occluder (101,102). The computed resulting wall shear stress magnitudes at the edge of the leaflet exceeds 17 kPa for a fraction of a second at the instant of valve closure and first rebound after impact with the seat stop (72).

In the case of BHV, finite element analysis has been the popular technique employed to determine the stress distribution on the leaflets with the blood pressure applied as the load on the leaflets. Such analyses have also been employed to perform stress analysis with native aortic and mitral valves (103,104). Stress analysis with BHV geometry have incorporated the nonlinear material property of the leaflets and employed both the rigid and flexible stent support (84,85). These results have generally suggested a correlation between regions of high stresses with the leaflets in the fully closed position and calcification observed with implanted valves.

Numerical simulation of native and prosthetic heart valve function is quite challenging with the necessity of addressing several difficult issues. In the case of MHV simulation, the mesh generation for the detailed 3D geometry of the tilting disk and bileaflet valves, including the complex geometry of the hinge mechanism, is required. The simulation must also have the ability to deal with the moving leaflets. In the case of BHV simulation, it is necessary to incorporate the nonlinear anisotropic material property of the leaflets and compute the complex motion of the leaflets due to the external load imparted on the same by the surrounding fluid. In modeling the valve function, the fluid domain is most conveniently described using the Eulerian reference frame in which the fluid moves through a fixed mesh. A Lagrangian formulation is more appropriate for the leaflet motion in which the mesh moves together with the leaflet. The complete simulation of the heart valve function requires a fluid-structure interaction simulation and the two formulations are incompatible for such an analysis. Two methods have generally been employed to circumvent this problem. An Eulerian method used in the simulation of heart valve function is the fictitious domain method employed by de Hart et al. (105,106) and Baaijens (107). This simulation requires careful attention to accurate mesh representation for flows near the leaflet due to the use of fixed grid and numerical stability. It is also computationally very intensive. The second approach is the arbitrary Lagrangian–Eulerian (ALE) method in which the computational mesh is allowed

to deform (108) and move in space arbitrarily to conform to the moving boundaries. It has also been successfully employed in the heart valve simulation. The disadvantage with this method is the need for a mechanism to adapt or deform the mesh to conform to the boundary motion at each new time step. Large and complex deformation of the BHV leaflets within the computational domain makes the mesh adaptation very difficult when structured mesh is used and the mesh topology has to be maintained. Mesh regeneration has been employed to avoid the problems with the maintenance of mesh topology, and requires reinterpolation of the flow variables that can be expensive to perform and may result in large artificial errors. The ALE method recently has been employed in the simulation of prosthetic valve function by several investigators (102,109–111). More recently, a fluid-structure interaction simulation for the mechanical valve closing dynamics employing the ALE method has been presented for both two-dimensional (2D) (112) and 3D (72) geometry of a bileaflet valve. In this analysis in which the details of the hinge geometry was not included, the leaflet was specified to rotate around an axis and the motion of the leaflets was computed by solving the governing equation of motion for the leaflet with fluid-induced stresses specified as the external load. The pressure and velocity field is calculated employing the CFD solver employing the ALE method. The grid points on the leaflets are rotated, based on the solution of the equation of motion of the leaflet. An elliptic solver is employed to the entire mesh using the initial methods and the computed displacement of the leaflet grid points. This simulation has also clearly demonstrated the presence of abnormally high wall shear stresses in the clearance region of the leaflet and the valve housing at the instant of valve closure and leaflet rebound. These studies indicate that the shear stress-time magnitude present in this region far exceeds magnitudes suggested for platelet activation, and hence may be the critical factor for thrombus initiation with MHV implants.

SUMMARY

Since the introduction of the first prosthetic valve replacement for a diseased native heart valve > 40 years ago, numerous developments in design and manufacturing process have resulted in improved performance of these implants and patients are leading a relatively normal life. Continued efforts are underway to minimize the effect of thrombus deposition with MHV and to improve the durability of implanted BHV. State-of-the-art experimental techniques and computational simulations are being applied to improve our understanding on the relationship between the complex solid and fluid mechanics during the prosthetic valve function and its relationship with the problems still continuing to be observed with the implants. With the advent of high performance computers and advances in computational flow dynamics algorithms, more detailed 3D unsteady laminar and disturbed flow simulations are becoming a reality today. Development of fluid-structure interaction simulations, inclusion of detailed structural analysis of biological leaflet valves during the valve function, and the behavior of platelets

and red blood cells in the unsteady 3D flow field to simulate the platelet and red blood cell motion in the crevices are crucial for our further understanding of the mechanical valve function. However, complementary experimental studies to validate the simulations are also essential to gain confidence in the results of the complicated numerical simulations. A deterministic study of the effect of such stresses on the leaflet structures as well as formed elements in blood will require an analysis that includes computational algorithms that span multiple length and time scales. Efforts are underway to develop such simulations. These studies will also provide valuable information toward the development of tissue engineered valve replacements.

HEART VALVE PROSTHESES, IN VITRO FLOW DYNAMICS OF

STEVEN CECCIO
University of Michigan
Ann Arbor, Michigan

INTRODUCTION

The cardiac cycle begins with venous blood passing through the tricuspid valve in response to relaxation of the right ventricle. Then, during ventricular contraction,

the tricuspid valve closes and blood flows through the open pulmonary valve to the lungs. Similarly, oxygenated blood leaving the lungs crosses the mitral valve during filling of the left ventricle and is then ejected through the aortic valve when the left ventricle contracts. A normally functioning heart valve must open and close approximately once every second without posing significant resistance to flow during opening and without allowing significant leakage during closure.

Due to the critical role that heart valves play in controlling pressures and flows in the heart and throughout the body, valve disease is a serious health risk and can be fatal if not treated. In the United States almost 20,000 people die annually as a result of heart valve disease (1). Although the causes and mechanisms of heart valve diseases are varied, their effect can usually be reduced to either failure of the valve to open fully (stenosis) or failure to prevent leakage of blood (regurgitation). Patients with stenosis or regurgitation may experience chest pain, labored breathing, lightheadedness, and a reduced tolerance for exercise.

Because of the mechanical nature of valve dysfunction, treatments for severe valve disease usually involve surgical intervention to restore the flow control function of the valve. Early surgical treatments consisted of a surgeon using a tool, or his fingers, to reach into the beating heart and forcefully open a stenotic mitral valve. With the advent of cardiopulmonary bypass in the 1950s, the notion of fabricating and implanting a prosthetic valve became more feasible and by the early 1960s the first successful and repeatable prosthetic valve implants were performed by Starr (2,3). The valve he developed with Edwards, an engineer, consisted of a ball trapped in a rigid, dome-shaped cage. At the inflow edge of the valve was a cloth flange, the sewing ring, which enabled the surgeon to sew the valve into the patient's heart (see Fig. 1). Although crude in comparison to the native valve structure, this

Figure 1. Starr-Edwards ball-cage valve. (Courtesy of Edwards Lifesciences, Irvine, CA).

Starr-Edwards valve and subsequent models had been used successfully in >175,000 people by 1991 (4).

Over the past four decades, numerous valve designs have been developed and used clinically. There were ~80,000 heart valve-related surgeries in the United States in 1999, ~50,000 of which were implants of prosthetic aortic valves (5). But despite the success of prosthetic valve technology, currently no valve is optimal, so surgeons and engineers continue their collaborative efforts in pursuit of improved designs.

Due to the lower pressures in the right ventricle, the tricuspid and pulmonary valves are implicated far less in heart disease than the valves of the left heart (1). Consequently, prosthetic heart valve technology is focused almost entirely on mitral and aortic valves. The following discussion will focus on the primary tools, techniques, and data that are of interest when evaluating these valves *in vitro*.

NATIVE VALVE STRUCTURE AND HEMODYNAMICS

Although it has been shown that a prosthetic heart valve need not look like a native heart valve to have adequate *in vivo* function, it must have geometry suitable for the intended implantation site and must function without impeding other aspects of cardiac function. It is therefore important to understand the anatomy and physiology of native heart valves as well as the process of surgical implantation of prosthetic valves. These will be reviewed briefly here; more detailed reviews can be found elsewhere (6–10). Figure 2 shows schematic drawings of a cross-section of the left ventricle in systole and diastole.

The base, or inflow perimeter, of the aortic valve is contiguous with the left ventricular outflow tract and the anterior leaflet of the mitral valve. The valve is comprised of three flexible, triangular leaflets, each of which attaches along ~120° of the circumference of the aorta. The inflow attachment line curves upward from the annulus at

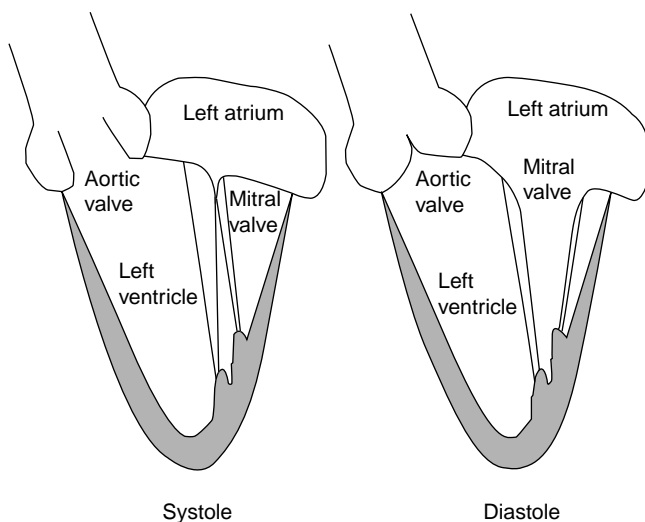

Figure 2. Schematic of the left ventricle and valves during systole and diastole.

both ends, giving the leaflet its curved, three-dimensional (3D) geometry. At the outflow aspect of the valve, each adjacent leaflet pair meet at a commissure, a junction point on the aortic wall, and the aorta surrounding the valve leaflets is comprised of three bulbous regions, the sinuses of Valsalva.

Contraction of the left ventricle causes ventricular pressure to increase until it exceeds that in the aorta at which point the aortic valve opens rapidly and allows flow into the aorta. The flow reaches its peak amplitude about one-third of the way through the flow cycle. As the left ventricle relaxes, ventricular pressure falls, which reduces the pressure gradient and causes flow in the aorta to decelerate. Eventually, the pressure in the aorta exceeds that in the left ventricle and the aortic valve closes. During forward flow, a vortex forms in each sinus, which may play a role in the subsequent closure of the leaflets (11).

Aortic flow continues forward for a short period of time after the reversal of the pressure gradient due to the momentum of the blood (12), and a small volume of blood, the closing volume, is pushed back into the ventricle at closure due to the motion of the closing leaflets. During diastole, the closed aortic valve is under a back pressure of 80–100 mmHg (10.66–13.33 kPa). Representative pressure and flow waveforms of the aortic valve are shown in Fig. 3. At a heart rate of 70 beats · min⁻¹, systole will typically last ~35% of the whole cardiac cycle, or ~300 ms. At an exercise heart rate of 120 beats · min⁻¹, the systolic ratio will increase to near 50%.

Although there are many factors involved in deciding whether a patient needs surgery, general guidelines suggest that a diseased aortic valve may be considered for replacement with a prosthesis when the area of the valve has been reduced to 0.5–1.0 cm² (compared to a normal range of 3–4 cm²), or when regurgitation has caused an ejection fraction of <50% (13). When a diseased aortic valve is replaced with a prosthetic valve, the aorta is cut open, all three leaflets are cut out, and any calcium is removed from the valve annulus. The diameter of the annulus is then measured to determine the appropriate sized prosthetic valve to use. The prosthetic valve is then implanted by stitching the sewing ring to the tissue of the native annulus, although the exact implantation process as well as the positioning of the valve will vary based on valve type.

Figure 3. Idealized waveforms of pressure and flow through the aortic valve.

The mitral valve is structurally and functionally distinct from the aortic valve. It has two primary, unequally sized leaflets, each of which is made from several segments. The longer anterior leaflet, adjacent to the aortic valve, is attached along one-third of the annulus, while the shorter posterior leaflet connects to about two-thirds of the annulus. The leaflets contain many furrows or wrinkles that allows the valve to occupy minimal space in the heart while still having a large surface area for preventing leakage and supporting the stress of closure. The annulus itself is not circular, but D-shaped, and has a 3D, saddle-shaped curvature (14).

Many tendonous chords emanate from the underside and edge of the leaflets and attach to the papillary muscles, which are part of the wall of the left ventricle. The chords and papillary muscles comprise the tensioning component of the mitral apparatus, helping the valve to support and balance the stresses on the leaflets during closure. The entire mitral apparatus is a dynamic and active structure: the annulus, leaflets, and papillary muscles all move in coordination throughout the cardiac cycle in support of proper valve function (15,16). Currently, no prosthetic mitral valve can replicate or synchronize with the complicated force and motion dynamics of the native mitral apparatus.

During left ventricular filling, diastolic flow through the mitral valve is equal to the subsequent flow out of the aortic valve, assuming there are no leaks through either valve. Although the same volume passes through the mitral valve, the flow profile is very different than that of aortic flow. First, diastolic flow occupies $\sim 65\%$ of the cardiac cycle, lasting ~ 557 ms at a heart rate of $70 \text{ beats} \cdot \text{min}^{-1}$. Due to the longer flow period, peak flow rates and pressure gradients are usually lower through the mitral valve than the aortic valve. Second, diastolic flow occurs in two phases. As the left ventricle relaxes, pressure falls to near zero and the mitral valve opens to allow ventricular filling from the left atrium, which acts as a compliant filling chamber and maintains a fairly constant blood pressure of ~ 15 mmHg (1.99 kPa). The pressure gradient between the atrium and the ventricle lessens as the ventricle fills, causing the flow to approach zero and the leaflets to nearly close. The left atrium then contracts, opening the leaflets again and sending a second bolus of blood, less than the first, into the ventricle. The two waves of the biphasic diastolic flow pattern are referred to as the E and A waves. The valve closes fully at the end of the A wave and is under a back pressure of >100 mmHg (13.33 kPa) during systole. Figure 4 shows a schematic representation of pressure and flow waveforms through the mitral valve.

The decision to surgically replace the mitral valve with a prosthesis, as with the aortic valve, is based on many factors. But general functional criteria include an effective orifice area $<1.0 \text{ cm}^2$ (depending on body size) or regurgitation causing an ejection fraction $<50\%$ (13). During surgical replacement, the left atrium is opened, the native leaflets are cut out, and any calcium is removed. As with aortic replacement, the diameter of the annulus is measured to determine the prosthetic valve size needed. For valves with stent posts, care must be taken that the posts do not impinge on the wall of the left ventricle. The chords

Figure 4. Idealized waveforms of pressure and flow through the mitral valve.

are generally removed, but may be left in the heart in some cases to provide structural support to the left ventricle. For some patients, the mechanical functionality of the mitral valve can be restored with surgical repair techniques, obviating the need for a prosthesis.

PROSTHETIC HEART VALVE TECHNOLOGY

A prosthetic heart valve must meet several basic functional requirements. In addition to having adequate opening and closing characteristics, it must also be durable, and biocompatible. All prosthetic valves compromise at least one of these features in favor of one of the others. The primary distinction between valve types is materials: Most valve designs use either synthetic, rigid components or flexible, biologically derived tissue. Based on these material features, a prosthetic valve is generally categorized as either a mechanical valve or a tissue valve.

Most mechanical heart valves (MHVs) are made from a rigid ring of metal or pyrolytic carbon, the outer perimeter of which is covered with a cloth sewing ring. The ring, or housing, contains one or more rigid occluders that are free to swivel on struts or hinges in response to a pressure gradient. The occluders are constrained within the housing, but are not mechanically coupled to it, allowing blood to flow completely around them, which helps to avoid flow stagnation.

Although they can adequately prevent backflow, MHVs do not create a seal during closure, and thus allow some regurgitation. The volume of blood regurgitated is tolerable for the patient, but the squeezing of blood through the closed valve creates high velocity, high shear jets that may be responsible for blood damage that leads to thrombosis (17). Whatever the mechanism, all MHV patients must take a daily dose of anticoagulant to counteract the thrombogenic effects of the valve. Without anticoagulation MHVs will develop clots that can impede valve function or become embolized into the bloodstream. One advantage of MHVs is that they are highly durable and can usually function for the duration of the recipient's life.

Although widely used, the Starr-Edwards valve was eventually surpassed by MHVs with better flow characteristics. Bileaflet valves and tilting disk valves are the two

Figure 5. Examples of two mechanical heart valves: A bileaflet St. Jude Mechanical valve, and a Medtronic tilting disc valve. (Courtesy of Medtronic, Inc.)

most popular types in use clinically (see Fig. 5). The St. Jude bileaflet mechanical valve is by far the most widely used mechanical valve. It accounted for >70% of all mechanical valves sold in the United States in 2003 (18). Most innovations in MHVs in the last 10 years have focused on optimizing this type of bileaflet design, either through improved materials, geometries, or sewing rings. Other manufacturers of mechanical heart valves include Carbomedics, Medtronic, Sorin, and Medical Carbon Research Institute.

Tissue heart valves (THVs), also called bioprosthetic valves, were developed based on the idea that valves made of biologic tissue and with a structure similar to the native heart valve would function better *in vivo* than rigid mechanical valves. The leaflets of these valves are made from animal tissue that has been treated with a dilute solution of glutaraldehyde. Glutaraldehyde cross-links the collagen in the tissue, which prevents its breakdown and reduces its antigenicity *in vivo*. The cross-linked tissue is slightly stiffer than fresh tissue, but it still retains a functional amount of flexibility.

Porcine THVs are made from the aortic valve of a pig. To construct the prosthesis, the aortic valve is first excised from the pig heart, trimmed to remove excess tissue,

incubated in glutaraldehyde, and then mounted on a cloth-covered frame with three commissure posts and a sewing ring. The frame, made of metal wire or plastic, provides structural support and allows ease of handling and implantation. The other main type of THV is the pericardial valve. Pericardium, the tissue that surrounds the heart, is separated from the heart of a cow or horse and then flattened and incubated in glutaraldehyde, producing a sheet of material that may be cut and assembled as desired to form a valve. Commercial pericardial valves typically incorporate three separate leaflets onto a three-pronged support structure similar to those used for porcine valves. Although structurally similar to the aortic valve, both porcine and pericardial valves are also implanted in the mitral position. Examples of a porcine valve and a pericardial valve are shown in Fig. 6. The Edwards Perimount pericardial valve is currently the most widely used THV, comprising >70% of all tissue valves used in the

Figure 6. Examples of two tissue heart valves: A Mosaic porcine tissue valve. (Courtesy of Medtronic, Inc.) A Perimount pericardial tissue valve. (Courtesy of Edwards Lifesciences, Irvine, California.)

United States (18). Other manufacturers of tissue valves include Medtronic, St. Jude, Sorin, and 3F Therapeutics.

In contrast to MHVs, THVs generally have an unobstructed flow orifice, seal during closure, and do not typically require long-term anticoagulation. However, THVs have limited structural durability compared to MHVs, which usually last the duration of the recipient's lifetime. Although some pericardial valves have performed well for as long as 17 years in patients (19), the THVs in general are expected to degenerate or calcify within 10–15 years, at which time they must be surgically replaced with a new prosthesis. Due to this limitation, THVs are typically only implanted in patients older than 65 years of age (13). Over the past several years there has been an increased use of tissue valves in the United States, while mechanical valve usage has declined, a trend that is expected to continue (18).

Another type of THV that was widely pursued in the 1990s is the stentless valve. This valve type, intended for aortic valve replacement only, is made from porcine aortic roots that are fixed in glutaraldehyde, but do not have any rigid support materials added. The surgeon must attach both ends of the device into the patient's aorta without the aid of a sewing ring or support structures. The intended benefit of these valves is better hemodynamics because of their flexibility and lack of a sewing ring, and greater durability due to lower stresses in the tissue. However, they are not used as extensively as other THVs because they are more difficult to implant, which results in extended surgery time. Examples of two stentless valves used clinically are shown in Fig. 7. Similarly, human aortic roots can be removed from cadavers and processed with preservative techniques to make an implantable replacement. These valves, called homografts or allografts, have all the perceived benefits of stentless valves, but are just as difficult to implant, and long-term clinical results have been mixed (5). The primary commercial source of homografts is Cryolife, which cryogenically preserves the aortic roots.

There have been numerous attempts at fabricating prosthetic valves from polymers but, to date, none have achieved clinical success. Polymer valves are conceptually attractive because they would be flexible, with a reproducible geometry and relatively economical and straightforward to manufacture, and ideally would be more durable than tissue valves, while not requiring chronic anticoagulation like mechanical valves. But design difficulties and calcification have prevented these valves from realizing their full potential (20). Like polymer valves, tissue-engineered valves have many theoretical advantages over current mechanical and tissue valves. As a result, processes for growing a valve *in vitro* from human cells seeded on a scaffold has been an area of active research (21–23), but has also not yet produced a clinically viable product.

IN VITRO TESTING

In vitro evaluations of prosthetic heart valves are performed to understand the detailed flow characteristics of a given design. The flow area, the amount of leakage, the ultrasound compatibility, the presence of deleterious flow

Figure 7. Examples of two stentless porcine heart valves: A Prima stentless valve. (Courtesy of Edwards Lifesciences, Irvine, Ca.) A Freestyle stentless valve. (Courtesy of Medtronic, Inc.)

patterns, the velocity magnitude of regurgitant jets, the motion of the leaflets during forward flow, and the position of the leaflets during closure can all be assessed *in vitro* and be used to improve valve designs and assess the appropriateness for human implantation.

Equipment

To evaluate the hemodynamic performance of prosthetic valves, a pulse duplicator or mock flow loop is implemented to act as an artificial left ventricle, and therefore must be able to simulate the pressure and flow waveforms shown in

Figure 8. Schematic of a pulse duplicator for *in vitro* heart valve testing.

Figs. 2 and 3 over a range of physiologic hemodynamic conditions.

Figure 8 is a schematic representation of a pulse duplicator for *in vitro* heart valve testing. Generally, the left atrium is simulated with an open or compliant reservoir that maintains a static fluid height above the mitral valve so as to provide a diastolic filling pressure of $\sim 10\text{--}15$ mmHg (1.33–1.99 kPa). The mitral valve should open directly into the left ventricle as it does anatomically. The left ventricle can be simulated with a rigid chamber with a volume similar to the human left ventricle ($\sim 70\text{--}100$ mL), although some pulse duplicators utilize a flexible, ventricular-shaped sac that can be hydraulically compressed to simulate the squeezing action of the heart (24,25). The aortic valve should be mounted at the outflow of the ventricular chamber so that flow enters the valve directly from the chamber. Tubing between the ventricle and the valve should be avoided as it will cause higher than physiologic velocities upstream of the valve. The flow exiting the aortic valve enters a tubular chamber with dimensions similar to the native aorta, including three sinuses and a diameter appropriate for the aortic valve being tested. Although not necessary for valve closure, the presence of sinuses allows for more realistic flow patterns behind the leaflets during systole.

The system should be instrumented to allow instantaneous pressure measurements in the left atrium, left ventricle, and aorta and flow measurements through both valves. The flowmeter must be able to accurately measure both forward flow, which can reach peak values of $30\text{ L}\cdot\text{min}^{-1}$, and leakage flows, which may be on the order of $1\text{ mL}\cdot\text{s}$. Test fluids can be either saline or a blood analog fluid with a density and viscosity similar to that of blood, $\sim 1.1\text{ g}\cdot\text{mL}^{-1}$ and 3.5 cp , respectively. A mixture of water and glycerin is the most common blood analog fluid. Because blood is a non-Newtonian fluid (i.e., its viscosity

varies with shear rate), polymeric solutions, which more closely mimic this property, have also been used for *in vitro* valve testing (26).

In order to produce physiologic waveforms, compliant and resistive elements must be present downstream of the aorta. Compliant elements are expansive chambers that may utilize air, springs, flexible beams, or compliant tubing to absorb fluid volume during the systolic stroke. The compliant element should be located as close as possible to the aortic valve to minimize “ringing” in the pressure and flow waveforms. The impedance of the arterial system can be simulated with simple pinch clamp on flexible tubing, or a variably restrictive orifice.

The flow is driven with a pulsatile pumping system that interfaces with the left ventricular chamber. The pump must be able to create physiologic beat rates, flow rates, and systolic/diastolic ratios. One type of pumping system utilizes positive and negative air pressure, cycled with solenoid valves and timers, to drive a flexible diaphragm (27). Alternatively, a large, cam-driven syringe (piston-cylinder) pump can be employed with controlled piston displacement designed to produce the desired systolic and diastolic timing. Syringe pumps driven by computer-controlled servo motors are the optimal pumping systems because they allow the greatest amount of control over the motion of the piston and can best simulate complicated physiologic flow patterns (e.g., biphasic diastolic flow).

Valve mounting in a pulse duplicator can be accomplished by mechanical compression of the sewing ring, or by suturing the ring to a gasket. However, any valve that is flexible and mechanically coupled to the native anatomy during implantation (e.g., a stentless aortic valve) must be tested in a valve chamber that mimics the dynamic motion of the valve *in vivo*, because this may affect hemodynamic performance. Standardized testing guidelines suggest that stentless valves be tested in flexible chambers that undergo a 4 and 16% change in diameter per 40 mmHg (5.33 kPa) pressure change (28).

Test Conditions and Data Analysis

Hemodynamic conditions considered typical for an adult would be the following: cardiac output: $5\text{ L}\cdot\text{min}^{-1}$; left atrial pressure: $10\text{--}15$ mmHg (1.33–1.99 kPa); left ventricular pressure: $120/0$ mmHg (systolic/diastolic) (15.99/0 g); aortic pressure: $120/80$ mmHg (systolic/diastolic) (15.99/10.66 kPa); heart rate: $70\text{ beats}\cdot\text{min}^{-1}$.

Although flow and pressure conditions are often quantified according to mean, peak, and minimum values this way, the shape of the pressure and flow waveforms are also important in determining the appropriateness and quality of the test condition. Excess “ringing”, large pressure spikes, and square waveforms are examples of unphysiologic waveform features that may be seen *in vitro*.

A thorough *in vitro* investigation of heart valve performance should also include different flow, heart rate, and pressure conditions that correspond to the range of physiologic hemodynamic conditions that the valve will experience *in vivo*. At rest, the heart rate may decrease to $45\text{ beats}\cdot\text{min}^{-1}$ or lower, while during exercise it may increase to $>120\text{ beats}\cdot\text{min}^{-1}$; cardiac output will vary

accordingly at these conditions, typically ranging from 2 to $7\text{ L} \cdot \text{min}^{-1}$. It is at these extremes that leaflet dynamics, for example, may change and reveal performance limitations of the valve.

Typically, a minimum of 10 cycles, or heart beats of flow, inflow pressure and outflow pressure are collected for analysis at each test condition. The waveforms are analyzed by first identifying the key crossing points that define the start and end of forward flow, regurgitant flow, and positive (forward flow) pressure gradient (see Figs. 3 and 4). These pressure and flow data are used to calculate the key variables that define the hemodynamic performance of a valve: the pressure gradient (ΔP), the effective orifice area (EOA), and regurgitant volume.

The pressure gradient is the most basic measure of valve resistance to flow. *In vivo*, a prosthetic aortic valve with a high pressure gradient will force the left ventricle to expend more energy than one with a low pressure gradient. The regions of positive pressure gradient for aortic and mitral valves are shown in Figs. 3 and 4. These pressures can be measured in a pulse duplicator through wall taps in the testing chambers or through a catheter inserted into the flow. The pressure gradient will increase with decreasing valve size and, for a given valve size, increasing flow rate. It has also been shown that aortic pressure gradient measurements can be dependent on left ventricular ejection time (29) and aortic pressure (30).

The EOA is not a physical valve dimension, but a calculation of the minimal flow area allowed by the open valve. Under pulsatile flow conditions, it is calculated as $Q_{\text{rms}}/[51.6(\Delta P)^{1/2}]$, where Q_{rms} is the root-mean square of the average flow rate through the valve. The EOA is a more useful measure than geometric orifice dimensions because mechanical valves, with occluders that occupy the orifice, restrict the orifice flow in variable ways based on the degree of opening and flow rate. Similarly, the extent of tissue valve leaflet opening will vary based on leaflet stiffness and flow rate. A method of dynamically measuring the actual valve area in an *in vitro* tester by measuring the amount of light that passes through it has also been proposed and tested (31).

All valves move some volume of fluid back into the inflow chamber during closure. The closing volume of a prosthetic valve is calculated from the area under the flow curve immediately after valve closure as shown in Figs. 3 and 4. This volume is a function of the valve area and the travel distance of the leaflets during closure. Although it will vary based on valve design, the closing volume is relatively small and typically does not have a significant hemodynamic effect. Leakage volume, by contrast, is the volume of blood that passes through the valve during closure, and is a critical measure of valve performance. Excessive leakage reduces the efficiency of the heart and can cause progressive deterioration of ventricular function. Ideally, the leakage volume through a valve is zero, although most mechanical valves allow some leakage of blood in order to provide "washout" of mechanical junctions. Tissue valves do not allow any leakage as long as there is adequate apposition, or coaptation, of the leaflets.

The total regurgitant volume is the sum of the closing and leakage volumes and represents the total fluid loss

during one valve closure. Regurgitation can also be expressed as a percentage of forward volume. Clinically, the ejection fraction, the ratio of the ejected blood volume to the left ventricular volume, is used to assess the hemodynamic severity of regurgitation. As with other hemodynamic variables, regurgitant volumes will vary with valve design, valve size, flow rate, pressure, and heart rate.

When assessing prosthetic valve regurgitation it is important to discriminate between transvalvular regurgitation and paravalvular regurgitation. Transvalvular regurgitation occurs through the valve mechanism, such as past the hinges or occluder gaps in mechanical valves or through regions of inadequate leaflet coaptation in tissue valves. Because prosthetic valves are sewn in place with a porous cloth sewing ring, leakage can also occur through the sewing ring or spaces created by inadequate fixation to the annulus. This is paravalvular leakage, occurring around or adjacent to the valve, and should be differentiated from transvalvular leakage. *In vitro*, test valves should be sealed to eliminate paravalvular leakage so that transvalvular leakage can be measured independently.

In vitro performance comparisons of different prosthetic valve designs are complicated by variations between labeled valve size and actual valve size (32). Most commercial prosthetic valves are sized according to diameter in 2 mm increments and typically range from 19 to 29 mm for aortic valves, and 25 to 31 mm for mitral valves. However, the diameter measurement is made at different locations based on manufacturer and valve type. The performance index (PI), which is the ratio of EOA to actual sewing ring area (33), is calculated in order to control for these variations and allow for more reliable valve-to-valve comparisons. Clinically, an EOA Index (EOAI) is calculated by dividing the EOA by the patient's body surface area, in order to normalize EOA values based on patient size and, indirectly, hemodynamic requirements.

Due to the variability of pulse duplicator systems and the sensitivity of test results on hemodynamic conditions, comparing valves evaluated in different test systems can also be problematic (34). Differences in pressure and flow waveform shapes, drive types, location of pressure taps, chamber geometries, and other system configuration characteristics can cause variations in measured valve performance. Comparative *in vitro* studies of different mechanical valves (35,36) and tissue valves (37) tested in the same pulse duplicator under the same conditions can be found in the literature. Figures 9–10 show *in vitro* pressure drop results for various tissue valves from one of these studies.

Doppler Ultrasound

Doppler echocardiography is the most widely used modality for assessing prosthetic valve performance *in vivo* and can be useful for *in vitro* studies as well. *In vitro* Doppler and imaging assessments are an important part of valve evaluations prior to human implants because they may reveal signature ultrasound features (e.g., acoustic shadowing, eccentric flow profiles, jet morphology), which are unique to the valve design and different from a native valve. It is important for clinical sonographers to understand these

Figure 9. *In Vitro* pressure drop data of various prosthetic aortic valves. (Reprinted with permission from *The Journal of Heart Valve Disease*.)

features so they can distinguish between normal and abnormal valve function. In addition, two-dimensional (2D) echo images of the valve can be used to obtain an axial cross-sectional view of the valve during cycling that can be useful in assessing the motion and coaptation morphology of tissue leaflets. And although a flowmeter can be used to quantify the amount of regurgitation through a valve, Color Doppler ultrasound allows for visualization of the size and shape of any jets and detecting their point of origin.

Doppler measurements and 2D imaging can be performed *in vitro* providing there is an acoustic window for the ultrasound beam that allows the transducer to be aligned roughly perpendicular to the axis of valve flow and does not attenuate the acoustic signal. It is also

Figure 10. *In Vitro* pressure drop data of various prosthetic mitral valves. (Reprinted with permission from *The Journal of Heart Valve Disease*.)

Figure 11. Ultrasound measurements in a pulse duplicator. In transducer position 1, the transducer is aligned with the flow and emits a sound wave that reflects off particles in the fluid; the return signal is measured by the transducer and the Doppler equation is used to calculate velocity. Transducer position 2 is used to obtain short-axis (cross-sectional) and long axis images of the valve as it opens and closes.

necessary to add small, insoluble particles to the test fluid to provide acoustic scatter for Doppler measurements and Color Doppler imaging. Figure 11 shows how an ultrasound transducer would be positioned on a pulse duplicator and the types of images that can be obtained.

Doppler measurements of pressure gradients can be performed *in vitro* to assess the hemodynamic performance of a valve as it would be done in a patient. During forward flow, continuous wave Doppler measures a real-time spectrum of velocities across the open valve. Standard echocardiographic software allows the user to acquire and analyze the spectrum and determine an average velocity.

Clinically, the average velocity value is used to compute pressure gradient using a simplified version of the Bernoulli equation. Ignoring viscous losses, acceleration effects, and changes in height, the Bernoulli relationship between two points, 1 and 2, on a streamline is:

$$P_1 + \frac{1}{2}\rho v_1^2 = P_2 + \frac{1}{2}\rho v_2^2 \quad (1)$$

where P is the pressure, ρ is the fluid density, and v is the velocity.

Rearranging Eq. 1 and expressing the upstream, or proximal valve velocity as v_p , and the downstream, or distal velocity as v_d , the pressure gradient ($P_1 - P_2 = \Delta P$) across a valve can be expressed as:

$$\Delta P = \frac{1}{2}\rho(v_d^2 - v_p^2) \quad (2)$$

Doppler ultrasound machines typically report velocity in units of meter per second ($\text{m} \cdot \text{s}^{-1}$) and pressure in units of millimeter of mercury (mmHg). Assuming a blood density of $\sim 1.1 \text{ g} \cdot \text{mL}^{-1}$ and applying the appropriate unit conversions, the $1/2$ term is approximated as $4 \text{ mmHg} \cdot \text{m}^{-2} \cdot \text{s}^{-2}$. A further simplification can be made if the proximal velocity term (the velocity at the left ventricular outflow tract for aortic valves) is small compared to the distal velocity.

Neglecting the proximal velocity term yields the equation used by ultrasound software programs to compute pressure gradient from continuous wave velocity measurements:

$$\Delta P = 4(v^2) \quad (3)$$

If the proximal velocity term is needed, it can be measured with pulsed wave Doppler ultrasound, which, unlike continuous wave Doppler, provides velocity spectra at a user-defined location in space (e.g., the left ventricular outflow tract).

Prior to the use of Doppler, hemodynamic assessment of prosthetic valves *in vivo* was performed by placing a pressure-measuring catheter into the heart. Comparisons between pressure gradients measured by catheter and by Doppler typically show some discrepancy between the two methods, causing some concern as to which method is more accurate. Several groups have performed *in vitro* and *in vivo* studies to compare and contrast catheter-based measurements and Doppler measurements (38–41). These comparisons are complicated by the fact that the two techniques use fundamentally different methods to arrive at the pressure gradient and they each have individual sources of approximation and error.

The primary valve-related reason for differences in Doppler and catheter measurements of pressure gradient is pressure recovery. Pressure recovery occurs when some portion of the downstream kinetic energy is converted back to potential energy (i.e., pressure). Like flow through a Venturi nozzle, the lowest pressure and highest velocity through a heart valve will occur at the narrowest point, which is typically the region immediately downstream of the valve. If the flow out of the valve is allowed to gradually expand and remains attached to the walls, there will be an increase, or recovery, of pressure further downstream relative to the pressure at the valve exit. Due to this local variation in pressure, the location of pressure measurement becomes critical. Because continuous wave Doppler measures velocities all along the beam path, it will detect the highest velocity (regardless of its location), which will then be used to calculate the pressure gradient. In contrast, catheters take direct pressure measurement at a specific location; if that location is not at the point of lowest pressure, catheter measurements of pressure gradient will tend to be lower than those derived from Doppler.

Pressure measurements across bileaflet MHVs (e.g., the St. Jude Mechanical) are further complicated because, during opening, the two side orifices are larger than the central orifice, resulting in a nonuniform velocity profile. This may be one reason why better agreement between *in vitro* Doppler and catheter measurements has been found for a tissue valve, which has an unobstructed central orifice, than for a bileaflet mechanical valve (39).

Flow Visualization

Clear chambers that provide visual access to the valve as well as the flow fields in its vicinity are an important feature of *in vitro* test systems. The use of video to assess leaflet dynamics can provide important information about valve performance that cannot be obtained from hemodynamic measurements or *in vivo* studies. Tissue contact with a stent, poor coaptation, asymmetric or asynchronous

leaflet closure, and leaflet rebound are all visual clues that either the valve design is inadequate or the test conditions are inappropriate.

Flow field visualization and measurements are equally important because thrombotic complications *in vivo* can be caused by unphysiologic, valve-induced flow patterns. Both flow stasis and high velocity leakage jets (and associated turbulent stresses) can trigger thrombosis and subsequent thromboemboli. *In vitro* pulsatile flow studies using blood are not a practical means of determining the thrombogenicity of a valve design because of the complexity and sensitivity of the coagulation process. Although the use of milk as an enzymatically coagulable test fluid has been reported (42–44), most *in vitro* assessments of a valve's thrombogenicity are made indirectly based on its flow characteristics.

Illuminating the flow field of interest with a sheet of laser light and seeding the fluid with neutrally buoyant particles will allow for qualitative visual assessment of flow patterns (i.e., uniformity and direction of forward flow, presence of vortices or recirculation zones, areas of wash-out during closure.) The motion of the particles can be analyzed quantitatively with digital particle image velocimetry (DPIV), which uses the translocation of seeded particles in consecutive, laser-illuminated video frames to compute the velocity of many particles at one point in time. With these numerous velocity measurements, a velocity map of the flow field can be created from any point in the cardiac cycle.

Velocity measurements can also be performed with laser Doppler velocimetry (LDV), which allows good temporal resolution of velocity, but only at a single point. Multiple point measurements at different locations can be made sequentially and then compiled in order to construct a phase averaged velocity profile of the entire flow field. Simultaneous LDV and DPIV measurements have been performed on a MHV in an attempt to integrate the relative benefits of each method (45). Thorough flow field measurements of several prosthetic heart valves, both tissue and mechanical, have been published by Yoganathan and co-workers (46,47). During forward flow, MHVs are seen to have disrupted or eccentric velocity profiles reflective of the open occluder position, while THVs tend to have more uniform, unobstructed flow profiles.

Since blood cell damage will likely occur above some critical shear stress threshold, *in vitro* velocity data is used to calculate shear stresses created throughout the flow cycle, and indirectly assess the potential for hemolysis and platelet activation *in vivo*. The MHV leakage jets, in particular, have the potential to create high shear stresses in blood (48). It is difficult, however, for *in vitro* flow characterization studies to be conclusive with regard to blood damage because of the myriad of variables that interact to trigger coagulation. In addition to the magnitude of shear stresses, the exposure time to those stresses, as well as flow stagnation, material surface interactions, and patient factors can contribute to prosthetic valve thrombosis.

Design Specific Testing

Guidelines for *in vitro* testing heart valves prior to human use were originally introduced by the U.S. Food and Drug

Administration (FDA) in 1982. A revised document, that included guidelines for testing stentless valves, was introduced in 1994 (28). The International Standards Organization publishes a similar set of guidelines for heart valve evaluation, including the equipment and data requirements for *in vitro* studies (49). Many of the testing techniques in use today are motivated by and in response to these guidelines. However, standardized guidelines are often insufficient for testing new and innovative designs, since each new valve design will have unique features that may require special testing methods to evaluate. A risk analysis or failure mode analysis can be used to assess the need for *in vitro* testing beyond that described in the standards.

In addition to predictive studies of *in vivo* performance, *in vitro* studies may be conducted retrospectively, in order to elucidate a particular failure mode seen after a valve has been used clinically. These types of studies typically require the development of new or improved testing methodologies to investigate a particular phenomenon, as shown in the following examples.

In 1988, structural failures of the Baxter Duromedics MHV were reported in several patients (50). Surface pitting was observed on the pyrolytic carbon leaflets of the explanted valves, suggestive of cavitation-induced erosion. Cavitation occurs in a fluid when the pressure drops rapidly below the vapor pressure of the fluid, causing the formation of small vaporous cavities, which collapse violently when the pressure increases. Many *in vitro* studies were conducted, employing novel measurement techniques, to assess the propensity for cavitation to occur during leaflet closure of mechanical heart valves (51,52) and cavitation testing is now part of U.S. Food and Drug Administration (FDA) required preclinical testing for all new MHVs.

In the mid-1990s, the Medtronic parallel bileaflet valve experienced an unanticipated number of thrombosed valves in early clinical trials (53). Explanted valves were observed to have clot formation in the hinge region of the valve, indicating a flow-related problem in this vicinity (54). These failures occurred despite the full set of required tests having been conducted with apparently satisfactory results. Prototype valves with clear housings were constructed to allow flow visualization studies in the region of the hinge mechanism (55). Results of these studies suggested the geometry of the hinge created stagnant flow regions which may have been responsible for the clinical failures.

Clinical studies of patients with stentless valves revealed that some developed aortic regurgitation several years after implantation (56,57). Because these valves lack a support structure, it was believed that age-related dilation of the aorta strained the outflow edge of the valve, which lead to insufficient leaflet coaptation. Although FDA testing requirements for stentless valves included flow testing at elevated aortic pressures in compliant chambers, testing of mechanical dilation without an increase in pressure was not required. An *in vitro* study using canine hearts showed that simply pulling the aorta outward at the commissures with sutures prevented the aortic leaflets from closing in the center (58). This study helped

confirm the need to band the aorta during implantation of some stentless valves in order to prevent later dilation.

In some cases, *in vitro* testing may also be employed to test the actual valve that was explanted from a patient. Depending on the age and condition of the valve, it may be mounted in a pulse duplicator and studied for signs of performance, structural or manufacturing abnormalities responsible for an adverse event in a patient.

Finally, *in vitro* flow studies may be conducted using valves excised from animal hearts in order to study the flow or mechanical dynamics of the native valve that in turn may be used to design improved prosthetic devices. Fresh porcine aortic roots have been installed in pulse duplicators to study the motion of the aortic valve as well to serve as a testing chamber for prosthetic valves (59–61). The porcine mitral apparatus, including chords and papillary muscles, has also been mounted and tested *in vitro* (62,63).

FUTURE DIRECTIONS

After more than four decades of prosthetic heart valve development, surgeons have come to rely on just a few valve designs, both mechanical and tissue, for the large majority of implants. These valves have achieved widespread use because their performance is reliable and their limitations and failure modes are known and reasonably predictable. None of these valves are ideal, however, and new designs that try to improve upon the state of the art will continue to emerge.

Although polymer valves and tissue-engineered valves still hold promise, the greatest change to be expected in the near future is not the valve itself but the way it is implanted in the heart. The success of catheter-based technologies in treating other heart diseases (e.g., coronary stents, septal defect closure devices) has inspired the pursuit and clinical evaluation of a prosthetic heart valve that can be placed in the beating heart with a catheter (64–66). This technology is attractive because it would not require opening the chest and stopping the heart, nor the use of cardiopulmonary bypass equipment.

Catheter-delivered valves will still require all the testing and analysis described above, but will also necessitate new equipment and methodologies that take into account their unique delivery and implantation method. For example, the actual delivery and deployment of these valves may first need to be simulated under *in vitro* pulsatile conditions, requiring testers that simulate the entry point and anatomy of the delivery path. Once deployed, the ability of the valve to seal around its perimeter and remain in place without migrating must be evaluated, which will require deployment chambers with the appropriate surface properties, mechanical properties, and dynamic motion. Also, current *in vitro* valve tests rarely simulate coronary flow out of the sinuses. But when testing valves that are placed in the aortic annulus under image guidance, rather than direct visualization, it will be important to evaluate valve designs in terms of their propensity to block coronary flow.

With aging populations in the United States and Europe, heart valve disease is likely to remain a significant and prevalent problem. Better, more efficient prosthetic heart

valve technology will surely emerge to address this need and *in vitro* testing technologies will need to keep pace to continue helping to improve these devices and ensure their safety and efficacy for human use.

HEART VALVES, PROSTHETIC

ROBERT MORE
Austin, Texas

INTRODUCTION

Blood flow through the four chambers of the normal human heart is controlled by four one-way valves. These valves open and close in response to local pressure gradients and flow during the cardiac cycle. The atrioventricular mitral and tricuspid valves open to admit blood flow from the atria into the ventricles during diastole and then close during systolic ventricular contraction to prevent backflow into the atria. The semilunar aortic and pulmonary valves open during systole to eject blood from the ventricles and then close during diastole to prevent backflow. Various pathological states, either congenital or acquired, may result in the failure of one or more of these valves. A valve may become stenotic, in which case forward flow through the valve is impaired, or a valve may become incompetent or regurgitant, closing improperly, which allows excessive backflow losses. Loss of valve function has a profound degenerative effect on quality of life and is ultimately life-threatening.

THE CHALLENGE

The goal for valve prosthesis design is to provide a functional substitute for a dysfunctional native valve that will endure for a patients' lifetime while requiring minimal chronic management. The development of open-heart surgery opened the technical possibility of valve replacement in the late 1950s and early 1960s. However, the practicality of an effective, durable artificial heart valve was to prove

elusive in the early 1960s because of problems with valve construction materials causing blood clotting, material fatigue, and degradation. Materials, related problems were greatly diminished when Carpentier (1) introduced the use of aldehyde preserved biological valves in the early 1960s. In 1963, Bokros discovered isotropic pyrolytic carbon (PyC), and shortly thereafter Gott and Bokros discovered the remarkable blood compatibility of PyC (2). These events led to two separate avenues of approach to the development of successful heart valve replacements, namely *biological valves*, derived from biological valves themselves or biological tissues, and *mechanical valves*, manufactured from synthetic materials. Significant process has occurred toward the goal of a lifelong valve substitute, last 30 years to the extent that valve replacement surgery is now a commonplace procedure worldwide. However, today's valve prostheses are nonideal and a tradeoff remains between long-term durability and the need for chronic anticoagulant management.

Although the history of early development of replacement heart valves is fascinating in its own right, it is well chronicled and, thus, will not be addressed here (3–5). See <http://members.evansville.net/ict/prostheticvalveimage-gallery.htm> for a chronology of valve designs. Rather, the focus here is to contemporary replacement heart valve designs, which is a story of interplay between advances in materials technology, design concepts, methods for evaluation, and regulatory issues.

EVOLUTION OF REGULATION

Prior to 1976, heart valve prostheses were unregulated devices—clinical studies, use, and introduction to the marketplace could be initiated without a formalized performance evaluation conducted under regulatory oversight. Regulation in the United States by the Food and Drug Administration (FDA), and by similar agencies in other countries, became necessary because not all valve prostheses were clinically successful. With the passage of the Medical Device Amendments in 1976, heart manufacturers were required to register with the FDA and to follow specific control procedures. Heart valve replacements were required to have premarket approval (PMA) by the FDA before they could be sold. To quote from the FDA website, <http://www.FDA.gov>, (the) “FDA’s mission is to promote and protect the public health by helping safe and effective products reach the market in a timely way, and monitoring products for continued safety after they are in use”.

The establishment of FDA oversight was a watershed event because it formalized the approval process and led to the development of criteria for evaluating new valve prosthesis designs. The preclinical performance tests and clinical performance evaluation criteria that have been developed are given in the FDA Document *Replacement Heart Valve Guidance - Draft Document, October 14, 1994* (6). This document may be downloaded from the FDA website at: <http://www.fda.gov/cdrh/ode/3751.html>. The document is deliberately labeled “Draft” because it is a “living” document that is periodically updated as heart valve technology evolves. Furthermore, requirements for

postmarket monitoring exist to continually verify valve safety and effectiveness.

A parallel international effort gave rise to the International Standards Organization (ISO) Standard 5840, *Cardiovascular Implants-Cardiac Valve* (7), which is currently being harmonized with the European Committee for Standardization (CEN) to produce a European Standard EN prEN12006. A major benefit of the European Union (EU) is that member countries agree to recognize a single set of standards, regulatory processes and acceptance criteria. Prior to the establishment of the European Union, each individual country imposed their own standards and regulatory requirements. The ISO committee hopes to ultimately merge with or at least to philosophically harmonize the ISO, EN requirements with the FDA Guidance Document requirements in order to produce a single international standard.

The regulatory approval process for a new heart valve design consists of two general stages, a preclinical study and a subsequent clinical study. The preclinical study consists of *in vitro* tests, orthotopic animal implants, and a survey of manufacturing quality assurance systems. When the preclinical requirements are satisfied, the FDA or EU agency may issue an Investigational Device Exemption (IDE) that allows human clinical trials. Clinical trials are conducted according to specified study designs, patient numbers, and evaluation methods. Upon the successful completion of clinical trials, the regulatory agency such as the FDA may issue a PMA, or equivalent EU approval, that allows the open marketing of the valve design. As a result of the importance and complexity of regulatory requirements in heart valve design, evaluation, manufacture, marketing, and monitoring, major heart valve companies now have dedicated “Regulatory Affairs” departments.

DEMOGRAPHICS AND ETIOLOGY

Patients require heart valve replacement for a number of reasons, which vary by sex, valve position, and the prevailing levels of socioeconomic development. Valves become dysfunctional because of stenosis, inadequate forward flow when open or insufficient and excessive backflow when closed. A summary of typical patient data by sex, lesion, and disease state that led to dysfunction is given in Table 1. This data is taken from PMA studies of the On-X mechanical valve conducted in North America and Western Europe (8,9).

Patients in developing countries tend to require valves at a younger age (mean 33 years) and have a significantly higher incidence of rheumatic disease and endocarditis. The proportion of aortic implants relative to mitral implants is higher in North America and Western Europe, whereas the proportion of mitral implants and double-valve implants is higher in the developing countries.

CLINICAL PERFORMANCE

Regulatory agencies (6,7) gage the results of observational clinical (IDE) trials in terms of Objective Performance

Table 1. Summary of Typical Patient Data

Category	Aortic	Mitral
Mean age years	60	59
Sex	%	%
Male	66	38
Female	34	62
Lesion	%	%
Stenosis	47	13
Insufficiency	21	48
Mixed/other	32	39
Etiology (can be > one per patient)	%	%
Calcific	50	16
Degenerative	28	27
Rheumatic	13	38
Congenital	10	2
Endocarditis	4	7
Previous prosthetic valve dysfunction	3	3
Other	3	16

Criteria (OPC). Ultimately, the performance of a new investigational device is compared with existing devices. The OPCs are linearized complication rate levels. An IDE study uses statistical methods to demonstrate that observed complication rates for the investigational device are less than two times the OPC rate. The linearized rates are given in units of percent per patient year (6,7) in Table 2. A patient year is simply the total post implant follow-up duration in years for patients enrolled in the study. For example, 100 patients followed one year each post implant is 100 patient years (pt-yr). For the occurrence of complication events, the linearized rate is $100\% \times (\text{number of events}/\text{number of patient years})$. Currently, a followup of 400 patient years is the minimum FDA regulatory requirement for each valve position, aortic and mitral each.

Thromboembolism (blood clotting-related strokes) and hemorrhage (excessive bleeding) are measures of the stability of the valve design relative to hemostasis and chronic anticoagulation therapy. Perivalvular leaks occur at the interface between the valve sewing cuff attachment mechanism and the cardiac tissue and are a measure of how well the valve design seals. Endocarditis is any infection involving the valve. A number of other complications, or morbid events, including hemolysis, unacceptable hemodynamics, explant, reoperation, and death are also monitored and compared on the basis of percent per patient

Table 2. Linearized Rates in Units of Percent Patient Year

Complication	Mechanical Valve (%/pt-yr)	Biological Valve (%/pt-yr)
Thromboembolism	3.0	2.5
Valve thrombosis	0.8	0.2
All hemorrhage	3.5	1.4
Major hemorrhage	1.5	0.9

year. Other presentations of data often used are Kaplan Meier "Survival or Freedom from complications" plots or tables in which the percentage of the study population that has survived, or has not experienced a given complication, is plotted vs. implant duration in years (10).

HEMODYNAMIC EVALUATION

Methods of evaluating heart valve hemodynamic function, both natural and prosthetic, have advanced considerably in the past 30 years. With today's technology, most evaluations of valve performance can be performed noninvasively, and more information regarding valve design performance is available than ever before, both *in vivo* and *in vitro*. Early methods, such as auscultation, listening to valve sounds with a stethoscope, have been greatly improved on, and invasive catheter techniques are no longer needed except in special cases.

Cine fluoroscopy involves recording a fluoroscopic examination with film or digital recording media. It provides a direct dynamic visualization of radio-opaque prosthetic valve features and, thus, can be used to identify a valve type and to assess function. Cine fluoroscopy used in combination with a catheter delivered radio-opaque contrast media, cineangiography, provides a means for basic flow visualization. Noninvasive echocardiography, however, has become the most common and important method for assessing valve function.

The physics of echocardiography are simple; a beam of ultrasound (1–5 MHz) is aimed into the patient's chest and, as the propagating sound wave encounters the different tissue layers, some of the energy is reflected back. The existence and depth of the reflecting tissue layers are then inferred from the time history of the reflections relative to the incident beam and the strength of the reflection. The reflection time history and strength from an angular sweep are then used to construct a 2D tomographic image of the underlying tissue structures. Thus, cardiac structures and their motions are readily visualized.

Echocardiography also produces an angiographic image for visualizing flow by using the moving red blood cells as a contrast medium. A Doppler shift occurs between the frequency of the incident sound and the sound reflected by the moving red blood cells, which is in proportion to the cells' velocity. This information is used to map flow direction and velocity throughout the cardiac cycle. Furthermore, the Doppler frequency shifts can be rendered audible to produce sound signatures. Thus, echocardiography and Doppler echocardiography provide powerful visual and audible diagnostic tools to interrogate cardiac dynamic structure and function.

Although the above description of echocardiography is admittedly brief, the real complexity of echocardiography lies in transducer mechanics, sophisticated electronics, and computational techniques required to produce near real-time dynamic 2D images and flow maps. Further details are readily available; for example, a very accessible tutorial can be found at the <http://www.echocontext.com/basicEcho.asp> "Introduction to Echocardiography," prepared by Duke University, 2000.

For the purposes of heart valve evaluation, echocardiography and Doppler echocardiography give dynamic visualizations of valve component motion and reasonable measurements of flow velocities, flow distributions valve effective orifice areas, and transvalvular pressure differences. Definitions and technical details of valve evaluations can be found in Appendix M of the FDA Document *Replacement Heart Valve Guidance - Draft Document, October 14, 1994* (6,7). A summary of the important echocardiographic parameters for valve evaluation are listed below.

1. Visualizations of valve motion and structure: Provides a diagnostic tool for both the native valve and valve prostheses and can detect the presence of thrombosis.
2. Doppler measurements of transvalvular pressure difference (or gradient): A stenotic valve, with impaired forward flow, either native or prosthetic, will have an elevated transvalvular pressure difference. The transvalvular gradient (peak or mean) is determined by measuring the forward flow velocity through the valve. If the proximal velocity is greater than $1 \text{ m} \cdot \text{s}^{-1}$, then it is also measured. Velocity values are diagnostic and can be used to derive an estimate of the transvalvular pressure difference using the complete (long) Bernoulli equation,

$$\Delta P = 4(V_2^2 - V_1^2),$$

where ΔP is the peak pressure difference mmHg, V_2 is the continuous-wave Doppler peak transvalvular velocity ($\text{m} \cdot \text{s}^{-1}$), and V_1 is the proximal pulse-wave Doppler peak velocity ($\text{m} \cdot \text{s}^{-1}$). If the proximal velocity is less than $1 \text{ m} \cdot \text{s}^{-1}$, as is usual in the mitral position, the V_1 term can be dropped and, as such, the single-term equation is called the short Bernoulli equation. Forward flow velocity-time envelopes may be integrated to give mean velocity values or mean pressure values depending on the echo system's processing capabilities. The mean velocity values are substituted into the Bernoulli equation, or the mean transvalvular and proximal pressures are subtracted to give the mean transvalvular pressure difference.

3. Effective orifice area: A stenotic valve, either native or prosthetic, will have decreased effective orifice area. Effective orifice area is determined using the classical continuity equation:

$$\text{EOV}(\text{cm}^2) = \text{CSA} \, v t_{i1} / v t_{i2}$$

CSA is the cross-sectional area of the left ventricular outflow tract (LVOT) for the aortic position. Variables $v t_{i1}$ and $v t_{i2}$ are the velocity-time integrals at the pulse-wave proximal LVOT $v t_{i1}$ and transvalvular continuous wave for the aortic position $v t_{i2}$. For the mitral position, CSA is the aortic cross-sectional area; $v t_{i1}$ and $v t_{i2}$ are the velocity-time integrals for the continuous-wave transvalvular velocities for the aortic valve, $v t_{i1}$, and $v t_{i2}$ for the mitral valve.

4. Regurgitation: Regurgitation or incompetence is graded as trivial, mild, moderate, or severe according to the regurgitant flow jet size expressed as a height or area relative to the LVOT area in the aortic position or left atrium in the mitral position. An incompetent, leaky valve will have severe regurgitation.

As a result of variations in patient body size and because the valve must fit the native valve annulus, prosthetic valve designs are prepared in annulus sizes ranging from an approximate 19 mm annulus diameter up to 33 mm diameter. However, valve sizes are not scalar in the sense that a size 19 valve or its sizer will often not be 19 mm. The valve and its associated sizer are supposed to fit a 19 mm annulus. For this reason, it is critical to use the sizers and associated instrumentation provided by the manufacturer for a specific valve design.

Typically, a design will have six sizes in 2 mm diameter increments. The size differences can consist of larger valve components or larger sewing cuffs. In general, it is desired to present the largest internal diameter possible for flow. Thus, it is important to recognize that hemodynamic quantities vary strongly with valve size in the aortic position and, for this reason, aortic hemodynamics comparisons must be interpreted according to size. One can find studies in the literature that report single values for a valve design that lump together and ignore the effects of valve size, the utility of such information is limited to the engineer, but meaningful to the cardiologist (11).

Patient body surface area (BSA) is often used to normalize valve effective orifice area, to give an orifice area $\text{cm}^2 \cdot \text{m}^{-2}$. EOA is measured using echocardiography and BSA is calculated using the patient height and weight. The ratio of valve EOA to patient BSA is known as the indexed orifice area (IEOA)

Patient prosthesis mismatch has recently been recognized as a potential error in selecting valves for patients. It is possible to replace a diseased aortic valve with a valve prosthesis that is too small for the patient body size. A generally accepted criteria for sizing is that the indexed effective orifice area should not fall below a value of 0.85 (12).

Left ventricular mass regression is another contemporary measure of valve effectiveness. Ventricular dimensions are measured from echocardiography for patients preoperatively and postoperatively. When overloaded by a dysfunctional valve, the heart responds with an increase in mass. An effective prosthetic valve lowers the work load on the heart and thus causes a regression back toward normal size (13).

The information presented above provides a basic framework for evaluating and comparing valve design clinical performance: complication rates and hemodynamics. Complication rates are assessed using statistics presented as linearized rates, percent per patient year. However, the linearized rates tend to assume that the risk of a complication is constant with time (14), which may not hold for all complications. Furthermore, it is necessary to compare linearized rates determined for comparable population demographics, implant experience, and complication definition. Short-term clinical experience study rates do not

compare well with long-term clinical experience. For this reason, it is convenient to compare results from PMA pre-clinical studies. Such studies have comparable patient numbers, demographics, duration, statistics, and study methods.

Results from PMA preclinical studies can be found by searching a database for “Summary of Safety and Effectiveness” documents on the FDA website (<http://www.fda.gov/cdrh/>). A Summary of Safety and Effectiveness is prepared for each device that has received a PMA and contains a summary of the clinical study, the preclinical studies, and the manufacturing facilities. Furthermore, most valves in the United States are packaged with “Instructions for Use” that include the clinical complication and hemodynamics data. Most valve manufacturers have websites that either contain the pertinent data or provide relevant references to the literature because of the importance of this data for marketing purposes. In general, high survival, freedom from complications or low complication rates, low pressure gradients, high effective orifice areas, and low regurgitation are essential.

Much of the same type of information is also available in the open literature; however, because of differences in study design, methods, and size that occur, it is more difficult to compare results from different studies and sources. An excellent review of heart valve complication comparison problems can be found in a paper by G. Grunkmeier and Y. Wu, “Our complication rates are lower than theirs: Statistical critique of heart valve comparisons” (14). An excellent review of hemodynamics for a number of valves may also be found in a paper by Zang and Chambers (15). As with complication rates, hemodynamics comparisons based on studies in the open literature can be difficult because of differences in technique and quantity definitions.

Examples of valve comparisons with the above information will be presented in subsequent sections of this text.

VALVE DESIGN ELEMENTS

The challenge is to provide valve prostheses that can endure the aggressive biological and mechanical environment for a patients’ lifetime without structural or functional degradation. A myriad of disciplines, including medicine, biology, engineering design, materials engineering, structural engineering, and fluid mechanics, are required to meet this challenge. Advances in each of these disciplines over the past 30 years have made possible significant improvements in the safety and efficacy of valve prostheses. At the current state of development, common structural features exist among the various valve designs required to meet the goals of function and durability. Conceptually, a valve prosthesis is a simple one-way valve that opens easily to allow forward flow and closes adequately to prevent regurgitant losses during the cardiac cycle. Each design has:

- An orifice body that defines the open forward flow channel.
- Leaflets or occluders that reversibly open to permit forward flow and close (or occlude) to prevent reverse flow.

- Struts or pivots that capture and guide leaflet motion during opening and closing.
- A sewing cuff or sewing ring that is used to attach the valve to the cardiac anatomy.

In addition, bioprosthetic valves may have stents, which are metallic or polymeric structures that define and support the soft tissue valve shape.

Many of the design elements of valves are radio-opaque and present a unique appearance upon examination by X-ray or cine fluoroscopy. Guides to identifying valves by radiographic appearance have recently been published by Butany et al. (16,17).

The size, shape, strength, durability, and biocompatibility of these common design elements define the performance of the valve. Each element is, in turn, defined by the materials used in its construction, hence, the importance of materials technology.

MATERIALS TECHNOLOGY

The materials available in many ways dictate design possibilities. Our repertoire of manmade materials for mechanical valves includes certain polymers, metals, and pyrolytic carbons in a class generally known as biomaterials. For heart valve applications, the materials used must be blood- and tissue-compatible. The presence of the material itself, wear particles, or the material in combination with others cannot provoke adverse biological reactions. Some of the more important adverse biological reactions include intense inflammatory response, carcinogenicity, mutagenicity, or the inception of thrombosis.

The materials must be biodurable: The mechanical integrity must resist degradation by the *in situ* physiochemical environment. Assuming that the human heart beats approximately 40 million times a year, valve prostheses must endure on the order of 600 million cycles over a 15 year period without functional degradation due to exposure to the aggressive biological reactions and repeated cyclic stresses in the cardiac environment. Early valve designs failed within a short period because of thrombosis (blood clotting), and damage due to exposure to the rigorous biological environment manifest as distortion, wear, and fatigue. Additionally, the materials must tolerate sterilization without adverse effects. A more current requirement is that a material cannot interact adversely with high strength electromagnetic radiation, as may be encountered with modern diagnostic techniques such MRI (magnetic resonance imaging).

The short list of materials that meet these requirements for heart valve structural components includes isotropic pyrolytic carbons, certain cobalt-chrome alloys, and certain titanium alloys. The polymers most often used today in the fabric sewing cuffs are polyethylene terephthalate (PET, tradename Dacron) and polytetrafluoroethylene (PTFE, tradename Dacron). Polyacetyl (polyformaldehyde, tradename Delrin) and poly dimethyl siloxane (Silicone rubber) are used as occluders in some of the older designs. Some important physical and mechanical characteristics of these materials are given in Table 3.

Table 3. Representative Material Properties

Property	Unit	PyC	CoCr	Delrin
Density	$\text{g} \cdot \text{cm}^{-3}$	1.93	8.52	1.41
Bend strength	MPa	494	690 (uts)	90
Young's modulus	GPa	29.4	226	3.1
Hardness	HV	236 ^a	496	86 Shore D
Fracture toughness K_{Ic}	$\text{MN} \cdot \text{m}^{3/2}$	1.68		
Elongation at failure	%	2		30
Poisson's ratio		0.28	0.3	0.35

^aThe hardness value for PyC is a hybrid definition that represents the indentation length at a 500 g load with a diamond penetrant indenter.

As the mechanical properties of biological materials are more complex than for manmade materials, they will not be addressed here, rather references are suggested in the recommended reading section.

Each material used in a prosthetic heart valve must meet a battery of tests for biocompatibility as currently defined in the FDA Guidance document (8) ISO 5840 and ISO 10993. The interested reader can find the details of these tests in the reference documents.

DESIGN CONCEPTS

Two broad categories of valve prostheses have evolved, mechanical and biological, each with advantages and disadvantages. The selection of valve type for a given recipient is made by balancing the individual's needs relative to the valve type advantages and disadvantages. Factors for consideration in valve type selection include:

- Thromboembolism/Stroke,
- Bleeding Risk,
- Reoperation,
- Survival.
- Guidelines from The American Heart Association/American College of Cardiology (AHA/ACC) are listed below in Table 4 (18).

Table 4. AHA/ACC Guidelines^a

AHA/ACC Indications for Valve types	
Mechanical Valve	Tissue Valve
Expected long lifespan	AVR >65 years age, No risk factors for TE
Mechanical valve in another position	MVR >70 years age
AVR \leq 65 years age	Cannot take warfarin
MVR \leq 70 years age	
Requires warfarin due to risk factors	
Atrial fibrillation	
LV Dysfunction	
Prior thromboembolism	
Hypercoagulable condition	

^aAVR –aortic valve replacement MVR – mitral valve replacement.

In the absence of concomitant disease, aortic mechanical valves are recommended for patients less than 65 years of age and mitral mechanical valves for patients less than 70 years of age.

Biological valves offer the advantage that chronic anticoagulation therapy (warfarin) may not be required beyond an aspirin taken daily. Many patients benefit from biological valves because of an inability to tolerate or to comply with chronic anticoagulation. However, many patients with biological valves may require anticoagulation for other concomitant conditions, such as atrial fibrillation that pose a coagulation risk, and some physicians may recommend anticoagulation for mitral replacements.

The disadvantage is that biological valves have limited lifetimes for reasons inherent to host responses that degenerate the implant tissue and the relatively low fatigue resistance of the devitalized biological tissues. Expected patient survival (median) in the United States equals expected biological valve survival at 18 years for aortic valves and 69 years for mitral valves (19).

The risk of biological valve dysfunction increases inversely with age, with failure being more rapid in younger patients. Degenerative mechanisms such as calcification are accelerated in young growing patients, and an active lifestyle may more severely stress the valve. As a mitigating factor, biological valve degeneration tends to be gradual, hence readily detected so that a re-operation to replace the valve can be scheduled before the patients' health becomes compromised. Here, the tradeoff is the risk of re-operation vs. the risk of anticoagulant-related complications. Therefore, the ideal biological valve candidate patient tends to be an elderly person with a relatively sedentary lifestyle and an expected lifetime that is not likely to exceed the useful lifetime of the valve.

A mechanical valve has the advantage of unlimited durability, but has the disadvantage of requiring chronic anticoagulant therapy.

Many excellent resources are available on the Internet providing illustrations, some design, details, and performance details for valve prostheses. A general overview of valves and other devices approved for marketing in the United States can be found at the Cardiovascular and Thoracic Surgery website (<http://www.ctsnet.org/sections/industryforum/products/index.cfm>). Other very accessible resources include the Evansville Heart Center prosthetic heart valve gallery (<http://members.evansville.net/ict/prostheticvalveimagegallery.htm>) and the Cedar Sinai Medical Center (http://www.csmc.edu/pdf/Heart_Valves.pdf). Heart valve manufacturers also have websites that provide information regarding valves and performance. A partial list follows:

- ATS Medical, Inc. <http://www.atsmedical.com/>
- Carbomedics, A Sorin Group Company, <http://www.carbomedics.com/>, and Sorin Biomedica, http://www.sorin-cid.com/intro_valves.htm
- Cryolife, Inc., <http://www.cryolife.com/products/cryo-valvenew.htm>.
- Edwards Lifesciences, <http://www.edwards.com/Products/HeartValves>

- Medical Carbon Research Institute, LLC., <http://www.onxvalves.com/>
- Medical CV, http://www.vitalmed.com/products/medicalcv/omnicarbon_heart_valve.htm
- Medtronic, Inc., <http://www.edwards.com/Products/HeartValves>
- St. Jude Medical, Inc., <http://www.sjm.com/conditions/condition.aspx?name=Heart+Valve+Disease§ion=RelatedFeaturesProducts>

Many other resources are available, other manufacturers, a number of professional journals and archives of news stories, and press releases available on the web. A web search for “artificial heart valves” will yield more than 300,000 sites. The sites listed above are given as a simple quick start for the reader, without implied endorsement.

As a point of interest, the valve manufacturers’ websites are highly colored by competitive marketing and tend to present a rather focused view. However, they often provide copies of studies in the literature along with supplemental interpretative information. As an example, aspects of the selection of type, biological and mechanical, for a given patient are controversial. To address this controversy, the Edwards Lifesciences and St. Jude Medical sites have detailed, authoritative panel discussions of issues related to valve selection that are well worth reviewing.

BIOLOGICAL VALVES

Bioprosthetic valve replacements tend to mimic the semilunar aortic valve directly by using a natural aortic valve from a donor (allograft) or an aortic valve from another species (xenograft). Alternatively, the natural aortic valve may be imitated by design using a combination of non-valvular natural tissues and synthetic materials (heterograft). Typically, the semilunar aortic-type valve is used in all positions for valve replacement.

The native aortic valve can be visualized as a short flexible tube within a longer tube. The outer tube, the aorta, has three symmetric scalloped bulbous protuberances (sinus of Valsalva) at its root. Within the sinus of Valsalva, there is the short inner tubular aortic valve, with a length approximately the same as the diameter. The aortic valve tube is constrained at three equidistant points along its upper circumference at the commissures. When pressurized from above, the aortic valve tube wall collapses onto itself into three symmetric crescent-shaped leaflet cusps. Along the lower circumference, the leaflets attach to the aorta wall following the scalloped curve of the aortic root. When pressurized from below, the valve opens, the cusps rise together and separate to form the short open internal tube, which is the flow region of the valve. When closed, the internal tube walls, cusps, collapse, inflate, and form a seal (coaptation) at the center of the valve (nodus Aranti) along lines 120° apart (see Fig. 1). A good dynamic, multimedia visualization of this collapsing tube concept of the aortic valve can be found at the 3F Technologies website (<http://www.3ftherapeutics.com/us/products.html>).

Figure 1. Mitroflow bovine pericardial prostheses heterograft shown in two sizes. This figure illustrates the collapsed tube concept of aortic valve structure.

Valves constructed from biological materials have several categories, including:

- Homograft (also Allograft), native valves taken from members of the same species,
- Xenograft (also Heterograft), valves taken from other species,
- Autograft, valves transposed from one position to another in the same patient. Valves may also be constructed from nonvalvular tissues such as pericardium, dura mater, or fascia lata and the tissues may be autogenic, allogenic, or xenogenic. Valves may be stented (with added rigid support structures) or unstented.

Valves transplanted from one individual to another do not remain vital. Although the valve may be initially coated with endothelium, the valve eventually becomes acellular with only the extracellular matrix collagenous structures remaining. A biological tissue originating from another species (xenograft) must be killed and stabilized by aldehyde cross-linking or some other method. Fixation masks autoimmune rejection processes and adds stability and durability. However, the tissue again consists of an acellular, but now cross-linked, extracellular matrix collagenous structure. Biological valves lifetimes are limited due to degradation of the relatively fragile nonvital, acellular material, which results in structural and functional failure. Degradation processes are exacerbated by calcification and elevated applied stress levels in the cardiovascular environment.

Valve Homografts (Also Allograft)

Use of an orthotopic implanted homologous cardiac valve (e.g., a valve transplant from the same species) as a valve substitute was first successfully accomplished in humans by Donald Ross in 1962 (20). Harvest must occur as rapidly as possible following the donor’s death, if within 48 h, the valve may still be vital. However, with human or animal origin, a risk of disease transmission exists, particularly if the valve is not sterilized. Furthermore, competition exists with the need for intact donor hearts for

heart transplantation, so the supply of homografts is limited.

During the period between 1962 and 1972, homografts were widely used because other valve substitutes were not yet satisfactory. As other valve substitutes became effective and more readily available during the 1970s, homograft use decreased. With the development of cryopreservation technology in the mid-1980s and commercialization by Cryolife, homograft use has increased again. However, unless the homograft is an autograft (from the same patient), it becomes a devitalized acellular, collagenous structure within the first year of implantation (21). Homograft lifetime in the aortic position tends to be limited to approximately 10 years due to primary tissue failure because of the inherent fragility of the devitalized, acellular homograft.

The most successful use of homografts is for a pulmonary valve replacement in the Ross procedure in which the patient's own viable pulmonary valve (autograft) is transplanted into the aortic position as a replacement for diseased aortic valve and a heterograft used to replace the patient's pulmonary valve (22). In principal, the autograft pulmonary valve in the aortic position remains vital and grows with the patient. The heterograft in the pulmonary position endures well because the pressure loads and the consequences of regurgitation are much less severe on the right side of the heart.

Xenografts

Aldehyde-fixed porcine xenograft valves were initially developed in 1969 by Carpentier et al. (1), which consisted of porcine aortic valves mounted on a stent frame to maintain shape and then fixed with dilute gluteraldehyde (see Fig. 2). Aldehyde fixation masks autogenic host reactions, cross-links the extracellular matrix collagen, and kills the native valve cells. Infectious cells and viri are also cross-linked and killed, so fixation provides a means of disinfection. During the same time period, Hancock et al.

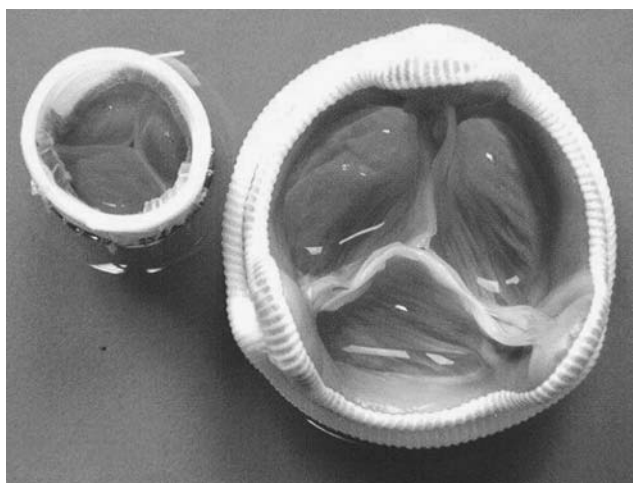

Figure 2. A porcine valve xenograft design (Xenomedita) shown in two sizes. Here, a porcine valve is mounted in a stented structure.

independently developed another porcine prosthesis (23). Yet another design, constructed from bovine pericardium, was developed by Ionescu in 1971 (24). These valves provided readily available alternatives to homografts and were widely used during the early 1970s. Although these valves offered freedom from chronic anticoagulation, lifetimes were limited to around 10 years. The valves failed because of calcification, leaflet tears, and perforations. Freedom from reoperation 15 years post implant was about 50% for the porcine valves and slightly worse for the bovine pericardial valves. Other important lessons were learned the Hancock valve polymeric Delrin stents would creep, leading to valve dysfunction. With the Ionescu valve, a suture located at the valve commissures initiated tears in the leaflets. The attachment of leaflets at the commissures tends to be the most highly stressed point, because of pressure and reversed bending stresses, which leads to commissural tearing.

Xenograft biological valve replacements have gone through three generations of evolution. The first generation and some of its problems are described above by Hancock and Ionescu. Tissues used in these valves were fixed with aldehydes at high pressure in the closed position. As the collagen fibers within the porcine leaflets tend to have a wavy or crimped structure, the high pressure fixation tended to straighten the fibers out, removing the crimp, which was found to have an adverse effect on fatigue endurance.

For the second generation valves, low and zero pressure aldehyde fixation were used, flexible stent materials were employed, and assembly strategies improved. These improvements retained the natural collagen crimp and lowered stresses at the commissural attachment. Also, additional fixation treatments and chemical posttreatments were employed in hopes of reducing calcification.

Contemporary third-generation valves tend to use fixation at physiological pressures, flexible stents materials, and include stentless designs. Some of these newer aortic valve designs are challenging the age limits given above for valve-type selection (25). A number of stentless designs are available that typically consist of a xenograft or homograft valve mounted in fabric or tissue to enable sewing (see Fig. 3). Some designs include the portions of the aortic arch along with the valve. Stenting and annular support structures tend to decrease the annular flow area. Removal of the stents should enhance hemodynamic performance.

A unique design using equine pericardium and an external expandable stent for use with a transcatheter delivery system is under development by 3F Therapeutics. Furthermore, tissue engineering concepts are being explored as a means of developing valve scaffolding structures in expectation that the host cells will infiltrate, populate, and ultimately render the scaffolding into an autologous tissue structure. One such example is a chemically decellularized valve in development by Cryogenics. Carbomedics has also developed a method for nonaldehyde cross-linking and decellularization of collagenous cardiac tissues (26).

Hemodynamics for some of the contemporary biological valves cited from FDA PMA Summaries of Safety and

Figure 3. A stentless pericardial aortic valve. Sorin Biomedica Pericarbon.

Effectiveness and the literature for uniform echocardiographic protocols and comparable patient experience are listed in Tables 5 and 6. All of the contemporary biological valves exhibit satisfactory hemodynamics and acceptably low risk of valve-related complications.

MECHANICAL VALVES

Contemporary mechanical valves are primarily bileaflet valve designs constructed from pyrolytic carbon (PyC).

Some monoleaflet valves and ball in cage valves, such as the Medtronic Hall valve and the Starr-Edwards valve, are still used. Some examples of bileaflet and monoleaflet designs are shown in Fig. 4. The bileaflet designs consist of two flat half circular leaflets inserted into a cylindrical annulus. The orifice may be stiffened by external metallic rings and is encircled by a fabric sewing cuff. Small depressions, or extrusions, within the orifice accept mating features on the leaflet and provide a pivot mechanism to capture and guide the leaflets during opening and closing excursions. Figure 5 provides a cut-away illustration of general bileaflet valve features. Figure 6 provides a high detail view of a hinge pivot.

PyC is used almost exclusively in bileaflet design structural components because of excellent blood compatibility, biostability, strength, and fatigue endurance. This biomaterial is an isotropic, fine-grained turbostratic carbon that is typically prepared as a coating on an inner graphite substrate. Most PyC valve components are on the order of slightly less than 1 mm in thickness and have a low enough density so as to be easily moved by cardiovascular flow and pressure. Two general types are available, silicon-alloyed and pure carbon; both have roughly equivalent and adequate properties for heart valve application. The history of PyC applications in heart valves and its material science is another story in itself and will not be addressed here. Rather, sources about PyC can be found in the recommended reference list.

Supraannular placement has been the most prominent design evolution in contemporary mechanical valves. Originally, the sewing cuff girdled the mechanical valve orifice at approximately mid-height and was intended to fit entirely within the native valve annulus. However, inserting the bulk of the sewing cuff and valve into the native annulus reduces the available flow area. Supraannular designs are modifications to the sewing cuff and valve orifice exterior wall that allow the sewing cuff to be positioned above the annulus, which removes the sewing cuff bulk from within the native annulus and, thus, increases the available flow area.

Figure 4. Three mechanical valve designs shown attached to aortic grafts. Left to right: St. Jude Medical bileaflet, Carbomedics bileaflet, and Medtronic-Hall monodisk.

Effectively, a supraannular sewing cuff allows the placement of an upsized valve relative to the intraannular cuff. Most often, the valve orifice and leaflet components are unchanged, only the sewing cuff is modified. Thus, supraannular cuffs are a subtle modification in that the renamed supraannular design is not really a new design, rather it is just an upsized version of the original valve. Virtually every bileaflet valve manufacturer now has supraannular cuffs. Renaming the supraannular versions has caused a bit of confusion because it is not always obvious that improved hemodynamic performance is due solely to the placement of an upsized valve of the same design. However, two recent designs, the Medical Carbon Research Institute On-X valve and the SJM Regent, actually incorporate significant design features as supraannular valves beyond a modified sewing cuff.

Hemodynamics for some contemporary mechanical valves are given in Tables 7 and 8 (27–38). All of the contemporary mechanical valves exhibit satisfactory hemodynamics and acceptably low risk of valve-related complications. As a

Figure 5. A cut-away view of the On-X valve showing leaflets in the closed (left) and open (right) positions. The valve orifice and annulus ring has pivot depressions in the inside diameter wall and is encased in a sewing cuff. The orifice wall has a bulge and two external metal wires for stiffening.

Figure 6. Detail of the St. Jude Medical bileaflet valve pivot mechanism. A tab on the leaflet inserts into a butterfly shaped depression in the valve annulus ring. The pivot depression retains and guides the leaflet motion during opening and closing excursions.

point of interest, only aortic hemodynamics are presented for both the biological and mechanical valve designs, because clinical data for aortic valves demonstrates a strong dependence on valve size. Effective orifice areas increase and pressure gradients decrease with increasing valve annulus size. Clinical hemodynamic data for mitral valves typically does not depend as strongly on annulus size (15). Mitral sizes range from 25 to 33 mm annulus diameters. In many designs, the larger annulus diameter sizes, above 27–29 mm, are attained by increasing the sewing cuff bulk. However, the difference between effective orifice area and pressure gradients with size is minimal. For mechanical mitral valves, mean pressure gradients are on the order of 4 mmHg and effective orifice areas of 2.5–3 cm².

COMPARISON OF BIOLOGICAL AND MECHANICAL

Detailed comparisons of biological and mechanical valve experience in large multicenter randomized studies have been recently published (39–41). Freedom from complications were found to be roughly comparable. Rates for thromboembolism and stroke have been found to be the same, and strongly related to nonvalve factors. Bleeding is more common for mechanical valves, but depends on the anticoagulant control and the use of aspirin. Freedom from reoperation is significantly better for mechanical valves. At 15 years, the freedom from reoperation for mechanical valve patients exceeded 90%, whereas while for biological valves, the percent free from reoperation was 67% for the aortic position and 50% for the mitral position. Survival at 15 years was slightly better with aortic mechanical valves, mortality of 66 versus 79% for biological valves. No difference existed in survival for mitral valves. Overall, the survival of biological and mechanical valve patients was similar over extended periods, with the tradeoff being an increased risk of hemorrhage with mechanical valves vs. and increased risk of reoperation for biological valves. This risk of reoperation for biological valves increases in time. Thus, valve type selection is a balance

between the patient ability to tolerate chronic anticoagulation therapy and the risk of re-operation. To reiterate the AHA/ACC criteria, in the absence of concomitant disease, aortic mechanical valves are recommended for patients less than 65 years of age and mitral mechanical valves for patients less than 70 years of age.

IMPROVEMENTS IN ANTICOAGULATION AND DURABILITY

As mentioned earlier, although contemporary PyC mechanical valves have virtually unlimited durability and extremely low incidences of structural failure, the biocompatibility is not perfect. Hence, because of imperfect biocompatibility, chronic anticoagulation therapy is required, which is the disadvantage of mechanical valves. Anticoagulation therapy carries with it the risk of hemorrhage, thromboembolism, and thrombosis.

Valve thrombogenicity can be thought of in terms of an extrapolation of Virchow's triad from veins to valves. Here, a predisposition to thrombogenicity is attributed to three factors, (1) the blood compatibility of the artificial valve material, (2) the hemodynamics of blood flow through the valve, and (3) patient specific hemostasis. In effect, resistance to valve thrombogenicity occurs through a balance of all three factors. Conversely, valve thrombosis could be provoked by a poor material, poor hemodynamics, or a patient-specific hypercoagulable condition.

Improvements are being made in the need for and control of anticoagulant therapy for mechanical valve patients. Anticoagulant-related complications have been shown to be reduced by the use of INR (international normalized ratio) self-monitor units (42). The success of

INR self-monitoring leads to the possibility of reduced anticoagulant levels, which affects the patient-specific hypercoagulable condition of Virchow's triad. Valve manufacturers have also made improvements in material quality and hemodynamics to the extent that aspirin-only and reduced warfarin level studies are planned and in place for certain low risk aortic mechanical valve patients (43).

On the other hand, concurrent improvements in biological valve design and tissue treatments can lead to extended durability, which reduces the risk of re-operation. However, comparison of Tables 5 and 8 for effective orifice areas shows that biological valves tend to be more stenotic than mechanical valves. In the interest of avoiding patient-prosthesis mismatch, smaller patients tend to be better candidates for biological valves. Valve selection should ultimately be a matter of patient and surgeon preference.

FUTURE DIRECTIONS

Advances in tissue engineering probably hold the brightest promise, because a viable, durable, autologous valve is the best possible valve replacement. However, until realized, improvements in materials technology, anticoagulant therapy, and valve hemodynamics can all be expected to improve the outcome of valve replacements. Developments in techniques for valve annuloplasty and valve repair (44) have been highly successful in allowing the surgical restoration of the native valve, which often eliminates the need for a valve replacement. In fact, mitral valve implant rates have decreased with the popularity of valve repair. Strides are also being made in minimally invasive techniques, robotic surgery, and transcatheter surgery so as to minimize the risk and trauma of valve replacement surgery.

CONCLUSION

Valve replacements are a commonplace occurrence worldwide, and many advances in design and patient management have been made over the past 30 years. Current replacements are certainly safe and effective. Surgical outcomes and patient quality of life can only be expected to improve.

INTRODUCTION

Artificial hearts are broadly defined as devices that either supplement or replace the native (natural) heart. These devices can be classified into two groups: ventricular assist devices and total artificial hearts. This article will define the clinical need, review the native heart anatomy and function, describe design considerations for ventricular assist devices and total artificial hearts, review selected designs, and recommend areas for future development.

CLINICAL NEED

Cardiovascular disease accounted for 38% of all deaths (almost 1.4 million people) in the United States in 2002 (1). Coronary heart disease (53%) represented the majority of these deaths, followed by stroke (18%), and congestive heart failure (6%). Almost 4.9 million Americans suffer from congestive heart failure, with ~550,000 new cases diagnosed each year. Over 80% of men and 70% of women with congestive heart failure under the age of 65 will die within 8 years. In people diagnosed with congestive heart failure, sudden cardiac death occurs at six to nine times the rate of the general population.

One treatment for congestive heart failure is heart transplantation. It is estimated that 40,000 Americans could benefit from a heart transplant each year (1,2). However, only ~2100 donor hearts were available each year from 1999 to 2004. The number of donor hearts dropped during this period, from a high of 2316 in 1999 to 1939 in 2004. Over 3300 patients were on the waiting list for a donor heart at any time during this period, with >65% of these patients on the waiting list for >1 year. From 1998 to 2004, ~630 patients died each year waiting for transplant.

These numbers clearly demonstrate the clinical need for ventricular assist devices and total artificial hearts that support the patient until transplant (bridge to transplant) or permanently assist or replace the natural heart (destination therapy).

Figure 1. Anatomy of the Native Heart. The heart is composed of two pumps (right and left side) that work simultaneously. The right pump delivers blood to the pulmonary circulation (the lungs), while the left pump delivers blood to the systemic circulation (the body). Each pump consists of an atrium and ventricle. [Reprinted with permission from Gerard J. Tortora and Bryan H. Derrickson, *Principles of Anatomy and Physiology, 11th ed.*, Hoboken (NJ): John Wiley & Sons; 2006.]

NATIVE HEART ANATOMY AND FUNCTION

The anatomy of the native (or natural) heart is shown in Fig. 1. The heart is composed of two pumps (right and left side) that work simultaneously. The right pump delivers blood to the pulmonary circulation (the lungs) while the left pump delivers blood to the systemic circulation (the body). Each pump consists of an atrium and ventricle that make up the heart’s four distinct chambers: right atrium, right ventricle, left atrium, and left ventricle. The atria act as priming chambers for the ventricles. The ventricles pump blood out of the heart to either the pulmonary or systemic circulation. Heart valves located between each atrium and ventricle and at the outlet of each ventricle maintain flow direction during pulsatile flow.

Blood from the systemic circulation enters the right atrium through the superior vena cava (from the head and upper extremities) and inferior vena cava (from the trunk and lower extremities). The blood is then pumped to the right ventricle, which pumps blood to the pulmonary circulation via the pulmonary arteries. Oxygenated blood returns to the left atrium heart from the lungs via the pulmonary vein and is then pumped to the left ventricle. The left ventricle pumps blood to the systemic circulation via the aorta.

Table 1 lists the nominal pressures and flows in the native heart (3). A ventricular assist device or total artificial heart must be able to generate these pressures and flows in order to meet the needs of the recipient.

DESIGN CONSIDERATIONS FOR VENTRICULAR ASSIST DEVICES AND TOTAL ARTIFICIAL HEARTS

Several design considerations must be taken into account when developing a ventricular assist device or total artificial heart. These considerations are detailed below:

1. *Size of the Intended Patient:* The size of the patient will determine the amount of blood flow required to adequately support the patient. This then determines the size of the ventricular assist device or total artificial heart. For example, a total artificial heart designed for adults would most likely be too large to be implanted within small children. A larger ventricular assist device may be placed externally, while a smaller ventricular assist device could be placed within the native heart. In addition, the size of the patient may dictate the location of some of the components. For example, the power sources may be located either internally (in the abdominal cavity) or externally depending on the size and type of the power source.
2. *Pump Performance:* A ventricular assist device or total artificial heart can be used to support or replace the native heart. Each of these support modes requires a different cardiac output. For example, a ventricular assist device can provide

Table 1. Nominal Pressures and Flows in the Native (Natural) Heart

Pressures	
Left ventricle	120 mmHg (16.0 kPa) peak systolic normal (into aorta) 10 mmHg (1.33 kPa) mean diastolic (from left atrium)
Right ventricle	25 mmHg (3.33 kPa) peak systolic (into pulmonary artery) 5 mmHg (0.667 kPa) mean diastolic (from right atrium)
Flows	
Normal healthy adult at rest: 5 L·min ⁻¹	
Maximum flow: 25 L·min ⁻¹	

either a portion of the blood flow required by the patient (partial support) or the entire blood flow (total support). In addition, the decision must be made whether to include a controller that will either passively or actively vary the cardiac output of the ventricular assist device or total artificial heart based on the patient demand.

3. *Reliability:* The National Institutes of Health (NIH) proposed a reliability goal for ventricular assist devices and total artificial hearts of 80% for a 2 year operation with an 80% confidence level before an artificial heart can begin clinical trials. However, the desired reliability may need to be more demanding for long-term clinical use, such as 95% reliability with 95% confidence for a 5 year operation. The design and components of ventricular assist devices and total artificial hearts must be carefully selected to achieve this reliability goal.
4. *Quality of Life:* The patient's quality of life can have a significant impact on the design of a ventricular assist device or total artificial heart. It is important to clearly define what constitutes an acceptable quality of life. For example, if a patient desires to be ambulatory following the implantation of a ventricular assist device or total artificial heart, the power supply must be easily transportable. The environment of the patient (home, work, car, etc.) should also be considered to insure proper function in these different environments. The patient should be able to monitor basic pump operation without the need for a physician or other trained medical personnel. The ventricular assist device or total artificial heart should be designed to clearly provide information through displays and provide alarms to warn the patient of potentially dangerous situations, such as a battery that is running low on power.

VENTRICULAR ASSIST DEVICES

A ventricular assist device (VAD) is designed to assist or replace the function of either the left or right ventricle. These devices are intended to provide either temporary support until a donor heart has been located or the native heart has recovered function, or as a permanent device.

As shown in Table 1, the left ventricle pumps against a higher pressure system than the right ventricle. Therefore, the left ventricle is typically more in need of assistance. Consequently, left ventricular assist devices (LVADs) are more prevalent than right ventricular assist devices (RVADs).

Ventricular assist devices can generate either pulsatile or continuous (nonpulsatile) flow.

Pulsatile

Pulsatile flow ventricular assist devices are composed of a single ventricle that mimics the native ventricle. The ventricle is placed either outside the patient's body or within the abdominal cavity. There are two types of pulsatile flow ventricular assist devices: pneumatic and electric.

Figure 2. Penn State/Thoratec Pneumatic Ventricular Assist Device. The ventricle contains a flexible blood sac made of segmented polyurethane that is housed within a rigid polysulfone case. Mechanical heart valves are located in the inlet and outlet positions of the ventricle to control flow direction. Air pulses that are generated by an external drive unit are used to periodically compress the flexible blood sac. (Reprinted with permission from Thoratec Corporation.)

Pneumatic Ventricular Assist Devices. Figure 2 shows a pneumatic ventricular assist device that was originally developed by the Pennsylvania State University and later purchased by Thoratec Corporation (Pleasanton, CA) (4). The ventricle contains a flexible blood sac made of segmented polyurethane that is housed within a rigid polysulfone case. This blood sac is extremely smooth to prevent the formation of clots (or thrombi). Mechanical heart valves are located in the inlet and outlet positions of the ventricle to control flow direction. Air pulses that are generated by an external drive unit are used to periodically compress the flexible blood sac. An automatic control system varies the cardiac output by adjusting the heart rate and the time for ventricular filling in response to an increase in filling pressure.

The device is placed outside the patient on the patient's abdomen (paracorporeal). The device can be used to assist a single ventricle, or simultaneously with an additional device that assists the both ventricles, as shown in Fig. 3. For the LVAD configuration (right pump in Fig. 3), the inlet cannula is inserted into the apex of the left ventricle and connected to the inlet port of the ventricular assist device. The outflow cannula is attached between the outflow port of the ventricular assist device and the ascending aorta. For the RVAD configuration (left pump in Fig. 3), the inlet cannula is connected to the right atrium and the outlet cannula to the main pulmonary artery. For both types of configurations, the inflow and outflow cannulae pass through the skin below the rib cage. Over 2850 implants have occurred worldwide with the longest duration of 566 days (5). An implantable version of this pump (with a titanium pump casing) was approved by the FDA in August of 2004 (6).

Permission Pending

Figure 3. Implant Location of Penn State/Thoratec Pneumatic Ventricular Assist Device in the RVAD (left) and LVAD (right) Configuration. For the LVAD configuration, the inlet cannula is inserted into the apex of the left ventricle and connected to the inlet port of the ventricular assist device. The outflow cannula is attached between the outflow port of the ventricular assist device and the ascending aorta. For the RVAD configuration, the inlet cannula is connected to the right atrium and the outlet cannula to the main pulmonary artery. For both types of configurations, the inflow and outflow cannulae pass through the skin below the rib cage. (Reprinted with permission from The Cleveland Clinic Foundation.)

Another type of pneumatic ventricular assist device is the Thoratec HeartMate IP (intraperitoneal). The HeartMate IP is an implantable blood pump that is connected to an external drive unit via a percutaneous air drive line (7). The interior of this device is shown in Fig. 4. A unique feature of this device is the use of a textured blood surface in the ventricle that promotes the formation of a cell layer. The cell layer is believed to decrease thrombus formation because the layer mimics the blood contacting surface of a blood vessel. Bioprosthetic heart valves are used to regulate the direction of flow. The HeartMate IP has been implanted in >1300 patients worldwide with the longest duration of 805 days.

Two other types of pneumatic devices include the BVS5000 and AB5000 (both made by ABIOMED, Danvers, MA). Both devices are intended to provide cardiac support as a bridge to transplant or until the native heart recovers. The BVS5000, illustrated in Fig. 5, is an external dual-chamber device that can provide support to one or both ventricles as a bridge to transplant (8). The chambers utilize polyurethane valves to regulate the flow direction. More than 6000 implants have been performed worldwide (9). The AB5000 is a pneumatically driven, paracorporeal device that is similar to a single ventricle of the AbioCor total artificial heart (described in a later section) (10). This device was approved by the FDA in October of 2003 as has been used in >88 patients. The average duration of support is 15 days with the longest duration of 149 days.

Additional types of pneumatic devices include the Berlin Heart Excor (Berlin Heart AG, Berlin, Germany), the

Figure 4. Interior of Thoratec HeartMate IP Pneumatic Ventricular Assist Device. The cell layer is believed to decrease thrombus formation because the layer mimics the blood contacting surface of a blood vessel. (Reprinted with permission from Thoratec Corporation.)

MEDOS/HIA (Aachen, Germany), and the Toyobo Heart (National Cardiovascular Center, Osaka, Japan). The Berlin Heart Excor is available in a range of sizes (10–80 mL stroke volume) with either tilting disk or polyurethane valves, and has been implanted in >500 patients (11). The MEDOS/HIA system is also available in a range of sizes and has been implanted in >200 patients (12). The Toyobo LVAS has been implanted in >120 patients (13).

ELECTRIC VENTRICULAR ASSIST DEVICES

Electric ventricular assist devices mainly differ from their pneumatic counterparts in their source of power. Electric ventricular assist devices are typically placed within the

Figure 5. ABIOMED BVS 5000 Pneumatic Ventricular Assist Device. The BVS5000 is an external dual-chamber device that can provide support to one or both ventricles as a bridge to transplant (8). The chambers utilize polyurethane valves to regulate the flow direction. (Reprinted with permission from ABIOMED, Inc.)

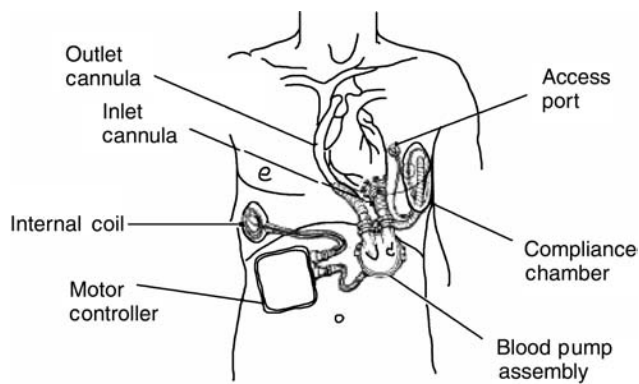

Figure 6. Penn State/Arrow Electric Ventricular Assist Device (LionHeart). The blood pump assembly utilizes a rollerscrew energy converter with a pusher plate. The motion of the pusher plate compresses the blood sac and ejects blood from the ventricle. Mechanical heart valves are used to control the direction of flow into and out of the pump. Energy passes from the external power coil to the subcutaneous (internal) coil by inductive coupling via the transcutaneous energy transmission system (TETS). (Reprinted with permission from Arrow International.)

abdominal cavity. The inlet cannula is inserted into the apex of the native left ventricle and connected to the inlet port of the device. The outlet cannula is attached between the outflow port of the device and the ascending aorta via an end-to-side anastomosis. These types of devices can be used as either bridge-to-transplant or as permanent implants (destination therapy).

Figure 6 illustrates an electric ventricular assist device (LionHeart) developed by the Pennsylvania State University in conjunction with Arrow International (Reading, PA) (14). The blood pump assembly utilizes a rollerscrew energy converter with a pusher plate. The motion of the pusher plate compresses the blood sac and ejects blood from the ventricle. Mechanical heart valves are used to control the direction of flow into and out of the pump. Energy passes from the external power coil to the subcutaneous (internal) coil by inductive coupling via the transcutaneous energy transmission system (TETS). The controller and internal battery supply are also implanted in the abdomen. The internal battery permits operation without the external power coil for ~20 min. Air displaced by the blood pump housing enters the polyurethane compliance chamber. Because the air in the compliance chamber can slowly diffuse across the wall of the compliance chamber, the air in the chamber is periodically replenished via the subcutaneous access port. The LionHeart is intended to be used as destination therapy. This device was approved for use in Europe in 2003.

Another type of electric ventricular assist devices is the Novacor LVAS (left ventricular assist system), produced by WorldHeart Corporation (Ottawa, ON). The Novacor LVAS, illustrated in Fig. 7, contains a polyurethane blood sac that is compressed between dual pusher plates (15). The pusher plates are actuated by a solenoid that is coupled to the plates via springs. Bioprosthetic heart valves are utilized to control the direction of flow. A percutaneous power line connects the pump to an external battery pack and controller. The Novacor LVAS has been implanted in

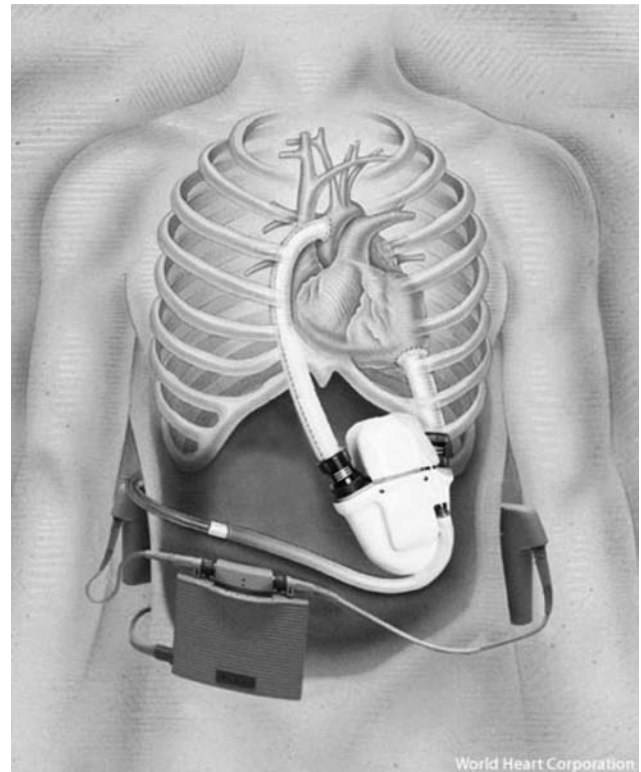

Figure 7. WorldHeart Novacor Electric Ventricular Assist Device. The Novacor contains a polyurethane blood sac that is compressed between dual pusher plates. The pusher plates are actuated by a solenoid that is coupled to the plates via springs. A percutaneous power line connects the pump to an external battery pack and controller. (Reprinted with permission from World Health Corporation, Inc.)

over 1500 patients worldwide. The longest implant duration is >6 years. No deaths have been attributed to device failure with only 1.4% of the devices needing replacement. The Novacor LVAS is approved as a bridge-to-transplant in the United States and Europe and is in clinical trials for destination therapy in the United States.

The HeartMate XVE (illustrated in Fig. 8) is a derivative to the HeartMate IP (7). The HeartMate XVE uses an electric motor and pusher plate system to pump blood. A percutaneous power line is used to connect the pump to an external battery pack and controller. The HeartMate VE (an earlier version of the XVE) and XVE have been implanted in >2800 patients worldwide with the longest duration of 1854 days. The HeartMate SNAP-VE was recently approved by the FDA as destination therapy.

The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) study examined the clinical utility of ventricular assist devices (16). Patients with end-stage heart failure who were ineligible for cardiac transplantation were split into two groups. The first group ($n = 68$) received the HeartMate VE LVAS while the second group ($n = 61$) received optimal medical management. The results showed a reduction of 48% in the risk of death from any cause in the LVAD group versus the medical-therapy group ($p = 0.001$). The 1 year survival was 52% for the VAD group and 25% for the medical-therapy group ($p = 0.002$). The 2 year survival

Figure 8. Thoratec HeartMate XVE Electric Ventricular Assist Device. The HeartMate XVE uses an electric motor and pusher plate system to pump blood. A percutaneous power line is used to connect the pump to an external battery pack and controller. (Reprinted with permission from Thoratec Corporation.)

was 23% for the VAD group and 8% for the medical-therapy group ($p = 0.09$). Finally, the median survival was 408 days for the VAD group and 150 days for the medical-therapy group. This study clearly showed the clinical utility of ventricular assist devices.

Continuous Flow

Continuous flow ventricular assist devices deliver nonpulsatile flow. Consequently, they do not require heart valves to regulate the direction of blood flow. Continuous flow ventricular assist devices are classified as either centrifugal flow or axial flow pumps based on the direction of the flow as it passes through the pump. These types of pumps are implanted in a similar fashion as their pulsatile counterparts.

Continuous flow assist devices have several potential advantages over pulsatile systems. First, these devices are typically smaller than their pulsatile counterparts and can be used in smaller patients (such as small adults and children). In addition, these pumps have fewer moving parts and are simpler devices than pulsatile systems. These types of devices typically require less energy to operate than the pulsatile pumps.

However, continuous flow pumps have several potential disadvantages. The main disadvantage is that the long-term effects of continuous flow in patients are unknown. Some studies suggest that continuous flow results in lower tissue perfusion (17,18). In addition, these types of devices typically have higher fluid stresses than their pulsatile counterparts, potentially exposing blood components to stress levels that may damage or destroy the cells. However, due to the short residence time of the blood compo-

nents within these pumps, the potential for damage or destruction is reduced (19). Finally, feedback control mechanisms for altering pump speed and flow in response to patient demand are complex and unproven.

Centrifugal Flow Ventricular Assist Device. In a centrifugal flow ventricular assist device, the direction of the outlet port is orthogonal (at a right angle) to the direction of the inlet port. Blood flowing into a centrifugal pump moves onto a spinning impeller. This causes the blood to be propelled away from the impeller due to centrifugal forces. The blood is then channeled to the outlet port by a circular casing (known as the volute) around the impeller. Finally, the blood is discharged through the outlet at a higher pressure than the inlet pressure.

The impeller typically consists of various numbers and geometric configurations of blades, cones, or disks. Typical motor speeds (or rotation rates) for centrifugal flow pumps range vary from 1500 to 5000 rpm (revolutions per minute). This results in flow rates of 2–10 L·min⁻¹. Many centrifugal flow pumps utilize electromagnetic impellers that do not make any contact with the interior of the pump when the impeller is spinning. The inlet and outlet ports are connected to the native ventricle and the aorta, respectively, as described previously for pulsatile electric ventricular assist devices.

A major drawback with centrifugal flow pumps is that they are outlet pressure sensitive and may not produce flow if the outflow pressure (the pressure that the pump is working against) becomes greater than the outlet pressure. When this happens, the impeller will continue to spin without producing any flow. In order for the pump to produce flow, either the outflow pressure must be reduced or the impeller speed must be increased (to increase the outlet pressure).

The Bio-Pump (Medtronic BioMedicus, Inc., Minneapolis, MN), shown in Fig. 9, is an extracorporeal, centrifugal flow pump that was originally developed for cardiopulmonary bypass (20). It has been used to provide support for one or both ventricles as a bridge to transplant for short periods

Figure 9. Medtronic BioMedicus Bio-Pump Centrifugal Flow Ventricular Assist Device. The Bio-Pump is an extracorporeal, centrifugal flow pump that was originally developed for cardiopulmonary bypass. It has been used to provide support for one or both ventricles as a bridge to transplant for short periods. (Reprinted with permission from Medtronic, Inc.)

Figure 10. Thoratec HeartMate III Centrifugal Flow Ventricular Assist Device. The HeartMate III is a centrifugal pump that features a magnetically levitated impeller. (Reprinted with permission from Thoratec Corporation.)

(5 days or less). The pump consists of an acrylic pump head with inlet port and outlet ports placed at right angles to each other. The impeller consists of a stack of parallel cones within a conical acrylic housing. A single magnetic drive unit is coupled with a magnet in the impeller. The pump is driven by an external motor and power console. Two different sizes are available to provide support for both adults and children. Recipients of the Bio-Pump have had mixed results (21). The Sarns/3M Centrifugal system (Terumo, Ann Arbor, MI) is another centrifugal pump that is used primarily for cardiopulmonary bypass (22).

The HeartMate III (Thoratec), shown in Fig. 10, is a centrifugal pump that features a magnetically levitated impeller (23,24). The entire pump is fabricated from titanium. The interior of the pump uses the same type of textured blood contacting surfaces utilized in the HeartMate VE. In addition, the HeartMate III incorporates a TETS that permits it to be fully implantable as a permanent device for destination therapy. The controller is designed to respond automatically to the patient's needs and to permit both pulsatile and continuous flow. This pump is currently under development. Other centrifugal pumps that utilize a magnetically levitated impeller include the HeartQuest (MedQuest, Salt Lake City, UT) (25) and the Duraheart (Terumo) (26). The Duraheart was first implanted in 2004.

Two centrifugal flow pumps utilize hydrodynamic forces, rather than magnetic levitation, to suspend the impeller: the CorAide (Arrow International) (27) and the VentrAssist (Ventracor Limited, Chatswood, Australia) (28). The CorAide (shown in Fig. 11) began clinical trials in Europe in 2003 (29), while the VentrAssist (shown in Fig. 12) began clinical trials in Europe in 2004 (30).

Axial Flow Ventricular Assist Devices. An axial flow ventricular assist device is also composed of an impeller spinning in a stationary housing. However, the blood that flows into and out of the device travels in the same direction

Figure 11. Arrow CorAide Centrifugal Flow Ventricular Assist Device. The CorAide utilizes a hydrodynamic bearing, rather than magnetic levitation, to suspend the impeller. (Reprinted with permission from Arrow International, Inc.)

as the axis of rotation of the impeller. The impeller transfers energy to the blood by the propelling, or lifting, action of the vanes on the blood. Stators (stationary flow straighteners) stabilize the blood flow as it enters and exits the impeller. Magnets are embedded within the impeller and are coupled with a rotating magnetic field on the housing. The pumps are typically constructed of titanium.

Axial flow pumps run at speeds of 10,000–20,000 rpm, generating flow rates of up to $10 \text{ L}\cdot\text{min}^{-1}$. These high motor speeds are not expected to cause excessive hemolysis (damage to blood components) because of the limited exposure of blood within the axial flow pump (19). Like centrifugal pumps, axial flow pumps are also outlet pressure sensitive and may not produce flow in cases when the outflow pressure exceeds the outlet pressure. Mechanical bearings are typically used to support the impeller within the stator.

Figure 13. MicroMed DeBakey Axial Flow Ventricular Assist Device. The MicroMed is connected to an external controller and power unit. The pump speed is varied manually to meet the needs of the patient. (Reprinted with permission from Micromed Technology, Inc.)

Figure 13 shows the MicroMed DeBakey VAD (MicroMed Technology, Houston, TX) axial flow pump. This device operates from 7500 to 12,000 rpm and can provide flows up to $10 \text{ L}\cdot\text{min}^{-1}$ (31). The flow curves, speed, current and power are displayed in a bedside monitor unit. A pump motor cable along with the flow probe wire exit transcutaneously from the implanted device and connect to the external controller and power unit. The pump speed is varied manually to meet the needs of the patient. The pump can be actuated by two 12 V dc batteries for 4–6 h. This device was approved in Europe in 2001 (32). Clinical trials in the United States began in 2000. Over 280 patients have received the MicroMed DeBakey VAD as of January 2005 worldwide. Although this device was originally approved as a bridge to transplant, clinical trials are underway to use the device for destination therapy.

Figure 14 shows the HeartMate II (Thoratec) axial flow ventricular assist device. The rotating impeller is surrounded by a static pump housing with an integral motor (33). The pump's speed can be controlled either manually or by an automatic controller that relies on an algorithm based on pump speed, the pulsatility of the native heart, and motor current. The HeartMate II is designed to operate between 6000 and 15,000 rpm and deliver as much as $10 \text{ L}\cdot\text{min}^{-1}$. The initial version of this device is powered through a percutaneous small-diameter electrical cable connected to the system's external electrical controller. A fully implantable system utilizing a TETS is under development. The first implant HeartMate II implant occurred in 2000 (34). Clinical trials in Europe and the United States are ongoing. This device is intended for both bridge to transplant and destination therapy.

Figure 15 illustrates the Jarvik 2000 (Jarvik Heart, New York). The Jarvik 2000 is intraventricular axial flow pump. The impeller is a neodymium–iron–boron magnet, which is housed inside a welded titanium shell and supported by ceramic bearings (35). A small, percutaneous cable delivers power to the impeller. All of the blood-contacting surfaces are made of highly polished titanium. The normal operating range for the control system is 8000–12,000 rpm, which generates an average pump flow rate of $5 \text{ L}\cdot\text{min}^{-1}$. The pump is placed within the left ventricle with

Figure 14. Thoratec HeartMate II Axial Flow Ventricular Assist Device. The rotating impeller is surrounded by a static pump housing with an integral motor. The pump's speed can be controlled either manually or by an automatic controller that relies on an algorithm based on pump speed, the pulsatility of the native heart, and motor current. (Reprinted with permission from Thoratec Corporation.)

a sewing cuff sutured to the ventricle, eliminating the need for an inflow cannula. Over 100 patients have received the Jarvik 2000 as a bridge to transplant or destination therapy, with the longest implant duration of > 4 years (36).

Figure 15. Jarvik 2000 Axial Flow Ventricular Assist Device. Unlike most other axial flow devices, the Jarvik 2000 is intraventricular axial flow pump. The impeller is a neodymium–iron–boron magnet, which is housed inside a welded titanium shell and supported by ceramic bearings. (Reprinted with permission from Jarvik Heart, Inc.)

TOTAL ARTIFICIAL HEARTS

The total artificial heart (TAH) is designed to support both the pulmonary and systemic circulatory systems by replacing the native heart. Two types of artificial hearts have been developed: pneumatic and electric.

Pneumatic Total Artificial Heart

A pneumatic total artificial heart is composed of two ventricles that replace the native left and right ventricle. Each ventricle is of similar design to the Penn State/Thoratec pneumatic ventricular assist device (as described in a previous section) (4). Both ventricles are implanted within the chest. The air pulses are delivered to the ventricles via percutaneous drivelines. An automatic control system varies cardiac output by adjusting the heart rate and the time for ventricular filling in response to an increase in filling pressure.

Pneumatic total artificial hearts are currently used as a bridge to transplant. Several different pneumatic artificial hearts have been used clinically around the world. The only pneumatic TAH approved as a bridge to transplant in the United States is the CardioWest (SynCardia, Tucson, AZ) TAH, illustrated in Fig. 16 (37). The CardioWest (with a stroke volume of 70 mL) is based on the Jarvik-7, which has a stroke volume of 100 mL. A study of 81 recipients of the CardioWest revealed a survival rate to transplant of 79% and a 1 year survival rate of 70%.

Pneumatic total artificial hearts have also been used as a permanent replacement device. The Jarvik-7 pneumatic TAH was permanently implanted in five patients (38).

Figure 16. SynCardia CardioWest Pneumatic Total Artificial Heart. The CardioWest is based on the Jarvik-7 and is the only pneumatic TAH approved as a bridge to transplant in the United States. (Reprinted with permission from SynCardia Systems, Inc.)

Although the longest survivor lived for 620 days, all five patients had hematologic, thromboembolic, and infectious complications. The pneumatic artificial heart is no longer considered for permanent use because of infections associated with the percutaneous pneumatic drive lines and quality of life issues related to the bulky external pneumatic drive units.

Electric Total Artificial Heart

The electric TAH is completely implantable and is designed for permanent use. The Penn State/3M Electric TAH is shown in Fig. 17. The artificial heart is composed of two blood pumps that are of similar design to the Penn State/Arrow electric ventricular assist device (39). However, the electric TAH uses a single implantable energy converter that alternately drives each ventricle. The implantable controller adjusts the heart rate in response to ventricular filling and maintains left–right balance. The design for this system was completed in 1990 and was the first to incorporate the controller, transcutaneous energy transmission system (TETS), telemetry, and internal power (via rechargeable batteries) into a completely implantable system. The Penn State electric TAH has been successfully implanted in animals for >1 year without thromboembolic complications. In 2000, ABIOMED acquired the rights to the Penn State/3M Electric TAH.

The ABIOMED AbioCor TAH, illustrated in Fig. 18, uses an electrohydraulic energy converter to alternately compress each blood sac (40,41). In addition, the AbioCor uses polymer valves to control flow into and out of each ventricle. The AbioCor is currently undergoing clinical

Figure 17. Penn State/3M Electric Total Artificial Heart. This artificial heart is composed of two blood pumps that are of similar design to the Penn State/Arrow electric ventricular assist device. However, the electric TAH uses a single implantable energy converter that alternately drives each ventricle.

Figure 18. ABIOMED AbioCor Electric Total Artificial Heart. The AbioCor TAH uses an electro hydraulic energy converter to alternately compress each blood sac. The AbioCor is currently undergoing clinical trials in the United States. Two patients were discharged from the hospital, with one patient surviving for > 1 year. (Reprinted with permission from ABIOMED, Inc.)

trials in the United States. Fourteen critically ill patients (with an 80% chance of surviving < 30 days) have been implanted. Two patients were discharged from the hospital (one to home), with one patient surviving for > 1 year. The causes of death were typically end organ failure and strokes. One pump membrane wore out at 512 days. Smaller, improved totally implantable artificial hearts are currently under development.

FUTURE DIRECTIONS OF RESEARCH

The ventricular assist devices and total artificial hearts presented in this article successfully provide viable cardiac support by either assisting or replacing the native heart. However, there are several areas for future research on artificial hearts. These include the following: Power sources to permit longer intervals between battery changes; Improved control schemes for both pulsatile and nonpulsatile devices that enhance the response of the cardiac assist device to meet physiologic demands; Decrease thromboembolic events associated by modifying the device geometry and/or blood-contacting materials; Determine the long-term effects of continuous, nonpulsatile flow; Decrease incidence of infection by the elimination of all percutaneous lines and creating smaller implantable electronic components; Reduced pump sizes to fit smaller adults, children, and infants; Increased reliability for 5 or more years to 95% (with a 95% confidence level).

Significant progress has been made in the last 20 years. One can only imagine what the next 20 years will bring!

HEART-LUNG MACHINES

DAVID D'ALESSANDRO
ROBERT MICHLER
Montefiore Medical Center
Bronx, New York

INTRODUCTION

The heart-lung machine is perhaps the most important contribution to the advancement of surgery in the last century. This apparatus was designed to perform the functions of both the human heart and the lungs allowing surgeons to suspend normal circulation to repair defects in the heart. The development of a clinically safe and useful machine was the rate-limiting step to the development of modern cardiac surgery. Since its inception, the heart-lung machine has enabled the surgical treatment of congenital heart defects, coronary heart disease, valvular heart disease, and end-stage heart disease with heart transplantation and mechanical assist devices or artificial hearts.

The heart-lung machine consists of several components that together make up a circuit that diverts blood away from the heart and lungs and returns oxygenated blood to the body. Commercial investment and production of these components has resulted in wide variability in the design of each, but the overall concept is preserved. During an operation, a medical specialist known as a perfusionist operates the heart-lung machine. The role of the perfusionist is to maintain the circuit, adjust the flow as necessary, prevent air and particulate emboli from entering the circulation, and maintain the various components of the blood within physiologic parameters.

HISTORY OF CARDIAC SURGERY AND ASSISTED CIRCULATION

The emergence of modern heart surgery and the ability to correct congenital and acquired diseases of the heart were dependent on the work of innovative pioneers who developed a means to stop the heart while preserving blood flow to the remainder of the body. This new technology was aptly named *cardiopulmonary bypass* (CPB), which simply

Reading List

- Lee J, et al. Reliability model from the in vitro durability tests of a left ventricular assist system. *ASAIO J* 45(6):595–601 1999.

means circulating blood around the heart and lungs. Since the inception of the heart-lung machine, continued refinements and widespread adoption of CPB led to the rapid growth of congenital and adult heart surgery.

Lessons learned during World War II and corresponding advances in critical care emboldened surgeons to consider surgical solutions for diseases of the heart, an organ long considered to be inoperable. One such surgeon was Dr. Dwight Harken who pioneered closed heart surgery, which he initially used to remove foreign bodies from the heart such as bullets and shrapnel. Having achieved success with this approach, he and others modified the techniques, developing a blinded technique for performing closed valvuloplasty primarily used to ameliorate rheumatic valvular disease. Although this method proved safe and reproducible, its applicability to other diseases of the heart was limited.

The next leap came when surgeons attempted open-heart procedures using brief periods of total circulatory arrest. As the brain is highly sensitive to hypoxic injury, very few patients were successfully treated with his approach. The safety of circulatory arrest was greatly increased when Dr. Bill Bigelow at the University of Minnesota introduced the concept of induced hypothermia. This method of lowering body temperature to reduce metabolic demand provided protection for the oxygen-starved organs allowing for modestly longer periods of circulatory arrest. Inspired by Bigelow's work, Lewis and Taufic first used this approach clinically on September 2, 1952, at the University of Minnesota (1). Under moderate total body hypothermia, Lewis and Taufic used a short period of circulatory arrest to repair a congenital defect in a 5 year-old girl. This was a landmark achievement in surgery and marks the true beginning of open-heart surgery. For the first time, surgeons had the ability to open the heart to repair defects under direct vision. Despite this great achievement, however, the relatively brief periods of circulatory arrest that this technique provided were sufficient only for the repair of simple defects and did little to broaden the scope of surgically treatable cardiac diseases.

The development of assisted circulation was a quantum leap in the field of cardiac surgery. Although investigation into mechanical means of circulation began during the early part of the twentieth century, an effective and safe design would not emerge for several years. An alternative approach named *cross-circulation* was used for several years in the interim. Dr. C. Walt Lillehei, again at the University of Minnesota, was the first to use this technique clinically when on March 26, 1954, when he repaired a VSD in a 12 month-old infant. During this operation, the child's mother acted as a blood reservoir, a pump, and an oxygenator, allowing a safe period of extended circulatory arrest to repair a complicated congenital defect. The child's circulation was connected in series to her mother's diverting oxygen poor blood away from the patient's heart and lungs and returning oxygen-saturated blood to her arterial system. Although many were amazed by and congratulatory of Dr. Lillehei's efforts, critics were outspoken of their disapproval of a technique that risked the death of two patients for the benefit of one. Nevertheless, these early successes provided proof of the concept and a mechanical substitute for cross-circulation soon followed.

Figure 1. John and Mary Gibbon with their heart-lung machine. (Reprinted with permission from Thomas Jefferson University Archives.)

John and Mary Gibbon are credited with building the first usable CPB machine, a prototype of which John Gibbon employed in 1935 to support a cat for 26 min (2) (Fig. 1). This pump, which used two roller pumps and other similar early designs, were traumatic to blood cells and platelets and allowed for easy air entry into the circulation, which often proved catastrophic. Later, in 1946, Dr. Gibbon in collaboration with Thomas Watson, then chairman of IBM, made further refinements. Together they were able to successfully perform open-heart surgery in dogs, supporting the animals for period exceeding 1 h (3). Finally on May 6, 1953, Dr. Gibbon used his heart-lung machine to successfully repair an atrial septal defect in an 18 year-old girl, marking the first successful clinical use of a heart-lung machine to perform open-heart surgery. Gibbon's first attempt in 1952 followed two unsuccessful attempts by Clarence Dennis et al. in 1951 (4), and it too ended in failure. Sadly, subsequent failures led Gibbon to finally abandon this new technology, finally giving up heart surgery completely.

Kirklin's group at the Mayo Clinic modified the Gibbon pump oxygenator and reported a series of eight patients in 1955 with a 50% survival (5). Around the same time, Frederick Cross and Earl Kay developed a rotating disk oxygenator that had a similar effectiveness (6,7). This apparatus was similar in design to that used by Dennis et al. several years earlier (8). While this Kay-Cross unit became commercially available, it shared many of the

Figure 2. Typical cardiopulmonary bypass circuit demonstrating the various components. This circuit contains four accessory pumps for suction/venting and the administration of cardioplegia. (Reprinted with permission from Ref. 13.)

limitations of the Gibbon system. These pumps were cumbersome, difficult to clean and sterilize, and were inefficient and thus wasteful of blood.

Collaboration between Richard DeWall and Lillehei provided the next advance in pump oxygenators, and in 1956, they reported their first clinical experience using a bubble oxygenator in seven patients, five of whom survived (9). Further refinements by Gott et al. (10) resulted in a reproducible, disposable plastic sheet oxygenator, a system that was readily accepted by pioneering centers around the world. The bubble oxygenator became the predominant pump oxygenator for the next three decades. More recently, the membrane oxygenator, an early design of which was described by Kolff et al. in 1956 (11), has replaced it. Lande et al. described the first commercially available disposable membrane oxygenator (12), but its advantages to the bubble oxygenator were not readily apparent. By the mid-to-late 1980s, advanced microporous membrane oxygenators began to supplant the bubble oxygenator in the clinical arena and they remain the predominant design in use today (Fig. 2).

THE CIRCUIT

The first requirement of a CPB circuit is a means to evacuate and return blood to the circulation. Special drainage and return catheters known as cannulae have been devised for this purpose. One or more venous cannulae are placed in a central vein or in the heart to empty the heart. The venous cannulae are connected to a series of poly(vinyl chloride) tubing that deliver the blood to the remainder of the circuit.

The next component is a reservoir that collects and holds the blood. The reservoir is often used to collect shed blood from the operative field and to store excess blood volume while the heart and lungs are stopped. Drainage of the blood is accomplished by gravitational forces and is sometimes assisted with vacuum. The movement of blood

through the remainder of the circuit, however, requires the use of a pump. Many pump designs have been used over the years, but the most common in current use are the roller pump and the centrifugal pump. A roller pump is a positive displacement pump and has been the most prolific design to date for this purpose. These pumps use rollers mounted on the ends of a rotating arm that displace blood within the compressed tubing, propelling it forward with faint pulsatility. Both the rate and direction of rotation and the occlusion pressure can be adjusted to adjust the flow. In contrast, centrifugal pumps use a magnetically driven impeller design that create a pressure differential between the inlet and the outlet portion of the pump housing propelling blood. Less traumatic to the blood elements, the centrifugal pump has largely replaced the roller pump for central circulation at most large centers.

The blood is actively pumped through a series of components before it is returned to the body. A heat exchange system is used to first lower the blood and body temperature during heart surgery. Controlled hypothermia reduces the body's energy demands, safely allowing reduced or even complete cessation of blood flow, which is necessary during certain times in the course of an operation. Reversing the process later rewarms the blood and body.

The pump oxygenator is by far the most sophisticated component of the circuit. As discussed, the membrane oxygenator is the predominant design in use today. Membrane oxygenators employ a microporous membrane that facilitates gas exchange in the circulating blood. Pores less than 1 μm prevent the leakage of serum across the membrane yet allow efficient gas exchange. An integrated gas mixer or blender enables the perfusionist to adjust the oxygen and carbon dioxide content in the blood and thus regulate the acid-base balance. In addition, an inhalational gas vaporizer provides anesthetic to the patient for the period during CPB. In line oxygen saturation monitors supplemented with frequent blood gas analysis ensure physiologic requirements are met during CPB.

Finally, an in line filter (typically 40 μm) prevents air and thromboembolic particles from returning to the arterial circulation. In parallel with this circuit, several additional roller pumps are used to provide suction that returns shed blood from the operative field. These are critical in open-heart procedures where a dry operative field is imperative for good visualization. An additional pump is often needed to deliver a cardioplegia solution, a mixture of blood and hyperkalemic solution used to stop the heart. Various monitors, hemofiltration units, blood sampling manifolds, gauges, and safety valves are usually present.

The main arterio-venous circuit is generally primed with a balanced electrolyte solution, which obviates the need for the blood prime used in the earlier, higher volume circuits. Other prime constituents include buffers such as sodium bicarbonate, oncotics such as albumin and mannitol, and anticoagulation in the form of heparin. Some protocols also call for the addition of an antifibrinolytic such as aminocaproic acid or aprotinin to the prime.

The overall construction of the CPB circuit is highly variable among institutions depending on the preferences of the surgeons and perfusionists. Although the principals of perfusion are universal, individual and group practices

are not. Perfusionists are a highly trained group of specialists dedicated to the safe operation of the heart–lung machine. Perfusion education and training has evolved concurrently with improvements in the bypass circuit, and accredited perfusion programs are included in many allied health curriculums at select universities. Perfusionists are required to pass a board examination, and many government organizations are now enacting licensure legislation. These persons must be able to adapt to the ever-changing technology present in cardiac surgery as well as to protocols and circuitry that vary among surgeons and institutions.

FUTURE DIRECTIONS

There are many commercial designs currently available that incorporate several of these components into a single disposable unit. Some units, for example, combine a reservoir with a membrane oxygenator and a heat exchanger. Continued innovation has resulted in more efficient, compact designs that limit the blood contacting surface area and decrease the need for large priming volumes and thus the need for patient transfusions. Improving biocompatibility of materials has lessened the inflammatory response that is associated with extracorporeal (outside the body) circulation. Sophisticated cannula designs are less traumatic to the vessels and have improved flow dynamics, causing less shear stress on circulating red blood cells. New safety mechanisms such as alarm systems, pop-off valves, and automatic air evacuation devices will further increase the efficacy of these lifesaving machines.

The field of cardiac surgery is similarly evolving. Minimally invasive approaches to many heart operations are developing driven by patient demand as well as efforts to reduce postoperative hospital stay and patient morbidity. Recent debate has also focused on the possible adverse neurologic sequelae associated with the use of CPB. A growing number of coronary bypass procedures are now performed without the use of a heart–lung machine. Some centers have demonstrated success with this approach, decreasing the need for postoperative blood transfusions and end-organ dysfunction. To date, however, there is no conclusive evidence that avoidance of the heart lung machine results in improved neurologic outcomes or patient survival.

The creation of the heart–lung machine was the rate-limiting step to the development of the field of cardiac surgery. The ability to stop the heart while preserving flow the remainder of the heart has given surgeons the ability to repair defects in the heart and great vessels in patients of all ages. The pioneers in this field demonstrated remarkable courage and conviction in persevering in the face of overwhelming odds. Their collaborative efforts during one of the most prolific periods in the history of medicine have had a remarkable impact on human health. The future of cardiac surgery is largely dependent on continued advances in perfusion techniques and in the components of the heart–lung machine. In this endeavor, industry plays a pivotal role in developing and manufacturing improved products tailored to meet the needs of an everchanging field. Ultimately, evidence-based outcomes research will

help ensure these innovations result in improved outcome for patients.

HEAT AND COLD, THERAPEUTIC

MARY DYSON
United Kingdom

INTRODUCTION

Therapeutic levels of heating accelerate the resolution of inflammation, relieve pain, and promote tissue repair and

regeneration. Therapeutic levels of cooling reduce inflammation, relieve pain, and can reduce the damage caused by some injurious agents. To use therapeutic heating (thermotherapy) and therapeutic cooling (cryotherapy) effectively, the clinician should know:

- The physiological effects of heat and cold
- What devices are available to produce temperature changes
 - How they work
 - When and when not to use them
 - Their advantages and disadvantages.

This information assists the clinician in selecting the most suitable therapy and device for each patient.

The aim of this article is to provide this information, following a brief description of the history of these therapies, (this being included because history informs current and future usage).

HISTORY OF THERMOTHERAPY AND CRYOTHERAPY

Heat and cold have been used to treat diseases, aid healing, and reduce pain for many millennia. Exposure to the warmth of sunlight and thermal mineral springs continues to be used to this day. The ancient Greeks and Romans also advocated heated sand and oils for the treatment of injuries (1). Heated aromatic oils were rubbed on the body before massage, a form of therapy still in use today. In contrast, lesions accompanied by burning sensations (e.g., abscesses) were commonly treated by the application of cooling substances such as cold water and ice packs, another form of therapy still in use today. Fever was treated with cold drinks and baths; eating snow alleviated heartburn.

Thermotherapy

In the seventeenth century, one treatment for arthritis and obesity was to bury patients up to their necks in the sun-warmed sand of beaches. Warm poultices made from vegetable products such as leaves and cereals were used to treat musculoskeletal and dermal ailments. Molten wax was used to treat bruises around the eyes and infected eyelids, a technique not recommended because of the danger of getting hot wax into the orbit and damaging the eye.

In the eighteenth century, hot air produced by ovens and furnaces was used to induce perspiration and improve the circulation (2).

In the nineteenth century, Guynot found that wounds healed faster when the ambient temperature was 30 °C than when the ambient temperature was lower than this. After the invention of electric light bulbs, these were used to produce light baths and heating cabinets that were used to treat neuralgia, arthritis, and other conditions. Different wavelengths of light were also produced, initially by the use of prisms and passing light through media of different colors, and most recently by the use of lasers. There is evidence that different wavelengths of the electromagnetic spectrum including light and infrared radiation have

different biomedical effects (3). When light is used to produce heat, both phototherapeutic and thermotherapeutic effects are produced that may reinforce each other.

In the late nineteenth and early twentieth century, the availability of electricity as a power supply led to the development of a host of novel thermotherapeutic devices including whirlpool baths, paraffin baths, and diathermy machines. In diathermy, high frequency electric currents are used to heat deeply located muscles. This effect was discovered in the 1890s when d'Arsonval passed a 1 A current at high frequency through himself and an assistant. He experienced a sensation of warmth (4). d'Arsonval worked on the medical application of high-frequency currents throughout the 1890s, work that led to the design of a prototype medical device by Nagelschmidt in 1906 and the coining of the term "diathermy" for what had previously been known as "darsonvalization." The first diathermy machines were long wave, and in the second decade of the twentieth century, these were used to treat a wide range of diseases, including arthritis, poliomyelitis, and unspecified pelvic disorders. In 1928, short-wave diathermy was invented, superceding long-wave diathermy in Europe after the Second World War.

Therapeutic ultrasound also became popular in the post-war period, initially as a method of heating tissues deep within the body to relieve pain and assist in tissue repair. It was demonstrated experimentally that ultrasonic heating was accompanied by primarily nonthermal events such as micromassage, acoustic streaming, and stable cavitation. These events, which also occur at intensities less than are required to produce physiologically significant heating of soft tissues, produce cellular events that accelerate the healing process (3,5). Therapeutic ultrasound is generally used at frequencies in the 0.75–3 MHz range. The higher the frequency, the shorter the wavelength and the lower the intensity needed to produce physiologically significant heating of soft tissues. However, higher frequencies, because they are more readily absorbed than lower frequencies, are less penetrative and are therefore less suitable for heating deep soft tissues. Since the 1990s, low kilohertz ultrasound, also known as long-wave ultrasound, has been used to initiate and stimulate the healing of chronic wounds (6). Although long-wave ultrasound is not primarily a heating modality (7), as with all therapies in which energy is absorbed by the body, it is inevitably transduced into heat, although in this instance insufficient to be clinically significant (8).

Cryotherapy

Until the invention in 1755 of artificial snow, which was made by placing a container of water over nitrous ether as the latter vaporized, only cold water and naturally occurring ice and snow were available as means of cooling the body. In the nineteenth century, ice packs were used over the abdomen to reduce the pain of appendicitis and over the thorax to reduce the pain of angina. Ice was also used as a local anesthetic. In 1850, evaporative cooling methods were introduced; for example, ether applied to the warm forehead had a cooling effect as it evaporated. Since the early days of physical therapy, the local application of ice has

been used to treat acute musculoskeletal injuries; usually a combination of rest, ice, compression, and elevation (RICE) are recommended.

Contrast Bath Hydrotherapy

Hydrotherapy is the use of water as a therapeutic agent. Hot or cold water, usually administered externally, has been used for many centuries to treat a wide range of conditions, including stress, pain, and infection. Submersion in hot water is soothing and relaxing, whereas cold water may be anti-inflammatory and limit the extent of tissue damage. In contrast bath hydrotherapy, the patient is exposed to hot and cold water alternately to stimulate the circulation. The blood vessels dilate in the heat and constrict in the cold. Pain is also reduced. Contrast baths have been used to treat overuse injuries such as carpal tunnel syndrome and tendonitis of the hand and forearm (<http://www.ithaca.edu/faculty/nquarrie/contrast.html>). Although there has been little research on the efficacy of contrast baths, they remain in use and may be of clinical value (9).

THE PHYSIOLOGICAL EFFECTS OF HEAT AND COLD

When healthy we keep a fairly constant body temperature by means of a very efficient thermoregulatory system. We are homoeothermic organisms. Homoeothermic is a pattern of temperature regulation in which cyclic variation of the deep body (core) temperature is maintained within arbitrary limits of $\pm 2^\circ\text{C}$ despite much larger variations in ambient temperature. In health and at rest, our core temperature can be maintained by the thermoregulatory system within $\pm 0.3^\circ\text{C}$ of 37°C in accordance with the body's intrinsic diurnal temperature cycle. Superimposed on the diurnal temperature cycles are monthly and seasonal temperature cycles. Hyperthermia is a core temperature greater than 39°C . Hypothermia is a core temperature less than 35°C .

The physiological effects of heat and cold are generally independent of the agent producing the temperature change, although in some cases, for example, ultrasound therapy, primarily nonthermally induced events accompany those induced thermally (3).

Physiological Effects of Heat

Heating of tissues occurs when these tissues absorb energy. The different effects of heating are due to many factors, including the following (10):

- The volume of tissue absorbing the energy
- The composition of the absorbing tissue
- The capacity of the tissue to dissipate heat, a factor largely dependent on its blood supply
- The rate of temperature rise
- The amount by which the temperature is raised

Cell Metabolism. Cell metabolism increases by about 13% for each 1°C increase in temperature up to the temperature at which the proteins of the cell, many of which

are vital enzymes, coagulate. Enzyme activity first increases as the temperature increases, then peaks, then declines as the enzymes denature, and is finally abolished when the temperature reaches about 45°C when heat kills the cells. Only temperature increases less than those producing enzyme denaturation are therapeutic. The cells' membranes are particularly sensitive to heat, which increases the fluidity of their lipoproteinaceous components, producing changes in permeability (11). At sublethal temperatures, heat-shock proteins, which give some protection to cells reexposed to heat, accumulate in the cells.

Abnormal and normal cells are affected differently by mild hyperthermia ($\sim 40^\circ\text{C}$). Synthesis of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins can all be inhibited by mild hyperthermia in abnormal cells, irreversibly damaging their membranes and killing the cells; this does not occur in normal cells subjected to mild hyperthermia (12). The technique can therefore be used to kill abnormal cells selectively.

Collagen. The extensibility of collagen is increased by thermotherapy. Raising the temperature of a highly collagenous structure such as a tendon increases the extent of elongation produced by stretch of a given intensity (13). Joint capsules are also highly collagenous, so thermotherapy decreases the resistance of a joint to movement. Cryotherapy, however, increases this resistance. Changes in resistance to movement are also due to changes in the viscosity of the synovial fluid.

Laboratory experiments suggest that heat should be applied to tendons with caution because *in vitro* exposure of excised tendons to temperatures in the range of $41\text{--}45^\circ\text{C}$ is accompanied by a reduction in their tensile strength (13). It is unlikely, however, that the stresses produced by passive stretch during physical therapy and normal exercise will reach the levels at which rupture occurs, although overvigorous exercise could be damaging, particularly in those who ignore protective pain.

Blood Flow. Thermotherapy causes blood vessels to widen (vasodilatation), increasing local blood flow and causing the skin to redden (erythema). Heat-induced vasodilatation has several causes, including the following:

- The direct effect of heat on the smooth muscle cells of the arterioles and venules.
- If there is local damage, then the damage-induced release of vasodilators such as bradykinin will cause further vasodilatation.

Bradykinin, histamine, and other chemical mediators released in response to injury and to heating increase capillary and venule permeability that, together with an increase in capillary hydrostatic pressure, can produce local swelling of the tissues (edema). The application of local heat immediately after injury should therefore be avoided (14).

Heating also induces changes in blood flow in subcutaneous tissues and organs. These changes depend on the amount of heating. First blood flow increases in these structures, but then it decreases if heating is sufficient for the core temperature to rise, as blood is diverted to the

skin where heat is lost from it to the external environment as part of the thermoregulatory process.

Different local heating techniques can have different effects on blood flow, due to differences in their depth of penetration. Methods producing superficial heating include infrared radiation and contact with a heated material; those producing deep heating include short-wave and microwave diathermy. Infrared (IR) radiation increases cutaneous blood flow (15) but not in the underlying skeletal muscle (16). In contrast, diathermy increases blood flow and temperature in both skin and skeletal muscle in humans (17), hyperemia being sustained for at least 20 min after the cessation of treatment, probably because of an increase in the metabolic rate of the heated tissues.

Neurological Effects. Therapeutic heat produces changes in muscle tone and pain relief.

Muscle Tone. Increased muscle tone can sometimes be reduced by the application of either superficial or deep heat. In 1990, Lehmann and de Lateur (18) showed that heating skin and skeletal muscle of the neck relieved muscle spasm secondary to underlying pathology. The Ia afferents of muscle spindles increase their firing rate on receipt of heat within the therapeutic range, as do tendon organs (19). Most secondary afferents decrease their firing rate (20). Collectively these neurological changes reduce muscle tone locally.

Pain Relief. People in pain generally consider heat to be beneficial, even on the intense pain experienced by patients with cancer (21).

Therapeutic heat produces vasodilatation and may therefore relieve pain related to ischemia. Pain related to muscle spasm may also be relieved by therapeutic heat; this reduces muscle spasm secondary to underlying pathology (18). Heat may also act as a counterirritant and relieve pain via the pain gate mechanism (22), in that the thermal sensations take precedence in the central nervous system over nociceptive sensations.

Increasing the temperature within the therapeutic range increases the velocity of nerve conduction. An increase in sensory conduction increases the secretion of pain-relieving endorphins.

Tissue Injury and Repair. The initial response of vascularised tissues to injury is acute inflammation. This is characterized by:

- Heat
- Redness
- Swelling (edema)
- Pain
- Loss of function

During it a host of chemical mediators and growth factors are secreted; these collectively limit the extent of tissue damage and lead to healing. The application of therapeutic levels of heat can accelerate the resolution of acute inflammation leading to faster healing. Although uncomfortable, acute inflammation is not a disease but a

vital component of tissue repair and regeneration. The pain associated with it is generally of a short duration and is of survival value in eliciting protective actions.

The management of acute trauma by thermotherapy and cryotherapy is based on a pathophysiological model often referred to as the secondary injury model (23). According to this model, secondary injury is the damage that occurs as a consequence of the primary injury in previously unaffected cells. The mechanisms initially hypothesized as producing this damage were classified as being either enzymatic or hypoxic (24). Since then, knowledge of the mechanisms involved in cell death from trauma has increased dramatically and a third mechanism is now postulated, namely the delayed death of primary injured cells. A review and update by Merrick in 2002 (25) attempts to reconcile the secondary injury model with current knowledge of pathophysiology. Secondary hypoxic injury has been reclassified as secondary ischemic injury, and specific mechanisms for ischemic injury have been identified. In addition to changes of vascular origin, there is now evidence that apparently secondary injury may be due, in part, to the delayed death of cells subjected, for example, to mitochondrial damage during the primary trauma. A better understanding of secondary injury should inform methods of treatment, some of which, although traditional, may need to be altered to improve their effectiveness. For example, the rationale that short-term cryotherapy of acute injuries was effective because it limited edema through vasoconstriction has been replaced by the currently accepted theory that it also retards secondary injury, regardless of the cellular mechanisms by which this occurs, be they lysosomal mechanisms, protein denaturation mechanisms, membrane permeability mechanisms, mitochondrial mechanisms, and/or apoptotic mechanisms (25). By reducing metabolic demand, the application of cryotherapy as soon as possible after an acute injury should reduce the speed and, possibly the extent, of secondary injury. There is evidence that continuous cryotherapy for 5 hours after a crush injury inhibited the loss of mitochondrial oxidative function that follows such injuries (25). The effect of continuous and intermittent cryotherapy for other durations on this and other pathophysiological events remains to be examined. This must be done if clinical treatments are to be improved.

Systemic and local therapeutic heating can reduce post-operative wound infection (26). The use of a warm-up dressing (Augustine Medical), which radiates heat and provides a moist wound environment, eradicated methicillin-resistant *Staphylococcus aureus* (MRSA) infection from pressure ulcers within 2 weeks (27). It should be appreciated that patients with MRSA-infected pressure ulcers, also known as pressure sores and bed sores, have increased morbidity and mortality; these ulcers can kill. Warming the tissues induces vasodilatation, giving rise to the high oxygen tension required for the production of oxygen-free radicals; these are an important part of the body's defense against bacterial infection (28) and initiate collagen synthesis and re-epithelialization. Vasodilatation also aids healing by increasing the efficiency with which the cells and growth factors needed for this are transported to the injured region and the efficiency with which waste products are removed from it.

Warming has been shown to increase the proliferation of fibroblasts (29), the cells that synthesize collagen, and of endothelial cells (30), the cells lining blood vessels, *in vitro*. If this also occurs *in vivo*, then warming will accelerate the formation of granulation tissue. More research is required to confirm whether therapeutic heating reduces the risk of wound infection and accelerates healing in a clinically significant fashion. The data gathered to date suggest that it may. If so, then “there is a real prospect of reducing complications, improving patient outcomes, shortening hospital stays and minimizing costs” (31).

Physiological Effects of Cold

The physiological effects of therapeutic cold (9) depend on a range of factors, including

- The volume of tissue to which cooling is applied
- The composition of the tissues cooled
- The capacity of the tissues to moderate the effects of cooling
- The rate of temperature fall
- The amount by which the temperature of the tissues is lowered

Cell Metabolism. The vital chemical processes occurring in cells generally slow as the temperature is lowered. These processes are catalyzed by enzymes, many of which are associated with the cells’ membranes. Cell viability relies on passive and active membrane transport systems, the latter involving ionic pumps activated by enzymes. These transport systems are necessary to maintain the intracellular ionic composition required for cell viability. Below a threshold temperature, the pumps fail, and consequently, the membranes lose their selective permeability; the intracellular concentration of Na^+ and Ca^{2+} increases whereas that of K^+ decreases. Between normal body temperature and this threshold, cooling is therapeutic. The application of therapeutic levels of cold can reduce cell degeneration and therefore limit the extent of tissue damage (31). The induction of mild hypothermia in the brain of a baby starved of oxygen at birth can interrupt the cascade of chemical processes that cause the neurons of the brain to die after being deprived of oxygen (32), reducing disability.

Collagen. Collagen becomes stiffer when cooled. People with rheumatoid arthritis generally experience a loss of mobility of their affected joints at low temperatures, due in part to increased stiffness of the collagen of their joint capsules (9).

Blood Flow. Lowering the skin temperature is detected by dermal thermoreceptors that initiate an autonomic reflex narrowing of the blood vessels of the skin (vasoconstriction). This results in reduction of the flow of blood to the dermis. Cold also has a direct constrictor effect on the smooth muscle of the blood vessels, and the arteriovenous anastomoses that shunt blood to the skin close. The resulting reduction in the flow of blood to the dermis diminishes heat loss through it. Countercurrent heat exchange between adjacent arteries and veins reduces heat loss.

These processes collectively reduce the rate at which the core temperature of the body falls.

Dermal vasoconstriction induced by lowering the temperature of the skin to approximately 10°C is followed after a few minutes by cold-induced vasodilatation (CIVD) followed by cycles of alternating vasoconstriction and vasodilatation, resulting in alternating decrease and increase on dermal blood flow. Originally thought to be either a local neurogenic axon reflex or due to the local release of vasodilator materials into the tissues, CIVD is now believed to be due to paralysis of vascular smooth muscle contraction in direct response to cold (33). This reaction may provide some protection to the skin from damage caused by prolonged cooling and ischemia. However, in CIVD of the skin, the erythema produced is a brighter red than in erythema produced by heating because at low temperatures, the bright red oxyhemoglobin dissociates less readily than at higher temperatures. Therefore, although in CIVD the skin receives oxygen-rich blood, it is still starved of oxygen, suggesting that cryotherapy may not aid wound healing (9).

In contrast to skin, the blood flow in the skeletal muscles is determined more by local muscle metabolic rate than by temperature changes at the skin because muscles are insulated from these by subcutaneous fat.

Neurological Effects. Cold can be used therapeutically to affect muscle tone and pain.

Muscle Tone. Although cooling generally decreases muscle tone, this can be preceded by a temporary increase in tone (34), possibly related to tactile stimulation accompanying the application of cryotherapy by means of ice massage. Decrease in muscle tone in response to cryotherapy is likely to be due to a decrease in muscle spindle sensitivity as the temperature falls, together with slowing of conduction in motor nerves and skeletal muscle fibers.

Pain Relief. The immediate response of the skin to cold is a stimulation of the sensations of cold and pain. However, if the cold is sufficiently intense, nerve conduction is inhibited, causing both sensations to be suppressed. Less intense cold can be used as a counterirritant, its effects being explicable by the pain gate theory of Wall and Melzack (35). Enkephalins and endorphins may also be involved (36).

Tissue Injury and Repair. Cryotherapy has beneficial effects on the acute inflammatory phase of healing in that it reduces bleeding, decreases edema at the injury site, gives pain relief, and reduces local muscle spasm, as described above. Once these events have occurred, it should be replaced by thermotherapy because, as previously described, this accelerates the resolution of acute inflammation leading to faster healing.

DEVICES AVAILABLE FOR PRODUCING TEMPERATURE CHANGE

Thermotherapy Devices

These can be classified into those producing superficial heating and those producing deep heating. All should be

Figure 1. Hydrocollator pack for moist heating by conduction. Each pack consists of silica gel covered by cotton fabric. After submersion in hot water, the pack is applied to the area to be heated over layers of terry cloth.

used with caution in patients unable to detect heat-induced pain or over tissues with a poor blood supply because these cannot dissipate heat efficiently.

Superficial Heating. This is provided by devices that transfer energy to the body by conduction, convection, or radiation (37).

Conduction. Devices that heat by conduction include hydrocollator packs, hot water bottles, electric heating pads, and baths of heated paraffin wax.

Hydrocollator packs Figs. 1 and 2 consist of cotton fabric bags containing a silica gel paste that absorbs water equal to 10 times its weight. They are placed in thermostatically controlled tanks of hot water, and after they have absorbed this, one or more packs are placed on towel-covered skin, into which heat is conducted until the pack has cooled, usually or 20–30 min, depending on the ambient temperature. Heat is also conducted into the subcutaneous tissues to a depth of about 5 mm. The transportation of blood warmed in the superficial tissues to deeper tissues may result in the latter also becoming warmer. Hot water bottles and thermostatically controlled electric heating pads act in a similar fashion.

Figure 2. Hydrocollator packs being heated in a thermostatically controlled tank containing hot water.

When and When Not to Use These Devices. They are useful in the relief of pain and muscle spasm. Abdominal cramps can be treated effectively through the induction of smooth muscle relaxation. Superficial thrombophlebitis and localized skin infections such as boils or furuncles may also be treated by heat conduction with these devices. It has been advised that these and other primarily heating devices should not be used over injured tissue within 36 h of the injury. Nor should they be used where there is decreased circulation, decreased sensation, deep vein thrombophlebitis, impaired cognitive function, malignant tumors, a tendency toward hemorrhage or swelling, an allergic rash, an open cut, skin infection, or a skin graft (<http://www.colonialpt.com/CPTFree.pdf>). A search of English-language textbook and peer-reviewed sources and computerized databases from January 1992 to July 2002 (38) has revealed “generally good agreement among contraindication sources for superficial heating devices”; however, agreement ranged from 11% to 95% and was lower for pregnancy, metal implants, edema, skin integrity, and cognitive/communicative concerns.

Advantages and Disadvantages. The moist heat produced by the hydrocollator packs has a greater sedative effect than the dry heat produced by the other conduction devices listed above. The hydrocollator packs are, however, heavy because of the amount of water they absorb and should not be applied to very frail patients, for example those with advanced osteoporosis. Hot water bottles occasionally leak, producing scalding and should therefore be inspected after filling and before each use. Electric pads should be thermostatically controlled and used with an automatic timer to reduce the risk of burning the skin.

Paraffin Wax Baths. Molten paraffin wax is mixed with liquid paraffin wax and kept molten in a thermostatically controlled bath (Fig. 3) at between 51.7 and 59.9 °C. Typically used for heating hands or feet, these are either dipped into the bath several times so that a thick layer of wax forms on them, or immersed in the bath for 20–30 min. After dipping, the hand or foot is wrapped in a cotton towel to retain the heat; after 20–30 min, the towel and wax are peeled off.

When and When Not to Use These Devices. Paraffin wax baths are suitable for treating small areas with irregular surfaces. The heat provides temporary relief of joint stiffness and pain in patients with chronic osteoarthritis and rheumatoid arthritis. By increasing the elasticity of collagen, it helps to increase soft-tissue mobilization in the early stages of Dupuytren’s contracture and after traumatic hand and foot injuries provided that the lesions have closed. Paraffin wax baths should not be used to open or infected wounds.

Advantages and Disadvantages. Molten paraffin wax is suitable for applying heat to small irregular surfaces such as those of the hands and feet. The baths can be used several times without changing the wax, and several patients can be treated at the same time if the baths are sufficiently large.

Figure 3. Paraffin wax bath used for heating hands and feet by the dip method.

A disadvantage is that the wax collects debris from the surface of the skin and other particles that settle at the bottom of the bath and are difficult to remove without emptying the bath. Treatments must be supervised and the temperature of the wax monitored to avoid the risk of burning.

Convection. This involves immersion of either the whole of the body or part of the body in heated water. Hubbard tanks (Fig. 4), hydrotherapy pools (Fig. 5), akin

Figure 4. Hubbard tank used for partial or total body submersion.

to heated swimming pools, and baths can be used for either total or partial immersion. The Hubbard tanks can be fitted with agitation devices. Some baths incorporate low-frequency ultrasound transducers. It is recommended that the water temperature should not exceed 40.6 °C when used for total immersion and 46.1 °C when used for partial immersion (1). Treatments typically last for 20–30 min.

Hydrotherapy is useful for treating multiple arthritic joints simultaneously and for treating extensive soft-tissue injuries. Although total immersion can raise the core body temperature, the main use of hydrotherapy is for the relief of pain, muscle spasm, and joint stiffness. Exercise regimes can be incorporated into hydrotherapy treatment to take advantage of the increase in joint movement made possible by the decrease in joint stiffness and the pain associated with movement. The addition of an agitation device to a Hubbard tank allows it to be used for the gentle debridement of burns, pressure ulcers, and other skin conditions, provided that thorough cleaning and disinfection of the tank are carried out between treatments. Baths incorporating low frequency (kHz) ultrasound transducers have the additional advantage that they can stimulate the repair process as well as assist in debridement.

The greater the surface of the body that is immersed, the greater the number of joints and the greater the area of skin and subcutaneous tissue that can be heated. Immersion also provides buoyancy, helping the patient to exercise more easily.

Disadvantages are that

- Each patient needs one-to-one supervision to ensure that the mouth and nose are kept free from water.
- The equipment is relatively expensive and is time-consuming to maintain.

Radiation. Heat transmission by radiation is generally provided by infrared lamps (Fig. 6). These are photon producers, emitting wavelengths from the red end of the visible part of the electromagnetic spectrum, together with IR. The production of visible light provides a visual indication when the lamps are active. The IR component provides heating.

Infrared emitters used for heating are either nonlaser or laser devices, the former being the most commonly used.

Nonlaser.

- Luminous
- Nonluminous

Luminous emitters are effectively light bulbs, each mounted in the center of a parabolic reflector that projects a bright beam like a floodlight. About 70% of the energy emitted consists of IR rays in the wavelength range of 700–4000 nm.

Luminous emitters can be classified into those with large, high-wattage (600–1500 W) bulbs, and those with smaller, lower wattage (250–500 W) bulbs.

1. The large luminous emitters are used to treat large regions of the body such as the lumbar spine. They

Figure 5. Hydrotherapy pool used for partial or total body submersion.

are positioned about 0.6 m from the patient and used for 20 min.

2. The small luminous emitters are used to treat smaller regions of the body such as the hands and feet.

Figure 6. Luminous generator infrared lamp used for superficial heating by radiation. The height and angle of the lamp can be adjusted.

They are positioned closer to the patient, about 0.45–0.5 m away, and they are typically used for 20 min.

The former produce a greater sensation of warmth than the latter. The skin becomes temporarily erythematous, resembling blushing. If the heat is too great because, for example, the lamp is too close to the skin, *erythema ab igne*, a mottled appearance indicative of damage, may be produced.

Nonluminous emitters are usually cylinders of either metal or an insulating material, the radiation source, around which a resistance wire, the heat source, is coiled. They emit longer wavelengths of IR that penetrate deeper than the shorter IR wavelengths of the luminous emitters. About 90% of the emission of the nonluminous IR device is in the wavelength range of 3500–4000 nm.

When and When Not to Use These Devices. IR radiation when used as a heating modality can alleviate pain and muscle spasm. It also accelerates the resolution of acute inflammation. It should not be applied to skin that is photosensitive. It should only be applied to skin free from creams that, if heated, could burn the skin. Goggles should be worn to protect the eyes from radiation damage to either the lens or retina. Patients with abnormally low blood pressure should not receive any form of treatment that increases the temperature of large areas of skin and subcutaneous tissue because of the redistribution of blood to these areas and away from vital organs such as the brain, heart, and lungs.

Advantages and Disadvantages. IR heating is suitable for use in the home as well as in clinics and hospitals. Because the devices described in this section are noncontact, they can be used to treat open and infected wounds, but only for short periods because they cause fluid evaporation and wounds need to be kept moist if they are to heal efficiently.

The main disadvantage is that of burning if the IR heater is placed too close to the patient. Only mechanically stable devices should be used to ensure that they do not fall on the patient.

Laser. Lasers emitting IR energy have been used to treat injured tissue in Japan and Europe for over 25 years (39). The term "LASER" is an acronym for light amplification by the stimulated emission of radiation. Laser devices are a very efficient means of delivering energy of specific wavelengths to injured tissue. Laser radiation is coherent; that is the waves are in phase, their peaks and troughs coinciding in time and space. Some semiconductor diodes produce coherent and others noncoherent IR radiation. Both can accelerate repair and relieve pain, as does red light (39). The technique of using low intensity lasers therapeutically is usually referred to as LILT, an acronym for low intensity laser therapy, or low level laser therapy (LLLT) to distinguish it from the surgical use of high intensity lasers. Surgical CO₂, ruby, and Nd-YAG surgical lasers can be used for thermal biostimulation provided that the amount of energy absorbed by the tissues is reduced sufficiently. Manufacturers achieve this either by defocusing and spreading the beam over an area large enough to reduce the power density below the threshold for burning or by scanning rapidly over the area to be treated with a narrow beam. The patient will then feel only a mild sensation of heat (39).

Nonsurgical lasers are typically used at power densities below those producing a sensation of heating; although their bioeffects are primarily nonthermal, absorption of light inevitably involves some heating. LILT can be used in either continuous or pulsed mode, the latter further reducing heating.

Single probes, each containing a single diode, are used to treat small areas of skin and small joints. Some are suitable for home use; their output is generally too low to produce the sensation of heat although the radiation they emit is transduced into heat after absorption. The effects of these devices on pain and tissue repair are essentially nonthermal. Clusters of diodes are used in clinics and hospitals to treat large areas of skin, skeletal muscle, and larger joints. These cluster probes generally include, in the interest of cost-effectiveness, nonlaser diodes. Treatment times vary with the type of probe and the area to be treated. Typically they range from about 3 to 10 min. They are calculated in terms of the time taken to deliver an effective amount of energy, generally 4 or more J · cm⁻², joules being calculated by multiplying the power density of the probe (in W · cm⁻²) by the irradiation time in seconds. The larger cluster probes have sufficient output to produce a sensation of warmth. They also have essentially nonthermal effects that assist in the relief of pain and the stimulation of tissue repair (39).

When and When Not to Use These Devices. LILT devices are effective on acute and chronic soft-tissue injuries of patients of all ages. Most are designed for use in clinics and hospitals, but small, handheld devices are also available for home use as part of a first aid kit. The radiation they produce is absorbed by all living cells and transduced into chemical and thermal energy within these cells, which are

activated by it. Temporary dilation of superficial blood vessels occurs, aiding oxygenation.

Contraindications for LILT have been described in some detail by Tuner and Hode (39). They include the following:

- As a matter of prudence, LILT should not be applied over the abdomen during pregnancy to ensure that no harm comes to the fetus although it can be applied to other parts of the body.
- In patients with epilepsy who may be sensitive to pulses of light in the 5–10 Hz range, it is advisable to use either unpulsed (continuous) LILT or much higher pulsing frequencies.
- Treatment over the thyroid gland is contraindicated because this gland may be sensitive to absorbed electromagnetic radiation in the red and IR parts of the spectrum.
- Patients with cancer or suspected cancer should only be treated by a cancer specialist.

Advantages and Disadvantages. LILT is easy to apply directly to the skin. The treatment is rapid and painless, the only sensations being of those of contact and, if the power is sufficiently high, of warmth. If used over an open wound, this should first be covered with a transparent dressing through which the radiation can pass unimpeded. The use of goggles is recommended as a precaution. The larger devices require clinical supervision, but some of the smaller predominantly nonthermal devices are suitable for home use.

Deep Heating. Deep heating devices produce heat within the tissues via electrostatic, electromagnetic, and acoustic fields. The term diathermy is used to describe the conversion or transduction of any form of energy into heat within the tissues. The devices used for deep heating include short-wave, microwave, and ultrasound generators. They are relatively expensive and should only be used by trained operators.

Short-Wave diathermy (SWD). SWD equipment Figs. 7 and 8 produces nonionizing radiation in the form of radio waves in the frequency range of 10–100 MHz. The most commonly used frequency is 27.12 MHz; this has a wavelength of 11 m.

SWD machines consist of:

- An oscillating circuit that produces the high frequency current
- A patient circuit connected to the oscillating circuit through which electrical energy is transferred to the patient
- A power supply

The patient's electrical impedance is a component of the patient circuit. Because the patient's electrical impedance is variable, the patient circuit must be tuned to be in resonance with the oscillating circuit to ensure maximum flow of current through the patient.

Figure 7. SWD equipment. The SW energy leaving the insulated disk-shaped applicators produces small eddy currents in the tissues, thus heating them.

The most commonly used means of application of SWD are as follows:

- The capacitor plate technique
- The inductive method

The capacitor plate technique entails the placement of two capacitor plates near to the part of the patient's body that is to be heated, with a spacer between each plate and

the skin. The spacer allows the electric radiation to diverge just before entering, preventing thermal damage to the surface of the skin. The current density depends on the resistance of the tissues and on capacitance factors. Both subcutaneous fat and superficial skeletal muscle can be heated with this technique. The patient feels a sensation of warmth. Treatment is usually for 20 min · day⁻¹.

In the inductive method, a high-frequency alternating current is applied to a coiled cable generally incorporated into an insulated drum that is placed close to the part of the body requiring treatment. Alternatively, but these days rarely, an insulated cable is wrapped around the limb to be treated. The passing of an electric current through the cable sets up a magnetic field producing small eddy currents within the tissues, increasing tissue temperature. The patient feels a sensation of warmth. Treatment is usually for 20 min · day⁻¹.

Pulsed Shortwave. Some SWD devices allow the energy to be applied to the patient in short pulses. This form of application is termed pulsed short-wave diathermy (PSWD). The only physical difference between SWD and PSWD is that in the latter the electromagnetic field is interrupted at regular intervals. Pulsing reduces the amount of energy available for absorption by the tissues and therefore reduces the thermal load, allowing its non-thermal effects to be exploited without the risk of a potentially damaging thermal overload. It has been suggested that the applied energy produces ionic and molecular vibration affecting cellular metabolism (40).

With some PSWD machines, the therapist can vary the:

- Pulse repetition rate (PRR)
- Pulse duration (PD)
- Peak pulse power (PPP).

The mean power applied is the product of these three variables.

Figure 8. Applicator heads for administration of SWD to produce deep heating of tissues.

Figure 9. Microwave diathermy equipment. The microwave generator contains a magnetron that produces high frequency alternating current. This current is carried by a coaxial cable shown on the left to a transducer (upper left) containing an antenna and a reflector. The antenna converts the electric current into microwaves that are collected by the reflector. This focuses them and beams them into the body, where they are transduced into heat.

Tissues with good conductivity, such as muscle and blood, i.e., with a high proportion of ions, should absorb energy preferentially from the SWD field. However, there is still debate about which tissues are heated the most during SWD and PSWD treatments.

Microwave Diathermy. Microwaves are that part of the electromagnetic spectrum within the frequency range of 300 MHz–300 GHz and, therefore, with wavelengths between 1 m and 1 mm. Microwave diathermy, although deeper than superficial (surface) heating, is not as deep as capacitative short-wave or ultrasonic heating (40).

Microwave generators (Fig. 9) contain a magnetron, which produces a high frequency alternating current that is carried to a transducer by a coaxial cable. The transducer consists of an antenna and a reflector. The electric current is transduced into electromagnetic energy on passing through the antenna. The reflector focuses this energy and beams it into the tissues to be heated (1).

On entering the body the microwave energy is absorbed, reflected, refracted, or transmitted according to the physical properties of the tissues in its path. When microwaves

are absorbed, their energy is transduced into heat. Tissues with a low water content (e.g., superficial adipose tissue) absorb little microwave energy, transmitting it into those with a high water content (e.g., skeletal muscle) that are very absorptive and therefore readily heated, warming adjacent tissues by conduction. As with SWD, there is no objective dosimetry, the intensity of treatment being judged by the patient's sensation of warmth (41).

When and When Not to Use These Devices. As with other forms of heating, SWD and microwave diathermy are used to relieve pain and muscle spasm. They are also used to stimulate repair.

According to the Medical Devices Agency of the United Kingdom, there are several groups of patients on whom these devices must not be used:

1. Those with implanted drug infusion pumps because the energy provided during therapy may affect the pump's electronic control mechanisms causing temporary alteration in drug delivery.
2. Women in the first trimester of pregnancy should not be treated with SWD because heating may be teratogenic.
3. Patients with metallic implants because metals are heated preferentially and may burn the surrounding tissue.
4. Patients fitted with active (i.e., powered) implants such as neurostimulators and cardiac pacemakers/defibrillators because there have been reports of tissue damage, including nerve damage adjacent to stimulation electrodes on implanted lead systems.
5. Patients with pacemakers are also unsuitable for SWD because the frequency of the short-wave may interfere with cardiac pacing.

Patients with rheumatoid arthritis have had their joint pain reduced and walking time increased after treatment with microwave diathermy, and it has been suggested that the heat produced in the joints may have potentiated the effects of concurrent anti-inflammatory medication (42).

In the interests of safety, microwave diathermy should be restricted to patients in whom skin pain and temperature sensation are normal. It should not be used near the eyes, sinuses, and moist open wounds, all of which could be heated excessively because of their high water content. Nor should it be used on any of the groups of patients in whom SWD is contraindicated.

Advantages and Disadvantages. The devices do not need to be in direct contact with the body; however, the body part being treated must be immobile during treatment because movement interferes with the field, resulting in too little heating in some regions and too much in other. Its disadvantages include its potential for burning tissue exposed to it due, for example, to treatment over regions in contact with metal. As with SWD, the therapist must be careful to avoid being exposed to the radiation, bearing in mind that some of the microwaves will be reflected from the patient.

Figure 10. Portable ultrasound therapy equipment. The ultrasound transducer is housed in the head of the applicator shown on the right.

Ultrasound. Ultrasound therapy devices (Fig. 10) designed to produce clinically significant tissue heating operate at 0.75–3.0 MHz, the lower frequencies mechanical waves being more penetrative and affecting deeper tissues than the higher frequency waves. The ultrasound (US) is produced by the reverse piezoelectric effect when a high frequency alternating current is applied to a ceramic crystal causing it to vibrate at the same frequency. The crystal is located inside an applicator fitted with a metal cap into which these vibrations pass. A coupling medium such as either water or a gel with a high water content transmits the ultrasonic vibration into the tissues. US is transmitted readily by water and by tissue fluids. As US is more readily absorbed by protein than by fat, it can be used to heat muscle and collagenous tissue selectively without heating subcutaneous fat to a clinically significant level. Heating occurs where the US energy is absorbed. If the US enters the tissue at an angle other than 90°, it is refracted; the transducer should therefore be held perpendicular to the surface being treated.

Absorption, and therefore heating, is greatest at higher frequencies. As a consequence, it is generally accepted that higher frequency US (e.g., 3 MHz) penetrates less deeply into the body than lower frequency US (e.g., 1 MHz). However, in some circumstances, 3 MHz may heat deeper tissues than originally theorized, when for example, it is transmitted into muscle over a bony prominence via a gel pad coated on both sides with an ultrasound transmitting gel (43). In this clinical investigation, it was found that 3 MHz ultrasound applied over the lateral malleolus of the ankle heated the musculotendinous tissue deep to the peroneal groove 0.5 cm deeper than suggested by others. The 3 MHz ultrasound produced heating deeper into muscle in healthy volunteers than did the 1 MHz ultrasound. This interesting but surprising observation may be an artifact due to variations in coupling of the US transducers to the skin. The authors point out that air trapped at the gel/pad interfaces might result not only in non-uniform heating but also in hot spots on the US transducer faceplate and possibly the skin.

In recent years, US therapy devices producing kilohertz US have been developed (6); these are more penetrative than the MHz devices but produce little heat, using the nonthermal effects of US to produce their effects (7).

When US enters tissue, its intensity gradually decreases as energy is lost from the US beam by absorption, scattering, and reflection. This lessening of the force of the US is termed attenuation. US is scattered by structures smaller than its wavelength. It is reflected at the interfaces between materials with different acoustic impedances, e.g., air and skin, collagen and ground substance, periosteum, and bone. Muscle and bone are preferentially heated at their interfaces with other tissues, e.g., tendon and periosteum. This is because mode conversion occurs when US waves are reflected from these interfaces, the longitudinal incident waves being changed into reflected transverse waves, creating additional heating. Therapists can take advantage of this enhanced thermal effect to target inflamed joints. The thickness of tissue through which the US must pass for its intensity to be reduced to half the level applied to its surface is termed the half-value thickness. The half-value thickness of 1 MHz US is theoretically three times more than that of 3 MHz US although artifacts during clinical use may alter this (43).

The intensity range of US necessary to elevate tissue temperature to between 40 and 45 °C is 1.0–2.0 W · cm⁻² applied in continuous mode for 5–10 min (44). This increase is in the generally accepted thermal therapeutic range. Temperatures exceeding this can cause thermal necrosis and must be avoided. In poorly vascularized tissues, even the upper end of the therapeutic range can produce thermal damage. When US is absorbed or when mode conversion occurs, heat is generated in the tissues. This produces local increases in blood flow and softens collagenous deposits such as those in scars.

If the temperature increase is less than 1 °C, this is not considered to be clinically significant. Therapeutic effects produced by US used in a manner that produces a temperature increase of less than 1 °C are considered to be predominantly nonthermal. These effects, which include stable cavitation and acoustic streaming (3,44), occur at intensities lower than those necessary to produce therapeutic increases in temperature. The amount of acoustic energy entering the tissues can be reduced by pulsing the US. A commonly used pulsing sequence is 2 ms ON, 8 ms OFF. By reducing the total amount of energy supplied to the tissues, the thermal load on these tissues is reduced. The intensity during the pulse is sufficient to permit the predominantly nonthermal therapeutic events to occur. This is of particular value when ultrasound is used to treat tissue with a blood supply too poor to ensure adequate heat dissipation via the circulation.

The nonthermal therapeutic effects of US include stable cavitation and acoustic streaming. Cavitation is the production of bubbles of gas a few microns in diameter in fluid media such as tissue fluid and blood. The bubbles increase in size during the negative pressure or rarefaction part of the US wave and decrease during the positive pressure part. If the intensity is sufficiently great, the bubbles collapse, damaging the tissues. At lower intensities, within the therapeutic range, the

cavities are stable and acoustic streaming is increased around them. Acoustic streaming has been shown to cause reversible changes in membrane permeability to calcium and other ions, stimulating cell division, collagen synthesis, growth factor secretion, myofibroblast contraction, and other cellular events that collectively accelerate the resolution of acute inflammation leading to more rapid tissue repair (3).

When and When Not to Use These Devices. US therapy is used as a thermotherapeutic modality to treat acute and chronic injuries of the

- Skin, e.g., pressure ulcers and venous ulcers
- Musculoskeletal system, e.g., arthritis, bursitis, muscle spasms, and traumatic injuries to both soft tissue and bone.

In addition to superficial injuries, US can be used to heat tissues at a considerable depth from the surface of the skin. Sites of pathology such as damaged skeletal muscle, tendon, and ligaments within 5 cm of the surface can be heated preferentially; any adipose tissue superficial to these lesions is heated less because it absorbs less US than highly proteinaceous muscle, tendons, and ligaments. It is the most suitable form of thermotherapy to use on deeply located areas of damage in obese patients. At least 3 treatments per week are generally recommended, daily treatment being preferable. The treatment head should be moved throughout treatment to reduce the possibility of thermal tissue damage due to local hot spots and mechanical damage due to standing wave formation.

In the interests of safety, continuous US should only be used to heat tissues in patients sensitive to heat-induced pain. In patients lacking this sensitivity, pulsed ultrasound can be used. Although this may not heat the tissues significantly, nonthermal events will occur that can accelerate healing (3,44).

It should not be used either over tumors because it can increase cell division or over the eye because of the risk of collapse cavitation. Nor should it be used on any of the groups of patients in whom SWD is contraindicated.

Advantages and Disadvantages. Its differential absorption makes it the therapy of choice for treating muscle, tendons, ligaments, and bone without heating superficial adipose tissue.

The effects of ultrasound are, however, local and only small regions can be treated because of the small size of the treatment heads, rarely greater than 5 cm². Another disadvantage is that a coupling medium such as water or a gel with a high water content must be used to transit the US from the applicator to the tissues. If there is an open wound, this must be covered with an ultrasound transmitting dressing such as Opsite to the surface of which the coupling medium can be applied. Alternatively the intact tissue adjacent to the wound and from which reparative tissue grows into the wound can be treated (3). Care must be taken to ensure that there are no bubbles in the coupling medium because reflection from these

can reduce the efficiency to energy transfer from the treatment head to the tissue. If the US energy is reflected back into the treatment head because of inadequate coupling, this will increase in temperature and could burn a patient, lacking adequate sensitivity to heat-induced pain.

Cryotherapy

Cryotherapy produces a rapid fall in the temperature of the skin and a slower fall in the temperature of the subcutaneous tissues, skeletal muscle, and the core temperature of the body. The rate of fall in skeletal muscle and the core temperature is dependent, in part, on the amount and distribution of adipose tissue. In a slender person with less than 1 cm of adipose tissue in the hypodermis, cooling extends almost 2.5 cm into the skeletal muscle after 10 min of applying cryotherapy to the skin surface. In an obese person with more than 2.5 cm of adipose tissue in the hypodermis, cooling extends only 1 cm into the muscle in the same time (1). To get deeper cooling in an obese person, the cooling agent must be applied for longer than in a slender person, for example, 30 min compared with 10 min to get adequate cooling extending 2.5 cm into the muscle. This concept has been confirmed recently by Otte et al. (45) who found that although 25 min of treatment may be adequate for a slender patient with a skinfold of 20 mm or less, 40 min is needed if the skinfold is between 21 and 30 mm, and 60 min if the skinfold is between 30 and 40 mm. The subcutaneous adipose tissue thickness is an important determinant of the time required for cooling in cryotherapy.

Cryotherapy is used to relieve pain, retard the progression of secondary injury, and hasten return to participation in sport and work. In a literature review by Hubbard et al. in 2004 (46), the conclusion drawn was that cryotherapy may have a positive effect on these aims, but attention was drawn to the relatively poor quality of the studies reviewed. There is a clear need for randomized, controlled clinical studies of the effect of cryotherapy on acute injury and return to participation in sport or work.

The main equipment used in cryotherapy is a refrigerator/freezer necessary for cooling gels and for producing ice. The ice is mixed with water, reducing the temperature of the water to just above its freezing point. The temperature of an injured limb can be reduced by immersing it in this ice/water mixture, an effective but initially uncomfortable experience for the patient. Alternatively, a cold compress containing the mixture can be applied to the region to be cooled. Also, a terry cloth can be soaked in the mixture, wrung out, and then applied. Blocks of ice can be used to massage an injured area if the skin over the injury is intact, an initially uncomfortable experience for both patient and therapist.

Another technique is to spray a vapor coolant on the skin. As the coolant evaporates, the temperature of the skin is reduced, but there is no clinically significant cooling of subcutaneous tissues. Ethylene chloride, chlorofluoromethane, or preferably a non-ozone-depleting vapor coolant, is sprayed over the area to be treated in a stroking fashion at a rate of about 1 cm · s⁻¹ (1). Concern over the ozone-depleting properties of chlorofluorocarbons has led

to the development of vapor coolant sprays that are not ozone-depleting (<http://www.gebauerco.com/Default.asp>) and that may be substituted for those noted above.

When and When Not to Use Cooling. The main use of cryotherapy is after acute skin and musculoskeletal injury to reduce swelling, bleeding, and pain. It helps give temporary relief to painful joints. It also reduces muscle spasms and spasticity, again temporarily. Trigger points, myofascial pain, and fibrositis may be treated with vapor coolant sprays.

Cooling is an excellent way of minimizing the effect of burns and scalds by reducing the temperature at the injury site provided that it is done as soon as possible after the incident. It can also slow brain damage after the deprivation of oxygen in, for example, babies for whom delivery has been prolonged and difficult. A cool cap filled with chilled water is placed on the baby's head within a few hours of birth and kept there for several days while the baby is in intensive care. A computerized controller circulates cold water through the cap, reducing the temperature of the brain by several degrees, minimizing cell death within the brain. The results of a clinical trial showed a significantly lower disability and death rate in children at risk of post-natal brain damage due to oxygen deprivation if they were given this treatment than in those whose brains had not been cooled in this way (47). It has been suggested that a similar technique may help patients with hemorrhagic strokes where bleeding has occurred on to the surface of the brain.

Mild systemic hypothermia has also been reported to reduce brain damage after severe head trauma. Patients in whom the core temperature was reduced to and maintained at 33–35 °C with a cooling blanket for 4 days had reduced extradural pressure, an increase in the free radical scavenger superoxide dismutase, and consequently, less neuron loss and improved neurological outcomes (48).

Retarding secondary injury is an important benefit of cryotherapy. Secondary tissue death occurring after the initial trauma has been attributed to subsequent enzymatic injury and hypoxic injury (23). Cryotherapy reduces tissue temperature, slowing the rate of chemical reactions and therefore the demand for adenosine triphosphate (ATP), which in turn decreases the demand for oxygen, leading to longer tissue survival during hypoxia. By decreasing the amount of damaged and necrotic tissue, the time taken to heal may be reduced. In an extensive review of the secondary injury model and the role of cryotherapy, Merrick et al. (24) addressed the following question: "Is the efficacy of short-term cryotherapy explained by rescuing or delaying the death of the cells that were primarily injured but not initially destroyed?" He recommended the replacement of the term "secondary hypoxic injury" by "secondary ischemic injury" because hypoxia presents tissue with the challenge of reduced oxygen only, whereas ischemia presents inadequacies in not only oxygen but also fuel and anabolic substrates and in waste removal, all of which may contribute to secondary injury. Short-term cryotherapy may lessen the demand for these necessities.

Cooling should not be used:

- In people who are hypersensitive to cold-induced pain

- Over infected open wounds
- In people with a poor circulation

Advantages and Disadvantages. Disadvantages are that many people find prolonged exposure to cold therapy uncomfortable. Frostbite can occur if the skin freezes, as is possible if vapor coolant sprays are overused. Furthermore, its effects on chronic inflammatory conditions are generally temporary.

SUMMARY

Changing the temperature of tissues can reduce pain, muscle spasms, spasticity, stiffness, and inflammation. Heating the tissues by a few degrees centigrade increases tissue metabolism and accelerates the healing process. Cooling tissue by a few degrees centigrade can limit secondary damage to soft tissues, nerves, and the brain after trauma.

The correct selection of either thermotherapy or cryotherapy depends on an understanding of the physiological effects of heat and cold, and on knowledge of the patient's medical condition. It is suggested that acute skin lesions and musculoskeletal injuries be treated:

- First by the application of cold as soon as possible after the injury to limit its extent
- Followed a few hours later by the application of moderate heat to accelerate the resolution of inflammation enabling healing to progress more rapidly.

It is recommended that the progress of healing be monitored noninvasively so that treatment can be matched to the response of the injury. In recent years this has become possible by means of high resolution diagnostic ultrasound or ultrasound biomicroscopy (49).

Having decided which is required, heat or cold, the next question is which modality to use. The following should be considered:

- Size and location of the injury
- Type of injury
- Depth of penetration of the modality
- Ease of application
- Duration of application
- Affordability
- Medical condition of the patient
- Contraindications

Patients heal their own injuries if they can to. This can be facilitated by the timely and correct application of therapeutic heat or cold. Their pain can also be relieved, improving their quality of life.

INTRODUCTION

“Arterial blood pressure and flow result from the interaction of the heart and the arterial system. Both subsystems should be considered for a complete hemodynamic profile and a better diagnosis of the patient’s disease”. This statement seems common sense, and a natural engineering approach of the cardiovascular system, but is hardly applied in clinical practice, where clinicians have to deal with limitations imposed by the clinical environment and ethical and economical considerations. The result is that the interpretation of arterial blood pressure is (too) often restricted to the interpretation of systolic and diastolic blood pressure measured using the traditional cuff around the upper arm (cuff sphygmomanometry). Blood flow, if even measured, is usually limited to an estimate of cardiac output.

The purpose of this article is to provide the reader with an overview of both established and newer methods and techniques that allow us to gain more insight into the dynamics of blood flow in the cardiovascular system (the hemodynamics), based on both invasive and noninvasive measurements. The emphasis is that hemodynamics results from the interaction between the action of the heart and the arterial system, and can be analyzed as the interplay between a (complex) pump and a (complex) tube network. This article, has been divided into three main sections. First the (mechanical function of the) heart is considered, followed by a major section on arterial function analysis. The final section deals with cardiovascular interaction.

THE HEART AS A PUMP...

The heart is a hollow muscle, consisting of four chambers, whose function is to maintain blood flow in two circulations:

the systemic (or large) and the pulmonary circulation. The left atrium receives oxygenized blood from the lungs via the pulmonary veins. Blood flows (through the mitral valve) into the left ventricle, where it is pumped into the aorta (through the aortic valve) and distributed toward the organs, tissue, and muscle for exchange of O₂ and CO₂, nutrients, and waste products. Deoxygenated blood is collected via the systemic veins (ultimately the inferior and superior vena cava) into the right atrium and flows, via the tricuspid valve, into the right ventricle, where it is pumped (through the pulmonary valve) into the pulmonary artery toward the lungs. Functionally, the pulmonary and systemic circulation are placed in series, and there is a “serial interaction” between the left and right heart. Anatomically, however, the left and right heart are embedded within the pericardium (the thin membrane surrounding the whole heart) and are located next to each other. The part of the cardiac muscle (myocardium) that they have in common is called the myocardial septum. Due to these constraints, the pumping action of one chamber has an effect on the other, a form of “parallel interaction”. In steady-state conditions, the left and right heart generate the same flow (cardiac output), on average ~6 L/min in an adult at rest.

The Cardiac Cycle and Pressure–Volume Loops

The most heavily loaded chamber is the left ventricle (LV), pumping ~80 mL of blood with each contraction (70 beats · min⁻¹), with intraventricular pressure increasing from ~5–10 mmHg (1 mmHg = 133.3 Pa) at the onset of contraction (i.e., at the end of the filling period or diastole) to 120 mmHg (6.0 kPa) in systole (ejection period) (Fig. 1). In heart physiology research, it is common to study the function of the ventricle using pressure–volume loops (PV loops; Fig. 1), with volume on the *x* axis and pressure on the *y* axis. Considering the heart at the end of diastole, it has reached its maximal volume (EDV; end-diastolic volume). Specialized pacemaker cells within the heart generate the (electrical) stimulus for the contraction, initiating the depolarization of cardiac muscle cells (myocytes). Electrical depolarization causes the muscle to contract and ventricular pressure increases. With this, the mitral valve closes, and the ventricle contracts at closed volume, with a rapidly increasing pressure (isovolumic contraction). When LV pressure becomes higher than the pressure in the aorta, the aortic valve opens, and the ventricle ejects blood. The ventricle then starts its relaxation, slowing down the ejection, with a decrease in LV pressure. At the end of ejection, the LV has reached its end-systolic volume (ESV), and LV pressure drops below the pressure in the aorta, closing the aortic valve. Relaxation then (rapidly) takes place at closed volume (isovolumic relaxation), until LV pressure drops below LA pressure and LV early filling begins (E-wave). After complete relaxation of the ventricle, contraction of the LA is responsible for an extra (late) filling wave (A-wave). The difference between EDV and ESV is the stroke volume, SV. Multiplied with heart rate, one obtains cardiac output (CO), the flow generated by the heart, commonly expressed in L · min⁻¹. The time course of cardiac and arterial pressure and flow is shown in Fig. 1.

Figure 1. The heart (a), and the variation in time of pressure, flow, and volume within the left ventricle (b). Plotting left ventricular pressure as a function of volume (c), a pressure–volume loop is obtained. (d) Illustrates the association between area’s defined within the pressure–volume plane and the mechanical energy.

Time Varying Elastance and Cardiac Contractility

The intrinsic properties of cardiac muscle are responsible for making the functional pumping performance of the ventricle determined by different factors (1): the degree to which the cardiac muscle is prestretched prior to contraction (preload), the intrinsic properties of the muscle (the contractility or inotropy), the load against which the heart ejects (the afterload), and the speed with which the contraction takes place (reflected by the heart rate; chronotropy). In *muscle physiology*, preload is muscle length and is related to the overlap distance of the contractile proteins (actin and myosin) of the sarcomere (the basic contractile unit of a muscle cell), while afterload is the load against which a muscle strip or fiber contracts. In *pump physiology*, ventricular end-diastolic volume is often considered as the best approximation of preload (when unavailable, ventricular end-diastolic pressure can be used as a surrogate). To characterize afterload, one can estimate maximal ventricular wall stress (e.g., using Laplace formula), but most often, mean or systolic arterial blood pressure is taken as a measure of afterload.

Most difficult to characterize is the intrinsic contractility of the heart, which is important to know in diagnosing the severity of cardiac disease. At present, the gold standard is still considered to be the slope of the end-systolic pressure–volume relation (2,3). To fully comprehend this measure, the time varying elastance concept has to be introduced.

Throughout a cardiac cycle, cardiac muscle contracts and relaxes. The functional properties of fully relaxed muscle-at the end of diastole-can be studied in the pressure–volume plane. This relation, sometimes called the (end-) diastolic pressure–volume relation (EDPVR), is nonlinear, that is, for higher volumes, a higher increase in pressure (ΔP) is required to realize a given increase in volume (ΔV). With the volume/pressure ratio defined as compliance, the ventricle behaves less compliant (stiffer) at high volume. The EDPVR represents the passive properties of the ventricular chamber.

Similarly, if one could “freeze” the ventricle at its maximal contraction (as is reached at the end of systole), and measure the pressure–volume relation of the chamber in

this maximally contracted state, one could assess the (end-) systolic pressure–volume relation (ESPVR) and the maximal stiffness of the ventricle. The ESPVR represents the active, contractile function of the ventricle. Throughout the cycle, the stiffness (or elastance) of the ventricle varies in between its diastolic and end-systolic value, hence the conceptual model of the time-varying elastance (Fig. 2).

The basis of this time-varying elastance model was laid by Suga et al. in the 1970s. They performed experiments in isolated hearts, and found that by increasing the initial volume of the heart (increasing preload), the maximally developed pressure in an isovolumic beat increased linearly with preload (2,3) (Frank–Starling mechanism). Obviously, the minimal pressure, determined by the passive properties, also increased. When they allowed these ventricles to eject against a quasiconstant afterload pressure, PV loops were obtained, with wider loops (higher stroke volume) being obtained for the more filled ventricles. When connecting all end-systolic points of the PV loops, it was found that the slope of this line, the end-systolic ventricular stiffness, was not different from the line obtained with the isovolumic experiments, demonstrating that it is independent of the load against which the ventricle ejects. Moreover, connecting data points on the PV loops occurring at the same instant in the cardiac cycle (isochrones), these points were also found to line up (Fig. 2). The slopes of these lines have the dimension of stiffness ($\Delta P/\Delta V$; mmHg·mL⁻¹ or Pa·mL⁻¹) or elastance (E). In addition, it is often assumed that these isochrones all have the same intercept with the volume axis (which is, however, most often not the case). This volume is called V_0 and represents the volume for which the ventricle no longer develops any pressure.

The slope of the isochronic lines, E , is given by $E = P/(V - V_0)$ and can be plotted as a function of time, yielding the time varying elastance curve, $E(t)$ (Fig. 2). The experiments of Suga and co-workers further pointed out that the maximal slope of the ESPVR, also called end-systolic (E_{es}) elastance, is sensitive to inotropic stimulation. The parameter E_{es} is, at present, still considered as the gold standard measurement of ventricular contractility.

Since these experiments, it has been shown that the ESPVR is not truly linear (4,5), especially not in conditions of high contractility or in small mammals. Since V_0 is a value derived from linear extrapolation of the ESPVR, one often finds negative values, which clearly have no physiological meaning at all. Nevertheless, the time varying elastance remains an attractive concept to concisely describe ventricular function. In practice, PV loops with altered loading conditions are obtained via inflation of a balloon in one of the caval veins, reducing venous return, or with a Valsalva maneuver. The PV loops can be measured invasively with a conductance catheter (6), or by combining intraventricular pressure (measured with a catheter) with volumes measured with a medical imaging technique that is fast enough to measure instantaneous volumes during the load manipulating operations (e.g., echocardiography).

The area enclosed within the PV loop is the work performed by the heart per stroke (stroke work, SW). Furthermore, when the heart contracts, it pressurizes the volume within the ventricle, giving it a potential energy (PE). In the PV plane, PE is represented by the area enclosed within the triangle formed by V_0 on the volume axis, the end-systolic point, and the left bottom corner of the PV loop (Fig. 1). The sum of SW and PE is also called the total pressure–volume area (PVA) and it has been shown

Figure 2. Pressure–volume loops recorded in the left ventricle during transient loading conditions (a), and the concept of the time-varying elastance (b). (c) Illustrates an alternative representation of ventricular function through the pump function graph.

that the consumption of oxygen by the myocardium, VO_2 , is proportional to PVA: $VO_2 = c_1PVA + c_2E_{es} + c_3$, with c_{1-3} constants to be determined from experiments. The constant c_1 represents the O_2 cost of contraction, c_2 is the O_2 cost of Ca handling related to the inotropic state, and c_3 is the O_2 cost of basal metabolism. Mechanical efficiency can then be expressed as the ratio of SW and VO_2 . Recent reviews of the relation between pressure–volume area and ventricular energetics can be found in Refs. 7,8.

Another measure of ventricular function, also derived from PV loop analysis, is the so-called preload recruitable stroke work (PRSW) (9). Due to the Frank–Starling effect (10), a ventricle filled up to a higher EDV will generate a higher pressure and/or stroke volume, and hence a higher SW. Plotting SW as a function of EDV yields a quasilinear relation, of which the slope is sensitive to the contractile state of the ventricle (9).

Alternative Ways of Characterizing LV Systolic Function

Pump function of the ventricle may also be approached in a way similar to hydraulic pumps through its pump function graph (11,12), where the pressure generated by the pump (e.g., mean LV pressure) is plotted as a function of its generated flow (cardiac output). With no outflow, the ventricle contracts isovolumically, and the highest possible pressure is generated. Pumping against zero load, no pressure is built up, but outflow is maximal. The ventricle operates at some intermediate stage, in between these two extreme cases (Fig. 2). One such pump function curve is obtained by keeping heart rate, inotropy, and preload constant, while changing afterload. Although the principle is attractive, it appears to be difficult to measure pump function curves *in vivo*, even in experimental conditions.

Assessing Cardiac Function in Real Life

Although pressure–volume loop-based cardiac analysis still has the gold standard status in experimental work, the applicability in clinical conditions is rather limited. First, the method requires intraventricular pressure and volume. While volumes can, more and more, be measured noninvasively with magnetic resonance imaging (MRI) and even real-time three-dimensional (3D) echocardiography, the pressure requirement still implies invasive measurements. Combined pressure–volume conductance catheters are available (6), but these require calibration to convert conductance into volume data. This requires knowledge of the conductance of the cardiac structures and blood outside the cardiac chamber under study (offset correction), and an independent measurement of stroke volume for scaling of the amplitude of the conductance signal. Second, and perhaps even more important, measuring preload-recruitable stroke work or the end-systolic pressure–volume relation requires that PV loops are recorded during transient loading conditions, which is experimentally obtained via inflation of a balloon in the caval vein to reduce the venous return and cardiac preload. It is difficult to (ethically) justify an extra puncture and the insertion of an additional catheter in patients, knowing also that these maneuvers induce secondary changes in the overall autonomic state of the patient and the release of catecholamines,

making this method limited to assess the pump function in a “steady state”. To avoid the necessity of the caval vein balloon, so-called “single beat” methods have been proposed, where cardiac contractility is estimated from data measured at baseline steady-state conditions (13,14). The accuracy, sensitivity, and specificity of these methods, however, remains a matter of debate (15,16).

Since it is easier to measure aortic flow than ventricular volume, indices based on the concept of “hydraulic power” have been proposed. As the ventricle ejects blood, it generates hydraulic power (P_{wr}), which is calculated as the instantaneous product of aorta pressure and flow. The peak value of power ($P_{wr,max}$) has been proposed as a measure of ventricular performance. However, due to the Frank–Starling mechanism, ventricular performance in general, and hydraulic power in particular, is highly dependent on the filling state of the ventricle, and correction of the index for EDV is mandatory. Preload-adjusted maximal power, defined as $P_{wr,max}/EDV^2$, has been proposed as a “single beat” (i.e., measurable during steady-state conditions) index of ventricular performance (17). It has, however, been suggested that the factor 2 used in the denominator is not a constant, but depends on ventricular size (18). It has been demonstrated that the most correct approach is to correct $P_{wr,max}$ for $(EDV - V_0)^2$, V_0 being the intercept of the end-systolic pressure–volume relation (19,20). Obviously, the index then loses its main feature, that is, the fact that it can be deduced from steady-state measurements.

In clinical practice, cardiac function is commonly assessed with ultrasound echocardiography in its different modalities. Imaging the heart in two-dimensional (2D) planar views (2 and 4 chamber long axis views, short axis views), allows us to visually inspect ventricular wall motion and to identify noncontracting zones. With (on-board) image processing software, parameters such as ejection fraction or the velocity of circumferential fiber shortening can be derived. Echocardiography has played a major role in quantifying “diastolic function”, that is, the filling of the heart (21,22). Traditionally, this was based on the interpretation of flow velocity patterns at the mitral valve (23) and the pulmonary veins (24). With the advent of more recent ultrasound processing tools, the arsenal has been extended. Color M-mode Doppler, where velocities are measured along a base-to-apex directed scanline, allows us to measure the propagation velocity of the mitral filling wave (25,26). More recent, much attention has been and is being paid to the velocity of the myocardial tissue (in particular the motion of the mitral annulus) (27). Further processing of tissue velocity permits us to estimate the local strain and strain rate within sample volumes positioned within the tissue. Strain and strain rate imaging are new promising tools to quantify local cardiac contractile performance (28,29). Further advances are directed toward real time 3D imaging with ultrasound and quantification of function. Some of the aforementioned ultrasound modalities are illustrated in Fig. 3.

An important domain where assessment of cardiac function is important, is in the catheterization laboratory (cath-lab), where patients are “catheterized” to diagnose and/or treat cardiovascular disease. Access to the vasculature is gained via a large vein (the catheter then ends in the right

Figure 3. Echocardiography of the heart. (29)]; (d) real-time 3D visualization of the mitral valve with the GE Dimension. (Courtesy of GE Vingmed ultrasound, Horten, Norway.)

atrium/ventricle/pulmonary artery: right heart catheterization) or large artery, typically the femoral artery in the groin (the catheter then resides in the aorta/left ventricle/left atrium: left heart catheterization). Cath-labs are equipped with X-ray scanners, allowing us to visualize cardiovascular structures in one or more planes. With injection of contrast medium, vessel structures (e.g., the coronary arteries) can be visualized (angiography) as well ventricular cavity (ventriculography). The technique, through medical image processing, allows us to estimate ventricular volumes at high temporal resolution. At the same time, arterial pressures can be monitored. Although one cannot deduce intrinsic ventricular function from pressure measurements alone, it is common to use the peak positive (dp/dt_{\max}) and peak negative value (dp/dt_{\min}) of the time derivative of ventricular pressure as surrogate markers of ventricular contractility and relaxation, respectively. These values are, however, highly dependent on ventricular preload, afterload, and heart rate, and only give a rough estimate of ventricular function. Measurement of dp/dt_{\max} or dp/dt_{\min} at different loading states, and

assessing the relation between changes in volume and changes in dp/dt , may compensate for the preload dependency of these parameters.

There are also clinical conditions where the physician is only interested in a global picture of cardiac function, for example, in intensive care units, where the principal question is whether the heart is able to deliver a sufficient cardiac output. In these conditions, indicator-dilution methods are still frequently applied to assess cardiac output. In this method, a known bolus of indicator substance (tracer) is injected into the venous system, and the concentration of the substance is measured on the arterial side (the dilution curve), after the blood has passed through the heart/cardiac output = [amount of injected indicator]/[area under the dilution curve]. A commonly used indicator is cold saline, injected into the systemic veins, and the change in blood temperature is then measured with a catheter equipped with a thermistor, positioned in the pulmonary artery. This methodology is commonly referred to as "thermodilution". With valvular pathologies, as tricuspid or pulmonary valve regurgitation, the method becomes less

accurate. The variability of the method is quite high, and the method should be repeated (three times or more) so that results can be averaged to provide a reliable estimate. Obviously, the method only yields intermittent estimates of cardiac output. Cardiac output monitors based on other measuring principles are in use, but their accuracy and/or responsiveness is still not optimal and they often require a catheter in the circulation (30,31).

Finally, it is also worth mentioning that cardiac MRI is an emerging technology, able to provide full 3D cardiac morphology and function data (e.g., with MRI tagging) (32,33). Especially for volume estimation, MRI is considered the gold standard method, but new modalities also allow us to measure intracardiac flow velocities. The high cost, the longer procedure, the fact that some materials are still banned from the scanner (e.g., metal containing pacemakers) or cause image artifacts and the limited availability of MRI scanner time in hospitals, however, make that ultrasound is still the first method of choice. For reasons of completeness, computed tomography (CT) and nuclear imaging are mentioned as medical imaging techniques that provide morphological and/or functional information on cardiac function.

The Coronary Circulation

The coronary arteries branch off the aorta immediately distal to the aortic valve (Fig. 4), and supply blood to the heart muscle itself. With their specific anatomical position, they are often considered as part of the heart, although they could as well be considered as being part of the arterial circulation. This ambiguity is also reflected in the medical specialism: coronary artery disease is the territory of the

(interventional) cardiologist, and not of the angiologist. The right coronary artery mainly supplies the right heart, while the left coronary artery, which bifurcates into the left anterior descending (LAD) and left circumflex (LCX) branch, mainly supplies the left heart.

As they have to perfuse the cardiac muscle, the coronaries protrude the ventricular wall, which has a profound effect on coronary hemodynamics (34,35). Upon ventricular contraction, blood flow in the coronaries is impeded, leading to a typical biphasic flow pattern, with systolic flow impediment, and predominantly flow during the diastolic phase (Fig. 4). This pattern is most obvious in the LAD, which supplies oxygenized blood to the left ventricle. The resistance of the coronary arteries is thus not constant in time, and contains an active component. When coronary flow is plotted as a function of coronary pressure, other typical features for the coronary circulation are observed. Under normal conditions, coronary flow is highly regulated, so that blood flow is constant for a wide range of coronary perfusion pressures (35,36). The level up to which the flow is regulated is a function of the activity of the ventricle, and hence of the metabolic demands. This seems to suggest that at least two different mechanisms are involved: metabolic autoregulation (flow is determined by the metabolic demand) and myogenic autoregulation. Myogenic autoregulation is the response of a muscular vessel on an increase in pressure: the vessel contracts, reducing its diameter and increasing its wall thickness, which tends to normalize the wall stress. It is only after maximal dilatation of the coronary vessels [e.g., through infusion of vasodilating pharmacological substances such as adenosine or papaverine, or immediately following a period of oxygen deficiency (ischemia)] that autoregulation

Figure 4. (a) Anatomical situation of the coronary arteries. (b) Demonstration of flow impediment during systole. (c) Coronary flow as a function of perfusion pressure, demonstrating the aspect of autoregulation and the non-zero intercept with the pressure axis (P_{zf} ; zero-flow pressure). (Reconstructed after Ref. 36.)

can be “switched off”, and that the pressure-flow relation becomes linear (Fig. 4). Note, however, that the pressure-flow relation does not pass through the origin: it requires a certain pressure value (zero-flow pressure P_{zf}) to generate any flow, an observation first reported by Bellamy et al. (37). The origin of P_{zf} is still not fully understood and has been attributed to (partial) vessel collapse by vascular tone and extravascular compression. This is a conceptual model, also known as the “waterfall” model, as flow is determined by the pressure difference between inflow and surrounding pressure (instead of outflow pressure) and pressure changes distal to the point of collapse (the waterfall) have no influence on flow (38,39). Note, however, that P_{zf} is often an extrapolation of pressure-flow data measured in a higher pressure range. It is plausible that the relation becomes nonlinear in the lower perfusion pressure range, due to the distensibility of the coronary vessels and compression of vessels due to intramyocardial volume shifts (35). Another model, based on the concept of an intramyocardial pump and capable of explaining phasic patterns of pressure and flow waves, was developed by Spaan et al. (35,40), and is mentioned here for reasons of completeness.

An important clinical aspect of the coronary circulation, which we will only briefly touch here, is the assessment of the severity of coronary artery stenosis (34). The stenosis forms an obstruction to flow, causes an extra pressure drop, and may result in coronary perfusion pressures too low to provide oxygen to the myocardial tissues perfused by that coronary artery. Imaging of the coronary vessels and the stenosis with angiography (in the cath-lab) is still an important tool for clinical decision making, but more and more attention has been attributed to quantification of functional severity of the stenosis. One of the most known indices in use are the coronary flow reserve (CFR), that is, the ratio of maximal blood flow (velocity) through a coronary artery (after induction of maximal vasodilation) and baseline blood flow (velocity), with values > 2 indicating sufficient reserve and thus a subcritical stenosis. Coronary flow reserve has the drawback that flow or velocity measurements are required, which are not common in the cath-lab. From that perspective, the fractional flow reserve (FFR) is more attractive, as it requires only pressure measurements. It can be shown that $FFR = P_d/P_a$ (with P_d the pressure distal to the stenosis and P_a the aorta pressure) is the ratio of actual flow through the coronary, and the hypothetical flow that would pass through the coronary in the absence of the stenosis (34,41). A FFR value > 0.75 indicates nonsignificant stenosis (34). Measurement of FFR is done in conditions of maximal vasodilation, and requires ultrathin pressure catheters (pressure wires) that can pass through the stenosis without causing (too much) extra pressure drop. Other indices combine pressure and flow velocity (42) and are, from fluid dynamic perspective, probably the best characterization of the extra resistance created by the stenosis. It deserves to be mentioned that intravascular ultrasound (IVUS) is, currently, increasingly being applied, especially when treating complex coronary lesions. In addition to quantifying stenosis severity, much research is also focused on assessing the histology of the lesions and their vulnerability and risk of rupture via IVUS or other techniques.

THE ARTERIAL SYSTEM: DAMPING RESERVOIR AND/OR A BLOOD DISTRIBUTING NETWORK...

Basically, there are two ways of approaching the arterial system (43): (1) one can look at it in a “lumped” way, where abstraction is being made of the fact that the vasculature is a network system with properties distributed in space; or (2) one can take into account the network topology, and analyze the system in terms of pressure and flow waves propagating along the arteries in a forward and backward direction.

Irrespective of the conceptual framework within which one works, the analysis of the arterial system requires (simultaneously measured) pressure and flow, preferably measured at the upstream end of the arterial tree (i.e., immediately distal to the aortic valve). The analysis of the arterial system is largely analogous to the analysis of electrical network systems, where pressure is equivalent to voltage and flow to current. Also stemming from this analogy is the fact that the arterial system is often analyzed in terms of impedance. Therefore, before continuing, the concept of impedance is introduced.

Impedance Analysis

While electrical waves are sine waves, with a zero time-average value, arterial pressure and flow waves are (approximately) periodical, but certainly nonsinusoidal, and their average value is different from zero (in humans, mean systemic arterial blood pressure is ~ 100 mmHg (13.3 kPa), while mean flow is ~ 100 mL \cdot s $^{-1}$). To bypass this limitation, one can use the Fourier theorem, which states that any periodic signal, such as arterial pressure and flow, can be decomposed into a constant (the mean value of the signal) and a series of sinusoidal waves (harmonics). The frequency of the first harmonic is cardiac frequency (the fundamental frequency), while the frequency of the n th harmonic is n times the fundamental frequency.

Fourier decomposition is applicable if two conditions are fulfilled: (1) the cardiovascular system operates in steady-state conditions (constant heart rate; no respiratory effects); (2) the mechanical properties of the arterial system are sufficiently linear so that the superposition principle applies, meaning that the individual sine waves do not interact and that the sum of the effects of individual harmonics (e.g., the flow generated by a pressure harmonic) is equal to the effect caused by the original wave that is the sum of all individual harmonics.

Harmonics can be represented using a complex formalism. For the n th harmonic, the pressure (P) and flow (Q) component can be written as

$$P_n = |P_n|e^{i(n\omega t + \Phi_{P_n})} \quad Q_n = |Q_n|e^{i(n\omega t + \Phi_{Q_n})}$$

where $|P_n|$ and $|Q_n|$ are the amplitudes (or modul) of the pressure and flow sine waves, having phase angles Φ_{P_n} and Φ_{Q_n} (to allow for a phase lag in the harmonic), respectively. Time is indicated by t , and ω is the fundamental angular frequency, given by $2\pi/T$ with T the duration of a heart cycle (RR-interval). For a heart rate of 75 beats \cdot min $^{-1}$, T is 0.8 s. The fundamental frequency is 1.25 Hz, and ω becomes 7.85 rad \cdot s $^{-1}$.

In general, 10–15 harmonics are sufficient to describe hemodynamic variables, such as pressure, flow, or volume

(44,45). Also, to avoid aliasing, the sampling frequency should be twice as high as the frequency of the signal one is measuring (Nyquist limit). Thus, when measuring hemodynamic data in humans, the frequency response of the equipment should be $> 2 \times 15 \times 1.25$ Hz, or > 37.5 Hz. These requirements are commonly met by Hi-Fi pressure tip catheters (e.g., Millar catheters) with a measuring sensor embedded within the tip of the sensor, but not by the fluid-filled measuring systems that are frequently used in the clinical setting. Here, the measuring sensor is outside the body (directly or via extra fluid lines) connected to a catheter. Although the frequency response of the sensor itself is often adequate, the pressure signal is being distorted by the transmission via the catheter (and fluid lines and eventual connector pieces and three-way valves). The use of short, rigid, and large bore catheters is recommended, but it is advised to assess the actual frequency response of the system (as it is applied *in vivo*) if the pressure data is being used for purposes other than patient monitoring. Note that in small rodents like the mouse, where heart rate is as high as $600 \text{ beats min}^{-1}$, the fundamental frequency is 10 Hz, posing much higher measuring equipment requirements with a frequency response flat up to 300 Hz.

Impedance Z is generally defined as the ratio of pressure and flow: $Z = P/Q$, and thus has the dimensions of $\text{mmHg} \cdot \text{mL}^{-1} \cdot \text{s}$ [$\text{kg} \cdot \text{m}^{-4} \cdot \text{s}^{-1}$ in SI units; $\text{dyn} \cdot \text{cm}^{-5} \cdot \text{s}$ in older units] if pressure is expressed in mmHg and flow in $\text{mL} \cdot \text{s}^{-1}$. The parameter Z is usually calculated for each individual harmonic, and displayed as a function of frequency. Since both P and Q are complex numbers, Z is complex as well, and also has a modulus and a phase angle, except for the steady (dc) component at 0 Hz, which is nothing but the

ratio of mean pressure and mean flow (i.e., the value of vascular resistance). For all higher harmonics, the modulus of the n th harmonic is given as $|Z_n| = |P_n|/|Q_n|$, and its phase, Φ_z , is given as $\Phi_{P_n} - \Phi_{Q_n}$.

Arterial impedance requires simultaneous measurement of pressure and flow at the same location. Although it can be calculated all over the arterial tree, it is most commonly measured at the entrance of the systemic or pulmonary circulation, and is called ‘input’ impedance, often denoted as Z_{in} . The parameter Z_{in} fully captures the relation between pressure and flow, and is determined by all downstream factors influencing this relation (arterial network topology, branching patterns, stiffness of the vessel, vasomotor tone, ...). In a way, it is a powerful description of the arterial circulation, since it captures all effects, but this is at the same time its greatest weakness, as it is not very sensitive to local changes in arterial system properties, such as focal atherosclerotic lesions.

The interpretation of (input) impedance is facilitated by studying the impedance of basic electrical or mechanical “building blocks” (43–45): (1) When a system behaves strictly resistive, there is a linear relation between the pressure (difference) and flow. Pressure and flow are always in phase, Z_n is a real number and Φ_z is zero. (2) In the case where there is only inertia in a system, pressure is ahead of flow; for sine waves, the phase difference between both is a quarter of a wavelength, or $+90^\circ$ in terms of phase angle. (3) In the case where the system behaves like a capacitor, flow is leading pressure, again 90° out of phase, so that Φ_z is -90° .

Figure 5 displays the input impedance of these fundamental building blocks, as well as Z_{in} calculated from the

Figure 5. (a and b) Impedance modulus (a) and phase angle (b) of fundamental electrical/mechanical building blocks of the arterial system: resistance (R ; $1.028 \text{ mmHg} \cdot \text{mL}^{-1} \cdot \text{s}$ ($137.0 \times 10^6 \text{ Pa} \cdot \text{m}^{-3} \cdot \text{s}$)), inertia [L ; $0.065 \text{ mmHg} \cdot \text{mL}^{-1} \cdot \text{s}^2$ ($8.7 \times 10^6 \text{ Pa} \cdot \text{m}^{-3} \cdot \text{s}^2$)] and compliance [C ; $2.25 \text{ mL} \cdot \text{mmHg}^{-1}$ ($16.9 \times 10^{-9} \text{ m}^3 \cdot \text{Pa}^{-1}$)]. (c and d) input impedance modulus (c) and phase (d) calculated from aortic pressure and flow given in Fig. 1.

aorta pressure and flow shown in Fig. 1. The impedance modulus drops from the value of total systemic vascular resistance at 0 Hz to much lower values at higher frequencies. The phase angle is negative up until the fourth harmonic, showing that capacitive effects dominate at these low frequencies, although the phase angle never reaches -90° , indicating that inertial effects are present as well. For higher harmonics, the phase angle is close to zero, or at least oscillating around the zero value. At the same time, the modulus of Z_{in} is nearly constant. For these high frequencies, the system seems to act as a pure resistance, and the impedance value, averaged over the higher harmonics, has been termed the characteristic impedance (Z_0).

The Arterial System as a “Windkessel” Model

The most simple approximation of the arterial system is based on observations of reverend Stephen Hales (1733), who drew the parallel between the heart ejecting in the arterial tree, and the working principle of a fire hose (46). The pulsatile action of the pump is damped and transformed into a quasicontinuous outflow at the downstream

end of the system, that is, the outflow nozzle for the fire hose and the capillaries for the cardiovascular system. In mechanical terms, this type of system behavior can be simulated with two mechanical components: a buffer reservoir (compliant system) and a downstream resistance. In 1899, Otto Frank translated this into a mathematical formulation (47,48), and it was Frank who introduced the terminology “windkessel models”, windkessel being the German word for air chamber, as the buffer chamber used in the historical fire hose. The windkessel models are often described as their electrical analogue (Fig. 6).

The Two-Element Windkessel Model. While there are many different “windkessel” models in use (49,50), the two basic components contained within each model are a compliance element, C ($\text{mL}\cdot\text{mmHg}^{-1}$ or $\text{m}^3\cdot\text{Pa}^{-1}$), and a resistor element, R ($\text{mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ or $\text{Pa}\cdot\text{m}^{-3}\cdot\text{s}$ in SI units). The compliance element represents the volume change associated with a unit change in pressure; R is the pressure drop over the resistor associated with a unit flow. In diastole, when there is no new inflow of blood into the compliance, the arterial pressure decays exponentially following $P(t) = P_0 e^{-t/RC}$. The parameter RC is the product

Figure 6. (a and b) Electrical analog and mechanical representation of a two- and three-element windkessel model. (c) Agreement between measured pressure, and the pressure obtained after fitting a two- and three-element windkessel model to the pressure ($1 \text{ mmHg} = 133.3 \text{ Pa}$) and flow data from Fig. 1. Model parameters are $R = 1.056 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($140.8 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$) and $C = 2.13 \text{ mL}\cdot\text{mmHg}^{-1}$ ($16.0 \times 10^{-9} \text{ m}^3\cdot\text{Pa}^{-1}$) for the two-element windkessel model; $R = 1.028 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($137.0 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$), $C = 2.25 \text{ mL}\cdot\text{mmHg}^{-1}$ ($16.9 \times 10^{-9} \text{ m}^3\cdot\text{Pa}^{-1}$) and $Z_0 = 0.028 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($3.7 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$) for the three-element windkessel model. (d and e) Input impedance modulus (d) and phase angle (e) of these lumped parameter models and their match to the *in vivo* measured input impedance ($1 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s} = 133.3 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$).

of R and C and is called the arterial decay time. The higher the RC time, the slower the pressure decay. It is the time required to reduce P_0 to 37% of its initial value (note that the 37% is a theoretical value, usually not reached *in vivo* because the next beat impedes a full pressure decay). One can make use of this property to estimate the arterial compliance: By fitting an exponential curve to the diastolic decaying pressure, RC is obtained and thus, when R is known we also know C (49,51–53). This method is known as the decay time method.

For typical hemodynamic conditions in humans at rest (70 beats \cdot min $^{-1}$, systolic/diastolic, and mean pressure of 120 (16.0 kPa), 80 (10.7 kPa), and 93 (12.4 kPa) mmHg respectively, stroke volume 80 mL), mean flow is 93 mL \cdot s $^{-1}$ (0.93×10^{-4} m $^3 \cdot$ s $^{-1}$), and R is 1 mmHg (mL \cdot s $^{-1}$) (133.3×10^6 Pa \cdot m $^{-3} \cdot$ s). Assuming that the whole stroke volume is buffered in systole, C can be estimated as the ratio of stroke volume and pulse pressure (systolic–diastolic pressure difference), ~ 2 mL \cdot mmHg $^{-1}$ (1.50×10^{-8} m $^3 \cdot$ Pa $^{-1}$). This value is considered as an overestimation of the actual arterial compliance (49,54). In humans, RC time is thus of the order of 1.5–2 s.

The question, How well does a windkessel model represent the actual arterial system?, can be answered by studying the input impedance of both. In complex formulation, the input impedance of a two-element windkessel model is given as

$$Z_{i\text{-WK2}} = \frac{R}{1 + i\omega RC}$$

with i the complex constant, and $\omega = 2\pi f$, f is the frequency. The dc value (0 Hz) of Z_{in} is thus R ; at high frequencies, it becomes zero. The phase angle is 0 at 0 Hz, and -90° for all other frequencies. Compared to input impedance as measured in mammals, the behavior of a two-element windkessel model reasonably represents the behavior of the arterial system for the low frequencies (up to third harmonic), but not for higher frequencies (43,49,54) (Fig. 6). This means that it is justified to use the model for predicting the low frequency behavior of the arterial system, that is, the low frequency response to a flow input. This property is used in the so-called “pulse pressure method”, an iterative method to estimate arterial compliance: with R assumed known, the pulse pressure response of the two-element windkessel model to a (measured) flow stimulus is calculated with varying values of C . The value of C yielding the pulse pressure response matching the one measured *in vivo*, is considered to be the correct one (55). Compared to the decay time method, the advantage is that the pulse pressure method is insensitive to deviations of the decaying pressure from the true exponential decay (53).

The Three-Element and Higher Order Windkessel Models. The major shortcoming of the two-element windkessel model is the inadequate high frequency behavior (43,49,56). Westerhof et al. resolved this problem by adding a third resistive element proximal to the windkessel, accounting for the resistive-like behavior of the arterial system in the high frequency range (56). The third element represents the characteristic impedance of the proximal

part of the ascending aorta, and integrates the effects of inertia and compliance. Adding the element, the input impedance of the three-element windkessel model becomes

$$Z_{i\text{-WK3}} = Z_0 + \frac{R}{1 + i\omega RC}$$

it making the phase angle negative for lower harmonics, but returns to zero for higher harmonics, where the impedance modulus asymptotically reaches the value of Z_0 . For the systemic circulation, the ratio of Z_0 and R is 0.05–0.1 (57).

The major disadvantage of the three-element windkessel model is the fact that Z_0 , which should represent the high frequency behavior of the arterial system, plays a role at all frequencies, including at 0 Hz. This has the effect that, when the three-element windkessel model is used to fit data measured in the arterial system, the compliance is systematically overestimated (53,58): the only way to “neutralize” the contribution of Z_0 at the low frequencies, is to artificially increase the compliance of the model. The “ideal” model would incorporate both the low frequency behavior of the two-element windkessel model, and the high frequency Z_0 , though without interference of the latter at all frequencies. This can be achieved by adding an inertial element in parallel to the characteristic impedance, as demonstrated by Stergiopoulos et al. (59), elaborating on a model first introduced by Burattini et al. (60). For the DC component and low frequencies, Z_0 is bypassed through the inertial element. For the high frequencies, Z_0 takes over. It has been demonstrated, fitting the four-element windkessel model to data generated using an extended arterial network model, that L effectively represents the total inertia present in the model (59).

Obviously, by adding more elements, it is possible to develop models that are able to further enhance the matching between model and arterial system behavior (49,50), but the uniqueness of the model may not be guaranteed, and the physiological interpretation of the model elements is not always clear.

Although lumped parameter models cannot explain all aspects of hemodynamics, they are very useful as a concise representation of the arterial system. Mechanical versions are frequently used in hydraulic bench experiments, or as highly controllable afterload systems for *in vivo* experiments. An important field of application of the mathematical version is for parameter identification purposes: fitting arterial pressure and flow data measured *in vivo* to these models, the arterial system can be characterized and quantified (e.g., the total arterial compliance) through the model parameter values (43,49).

It is important to stress that these lumped models represent the behavior of the arterial system as a whole, and that there is no relation between model components and anatomical parts of the arterial tree (43). For example, although Z_0 represents the properties of the proximal aorta, there is no drop in mean pressure along the aorta, which one would expect if the three-element windkessel model were to be interpreted in a strict anatomical way. The combination of elements simply yields a model that represents the behavior of the arterial system as it is seen by the heart.

Figure 7. (a) Shows both pressure ($1 \text{ mmHg} = 133.3 \text{ Pa}$) and flow velocity measured along the arterial tree in a dog [after Ref. (44).] (b) Pressure wave forms measured between the aortic valve (AoV) and the terminal aorta (Term Ao) in one patient. [Modified from Ref. 61.]

Wave Propagation and Reflection in the Arterial Tree

As already stressed, lumped parameter models simply represent the behavior of the arterial system as a whole, and as seen by the heart. As soon as the model is subjected to flow or pressure, there is an instantaneous effect throughout the whole model. This is not the case in the arterial tree: when measuring pressure along the aorta, it can be observed that there is a finite time delay between the onset of pressure rise and flow in the ascending and distal aorta (Fig. 7). The pressure pulse travels with a given speed from the heart toward the periphery.

When carefully analyzing pressure wave profiles measured along the aorta, several observations can be made: (1) there is a gradual increase in the steepness of the wave front; (2) there is an increase in peak systolic pressure (at least in the large-to-middle sized arteries); (3) diastolic blood pressure is nearly constant, and the drop in mean blood pressure (due to viscous losses) is negligible in the large arteries. The flow (or velocity) wave profiles exhibit the same time delay in between measuring locations, but their amplitude decreases. Also, by comparing the pressure and flow wave morphology, one can observe that these are fundamentally different.

In the absence of wave reflection (assuming the aorta to be a uniform, infinitely long elastic tube), dissipation would only lead to less steep wave fronts, and damping of maximal pressure. Also, in these conditions, one would expect similarity of pressure and flow wave morphology. Thus, the above observations can only be explained by wave reflection. This is, of course, not surprising given the complex anatomical structure of the arterial tree, with geometric and elastic tapering (the further away from the heart, the stiffer the vessel), its numerous bifurcations, and the arterioles and capillaries making the distal terminations.

The Arterial Tree as a Tube. Despite the complexity described above, arterial wave reflection is often approached in a simple way, conceptually considering the arterial tree

as a single tube [or T-tube (62)], with one (or 2) discrete reflection site(s) at some distance from the heart. Within the single tube concept, the arterial tree is seen as a uniform or tapered (visco-)elastic tube (63,64), with an “effective length” (65,66), and a single distal reflection site. The input impedance of such a system can be calculated, as demonstrated in Fig. 8 for a uniform tube of length 50 cm, diameter 1.5 cm, Z_0 of $0.275 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($36.7 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$) and wave propagation speed of $6.2 \text{ m}\cdot\text{s}^{-1}$. The tube is ended

Figure 8. Input impedance modulus and phase of a uniform tube with length 50 cm, diameter 1.5 cm, characteristic impedance of $0.275 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($36.7 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$) and wave propagation speed of $6.2 \text{ m}\cdot\text{s}^{-1}$. The tube is ended by a (linear) resistance of $1 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($133.3 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$).

by a (linear) resistance of $1 \text{ mmHg}\cdot\text{mL}^{-1}\cdot\text{s}$ ($133.3 \times 10^6 \text{ Pa}\cdot\text{m}^{-3}\cdot\text{s}$). The impedance mismatch between the tube and its terminal resistance gives rise to wave reflections and oscillations in the input impedance pattern, and many features, observed *in vivo* (67), can be explained on the basis of this model.

Assume there is a sinusoidal wave running in the system with a wavelength λ being four times the length of the tube. This means that the phase angle of the reflected wave, when arriving back at the entrance at the tube, will be 180° out of phase with respect to the forward wave. The sum of the incident and reflected wave will be zero, since they interfere in a maximally destructive way. If this wave is a pressure wave, measured pressure at the entrance of the tube will be minimal for waves with this particular wave length. There is a relation between pulse wave velocity (PWV), λ , and frequency f (i.e., $\lambda = \text{PWV}/f$). Thus, in an input impedance spectrum, the frequency f_{min} , where input impedance is minimal, corresponds to a wave with a wavelength that is equal to four times the distance to the reflection site, L : $4L = \text{PWV}/f_{\text{min}}$, or $L = \text{PWV}/4f_{\text{min}}$ and $f_{\text{min}} = \text{PWV}/4L$. Applied to the example of the tube, f_{min} is expected at $6.2/2 = 3.1 \text{ Hz}$. This equation is known as the “quarter wavelength” formula, and is used to estimate the effective length of the arterial system.

Although the wave reflection pattern in the arterial system is complex (68), pressure (P) and flow (Q) are mostly considered to be composed of only one forward running component, P_f (Q_f) and one backward running component, P_b (Q_b), where the single forward and backward running components are the resultant of all forward and backward traveling waves, including the forward waves that result from rereflection at the aortic valve of backward running waves (69).

At all times,

$$P = P_f + P_b \quad \text{and} \quad Q = Q_f + Q_b$$

Furthermore, if the arterial tree is considered as a tube, defined by its characteristic impedance Z_0 , the following relations also apply:

$$Z_0 = P_f/Q_f = -P_b/Q_b$$

since Z_0 is the ratio of pressure and flow in the absence of wave reflection (43–45), which is the case when only forward or backward running components are taken into consideration. The negative sign in the equation above appears because the flow is directional, considered positive in the direction away from the heart, and negative toward the heart, while the value of the pressure is insensitive to direction.

Combining these equations, $P = P_f - Z_0Q_b = P_f - Z_0(Q - Q_f) = 2P_f - Z_0Q$, so that

$$P_f = (P + Z_0Q)/2$$

Similarly, it can be deduced that

$$P_b = (P - Z_0Q)/2$$

These equations were first derived by Westerhof et al., and are known as the linear wave separation equations (67). In principle, the separation should be calculated on individual

Figure 9. Application of linear wave separation analysis to the pressure (1 mmHg = 133.3 Pa) and flow data of Fig. 1. The ratio of PP_b and PP_f can be used as a measure of wave reflection magnitude.

harmonics, and the net P_f and P_b wave then follows from summation of all forward and backward harmonics. In practice, however, the equations are often used in the time domain, using measured pressure and flow as input. Note, however, that wave reflection only applies to the pulsatile part of pressure and flow, and mean pressure and flow should be subtracted from measured pressure and flow before applying the equations. An example of wave separation is given in Fig. 9.

Note also that wave separation requires knowledge of characteristic impedance, which can be estimated both in the frequency and time domain (70). When discussing input impedance, it was already noted that for the higher harmonics ($>$ fifth harmonic), Z_{in} fluctuates around a constant value, Z_0 , and with a phase angle approaching zero. Assuming wave speed to be $\sim 5 \text{ m}\cdot\text{s}^{-1}$, the wave length λ for these higher harmonics (e.g., the fifth harmonic for a heart rate of $60 \text{ beats}\cdot\text{min}^{-1}$), being the product of the wave speed and wave period (0.2 s) becomes shorter (1 m) than the average arterial pathlength. Waves reflect at distant locations throughout the arterial tree (with distal ends of vascular beds $< 50 \text{ cm}$ to $\sim 2 \text{ m}$ away from the heart in humans), return back to the heart with different phase angles and destructively interfere with each other, so that the net effect of the reflected waves appears nonexistent. For these higher harmonics, the arterial system thus appears reflectionless, and under these conditions, the ratio of pressure and flow is, by definition, the characteristic impedance. Therefore, averaging the input impedance modulus of the higher harmonics, where the phase angle is about zero, yields an estimate of the characteristic impedance (43–45).

Characteristic impedance can also be estimated in the time domain. In early systole, the reflected waves did not yet reach the ascending aorta, and in the early systolic ejection period, the relation between pressure and flow is

Figure 10. Typical pressure wave contours measured noninvasively at the common carotid artery with applanation tonometry in a young and old subject, and definition of the “augmentation index” (AIx) (1 mmHg = 133.3 Pa). See text for details.

linear, as can be observed when plotting P as a function of Q (70,71). The slope of the Q – P relationship during early systole is the time domain estimate of Z_0 , and is in good agreement with the frequency domain estimate (70).

Both the time and frequency domain approach, however, are sensitive to subjective criteria, such as the selection of the early systolic ejection period, or the selection of the harmonic range that is used for averaging.

Pathophysiological Consequences of Arterial Wave Reflection. Figure 10 displays representative carotid artery pressure waves (\sim aorta pressure) for a young subject, (b), and for an older, healthy subject, (a). It is directly observed that the morphology of the pressure wave is fundamentally different. In the young subject, pressure first reaches its maximal systolic pressure, and an “inflection point” is visible in late systole, generating a late shoulder (P_2). In the older subject, this inflection point appears in early systole, generating an early shoulder (P_1).

Measurements of pressure along different locations in the aorta, conducted by Latham et al. (67), showed that, when the foot of the wave on one hand, and the inflection point on the other, are interconnected (Fig. 7): (1) these points seem to be aligned on two lines; (2) the lines connecting these characteristic marks intersect. This pattern is consistent with the concept of a pressure wave being generated by the heart, traveling down the aorta, reflect, and superimpose on the forward going wave. The inflection point is then a visual landmark, designating the moment in time where the backward wave becomes dominant over the forward wave (61).

In young subjects, the arteries are most elastic (deformable), and pulse wave velocity (see below) is much lower than in older subjects, or in patients with hypertension or diabetes. In the young, it takes more time for the forward wave to travel to the reflection site, and for the reflected wave to arrive at the ascending aorta. Both interact only in late systole (late systolic inflection point), causing little extra load on the heart. In older subjects, on the other hand, PWV is much higher, and the inflection point shifts to early systole. The early arrival of the reflected wave literally boosts systolic pressure, causing pressure augmentation, and augmenting the load on the heart (72). At the same time, the early return of the reflected wave impedes ventricular ejection, and thus may have a negative impact on stroke volume (72,73). An increased load on the heart increases the energetic cost to maintain stroke

volume, and will initiate cardiac compensatory mechanisms (remodeling), which may progress into cardiac pathology (74–76).

Wave Intensity Analysis. With its origin in electrical network theory, much of the arterial function analysis, including wave reflection, is done in the frequency domain. Besides the fact that this analysis is, strictly speaking, only applicable in linear systems with periodic signal changes, the analysis is quite complex due to the necessity of Fourier decomposition, and it is not intuitively comprehensible. An alternative method of analysis, performed in the time domain and not requiring linearity and periodicity is the analysis of the wave intensity, elaborated by Parker and Jones in the late 1980s (77).

Disturbances to the flow lead to changes in pressure (dP) and flow velocity (dU), “wavelets”, which propagate along the vessels with a wave speed (PWV), as defined above. By accounting for conservation of mass and momentum, it can be shown that

$$dP_{\pm} = \pm \text{PWV} \rho dU_{\pm}$$

where the “+” denotes a forward traveling wave (for a defined positive direction), while “–” denotes a backward traveling wave. This equation is also known as the water-hammer equation. Waves characterized by a $dP > 0$, that is, a rise in pressure, are called compression waves, while waves with $dP < 0$ are expansion waves. Note that this terminology still reflects the origin of the theory in gas dynamics.

Basically, considering a tube, with left-to-right as the positive direction, there are four possible types of waves: (1) Blowing on the left side of the tube, pressure rises ($dP > 0$), and velocity increases ($dU > 0$). This is a *forward compression wave*. (2) Blowing on the right side of the tube, pressure increases ($dP > 0$), but velocity decreases ($dU < 0$) with our convention. This is a *backward compression wave*. (3) Sucking on the left side of the tube, pressure decreases ($dP < 0$), as well as the velocity ($dU < 0$), but the wavefront propagates from left to right. This wave type is a *forward expansion wave*. (4) Finally, one can also suck on the right side of the tube, causing a decrease in pressure ($dP < 0$) but an increase in velocity ($dU > 0$). This is a *backward expansion wave*.

The nature of a wave is most easily comprehended by analysing the wave intensity, dI , which is defined as the product of dU and dP , and is the energy flux carried by the

Figure 11. The concept of wave intensity analysis, applied to pressure and flow measured in the ascending aorta of a dog.

wavelet. It can be deduced from the above that dI is always positive for forward running waves, and always negative for a backward wave. When dI is positive, forward waves are dominant; otherwise, backward waves are dominating. Analysis of dP reveals whether the wave is a compression or an expansion wave. Figure 11 shows the wave intensity calculated from pressure and flow velocity measured in the ascending aorta of a dog (71). A typical wave intensity pattern is characterized by three major peaks. The first one is a forward compression wave, associated with the ejection of blood from the ventricle. The second positive peak is associated with a forward running wave, but $dP < 0$, and this second peak is thus a forward running expansion wave, due to ventricular relaxation, slowing down the ejection from the heart. During systole, reflected waves are dominant, resulting in a negative wave intensity, but with, in this case, positive dP . The negative peak is thus a backward compression wave, resulting from the peripheral wave reflections.

Further, note that similar to Westerhof’s work (69), the wavelets dP and dU also can be decomposed in the forward and backward components (71). It can be derived that

$$dP_{\pm} = \frac{1}{2}(dP \pm \rho PWV dU) \quad \text{and} \quad dU_{\pm} = \pm \frac{1}{2} \left(\frac{dP}{\rho PWV} \pm dU \right)$$

The total forward and backward pressure and flow wave can be obtained as

$$P_+ = P_d + \sum_{t=0}^t dP_+$$

with P_d the diastolic blood pressure, which is added to the forward wave, and $P_- = \sum_{t=0}^t dP_-$ (71). Similarly, for the forward and backward velocity wave, it applies that

$$U_+ = \sum_{t=0}^t dU_+ \quad \text{and} \quad U_- = \sum_{t=0}^t dU_-$$

Wave Intensity in itself, dI , can also be separated in a net forward and backward wave intensity: $dI_+ = dP_+ dU_+$ and $dI_- = dP_- dU_-$ with $dI = dI_+ + dI_-$.

Wave intensity is certainly an appealing method to gain insight into complex wave (reflection) patterns, as in the arterial system, and the use of the method is growing (78–80). The drawback of the method is the fact that dI is calculated as the product of two derivatives dP and dU , and thus is highly sensitive to noise in the signal. Adequate filtering of basic signals and derivatives is mandatory. As for the more “classic” impedance analysis, it is also required that pressure and flow be measured at the exact same location, and preferably at the same time.

Assessing Arterial Hemodynamics in Real Life

Analyzing Wave Propagation and Reflection. The easiest approach of analyzing wave reflection is to simply quantify the global effect of wave reflection on the pressure wave morphology. This can be done by formally quantifying the observation of Murgó et al. (61), and is now commonly known as the augmentation index (AIx). This index was first defined in the late 1980s by Kelly et al. (81). Although different formulations are used, AIx is nowadays most commonly defined as the ratio of the difference between the “secondary” and “primary peak”, and pulse pressure: $AIx = 100 (P_2 - P_1) / (P_s - P_d)$, and expressed as a percentage (Fig. 10). For A-type waves (Fig. 10) with a shoulder preceding systolic pressure, P_1 is a pressure value characteristic for the shoulder, while P_2 is systolic pressure. These values are positive. For C-type waves, the shoulder follows systolic pressure, and P_1 is systolic pressure, while P_2 is a pressure value characteristic for the shoulder, thus yielding negative values for AIx (Fig. 10). There are also alternative formulations in use, for example, $100(P_2 - P_d) / (P_1 - P_d)$, which always yields a positive value ($< 100\%$ for C-type waves, and $> 100\%$ for A-type waves). Both are, of course, mathematically related to each other. Since AIx is an index based on pressure differences and ratios, it can be calculated from noncalibrated pressure waveforms, which can be obtained noninvasively using techniques such as applanation tonometry (see below). In the past 5 years, numerous studies have been published using AIx as a quantification of the contribution of wave reflection to arterial load.

It is, however, important to stress that AIx is an integrated measure and that its value depends on all factors influencing the magnitude and timing of the reflected wave: pulse wave velocity, magnitude of wave reflection, and the distance to the reflection site. This AIx is thus strongly dependent on body size (82). In women, the earlier return of the reflected wave leads to higher AIx. The relative timing of arrival of the reflected wave is also important, so that AIx is also dependent on heart rate (83). For higher heart rates, systolic ejection time shortens, so that the reflected wave arrives relatively later in the cycle, leading to an inverse relation between heart rate and AIx.

Instead of studying the net effect of wave reflection, one can also measure pressure and flow (at the same location) and separate the forward and backward wave using the

aforementioned formulas. An example is given in Fig. 9, using aorta pressure and flow from Fig. 1. The ratio of the amplitude of P_b (PP_b) and P_f (PP_f) then yields an easy measure of wave reflection, which can be considered as a wave reflection coefficient, although it is to be emphasized that it is not a reflection coefficient in a strict sense. It is not the reflection coefficient at the site of reflection, but at the upstream end of the arterial tree and thus also incorporates the effects of wave dissipation, playing a role along the pathlength for the forward and backward component.

Another important determinant of the augmentation index is pulse wave velocity, which is an interesting measure of arterial stiffness in itself. This is easily demonstrated via the theoretical Moens–Korteweg equation for a uniform 1D tube, stating that $PWV = \sqrt{Eh/\rho D}$ with E the Young elasticity modulus (400–1200 kPa for arteries), ρ the density of blood ($\sim 1060 \text{ kg} \cdot \text{m}^{-3}$), h the wall thickness, and D the diameter of the vessel. Another formula, sometimes used, is the so-called Bramwell–Hill (84) equation: $PWV = \sqrt{A \partial P / \rho \partial A} = \sqrt{A / \rho I / C_A}$ with P intra-arterial pressure, A cross-sectional area and C_A the area compliance, $\partial A / \partial P$. For unaltered vessel dimensions, an increase in stiffness (increase in E , decrease in C_A) yields an increase in PWV. The most common technique to estimate PWV is to measure the time delay between the passage of the pressure, flow, or diameter distension pulse at two distinct locations, for example, between the ascending aorta (or carotid artery) and the femoral artery (85). These signals can be measured noninvasively, for example, with tonometry (86,87) (pressure pulse) or ultrasound [flow velocity, vessel diameter distension (88,89)]. Reference work was done by Avolio et al., who measured PWV in large cohorts in Chinese urban and rural communities (90,91).

When the input impedance is known, which implies that pressure and flow are known, the “effective length” of the arterial system, that is, the distance between the location

where the input impedance is measured and an “apparent” reflection site at a distance L , can be estimated using the earlier mentioned quarter wavelength formula. Murgu et al. found the effective length to be $\sim 44 \text{ cm}$ in humans (61), which would suggest a reflection site near the diaphragm, in the vicinity of where the renal arteries branch off the abdominal aorta. Latham et al. demonstrated that local reflection is higher at this site (67), but one should keep in mind that the quarter wavelength formula is based on a conceptual model of the arterial system, and the apparent length does not correspond to a physical obstruction causing the reflection. Nevertheless, there is still no clear picture of the major reflection sites, which is complex due to the continuous branching, the dispersed distal reflection sites, and the continuous reflection caused by the geometric and elastic tapering of the vessels (45,64,67,68,92–96).

Central and Peripheral Blood Pressure: On the Use of Transfer Functions. Wave travel and reflection generally result in an amplification of the pressure pulse from the aorta (central) toward the periphery (brachial, radial, femoral artery) (44,45). Since clinicians usually measure blood pressure at the brachial artery (cuff sphygmomanometry), this implies that the pressure measured at this location is an overestimation of central pressure (97,98). It is the latter against which the heart ejects in systole, and which is therefore of primary interest.

In the past few years, much attention has been attributed to the relation between radial artery and central pressure (99–102). The reason for this is that radial artery pressure pulse is measurable with applanation tonometry, a noninvasive method (86,87,103). The relation between central and radial artery pressure can be expressed with a “transfer function”, most commonly displayed in the frequency domain (Fig. 12). The transfer function expresses

Figure 12. Demonstration of the aorta-to-radial pressure pulse amplification: (a and b) are carotid (as substitute for aorta pressure) and radial artery pressure measured in the same subject with applanation tonometry (1 mmHg=133.3 Pa). (c and d) Display the modulus and phase angle of the radial-to-aorta transfer function as published by Ref. (99).

the relation between the individual harmonics at both locations, with a modulus (damping or amplification of the harmonic) and a phase angle (the time delay). In humans, the aorta-to-radial transfer function shows a peak ~ 4 Hz, so that amplification is maximal for a harmonic of that frequency (99,101). It has been demonstrated that the transfer function is surprisingly constant, with albeit little variation among individuals (99). It is this observation that led to the use of generalized transfer functions, embedded in commercial systems, that allow us to calculate central pressure from a peripheral pressure measurement (104). In these systems, the transfer is commonly done using a time domain approach [autoregressive exogenous (ARX) models (100)]. There have been attempts to “individualize” the transfer function, but until now these attempts were unsuccessful (105). The general consensus appears to be that the generalized transfer function can be used to estimate central systolic blood pressure and pulse pressure (104), but that one should be cautious when using synthesized central pressures for assessing parameters based on details in the pressure wave (e.g., the augmentation index) (106). The latter requires high frequency information that is more difficult to guarantee with a synthesized curve, both due to the increase in scatter in the generalized transfer function for higher frequencies, and the absence of high frequency information in the peripherally measured pressure pulse (99,107).

One more issue worth noting is the fact that the radial-to-aorta transfer function peaks at 4 Hz (in humans), which implies that the peripheral pulse amplification is frequency, and thus heart rate dependent (83,108,109). In a pressure signal, most power is embedded within the first two to three harmonics. When heart rate shifts from 60 to 120 beats/min (e.g., during exercise), the highest amplification thus occurs for these most powerful, predominant harmonics, leading to a more excessive pressure amplification. This means, conversely, that the overestimation of central pressure by a peripheral pressure measurement is a function of heart rate. As such, the effect of drugs that alter the heart rate (e.g., beta blockers, slowing down heart rate) may not be fully reflected by the traditional brachial sphygmomanometer pressure measurement (97,98).

Practical Considerations. The major difficulty, transferring experimental results into clinical practice, is the accurate measurement of the data necessary for the hemodynamic analysis. Nevertheless, there are noninvasive tools available that do permit “full” noninvasive hemodynamic assessment in clinical conditions, as possible with central pressure and flow.

Flow is at present rather easy to measure with ultrasound, using pulsed Doppler modalities. Flow velocities can be measured in the left ventricular outflow tract and, when multiplied with outflow tract cross-section, be converted into flow. Also, velocity-encoded MRI can provide aortic blood flow velocities.

As for measuring pressure, applanation tonometry is an appealing technique, since it allows us to measure pressure pulse tracings at superficial arteries such as the radial, brachial, femoral, and carotid artery (86,87,103,110,111). The carotid artery is located close to the heart, and is often

used as a surrogate for the ascending aorta pulse contour (87,111). Others advocate the use of a transfer function to obtain central pressure from radial artery pressure measurement (104), but generalized transfer functions do not fully capture all details of a central pressure (106). Nevertheless, applanation tonometry only yields the morphology of the pressure wave and not absolute pressure values (although this is theoretically possible, but virtually impossible to achieve in practice). For the calibration of the tracings, one still relies on brachial cuff sphygmomanometry (yielding systolic and diastolic brachial blood pressure). Van Bortel et al. validated a calibration scheme in which first a brachial pressure waveform is calibrated with sphygmomanometer systolic and diastolic blood pressure (81,112). Averaging of this calibrated curve subsequently yields mean arterial blood pressure. Pulse waveforms at other peripheral locations are then calibrated using diastolic and mean blood pressure. Alternatively, one can use an oscillometric method to obtain mean arterial blood pressure, or estimate mean arterial blood pressure from systolic and diastolic blood pressure using the two-third/one-third rule of thumb (mean blood pressure = $\frac{2}{3}$ diastolic + $\frac{1}{3}$ systolic pressure). With the oscillometric method, one makes use of the oscillations that can be measured within the cuff (and in the brachial artery) when the cuff pressure is lowered from a value above systolic pressure (full occlusion) to a value below diastolic pressure (no occlusion).

Nowadays, ultrasound vessel wall tracking techniques also allow us to measure the distension of the vessel upon the passage of the waveform (88,113). These waveforms are quasi-identical to the pressure waveforms [but not entirely, since the pressure–diameter relationship of blood vessels is not linear (114,115)] and can potentially be used as an alternative for tonometric waveforms (112,116).

When central pressure and flow are available, the arterial system can be characterized using all described techniques, from impedance analysis, parameter estimation by means of a lumped parameter windkessel or tube model, analysis of wave reflection, and so on. The augmentation index can be derived from pressure data alone. A parameter that is certainly relevant to measure in addition to pressure and flow is pulse wave velocity, as it provides both functional information, and helps to elucidate wave reflection. For measuring the transit time (e.g., from carotid to femoral) of the arterial pressure pulse, the flow velocity wave or the diameter distension wave is the most commonly applied technique (85).

HEART-ARTERIAL COUPLING

The main function of the heart is to maintain the circulation, that is, to provide a sufficient amount of blood at sufficiently high pressures to guarantee the perfusion of vital organs, including the heart itself. Arterial pressure and flow arise from the interaction between the ventricle and the arterial load. In the past few years, the coupling of the heart and the arterial system in cardiovascular pathophysiology has been recognized (74–76,117,118). With ageing or in hypertension, for example, arterial stiffening leads to an increase of the pressure pulse and an early

Figure 13. Heart–arterial coupling using the E_a – E_{es} (a) of the pump function graph (b) framework. In both cases, the intersection between the curves characterizing the ventricle and the arterial system determines the working point of the cardiovascular system.

return of reflected waves, increasing the load on the heart (73,119), which will react through adaptation (remodeling) to cope with the increased afterload.

Factors affecting ventricular pump function are preload (venous filling pressure and/or end diastolic volume EDV), heart rate, and the intrinsic contractile function of the heart muscle (here assumed to be best represented by the slope of the end-systolic PV relation, E_{es}). The two main mechanical afterload parameters determining systolic and pulse pressure are total peripheral resistance (R) and total arterial compliance (C) (120,121). Arterial blood pressure and flow are thus determined by a limited number of cardiac and arterial mechanical factors.

The most common framework, however, to study the heart–arterial (or ventricular–vascular) coupling, is the E_a – E_{es} framework (23,122–124), where E_a is effective arterial elastance (125), and where E_a/E_{es} is a parameter reflecting heart–arterial coupling. In the pressure–volume plane, E_a is the slope of the line connecting the end-systolic point (ESV, ESP) with the end-diastolic volume point on the volume axis (EDV, 0) (Fig. 13). As such, $E_a = \text{ESP}/\text{SV}$, with SV the stroke volume. The parameter E_a can be written as a function of three-element windkessel parameters describing the arterial system (125), but it has been shown that E_a can be approximated as R/T with T the duration of the cardiac cycle (124,126).

The first major advantage of this framework is that it allows us to graphically study the interaction between the heart and the arterial system. Cardiac function is characterized by the ESPVR, which is a fully defined line in the PV plane. For a given preload (EDV) and arterial stiffness E_a , the line characterizing the arterial system can be drawn as well. The intersection of these two lines determines the end-systolic point (ESV, ESP), and thus the stroke volume and (end-)systolic pressure (Fig. 13).

Second, the analysis in the PV plane also allows us to calculate some energetic parameters, and to relate them to E_a/E_{es} . It can be shown that SW is maximal only when $E_a = E_{es}$. Thus when $E_a/E_{es} = 1$. Mechanical efficiency is maximal when $E_a/E_{es} = 0.5$, when arterial elastance is one-half of the end-systolic elastance (124). In normal hearts, the heart operates in conditions with an E_a/E_{es} ratio in the range 0.5:1, and it has been shown that this ratio is preserved in normal aging (74,75). Arterial stiffening is thus paralleled by an increase in ventricular end-systolic stiffness. This happens even in patients with heart failure,

but with preserved ejection fraction (76). In this patient population, both E_a and E_{es} are higher than expected with normal ageing, but the ratio is more or less preserved.

Although the E_a/E_{es} parameter certainly has its value, it has been shown under experimental conditions that the E_a/E_{es} range, where the heart operates near optimal efficiency, is quite broad (122,127). Thus the parameter is not a very sensitive tool to detect “uncoupling” of the heart and the arterial system, which commonly implies an increase in E_a and a poorer ventricular function (depressed E_{es}) leading to increased E_a/E_{es} ratios (128,129). Also, one should not focus only on the coupling, but also on the absolute values of E_a and E_{es} . Increased stiffening leads to hypertensive response in exercise, where small changes in volume (filling volumes, stroke volumes) have an amplified effect on arterial pressure and workload, and lead to an increased energy cost to increase stroke volume (75,76).

By using dimensional analysis, Stergiopoulos et al. (130) and later Segers et al. (131), demonstrated that blood pressure and stroke volume are mainly determined by ventricular preload, and by 2 dimensionless parameters: $E_{es}C$ and RC/T , where T is the heart period. The first is the product of ventricular (end-systolic) stiffness and arterial compliance; the latter is the ratio of the time constant of arterial blood pressure decay (RC) and the heart period.

It is also worth noting the link between the coupling parameters as proposed by Stergiopoulos et al., and E_a/E_{es} : $(RC/T)/(E_{es}C) = (R/T)/E_{es} \approx E_a/E_{es}$. E_a/E_{es} thus combines the two coupling parameters following from the dimensional analysis into a single dimensionless parameter. This is, however, at the cost of eliminating the contribution of total arterial compliance from the parameter. Within this perspective, the terminology of E_a as arterial stiffness, is perhaps not entirely justified, as it is a parameter related to peripheral resistance and the heart period, rather than to arterial compliance or stiffness (126).

Finally, it should be mentioned that heart–arterial interaction can also be studied within the pump function framework of Westerhof and co-workers (Fig. 13). While the function of the heart can be described with the pump function graph, the function of the arterial system can be displayed in the same graph. In its simplest approximation, considering only mean pressure and flow, the arterial system is characterized by the total vascular resistance. In a pump function graph, this is represented by a straight line: mean flow is directly proportional to mean arterial pressure.

The intersection with the pump function graph yields the working point of the cardiovascular system. Note, however, that although both the pump and arterial function curve are displayed in the same figure, their *y* axis is not the same.

HIGH FREQUENCY VENTILATION

J. BERT BUNNELL
Bunnell Inc.
Salt Lake City, Utah

INTRODUCTION

High frequency ventilators (HFVs) were designed to eliminate many of the problems that conventional ventilators

create as they try to mimic normal breathing. When we breathe normally, we draw gas into the lungs by creating a negative pressure with our diaphragm. Iron lungs were created to replicate that activity, and they worked very well for thousands of polio patients. However, when patients are sealed off in airtight iron lungs numerous practical problems unrelated to breathing arise.

Positive pressure ventilators made assisting ventilation much easier. Attaching the ventilator to the patient's lungs via an endotracheal (ET) tube greatly simplified patient care. But, lungs, especially premature lungs, are not designed to tolerate much positive pressure.

The lungs of prematurely borne infants have yet to be fully formed, and they lack the surfactant that enables alveoli to expand with very little pressure gradient. Hence, a considerable pressure gradient must be applied to ventilate them. Applying that pressure from the outside in, as *conventional* ventilators (CVs) have been doing since the early 1970s, causes problems. Tiny infant's airways get distended, alveoli are ruptured, and inflammatory sensors are triggered. Even if an infant receives artificial surfactant to lessen the need for assisted ventilation, and they grow new lung fast enough to survive, they may well develop chronic lung disease at a time when most of us were just taking our first breaths. Most premature infants outgrow their chronic lung disease, but many struggle mightily with every virus they encounter in their first few years of life, and they have an increased incidence of neurodevelopmental problems, such as cerebral palsy. Some infants lose those struggles and die of pneumonia.

Acute respiratory distress syndrome (ARDS) is the primary problem for mechanical ventilation of adults. This disease affects ~50 people per 100,000 with a mortality of 30–50%, and there have been few improvements in this mortality rate over the past several decades.

High frequency ventilators were developed in response to problems associated with CVs, but HFVs do not try to replicate normal breathing. They assist ventilation using much smaller tidal volumes delivered at rates ~10 times higher than normal. Animal and clinical studies indicate that smaller tidal volumes cause less lung injury (1,2).

Swedish anesthesiologists in the 1970s turned up the rate of their anesthesia ventilators to enable them to use smaller breaths to assist patients during neurosurgery (3). Their regular ventilators caused pulsations in blood pressure, causing brain movement every time the ventilator pushed in a breath, which was an obvious problem during microsurgery.

Auto accident victims whose heads went through car windshields also pose problems during surgery when access to the lungs has to pass right through the area of the face and neck where major reconstruction is required. So, another anesthesiologist, Dr. Miroslav Klain, began sticking needles into patients' necks to gain access to their tracheas, and he made it work by delivering very tiny breaths at very rapid rates (4).

The HFVs have shown great promise in supporting premature infants where fragile, underdeveloped and surfactant deficient lungs need to be gently ventilated until growth and maturation allow the newborn to catch up both anatomically and physiologically. In newborn infants,

where various modes of positive pressure ventilation have produced lung injury, HFVs have been widely accepted. Early studies using HFV to treat adults with severe ARDS have also shown promise in lessening lung injury and improving survival (5,6).

This article will review our current understanding of how HFVs work, the types of HFV equipment that are available for treating infants and adults, the results of several key animal and clinical studies that indicate how to optimize applications of HFVs, and what controversies remain to be resolved before HFVs can be considered as a primary mode of ventilation.

THEORETICAL BASIS FOR HFV: HOW HFVs WORK

High frequency ventilators are different from all other types of mechanical ventilators. They do not mimic normal breathing; rather, they facilitate gas exchange in a manner similar to panting in animals.

There are two elements to explaining how HFVs work with the higher than normal frequencies and smaller than normal tidal volumes. We begin with the assumption that ventilation or CO₂ elimination is proportional to minute volume or frequency times tidal volume, as

$$\dot{V}_{\text{CO}_2} \propto \dot{V}_{\text{min}} = f \times V_T \quad (1)$$

where \dot{V}_{CO_2} = rate of carbon dioxide elimination; \dot{V}_{min} = minute volume; f = ventilator frequency; and V_T = tidal volume.

If the practical limits of the high frequency end of this relationship are considered, there must be a lower limit on tidal volume size that will effectively provide alveolar ventilation. That lower limit is related to the effective or physiologic dead space of the lungs by the following equation:

$$\dot{V}_A = f \times (V_T - V_D) \quad (2)$$

where \dot{V}_A = alveolar ventilation, and V_D = effective or physiologic dead space.

Thus, as tidal volume approaches the size of the effective dead space of the lungs, ventilation of the alveoli becomes nil.

Physiologic Dead Space and the Lower Limit of Tidal Volume

Anatomic dead space of mammalian lungs is generally considered to be 2 mL·kg⁻¹ body weight (7). When one breathes normally, effective or physiologic dead space must be at least as large as anatomic dead space, because one pushes the dead space gas back into the alveoli ahead of the fresh gas during inhalation. What happens in the panting animal is another matter, as Henderson and associates described in 1915 (8).

Henderson et al. (8) demonstrated that panting animals breathe very shallowly as well as rapidly. They hypothesized that physiologic dead space changes at rapid respiratory rates in mammals, and they measured these effects on themselves. They also performed a series of experiments using smoke to demonstrate how inhaled gas penetrates through the anatomic dead space with rapid inhalations in a manner that makes physiologic dead space become less than anatomic dead space (Fig. 1).

Figure 1. Henderson's smoke experiment. (a) A long thin spike or jet stream of smoke shoots downstream when suddenly blown into a glass tube. (b) The jet stream disappears when flow stops and diffusion takes place. (c) This effect can be duplicated in the opposite direction if fresh gas is drawn back into the smoke filled tube with a sudden inhalation. (d) Imperfections in the tube walls (such as a bulb) have little effect on the shape of the jet stream. (Adapted with permission from Ref. 8, p. 8. © 1915, American Physiology Society.)

Regardless of how much physiologic dead space can be reduced in the panting animal, there is still the matter of providing adequate alveolar ventilation as defined by Eq. 2. Thus, the extent to which smaller tidal volumes can be used to ventilate the alveoli has to be balanced by an increase in breathing frequency, as defined by Eq. 1. Panting animals breathe very rapidly, of course, but humans do not pant as a rule. So, how can the benefits of increasing ventilator frequency for humans be explained?

The Natural Frequency of the Lungs

There is a mechanical advantage to ventilating lungs at frequencies higher than normal breathing frequency. This phenomenon was revealed by a diagnostic technique for measuring airway resistance called forced oscillations (9).

Applying forced oscillations to measure airway resistance requires a person to hold a large bore tube in their mouth and allow small volumes of gas to be oscillated in and out of their lungs by a large loudspeaker. The frequency of oscillations produced by the speaker is varied through a spectrum from low (~1 Hz) to high (~60 Hz), and the pressure amplitudes of the oscillations are measured along with the flow rate of the gas that is passing in and out of the lungs (Fig. 2 depicts the test set up). Although the volume of gas moving in and out of the lungs is a constant, pressure amplitude varies with frequency and is minimized at the resonant or natural frequency of the lungs.

The concept that the lungs have a natural frequency is explained by consideration of lung mechanics. There are three elements to lung impedance (those things that impede the flow of gas in and out of the lungs): airway resistance, lung compliance, and inertance. We normally are not concerned about inertance, since it is concerned with the energy involved in moving the mass in the system,

Figure 2. Measuring airway resistance at the resonant or natural frequency of the lungs using forced oscillations. (Used with permission. © 2003, Bunnell Inc.)

most of which is gas, and gas does not have much mass. Therefore, it does not take much energy to overcome inertance when one breathes: unless one is breathing very rapidly.

In the forced oscillations determination of airway resistance, the point of minimum pressure amplitude marks the frequency at which the energy necessary to overcome the elasticity of the lungs is supplied by the energy temporarily stored in the inertial elements of the system (i.e., the gas rushing in). (We normally measure lung elasticity inversely as lung compliance.) As the lungs recoil at the end of the gas-in phase, the elasticity of the lungs imparts its energy to turn the gas around and send it back out to the loudspeaker.

When the natural frequency or resonance is reached, the speaker and lungs exchange the gas being forced in and out of the lungs with ease. The lungs and the speaker accept the gas and recoil at just the right times to keep the gas oscillating back and forth with minimal energy required to keep the gas moving. At this point, the only element impeding gas flow is frictional airway resistance, which works against the gas coming in and going out. Its value can be calculated by dividing pressure amplitude by the gas flow rate when pressure amplitude is minimized.

The smaller the lungs are, the higher the natural frequency. The natural frequency of adult lungs is ~ 4 Hz, while that of premature infant lungs is closer to 40 Hz.

Putting Two and Two Together: How Can We HFV?

Combining the two concepts that describe the relationships of gas velocity, physiologic dead space, breathing frequency, and lung mechanics led us to HFV. We reported that one can then achieve adequate minute ventilation and compensate for very small tidal volumes in paralyzed animals by increasing ventilatory frequency to several hundred breaths per minute in 1978 (10). Pushing small volumes of gas into the lungs at high velocities reduced effective dead space volume and pushed the lower limit of effective tidal volume below anatomic dead space volume

(~ 2 mL \cdot kg $^{-1}$). Increasing frequency to near resonant frequency also allowed us to minimize airway pressure.

As HFVs were developed and clinical use in newborn intensive care units (NICUs) became widespread in the 1980 and 1990s, numerous theories and experiments refined our concepts of how it all works. A number of prominent physiologists and bioengineers tackled the analysis and interpretation of gas exchange within the lungs during HFV while clinicians were seeking to identify appropriate applications of the new technique and all its intricacies. A few notable contributions will be discussed here.

Fredberg (11) and Slutsky et al. (12) analyzed mechanisms affecting gas transport during high frequency oscillation, expanding traditional concepts of convection and diffusion to include their combined effects, and termed the collection: augmented transport. Their analyses and those of Venegas et al. (13) and Permutt et al. (14) revealed that our traditional appreciation of the relationship between minute volume and CO₂ elimination must be modified during HFV to reflect the increased contribution of tidal volume, as

$$V_{\text{CO}_2} \propto f^a \times V_T^b \quad (3)$$

where the exponent b is greater than the exponent a . For practical purposes, most people now accept this relationship as

$$\dot{V}_{\text{CO}_2} \propto f \times V_T^2 \quad (4)$$

Slutsky also explored the limitations of HFV by measuring the effect of bronchial constriction on gas exchange. When the peripheral airways of dogs were constricted by administration of histamine, HFOV was no longer as effective at higher frequencies. (This issue is discussed later when the effectiveness of various types of HFVs for different pathophysiologies are explored.)

Venegas and Fredberg explored the importance of frequency during HFV in their classic paper of 1994, subtitled: "Why does high frequency ventilation work?" (15). They found that the resonant frequency of the smallest prematurely born infant with RDS (respiratory distress syndrome) is approximately 40 Hz. At that frequency, the minimum pressure amplitude is required to ventilate the lungs. However, the shape of theoretical curves of pressure amplitude measured at the carina versus frequency for infants with various lung conditions is most interesting as illustrated in Fig. 3, which was constructed using their concepts.

Figure 3 illustrates four essential considerations concerning the application of HFV for newborn infants.

1. Decreasing lung compliance moves the optimal frequency for HFV to the right (i.e., toward higher frequencies).
2. Increasing airway resistance moves the optimal frequency for HFV to the left (i.e., toward lower frequencies); and
3. There is diminishing value in applying HFV for infants at frequencies above ~ 10 Hz as far as airway pressure is concerned.
4. Choosing to operate at the "corner frequency" is an appropriate choice for HFV since there is little benefit

Figure 3. Theoretical peak carinal pressures for infants with normal lungs and lungs with poor compliance (RDS), poor airway resistance (asthma), and both conditions (RDS + PIE). Note how infants with RDS are well served using the corner frequency (f_c) of ~10 Hz (600 breaths per minute, bpm). Larger patients will exhibit curves with nearly identical shapes, but they will all be shifted to the left. (Adapted with permission from Ref. 15.)

above that frequency and more chance for gas trapping. Venegas and Fredberg define corner frequency as that frequency above which airway pressure required to provide adequate ventilation no longer rapidly decreases.

In other words, ventilating premature babies at 10 breaths · s⁻¹ is *practically* as efficient as ventilating them at their theoretical resonant frequency of 40 “breaths” · s⁻¹, where the danger of gas trapping is greatly increased. Patients with increased airway resistance require more careful consideration of the decreased benefits of exceeding the corner frequency and are more safely ventilated at lower frequencies.

One can calculate the resonant and corner frequencies if values of lung compliance (C_L), airway resistance (R_{aw}), and inertance (I) are known, but that is rarely the case with patients in intensive care. Venegas and Fredberg provided the following formulas:

$$f_0 = 1/(2\pi\sqrt{\bar{C}_1}) \quad (5)$$

where f_0 = resonant frequency, and

$$f_c = 1/(2\pi CR) \quad (6)$$

where f_c = corner frequency. (Plug in typical values for lung compliance, inertance, and airway resistance of a premature infant, 0.5 mL · cm⁻¹ H₂O, 0.025 cm H₂O · L · s⁻², and 50 cm H₂O · L⁻¹ · s⁻¹, respectively, and $f_0 = 45 \cdot s^{-1}$ and $f_c = 6.4 \cdot s^{-1}$.)

Finally, Venegas and Fredberg illustrated the value of using appropriate levels of positive end-expiratory pressure (PEEP). The PEEPs of 5–10 cm H₂O dramatically decrease the pressure amplitude necessary to ventilate premature infants at all frequencies when lung compliance is normal, and at all frequencies above ~6 Hz when lung compliance is reduced.

HFV EQUIPMENT

Design Classifications

Figures 4–7 illustrate four different ways HFVs have been created. Figure 4 illustrates high frequency positive-pressure ventilation (HFPPV), which is basically a CV that operates at HFV rates. Early devices worked in this manner, but they seldom worked at the very high frequencies used with infants.

Figure 5 illustrates high frequency flow interruption (HFFI), where positive pressure oscillations are created by releasing gas under pressure into the breathing circuit via an HFV valve mechanism. The valve may be a solenoid valve or valves, a spinning ball with a hole in it, and so on. Early HFVs used long, small diameter exhaust tubes to increase impedance to gas flow oscillating at HFV frequencies in the expiratory limb so that the HFV oscillations would preferentially flow in and out of the patient.

High frequency oscillatory ventilators (HFOVs) work in a similar manner to HFFIs, as shown in Fig. 6, except that the pressure oscillations in the patient’s breathing circuit are caused by an oscillating piston or diaphragm. Again, the impedance of the expiratory limb of the circuit tubing must be higher than the impedance of the patient and his ET tube when the gas flowing through the circuit is oscillating at HFV frequencies. The major difference between HFOV and HFFI is that pressure in the ventilator circuit during HFOV oscillates below atmospheric pressure in an effort to actively assist the patient’s expiration. (This topic is discussed further below when gas trapping is addressed.)

Finally, Fig. 7 illustrates high frequency jet ventilation (HFJV), where inspiratory gas is injected into the patient’s ET tube via a jet nozzle. Jet nozzles have been fashioned out of needles or built into special ET tubes or ET tube adapters as discussed below.

Each HFV approach introduces fresh gas into the patient’s airway at about 10 times the patient’s normal breathing frequency. The last three designs incorporate a separate constant flow of gas that passes by the patient’s

Figure 5. Basic design of HFFIs. (Used with permission. © 2003, Bunnell Inc.)

Figure 6. Basic design of HFOVs. (Used with permission. © 2003, Bunnell Inc.)

ET tube and out a large orifice valve to control baseline PEEP and mean airway pressure in the circuit. The patient may also breathe spontaneously from this gas stream, which may be provided by a built-in mechanism or by a separate conventional ventilator. Conventional IMV (intermittent mandatory ventilation) may be combined with HFV in this way. Additional hybrid devices that are more difficult to characterize have also been created, but the currently most common used HFVs are HFOVs, HFJVs, and conventional ventilators with built-in HFOV modules.

In the early 1980s, the FDA (U.S. Food and Drug Administration) decided that $150 \text{ breaths} \cdot \text{min}^{-1}$ would be the lower limit of what they would define as an HFV, and they placed rigorous Class III restrictions on any ventilator that operates above that frequency. As a result, there have been only six HFVs approved for use in the United States, three for infants and children, two for adults, and one HFV that was granted Class II approval (i.e., not needing proof of safety and efficacy since it was substantially equivalent to devices marketed before 1976, the date U.S. law was amended to require proof of safety and efficacy before new products can be marketed). At least four other HFVs are available outside the United States.

Of the FDA approved devices, two HFVs have been withdrawn from the market by the major corporation that acquired the smaller companies that developed them. Therefore, we are left with one HFJV, one HFOV for infants and children, one HFOV for children and adults, and a Class II HFV hybrid device designed for patients of all sizes. These four devices will be discussed in more detail below.

HFJV: High Frequency Jet Ventilators

The HFJVs inject inspired gas into the endotracheal tube via a jet nozzle. The Bunnell LifePulse High Frequency

Figure 7. Basic design of HFJVs. (Used with permission. © 2003, Bunnell Inc.)

Figure 8. Bunnell life pulse HFV. (Used with permission. © 2003, Bunnell Inc.)

Ventilator is the only HFJV currently available for intensive care in the United States (Fig. 8). It was designed for infants and children up to ~ 10 years of age and operates at rates between 240 and 660 bpm. It is also used in tandem with a conventional ventilator, which provides for the patient's spontaneous breathing, delivery of occasional sigh breaths, and PEEP.

The LifePulse is a microprocessor controlled, pressure limited, time cycled ventilator that delivers heated and humidified breaths to the ET tube via a LifePort adapter (Fig. 9). A small Patient Box placed close to the patient's head contains an inhalation valve and pressure transducer for monitoring airway pressures in conjunction with the LifePort adapter. Peak inspiratory pressure (PIP) is feedback controlled by regulating the driving pressure (servo pressure) behind the jet nozzle. More detailed information on the device can be found on the manufacturer's website: www.bunl.com.

The theory of operation behind the LifePulse is that pulses of high velocity fresh gas stream down the center of the airways, penetrating through the dead-space gas, while exhaled gas almost simultaneously moves outward in the annular space along the airway walls. This countercurrent action facilitates mucociliary clearance while it minimizes effective dead space volume.

The pressure amplitude (ΔP) of LifePulse HFJV breaths is determined by the difference between PIP and the CV-controlled PEEP. Its value is displayed continuously on the LifePulse front panel along with mean airway pressure, PIP, PEEP, and Servo Pressure.

Servo Pressure on the LifePulse is a direct reflection of the gas flow needed to reach the set PIP, so it varies with the patient's changing lung mechanics. Alarm limits are automatically set around the Servo Pressure to alert the operator to significant changes in the patient's condition as well as the tubing connecting the patient to the HFJV.

Figure 9. LifePort ET tube adapter for HFJV. (Used with permission. © 2003, Bunnell Inc.)

A low limit alarm would infer that the patient’s lung compliance or airway resistance has worsened, and the LifePulse is using less gas (i.e., smaller tidal volumes) to reach the set PIP in that circumstance. A high limit alarm would infer that the patient’s condition has improved, larger tidal volumes are being delivered, and the operator should consider weaning PIP in order to avoid hyperventilation.

Alarm limits are also automatically set around monitored mean airway pressure.

HFOV: High Frequency Oscillatory Ventilators

The SensorMedics 3100A HFOV for infants and children and its sister model, the 3100B for adults, are the only pure HFOVs currently available in the United States. Sinusoidal oscillatory ventilation is produced by an electromagnetically driven floating piston with adjustable frequency and amplitude. Inspiratory gas is supplied as bias flow, which escapes from the very large diameter (1.5 in. ID, 38 mm) patient breathing circuit via a traditional dome valve that

controls mean airway pressure. All pressures are monitored at the connection to the ET tube. The SensorMedics 3100A HFOV is illustrated in Fig. 10 and more information is available at www.sensormedics.com.

The 3100 HFOVs operate on the principle that high frequency oscillations that are in tune with the natural frequency of the patients lungs will preferentially move in and out of the lungs, as opposed to the exhaust system of the patient circuit. Haselton and Scherer illustrated a new gas transport principle that applies to HFOV (16). Differences in the velocity profiles of inspiration and expiration during HFOV created by the branching architecture of the lungs enables inspiratory gas to advance down the center of the airways while exhaled gas moves up along the airway walls as the piston of the HFOV pulls the gas back. The net effect of many oscillations is similar to, but less pronounced than, the flow characteristics of HFJV flow in the airways. Fresh gas tends to flow down the center of the airways while exhaled gas recedes back along the airway walls.

Figure 10. SensorMedics 3100A high frequency oscillatory ventilator. (Used with permission. © 2003, SensorMedics Inc.)

The 3100 HFOVs have six control settings:

1. Frequency, which is adjusted to suit patient size and lung time constants.
- 2–4. Bias gas flow rate, Mean Pressure Adjust and Mean Pressure Limit, which together set mean airway pressure.
5. Power, which sets ΔP .
6. % Inspiratory Time, which sets I:E (inspiratory to expiratory time ratio; typically set at 33%).

Mean airway pressure is the primary determinant of oxygenation, and ΔP is the primary determinant of tidal volume and ventilation (CO_2 removal). However, all controls are open-loop: increasing frequency decreases tidal volume and visa versa, and changing bias gas flow rate or power may change mean airway pressure. Mean airway pressure is monitored in the HFOV circuit, so changes there are apparent, but changes in tidal volume due to setting changes or changes in a patient's lung mechanics are not apparent. Given the squared relationship between tidal volume and CO_2 removal noted above, changes in frequency move PaCO_2 in the opposite direction of what one would anticipate with conventional ventilation. (Increasing frequency increases PaCO_2 ; decreasing frequency decreases PaCO_2 .) Thus, continuous or frequent monitoring of arterial PaCO_2 is recommended during HFOV, as it is with all HFVs and conventional ventilation of premature infants due to the potential for cerebral injury associated with hyperventilation (more on that topic later).

HFFIs and Other Hybrids

Conventional infant ventilators with built-in HFV modules, such as the Dräger Babylog 8000 *plus* (Dräger Medical AG & Co. KGaA) and the popular Infant Star Ventilator, which will no longer be supported by its manufacturer after May 2006, have been widely used in the

United States, Canada, Europe, and Japan. In general, these hybrid HFVs are not as powerful as the stand-alone HFVs, so their use is limited to smaller premature infants (<2 kg). The VDR Servolator Percussionator (Percussionaire Corporation, Sand Point ID), however, was designed to ventilate adults as well as premature infants. (Detailed information on these devices can be viewed on the manufacturers' websites: www.draeger-medical.com and www.percussionaire.com.) The mechanical performances of these devices vary widely, as do their complexities of operation and versatilities as infant ventilators. (See the section Equipment Limitations.)

Design Philosophy for Clinical Applications

The philosophy for controlling arterial blood gases with HFVs is similar to that used with pressure-limited conventional ventilation, especially when HFVs are used to treat homogeneous lung disorders such as RDS (respiratory distress syndrome) in prematurely born infants. The alveoli of these surfactant-deficient lungs must be opened with some type of recruitment maneuver and kept open with appropriate mean airway pressure (P_{aw}) or PEEP in order for the lungs to make oxygen available to the blood stream. Ventilation is accomplished at a frequency proportionate to the patient's size and lung mechanics using a peak airway pressure or pressure amplitude above PEEP that creates a tidal volume that produces an appropriate arterial PCO_2 . Pulse oximeters, which report the oxygen percent saturation of arterial blood, are great indirect indicators of when lungs have opened up, because oxygenation is highly dependent on the number of alveoli that are open and participating in gas exchange with the blood stream. Chest wall motion is a good indirect indicator of ventilation since it reflects the amount of gas that is passing in and out of the lungs.

The usual approach to initiation of HFV is to choose a frequency that is appropriate for the size of the patient and his lung mechanics, starting with 10 Hz or 600 bpm for the smallest premature infant with RDS and working downward as the size of the patient increases and lung mechanics improve. A good rule of thumb is to choose a frequency 10 times greater than the patient's normal breathing frequency, which would put HFV for adults at rates <200 bpm. Higher rates may be used with HFOV since exhalation is nonpassive, but gas trapping can still result unless mean airway pressure is kept high enough to keep the airways open during the active exhalation phase. Operating an HFOV with a 33% inspiratory time ($I:E = 1:2$) lessens negative pressure during exhalation compared to longer I -times (e.g., $I:E = 1:1$) thereby decreasing the potential for causing airway collapse.

With HFJV, the shortest possible inspiratory time (~ 0.020 s) usually works best; it maximizes inspiratory velocity, which helps reduce effective dead space, and minimizes $I:E$, which allows more time for exhalation to avoid gas trapping. These characteristics also minimize mean airway pressure, which is very useful when treating airleaks and for ventilation during and after cardiac surgery. The high velocity inspirations also enable ventilation of patients with upper airway leaks and tracheal tears.

Treatment of obstructive lung disorders absolutely requires longer exhalation times, so HFV must be used at lower frequencies on these patients. HFJV *I:E* varies from 1:3.5 to 1:12 as frequency is reduced from 660 to 240 bpm when inspiratory time is held constant at its shortest value.

The HFV is not intended and may in fact be contraindicated for patients with asthma, unless helium–oxygen mixtures become part of the mix (17).

Once a frequency and duty cycle (% *I*-time or *I:E*) is chosen, airway pressure settings (PIP, PEEP, or ΔP) are set to provide HFV tidal volumes that noticeably move the chest. If chest wall movement is not apparent, ventilation is probably not adequate. Use of transcutaneous CO₂ monitoring is of great benefit here.

Finally, mean airway pressure (*Paw*) or PEEP must be optimized. Too little *Paw* or PEEP will lead to atelectasis and hypoxemia, and too much *Paw* or PEEP will interfere with cardiac output. One of the true benefits of HFV, however, is that higher *Paw* and PEEP can be used without increasing the risk of iatrogenic lung injury. (The small HFV tidal volumes do not create the same potential for creating alveolar “stretch” injury as larger CV tidal volumes do.) Pulse oximeters can be great indirect indicators of appropriate lung volume, but one must be vigilant in detecting signs of decreased cardiac output.

Conventional ventilation is sometimes required or available for tandem use with certain HFVs. The CV breaths are most useful with nonhomogeneous lung disorders and to facilitate alveolar recruitment with atelectatic lungs. The usual strategy is to reduce CV support when starting HFV (assuming the patient is on CV prior to HFV) to 5–10 bpm while optimal *Paw* and PEEP is being sought, and then reduce CV support further.

Now some of the performance differences in HFV equipment and how those differences may affect successful HFV implementation will be examined.

HFV Equipment Limitations

There have been few head-to-head comparisons of HFV equipment. The most recent comparison were by Hatcher et al. and Pillow et al. where they compared several neonatal HFOVs and found wide variations in performance, complexity, and versatility (18,19). Pillow et al. concluded that the clinical effects of manipulating ventilator settings may differ with each HFOV device. In particular, the pressure amplitude required to deliver a particular tidal volume varies with device, and the effect of altering frequency may result in very different effects on tidal volume and PaCO₂.

The first rigorous analysis of HFVs was undertaken by Fredberg et al. in preparation for the HiFi Study (20). They bench tested eight HFVs in an effort to provide the clinicians who were to participate in the study comparative data that they could use to select an HFV for use in their study. (They selected the Hummingbird HFOV, manufactured by MERA of Japan.) Despite the wide diversity of ventilator designs tested, certain common features emerged. In almost all devices, delivered tidal volume was sensitive to endotracheal tube size and airway resis-

tance and invariant with respiratory system compliance. These results supported the theoretical basis for why high frequency ventilation may be a better treatment for RDS compared to pressure-limited CV (conventional ventilation), because low lung compliance is its paramount pathophysiological feature.

These HFV bench tests also found that tidal volume decreased with increasing frequency with all HFOVs where *I:E* (inspiratory to expiratory time ratio) was held constant and was invariant with HFJV and HFFI devices where *I*-time was held constant. Peak inspiratory flow rates for a given tidal volume and frequency were significantly higher with the HFJV and HFFI as well. Proximal airway pressure was also a poor indicator of distal pressure with all devices.

Two other studies compared HFJV to HFOV. Boros and associates compared the pressure waveforms measured at the distal tip of the endotracheal tube of the Bunnell LifePulse HFJV and the Gould 4800 HFOV (precursor to the SensorMedics 3100A HFOV) in normal, paralyzed, and anesthetized cats (21). They found that the HFOV required higher PIP, ΔP , and *Paw* to get the same PaCO₂, PaO₂, and pH compared to HFJV. Likewise, PaCO₂ was higher and pH and PaO₂ were lower with HFOV when the same airway pressures were used. However, different frequencies were used with the two ventilators; 400 bpm with HFJV and 900 bpm (15 Hz) with HFOV.

Zobel and associates also found that HFJV was effective at lower airway pressure compared to HFOV (22). They used a piglet model of acute cardiac failure and respiratory failure and also measured airway pressure at the distal tip of the endotracheal tube. The HFJV used was an Acutronic AMS-1000[®] (Acutronic Medical Systems AG, Switzerland) operating at 150 bpm with an *I:E* of 1:2. The HFOV was a SensorMedics 3100A operating at 10 Hz and 1:2.

Why do HFOVs (presumably) operate at higher *Paw* compared to HFJV? The answer to this question may be related to gas trapping, HFV rates, and what happens during exhalation. In both of the animal studies just discussed, HFJV rate was considerably lower than HFOV rate. Exhalation is passive during HFJV, so lower rates must be employed to allow sufficient exhalation time to avoid gas trapping. The HFOVs suck the gas back out of the lungs during the expiratory phase, and the physiologic consequence can be, not surprisingly, airway collapse. However, the *Paw* employed during HFOV determines the importance of this effect.

Bryan and Slutsky set the tone for the future of HFVs when they noted that this mode of ventilation is ideally designed for treatment of patients with poor lung compliance (23). The higher *Paw* required to match the pathophysiology of such patients also serves to splint the airways open during HFOV so that the choking effect of active expiration is mitigated.

In conclusion, both modes of HFV can cause gas trapping; they just do it by different mechanisms. The HFOV can choke off airways when *Paw* is insufficient to mitigate the effect of active expiration, and HFJV will trap gas when expiratory time is insufficient to allow complete exhalation of inspired tidal volume. One cannot lower *Paw* during HFOV beyond the point where choking is made evident by

a rise in a patient's PCO_2 . With HFJV, one should not increase frequency beyond the point where PEEP *monitored* in the endotracheal tube, as it is with the Bunnell LifePulse, begins to rise inadvertently. If the automatically set upper alarm limit on mean airway pressure with the LifePulse is activated, there is a good chance that this rise in Paw is due to inadvertent PEEP. The remedy for that circumstance is to decrease HFJV frequency, which lengthens exhalation time and allows the PEEP to fall back to *set* level.

Airway Pressure Monitoring During HFV

While airway pressures were monitored at the distal tip of the ET tube in the animal studies noted above, monitoring at this location is seldom done currently, because the Hi-Lo ET tubes (formerly manufactured by Mallinckrodt, Inc.) are no longer available. Thus, airway pressure monitoring is done either at the standard ET tube adapter connection during HFOV or at the distal tip of the special LifePort adapter during HFJV. In either case, the pressure waveform measured deep in the lungs at the alveolar level is greatly damped (Fig. 11). Gerstmann et al. reported that measurement of pressure amplitude in the alveoli of rabbits during HFOV at 15 Hz was only 10% of that measured proximal to the ET tube (24).

Meaningful monitoring of airway pressure during HFOV is limited to mean airway pressure, and that is only representative of mean alveolar pressure in the absence of gas trapping, as noted above. Relative values of pressure amplitude at the proximal end of the ET tube are indicative of tidal volume size, and they are typically expressed as such by the various HFOVs.

Peak inspiratory pressure (PIP) and PEEP as well as Paw are measured during HFJV at the distal tip of the LifePort ET adapter. The PEEP is representative of alveolar PEEP at this location in the absence, again, of gas trapping. However, the PIP at this location is a gross overestimate of peak pressure in the alveoli. Mean airway pressure may slightly overestimate mean alveolar pressure as shown by the study of Perez-Fontan et al. (25).

HFV APPLICATIONS IN NEONATES AND CLINICAL OUTCOMES

Homogeneous Atelectatic Lung Disease (e.g., RDS) and Prevention of Lung Injury

Ever since the completion of the first multicenter, randomized, controlled HFV trial was published in 1989, reporting no benefit for premature infants with RDS and an increased risk of severe cerebral injury (26), the choice of HFV to prevent lung injury in preterm infants has been hotly debated. Some recent trails have demonstrated that if HFVs are implemented within hours of a premature infant's birth with the proper strategy, results are positive. Other recent studies have not been positive.

The HiFi Trial, as the first multicenter, randomized, controlled trial was labeled, was criticized for the general lack of clinical experience of the investigators and failure to adhere to the most appropriate strategy for recruiting and maintaining appropriate lung volume (15). Later multicenter, randomized controlled trials conducted in the 1990s using both HFJV and HFOV demonstrated significant reductions in chronic lung disease (CLD) measured at 36 weeks postconceptional age (PCA) in this patient population with practically no difference in adverse effects (27,28). (There was a slightly higher incidence of PIE in the experimental group of the HFOV study.) The demographics and results of these two trials are illustrated in Tables 1 and 2.

The results of the HFJV study were criticized for a lack of well-defined ventilator protocols for the conventionally ventilated control group, whereas protocols for both the HFOV and SIMV control groups in the HFOV study, conducted several years later, were well conceived and monitored during the study. Therefore, it is interesting to note that the major outcome measures of CLD at 36 weeks PCA in the control groups of the two studies were almost identical.

Other HFV studies revealed an increase in severe cerebral injury that appears to be related to hyperventilation and hypocarbia during HFV (29–32). Other criticisms of recent trials with negative or equivocal results include the same strategy issues plus choice of HFV devices, limited time on HFV before weaning back to CV, and so on (33).

Because of these mixed results, HFVs have yet to be generally accepted for early treatment of premature infants with RDS and prevention of lung injury.

Table 1. Demographics of Two Multicenter, Randomized Controlled Trials with HFOV and HFJV

Design/Demographics	HFJV Study ^a		HFOV Study ¹⁰	
	HFJV	CV	HFOV	SIMV
Number of Patients	65	65	244	254
Mean Birth Weight, kg	1.02	1.02	0.86	0.85
Mean Gestational Age	27.3	27.4	26.0	26.1
Age at Randomization, h	8.1	8.3	2.7	2.7
1 min/5 min Apgar Scores	3.5/7	4/7	5/7	5/7
$F_{I}O_2$ at Entry	0.62	0.69	0.57	0.60
Mean Airway Pressure at Entry	10	10	8.2	8.3

^aSee Ref. 9.

Table 2. Significant Respiratory and Clinical Outcomes of HFOV and HFJV Early Application Trials on Premature Infants with RDS

Significant Respiratory and Clinical Outcomes	HFOV Study		HFJV Study	
	HFOV	SIMV	HFJV	CV
Alive w/o CLD at 36 weeks PCA	56%	47%	68%	48%
	$p = 0.046$		$p = 0.037$	
Age at extubation, days	13	21	-	-
	$p < 0.001$			
Crossovers or Exits ^a	25/244 (10%)	49/254 (19%)	3/65 (5%)	21/65 (32%)
	$p = 0.07$		$p < 0.01$	
Success after Crossover			14/21 (67%)	0/3 (0%)
			$p = 0.06$	
Supplemental O ₂	27%	31%	5.5%	23%
	$p = 0.37$		$p = 0.019$	
PIE	20%	13%		
	$p = 0.05$			
Pulmonary Hemorrhage	2%	7%	6.3%	10%
	$p = 0.02$		$p > 0.05$	

^aSimilar failure criteria were prospectively defined in both studies. Those who met the criteria in the HFJV study were crossed over to the other mode, while those who met the criteria in the HFOV study exited the study and were treated with whatever mode of ventilation the investigators deemed appropriate, including HFJV (personal communication, David Durand, MD). Data on all patients were retained in their originally assigned group in both studies.

Homogeneous Restrictive Lung Disease (e.g., Congenital Diaphragmatic Hernia)

While theories support use of HFV in cases where the lungs are uniformly restricted by acute intra-abdominal disease or postsurgically in infants with congenital diaphragmatic hernia, omphalocele, or gastroschisis, there are no randomized controlled trials due to the rarity of these disorders. Despite this lack of controlled trials, HFV has been widely accepted as an appropriate treatment for this category of lung disease due to the futility of CV treatment in severe cases.

Keszler et al. demonstrated improved gas exchange and better hemodynamics with HFJV in an animal model of chest wall restriction (34) and later reported improved ventilation and hemodynamics in a series of 20 patients with decreased chest wall compliance (35). Fok et al. reported improved gas exchange with HFOV in eight similar patients who were failing CV (36).

Nonhomogeneous Atelectatic and Restrictive Lung Disease (e.g., RDS with Tension PIE)

Pulmonary interstitial emphysema (PIE) in the premature infant creates a non-homogeneous lung disease: parts of the lungs are collapsed as a result of surfactant deficiency while other parts become overexpanded with gas trapped in interstitial areas. Air leaks like PIE originate most commonly in premature infants near the terminal bronchial (37). As gas dissects into interstitial spaces, it invades and dissects airway and vascular walls moving towards the larger airways and vessels and the pleural space where pneumothoraces are formed (38). While positive-pressure CV may successfully penetrate such restricted airways, the consequence may well be accumulation of trapped gas in the alveoli and subsequent alveolar disruption, which produces the classical picture of PIE on X ray.

The HFJV quickly gained a reputation for superior treatment of PIE in the early days of its clinical application. A multicenter randomized trial of HFJV compared to rapid rate (60–100 bpm), short *I*-time (0.20–0.35 s) CV for the treatment of PIE confirmed anecdotal findings of faster and more frequent resolution of PIE on HFJV. Survival in the stratified group of 1000–1500 g birth weight infants was most evident (79% with HFJV vs. 44% with CV; $p < 0.05$). There was no difference in the incidence of adverse side effects.

There is, as yet, no comparable randomized trial of HFOV treatment for PIE. While anecdotal success has been reported, attempts to show an advantage with HFOV in a randomized controlled trial have so far been unsuccessful. It may be that the physical characteristics of the two types of HFVs coupled with the pathophysiologic characteristics of PIE are the reasons for this lack of success. Recall that one difference between HFV devices reported in the pre-HiFi bench studies by Fredberg et al. was that HFJVs squirt gas into the lungs at much higher flow rates compared to HFOV. That fact may make HFJV more sensitive to airway patency compared to HFOV.

Since CV breath distribution may be more affected by lung compliance while HFV breaths may be more affected by airway resistance, especially HFJV breaths with their high velocity inspirations, the distribution of ventilation in the nonhomogeneous PIE lung may be markedly affected by mode of ventilation. While the path of least resistance for CV breaths may lead to more compliant, injured areas of the lungs, HFJV breaths may automatically avoid injured areas where airway and vascular resistances are increased. Therefore, HFJV breath distribution may favor relatively normal airways in the uninjured parts of the lungs where ventilation/perfusion matching is more favorable.

The CV tidal volumes delivered with higher PEEP and *Paw* may dilate airways enough to help gas get into

restricted areas in babies with PIE, but those larger tidal volumes take longer to get back out. Much smaller HFV tidal volumes are more easily expired, especially those that were unable to penetrate the restricted airways where the lungs are injured.

Upper Airway Fistulas and Pneumothoraces

Theoretically, the small tidal volumes, high inspiratory velocities, and short inspiratory times of HFJV are ideally suited for treating pneumothoraces and broncho-pleural and tracheal-esophageal fistulae. Gonzalez et al. found that gas flow in chest tubes, inserted in a series of infants with pneumothoraces, dropped an average of 54% when six infants were switched from CV to HFJV (39). Their mean $PaCO_2$ dropped from 43 to 34 Torr at the same time that their peak and mean airway pressures measured at the distal tip of the ET tube dropped from means of 41–28 and 15 to 9.7 cm H_2O , respectively.

Goldberg et al. (40) and Donn et al. (41) similarly reported improved gas exchange and reduced flow through tracheal–esophageal fistulas.

Homogeneous Obstructive Lung Disease (e.g., Reactive Airway Disease, Asthma)

The HFV should theoretically not be of much benefit in treating lung disorders such as asthma wherein airway resistance is uniformly increased. Low rates and long expiration times should be more effective. However, recent work with HFJV and helium-oxygen mixtures (heliox) demonstrated interesting potential for treating such disorders in patients requiring no more than 80% oxygen.

Tobias and Grueber improved ventilation in a one-year old infant with respiratory syncytial virus and progressive respiratory failure related to bronchospasm with HFJV by substituting a mixture of 80% helium/20% oxygen for compressed air at the air/oxygen blender (42). They hypothesized that the reduced density of helium compared to nitrogen enhanced distal gas exchange. Gupta and associates describe another case where HFJV and heliox rescued a 5 month old infant with acute respiratory failure associated with gas trapping, hypercarbia, respiratory acidosis, and air leak (43). The combination of HFJV with heliox led to rapid improvements in gas exchange, respiratory stabilization, and the ability to wean the patient from mechanical ventilation.

Nonhomogeneous Obstructive Lung Disease (e.g., MAS) and ECMO Candidates

Clinical studies of infants with meconium aspiration syndrome (MAS) provide support for the use of HFV with this type of lung disease. These patients are potential candidates for extracorporeal membrane oxygenation (ECMO), so ability to avoid ECMO is a typical outcome variable in such studies.

Clark et al. randomized 94 full-term infant ECMO candidates to HFOV or CV in a multicenter study (44). Prospectively defined failure criteria were met by 60% of those infants randomized to CV while only 44% of those randomized to HFOV failed. Cross-overs to the alternate mode by those who failed were allowed, and 63% of those

who failed CV were rescued by HFOV, while only 23% of those who failed HFOV were rescued by CV. (The latter comparison was statistically significant.) Overall, 46% of the infants who met ECMO criteria required ECMO.

A similar single-center study of HFJV versus CV involved 24 ECMO candidates with respiratory failure and persistent pulmonary hypertension of the newborn (PPHN) (45). Most of the infants in the HFJV-treated group (8 of 11) and 5 of 13 of the conventionally treated infants had either MAS or sepsis pneumonia. Treatment failure within 12 h of study entry occurred in only two of the HFJV-treated infants versus seven of the conventionally treated infants. The ECMO was used to treat 4 of 11 HFJV infants versus 10 of 13 control infants. Zero of nine surviving HFJV-treated infants developed chronic lung disease compared to four of 10 surviving controls ($p = 0.08$). Survival without ECMO in the HFJV group was 5 of 11 (45%) versus 3 of 13 (23%) in the control group. There was no statistical significance in any of these comparisons due to the small number of patients.

The degree to which pathophysiology predicts positive outcomes with respect to the ability of HFVs to rescue infants that become ECMO candidates has been explored in two additional clinical studies. Baumgart et al. evaluated their success with HFJV prior to instituting an ECMO program in 73 infants with intractable respiratory failure who by age and weight criteria may have been ECMO candidates (46). They found survival after HFJV treatment to be much higher in infants with RDS and pneumonia (32/38, 84%) compared to MAS/PPHN (10/26, 38%) or congenital diaphragmatic hernia (3/9, 33%). All patients initially responded rapidly to HFJV as measured by oxygen index (O.I., calculated as mean airway pressure in cm H_2O multiplied by fraction of inhaled O_2 divided by P_{aO_2} in Torr). However, that improvement in survivors was realized and sustained during the first 6 h of HFJV treatment.

Paranka et al. studied 190 potential ECMO candidates treated with HFOV during 1985–1992 (47). All patients were born at 35 weeks gestational age or more and developed severe respiratory failure, as defined by an arterial to alveolar oxygen ratio ($P_{(A-a)O_2}$) < 0.2 or the need for a peak pressure of > 35 cm H_2O on CV. Fifty-eight percent (111 patients) responded to HFOV and 42% (79 patients) were placed on ECMO. Gas exchange improved in 88% of the infants with hyaline membrane disease (RDS), 79% of those with pneumonia, 51% with meconium aspiration, and 22% of those with congenital diaphragmatic hernia. They also found failure to demonstrate an improvement in $P_{(A-a)O_2}$ after six hours on HFOV to be predictive of failure.

During and After Cardiac Surgery

The ability of HFJV to hyperventilate while using lower mean airway pressure is a great asset when treating patients with cardiac problems. During surgery, the small tidal volumes and low mean airway pressure allow the surgeon to move the lungs out of the way, in order to visualize and work on the heart. After surgery, HFJV can gently hyperventilate the patient to encourage increased pulmonary blood flow while mean airway pressure is kept down (48–51).

PPHN and Nitric Oxide Therapy

Kinsella et al. demonstrated the potential of HFV to enhance delivery of nitric oxide (NO) for the treatment of PPHN in a large, multicenter, randomized controlled trial (52). Nitric oxide delivered with HFOV to infants with significant parenchymal lung disease was more effective than NO delivered by CV. NO has also been delivered successfully with HFJV (53). However, NO must be administered via the HFJV circuit in order for the patient to realize any beneficial effect from the gas (54). Inhaled NO does not work with HFJV when administered exclusively through the conventional ventilator circuit (55).

HFV APPLICATIONS IN CHILDREN AND ADULTS

While the bulk of the research and application of HFV has been aimed at the benefit of infants to date, the sheer number of potential applications for children and adults is far greater. Unfortunately, the number of HFVs available to treat adults is severely limited. There is only one instrument currently available in the United States specifically designed for ARDS in children and adults, the SensorMedics 3100B. (The Percussionaire VDR4-F00008 ventilator also provides HFV for adults. It was approved as a Class II device by the FDA.)

Acute respiratory distress syndrome is the obvious target for HFV treatment in adult intensive care. This syndrome affects ~50 per 100,000 population with a mortality of 30–50%. It is a clinical syndrome of noncardiogenic pulmonary edema associated with pulmonary infiltrates, stiff lungs, and severe hypoxemia (56). Although the pathology of ARDS involves a number of features similar to RDS in infants, such as hyaline membranes, endothelial and epithelial injury, loss of epithelial integrity, and increased alveolar-capillary permeability, it may have a much greater inflammatory component.

The only treatment shown to positively impact mortality over the past several decades came from the ARDSnet Trial where CVs were used with a low tidal volume ventilatory strategy designed to reduce iatrogenic lung injury (57). Comparative treatments in this multicenter study of 861 patients included an experimental group where mean tidal volumes for the first 3 days of their treatments were $6.2 \text{ mL} \cdot \text{kg}^{-1}$ body weight and a control group where tidal volumes were $11.8 \text{ mL} \cdot \text{kg}^{-1}$. The experimental group had lower mortality and fewer days on mechanical ventilators.

With ARDSnet trial pointing in the general direction of smaller tidal volumes, it is not surprising that recent HFV trials appear very promising, especially since HFV investigators focused on NICU patients and worked their way up the learning curve. The most important lesson learned, and one that took many years to learn in the treatment of infants, was the importance of recruiting and maintaining adequate lung volume during HFV. Adult trials of HFV for ARDS now begin with a Paw $5 \text{ cm H}_2\text{O}$ greater than that currently being used with CV. Just as was learned with infants, it is safe to use higher PEEPs and mean airway pressures with HFVs smaller tidal volumes.

HFV Clinical Trails with Children and Adults

The importance of starting early with HFV on adults and children with ARDS was highlighted in several anecdotal and pilot trials. Smith et al. treated 29 children with severe ARDS complicated by pulmonary barotrauma with HFJV (58). Twenty (69%) survived, and the only statistically significant difference between survivors and nonsurvivors was the mean time on CV before initiating HFJV (3.7 days in survivors vs. 9.6 days in nonsurvivors). Fort et al. similarly found that survivors in a pilot study of HFOV for adults with ARDS were on CV 2.5 days before initiation of HFOV, while nonsurvivors were on CV for 7.2 days (59). Expected survival in the pilot study was <20%, actual survival was 47%.

Arnold et al. compared HFOV to CV in children with respiratory failure (60). Optimizing lung volume was emphasized in both the experimental and control groups. The strategy for optimizing lung volume in the CV group was to lengthen inspiratory times and increase PEEP in order to decrease required PIPs. They found significant improvement in oxygenation in the HFOV group as well as a lower need for supplement oxygen at 30 days postenrollment.

A recent prospective trial of HFOV for ARDS had similar results. Mehta et al. treated a series of 24 adults with severe ARDS with HFOV (61). Five of the patients were burn victims. Within 8 h of HFOV initiation, $F_1\text{O}_2$ and PaCO_2 were lower and $\text{PaO}_2/F_1\text{O}_2$ was higher than baseline values during CV throughout the duration of the trial. An obvious focus was placed on recruiting and maintaining adequate lung volume while on HFOV, since Paw was also significantly higher than that applied during CV throughout the HFOV trial. Unfortunately, this increase in Paw was associated with significant changes in hemodynamic variables including an increase in pulmonary artery occlusion pressure (at 8 and 40 h) and central venous pressure (at 16 and 40 h), and a reduction in cardiac output throughout the study. Thus, Paw may not have been optimized. However, 10 patients were successfully weaned from HFOV and 7 survived. Again, there was a statistically significant difference in the time spent on CV prior to initiation of HFV: 1.6 days for survivors versus 5.8 days for the nonsurvivors.

Noting the importance of early intervention, Derdak et al. designed a multicenter, randomized, controlled trial comparing the safety and effectiveness of HFOV versus CV in adults with less severe ARDS (62). (The authors nicknamed their trial: the MOAT Study.) Inclusion criteria included $\text{PaO}_2/F_1\text{O}_2 \leq 200 \text{ mmHg}$ (26.66 kPa) on $\geq 10 \text{ cm H}_2\text{O}$ PEEP, and 148 adults were evenly randomized. Applied Paw was significantly higher in the HFOV group compared with the CV group throughout the first 72 h. The HFOV group showed improvement in $\text{PaO}_2/F_1\text{O}_2$ at <16 h, but this difference did not persist beyond 24 h. Thirty day mortality was 37% in the HFOV group and 52% in the CV group ($p = 0.102$). At 6 months, mortality was 47% in the HFOV group and 59% in the CV group ($p = 0.143$). There were no significant differences in hemodynamic variables, oxygenation failure, ventilation failure, barotraumas, or mucus plugging between treatment groups.

The MOAT Study indicates that HFOV is safe and effective for ARDS, and the FDA approved the SensorMedics 3100B for ARDS. Outcome data from this study are comparable to those of the ARDSnet Trial. The control group in the MOAT study was not ventilated with tidal volumes as small as those used in the experimental group of the ARDSnet trial (6–10 vs. 6.2 mL·kg⁻¹), but they were generally smaller than the ARDSnet control group (11.8 mL·kg⁻¹). Mortality at 30 days in the MOAT Study was not quite as good as that in the ARDSnet Trial (37 vs. 31%, respectively), but sepsis was much more prevalent in the MOAT Study compared to the ARDSnet Trial (47 vs. 27%, respectively).

STATUS OF HFV, RISKS, AND OUTLOOK FOR THE FUTURE

Are HFVs Safe and Effective?

Use of HFVs for newborn infants and adults began in the early 1980s. Fifteen randomized controlled trials with infants and about one-half that many randomized studies with children and adults were conducted over the next 20+ years. Over 1000 articles about HFV have been published. Yet, there are still questions about HFV safety and efficacy.

There are certainly adequate data to suggest that HFVs are effective in lessening chronic lung injury. The fact that not all studies have been successful in this regard is a reflection of differences in infant populations, ventilator strategies, and devices used. There is little argument that use of antenatal steroids, exogenous surfactant, and ventilator strategies using smaller tidal volumes have greatly improved mortality and morbidity of premature infants.

Not surprisingly, as clinicians have become more successful with HFV and other small tidal volume strategies, the age of viability of premature infants has gone down. Thus, the challenge of preventing chronic lung disease in NICU patients never gets easier, because the patients keep getting more premature.

What Are the Risks Associated with HFV in the NICU?

The greatest controversy in consideration of HFVs as a primary mode of ventilation of premature infants is safety, particularly whether HFV use increases the risk of cerebral injury. Clark et al. evaluated the probability of risk of premature infants suffering from intraventricular hemorrhage (IVH) or periventricular leukomalacia (PVL) by conducting a meta-analysis of all prospective randomized controlled trials of HFV published by 1996

(63). The meta-analysis showed that use of HFV was associated with an increased risk of PVL (odds ratio = 1.7 1.7 with a confidence interval of 1.06–2.74), but not IVH or severe (≥grade 3) IVH. In addition, since the largest study in the group by far was the HiFi Trial (14), where implementation strategy was reputed to be less than optimal, they repeated the analysis without that study. When the results of the HIFI study were excluded, there were no differences between HFV and conventional ventilation in the occurrence of IVH or PVL.

Since 1996, seven additional randomized controlled trials of early use of HFV have been conducted on 1726 patients. Only one of the newer studies demonstrated a possible increased risk of cerebral injury (64), and that study included 273 patients or 16% of the total in these 7 studies. Thus, a more current meta-analysis would be even more convincingly positive today, and one could even say that there is *little* evidence of increased risk of cerebral injury during HFV. Why then, is this matter still controversial?

The risk of causing cerebral injury in premature infants is associated with hyperventilation and hypocarbia as noted earlier. There will never be a randomized controlled trial to prove cause and effect here, for obvious reasons. Therefore, all we can do is try to avoid hyperventilation and hypocarbia and see if outcomes get better over time.

Avoiding hyperventilation and hypoxemia first requires proper monitoring. Pulse oximetry, transcutaneous CO₂ monitoring, and continuous or frequent arterial blood gas monitoring are essential during HFV. Control of PaCO₂ during HFV often requires optimization of PEEP, Paw, and pressure amplitude (ΔP) as shown in Fig. 12. The HFVs are noted for their ease of blowing off CO₂ at lower airway pressures compared to CV, so PEEP and Paw must often be increased above those used during CV, if hypoxemia is to be avoided.

With HFOV, one often adjusts mean airway pressure without knowing the resulting baseline pressure or PEEP, whereas with HFJV, PEEP is adjusted to get an appropriate Paw. Therefore, one must not be fearful of higher PEEP when higher mean airway pressure is required. PEEP as high as 10 cm H₂O is not unusual when HFJV is being used to treat premature infants.

One must also recognize that raising PEEP will reduce ΔP when PIP is held constant, as shown in Fig. 12, which causes both PaO₂ and PaCO₂ to rise.

Other safety concerns with early use of HFVs for preventing lung injury are interference with cardiac output by using too much PEEP or Paw. Since interference with

Figure 12. Adjusting pressure waveforms to correct arterial blood gases. (Used with permission. © 2003, Bunnell Inc.)

venous return by elevated intrathoracic pressure raises intracranial pressure, there is associated fear of causing IVH by this mechanism as well.

A related issue, for those HFVs with that capability, is using too many CV breaths or using overly large CV tidal volumes during HFV. The latter use increases the risk of causing lung injury when HFV is implemented with higher PEEP.

Optimizing PEEP and minimizing the risk of using too many CV breaths during HFV can be achieved at the same time. The following flowchart for finding optimal PEEP during HFJV illustrates this point (Fig. 13).

The flowchart in Fig. 13 is based on the concept that CV breaths will be most effective in opening up collapsed alveoli, while PEEP or baseline pressure will prevent alveoli from collapsing during exhalation. The longer *I* times and tidal volumes of CV breaths provide a greater opportunity to reach the critical opening pressure of collapsed alveoli, and if PEEP is set above the critical closing pressure of those alveoli, they will remain open throughout the ventilatory cycle. Once PEEP is optimized, there is less value in using CV in tandem with HFV.

Although Fig. 13 was designed for use during HFJV, its principles are equally applicable to HFOV when CV may not be available. In this case, mean airway pressure is raised until an improvement in oxygenation makes it apparent that alveolar recruitment has occurred. At that point, it should be possible to decrease mean airway pressure somewhat without compromising oxygenation. However, the appropriate strategy here would be to set a goal for lowering the fraction of inhaled oxygen ($F_{I}O_2$) before

attempting to lower *Paw*. In this way, one should avoid inadvertently weaning *Paw* too fast and risking catastrophic collapse of alveoli. An appropriate $F_{I}O_2$ goal in this circumstance might be 0.3–0.4 depending on the vulnerability of the patient to high airway pressures and the magnitude of the mean airway pressure present at the time.

The final risk to be mentioned here will be the greatest risk associated with HFV: inadequate humidification and airway damage. In unsuccessful applications of HFV in infants in the early 1980s, necrotizing tracheal bronchitis (NTB) was frequently noted at autopsy (65). First discovered during HFJV, it was subsequently discovered during HFOV as well (66). Fortunately, the development of better humidification systems coupled with earlier implementation of HFV seems to have eradicated this problem as an extraordinary adverse side effect. None of the 14 randomized controlled trials has found an increase in NTB associated with HFV treatment.

Humidification during HFV is challenging, especially for HFOVs that use high gas flow rates and HFJVs. Gas humidified under pressure will not hold as much water as unpressurized gas, so HFJVs must humidify their inspiratory gas at higher than normal temperatures in order to reach anything near 100% relative humidity at body temperature.

Bunnell Incorporated’s HFJV addressed this inherent problem by minimizing the driving pressure behind their jet nozzle using an inspiratory pinch valve in a little box placed near the patient’s head. The pinch valve reduces the pressure drop through that part of the system because of

Figure 13. Optimal PEEP flowchart. (Used with permission. © 2005, Bunnell Inc.) (Warnings: Lowering PEEP may improve SaO₂ in some cases. Optimal PEEP may be lower in patients with active air leaks or hemodynamic problems. Do not be shocked if optimal PEEP = 8 – 12 cm H₂O. Using IMV PIP with high PEEP is hazardous. Do not assume high PEEP causes overexpansion.)

the relatively large internal diameter (ID) of the tubing in the valve (0.13 in., 3.2 mm). Placing the pinch valve within 35 cm of the patient where inspired gas is delivered via a jet nozzle embedded in a special ET tube adapter also enables the LifePulse Ventilator to deliver its tiny tidal volumes without much driving pressure. (A typical driving pressure needed for HFJV with the LifePulse on a premature infant is between 1.5 and 3.5 psi.) The HFVs that work at higher pressures and gas flow rates sometimes provide humidity with liquid water. (See Acutronic jet ventilation systems on their website: www.acutronic-medical.ch.)

Working Within the Limitations of HFVs in the NICU

The HFVs have been widely accepted for treating newborn infants with lung injury. Whether HFV will ever be widely accepted as a primary mode of ventilation is another matter. There have been many advances in conventional ventilator therapy over the past several years and, to a certain extent, techniques used to optimize HFVs have been applied to CVs (67).

Like most therapies, the skill with which HFV is implemented is probably the most critical determinant of clinical success. Starting HFV on patients sooner rather than waiting for worsening lung disease to become nearly hopeless is also extraordinarily important. Having written protocols defining the patient population and how HFV is optimized for that patient population can also be very helpful.

Early-to-moderately early stage treatment of homogeneously noncompliant lungs is the most obvious choice as an appropriate indication for HFV. If hyperventilation and gas trapping are avoided and appropriate resting lung volume is achieved, better outcomes should result. The ability of all HFVs to ventilate lungs using less pressure, independent of lung compliance, is nearly universal as long as the lungs are not too large for the ventilator's output. Many of the HFV modes built into CVs are not powerful enough to ventilate even a term infant, so operators need to know the relative output capacities of their HFVs.

Using HFVs as rescue ventilators usually means that the underlying lung disorder has become nonhomogeneous or even obstructive. Ironically, most clinicians will only use HFVs as rescue ventilators even though these disorders are much harder to treat with HFV. Gas trapping is a much greater risk with heterogeneous obstructive disorders, and it may be avoided via use of small HFV tidal volumes. However, even HFV tidal volumes can be trapped if expiratory times are not several times greater than inspiratory times. The HFJVs with their very short I:E ratios and very high velocity inspiratory flows have been demonstrated to be more effective with these types of lung disease. Combined CV and HFJV have also been shown to work even better than pure HFJV in severe nonhomogeneous lung disorders (68).

What Are the Risks and Limitations Associated with HFV in Treating Children and Adults?

The only risks unique to HFV for children and adults are those associated with the necessity for delivering larger

tidal volumes at higher flow rates compared to HFV for infants. Humidification of HFV gases is crucial as was learned with the early trials in infants, and gas is more difficult to humidify under pressure, as discussed above. The most challenging mode of HFV in this respect is HFJV, since it takes elevated pressure to push gas through a jet nozzle. Perhaps this is one reason for the lack of success of the only HFJV for adults approved by the FDA for use with adults (the APT 1010 Ultrahigh Frequency Ventilator, developed by the Advanced Pulmonary Technologies, Inc., Glastonbury, CT). Humidification with this device was only provided via supersaturated entrained gas. However, the same corporation that pulled this product off the market is also planning to discontinue manufacturing the Infant Star HFV for infants, and that ventilator had no such humidification issues. Thus, it appears likely that these products were discontinued for other (i.e., business) reasons.

There is also danger of operator error when any machine is used by untrained or unskilled operators. Given the tendency for some hospitals to only use HFVs as last resort rescue ventilators, one must consider those types of risks. Since HFOV is most successful in homogeneous lung disorders, it only makes sense for it to be used relatively early in the course of ARDS before significant lung injury results from CV treatment. Once the patient's condition deteriorates into ARDS complicated by airleaks, chances for HFOV success may be significantly decreased.

Treating children and adults with HFVs also has to take optimal frequency into account. The primary determinant of optimal frequency is lung compliance, which is primarily determined by the patient's size. An adult's lung is larger than that of a child, which is larger than that of a term newborn, which is larger than that of a preemie. Thus, HFV frequency should be reduced as patient size increases. Optimal HFV for adults may occur at 150 bpm, whereas operation at that frequency with infants would not even be considered HFV.

Given the evidence that HFJVs have been more successful with nonhomogeneous lung disorders in infants, as described above, it would seem likely that HFJVs would find a role for treating adult patients with ARDS as well. Unfortunately, the application of HFJV for adults has been tarnished by a lack of success in very early studies.

Carlson et al. conducted a randomized controlled trial of HFJV versus volume-cycled CV on adults with acute respiratory failure (69). While they reported patients failing on CV improved more rapidly and in greater number when switched to HFJV compared to those who were failing on HFJV and crossed to CV, there were no advantages with respect to survival and total duration of stay in the ICU. Thus, they concluded that HFJV offered no obvious benefits over CV. The study was published in 1983, long before there was much appreciation of the need to optimize PEEP and maintain adequate lung volume during HFV. One wonders what results would come from a similar trial 20 years later, but such a trial will probably never happen now. The cost, time, and effort of seeking FDA approval for any Class III device is so high now, that HFJV may never find its way back into an adult ICU in the United States.

What Is the Outlook for HFV in the Future?

The HFVs evolved as people discovered problems with trying to replicate breathing in compromised patients. Unlike conventional ventilation, HFV is designed to facilitate gas exchange rather than mimic how people breathe normally. The differences between HFV and CV have led to creative solutions for many of the problems that investigators set out to solve, but they have also created their own problems.

It was discovered how HFVs can ventilate much more effectively than CV, and in the process, it was discovered how hypocapnia can lead to severe cerebral injury in premature infants.

The HFV still uses positive pressure where we create negative pressure to draw gas into the lungs. So, the problems related to use of ET tubes and its bypassing the normal humidification system of the body (i.e., the nose) are still there.

The HFV uses much smaller tidal volumes than CV, so the damage we have come to call volutrauma has lessened. In the process, it was discovered that more mean airway pressure or PEEP is required to keep sick lungs open while they are being ventilated. Then it was discovered that the new problems were associated with too much pressure in the thorax interfering with cardiac output.

So, HFVs do not solve all the problems, and they require increased vigilance to avoid creating new problems. However, the basic differences between HFV and CV provide a very reliable alternative to CV in circumstances where those differences are critical to survival.

The HFV tidal volumes are minimally affected by lung compliance and maximally affected by airway resistance when they are delivered via a jet nozzle. Therefore, in lung disorders where these conditions dictate treatment success or failure, wise users of HFVs have been very successful. When HFV users are not adequately trained or aware of the differences in HFV gas distribution caused by lung pathophysiology, success can be elusive.

Premature infants with RDS represent a large population with the potential of leading long and rich lives if they survive their first months of life with undamaged or even minimally damaged lungs and brains. Many randomized controlled trials have demonstrated the potential of HFVs to help these infants realize that potential.

The tens of thousands of adults who succumb to ARDS every year also have the potential of increased survival with less morbidity thanks to HFVs. These patients, when successfully treated with an HFV, will be considered rescued from a well-recognized disorder with a chronically high mortality rate.

Given the skill and training needed to master HFVs, their use may be considered risky indefinitely. As HFVs and associated monitoring equipment become better designed to help their users optimize assisted ventilation, HFV use should increase and evolve into earlier, more prophylactic applications to prevent lung injury. The HFVs are inherently a kinder, gentler form of mechanical ventilation. Hopefully, their true potential will someday be realized.

INTRODUCTION

Natural synovial joints, such as hips, are remarkable bearings in engineering terms. They can transmit a large dynamic load of several times bodyweight during steady-state walking, yet with minimal friction and wear achieved through effective lubrication and with little maintenance. However, diseases such as osteoarthritis and rheumatoid arthritis or trauma sometimes necessitate the replacement of these natural bearings. Artificial hip joints replace the damaged natural bearing material, articular cartilage. As a result, pain in the joint is relieved and joint mobility and functions are restored. Total hip joint replacement has been considered as one of the greatest successes in orthopaedic surgery in the last century in improving the quality of life of the patients. Currently, > 1 million hip joints are replaced worldwide each year, with ever increasing use of these devices in a wider range of patients.

The majority of current artificial hip joints consist of an ultrahigh molecular weight polyethylene (UHMWPE) acetabular cup against a metallic or ceramic femoral head as illustrated in Fig. 1. These devices can generally last 10–15 years in the body without too many problems. However, after this period of implantation, loosening of prosthetic components becomes the major clinical problem. It is now generally accepted that the loosening is caused by the osteolysis as a result of biological reactions to particulate wear debris mainly released from the articulating surfaces. Therefore, one of the main strategies to avoid the loosening problem and to extend the clinical life of the hip prosthesis is to minimize wear and wear particles. Application of *tribology*, defined as “the branch of science and technology concerned with interacting surfaces in relative motion and

Figure 1. A typical Charnley hip prosthesis consisting of an UHMWPE acetabular cup against either a metallic (stainless steel) or a ceramic (alumina) femoral head.

with associated matters (as friction, wear, lubrication, and the design of bearings” (Oxford English Dictionary), to biological systems (*biotribology*) such as artificial hip joints, can play an important role in this process. Coupled tribological studies of friction, wear and lubrication of the bearing surfaces, and biological studies of wear debris-induced adverse reactions become necessary.

HISTORICAL DEVELOPMENT

Early History: Hemiarthroplasty, Interposition Arthroplasty, and Total Hip Replacement

The first recognizable ball and socket joint was reported in Germany by Professor Gluck in 1890 in a dog with an ivory ball and socket hip joint. This did not gain popular support for use in humans until Hey Groves in Bristol reported his ivory hemiarthroplasty for fractured neck of femur in 1926. Attempts to use metal at this stage were unsuccessful. A significant breakthrough came in 1923. It began with a chance observation that a piece of glass left in an individual’s back for 1 year stimulated a fibrous tissue and fluid producing reaction. It formed a fluid-filled synovial sac (Smith Peterson 1948). Smith Peterson went on to insert a glass cup-shaped mould between the surfaces of an ankylosed hip. Although the glass broke, at the time of its removal the acetabulum and the head of the femur were found to be covered with a smooth lining of fibrous tissue. Over the next few years a number of different materials were used including Viscaloid, Pyrex, Bakelite, and finally Vitallium (chromium–cobalt–molybdenum alloy) in 1938. This material worked well and was used for ~ 1000 interposition arthroplasties at Massachusetts General Hospital alone over the next 10 years. It remained the standard treatment for hip arthritis until the advent of total hip replacement.

Charnley Era

Jean and Robert Judet reported their use of a replacement femoral head made of poly (methyl methacrylate) (PMMA). Although the prosthesis failed, it survived

long enough to squeak within the human body. It was this squeaking prosthesis that set Charnley on his quest for a low friction-bearing surface. He began with Teflon in 1958 and throughout the 1950s Charnley experimented with two thin cups of Teflon, one in the acetabulum and one over a reshaped femoral head. They failed within a year due to loosening of the cup and avascular necrosis of the femoral head. He abandoned this surface replacement for an endoprosthesis and as the acetabular cups wore through Charnley sought better wearing materials. He moved to high density PE and later to UHMWPE.

Low Friction Arthroplasty. Charnley began his cemented total hip replacement era with a large femoral head (Moore's hemiarthroplasties). He argued that distributing the load over a large area of contact would decrease wear. However, after loosening of these large head components, he began working on the low frictional torque prosthesis, which reduced the torque at the cement-bone and prosthesis interfaces. He achieved this by reducing the diameter of the femoral head from ~ 41 to 22 mm. In this way, Charnley developed his prosthesis of a 22 mm head on a metal stem, UHMWPE cup and PMMA cement. Charnley hips still have a survival today of $> 90\%$ at 10 years (1).

There continues to be debate as to the cause of up to 10% failures of Charnley hips. Early belief that it was due to the cement and cement particles led to the development of uncemented prostheses. Concern that the production of PE particles was producing bone lysis, led to the development of alternative bearing surfaces, for example, ceramics that wear less than metal against PE, and metal-on-metal prostheses, which produce lower volumes of wear debris. Impingement of the femoral prosthesis on the cup leading to loosening led to the narrowing of the neck of the femoral component and the use of cut away angle bore sockets. Concern about access of fluid to the femoral cement-prosthesis interface and subsequently to the cement-bone interface through cement deficiencies, with the production of osteolysis, have led some manufacturers to produce polished femoral stems. These self-locking tapers prevent fluid flowing between the cement and the femoral stem. The debate continues. It can be difficult to separate the improvements in surgical techniques that have improved the clinical results from the effect of modification and changes in materials used to produce joint replacements.

Current Developments

There is currently much interest in reducing the trauma of the surgery itself. These include surgical techniques of minimal incision surgery with the skin wound < 8 cm and a more conservative approach to femoral bone use at the time of surgery. Surface replacement has returned with "better" metal-on-metal surfaces, and a short-stemmed Judet type of metaphyseal fix femoral prosthesis is also available. Hydroxyapatite as a method of component fixation is also gaining popularity. The current short-term results of these techniques are interesting, and may lead to significant benefits especially for the younger patient in the future. However, the proof will only come from long-term clinical results that are not yet available.

JOINT ANATOMY AND ENVIRONMENT

The bearing material in the natural hip joint is articular cartilage, firmly attached to the underlying bone. Articular cartilage is an extremely complex material, consisting of both fluid (interstitial water) and solid (primarily collagen and proteoglycan) phases. Such a biphasic or poroelastic feature determines the time-dependent deformation of articular cartilage, and largely governs the lubrication mechanism of the natural hip joint. The lubricant present in the natural hip joint is synovial fluid, which is similar to blood plasma with hyaluronic acid added and becomes periprosthetic synovial fluid after total hip replacement. Rheological studies of these biological lubricants have shown shear-thinning characteristics, particularly at low shear rates and for the joint fluid taken from diseased or replaced joints (2).

The load experienced in the hip joint during steady-state walking varies both in direction and magnitude. The maximum load can reach five times bodyweight during the stance phase after heel-strike and is largely reduced in the swing phase after the toe-off. On the other hand, the speed is relatively low, particularly in the stance phase and during the motion reversal. However, the hip contact force can be substantially increased under other conditions. For example, the hip contact force has been reported to be 5.8 times bodyweight up a ramp, 6.6 times up and down stairs, and 7.6 times on fast level walking at a speed of $2.01 \text{ m} \cdot \text{s}^{-1}$ (3).

CURRENT BEARING SURFACES

Biomaterials used for current artificial hip joints include UHMWPE, stainless steel, cobalt chromium alloy (CoCr), and ceramics (alumina and zirconia). A number of combinations for the bearing surfaces using these materials have been introduced since 1950s in order to minimize wear and wear particle generation. These can generally be classified as soft-on-hard and hard-on-hard as summarized in Table 1.

Two main parameters that govern the tribology of the articulating surfaces are geometrical and mechanical properties. The geometrical parameters of the bearing surfaces are the diameters of the acetabular cup (D_{cup}) and the femoral head (D_{head}). The size of the hip prosthesis is usually characterized by its diameter, which is important for both clinical and tribological considerations, such as stability, dislocation, and sliding distance. In addition to size, the diametral mismatch or clearance between the cup and the head ($d = D_{\text{cup}} - D_{\text{head}}$) is also important, particularly for hard-on-hard bearing surfaces. From a tribological point of view, these geometric parameters can often be approximated as a single equivalent diameter (D) defined as

$$D = \frac{(D_{\text{head}}D_{\text{cup}})}{d} \quad (1)$$

Typical values of equivalent diameter used in current hip prostheses are summarized in Table 2. In addition, geometric deviations from perfectly spherical surfaces, such as nonsphericity and surface toughness, are also very

important factors in determining the tribological performance of the prosthesis.

The mechanical properties of the bearing surfaces are also important tribological determinants. Typical values of elastic modulus and Poisson's ratio are given in Table 3 for the biomaterials used in artificial hip joints. Other parameters, such as hardness, particularly in the soft-on-hard combinations, are also important, in that the hard surface should be resistant to third-body abrasion to minimize the consequences of polymeric wear.

COUPLED TRIBOLOGICAL AND BIOLOGICAL METHODOLOGY

The vast majority of studies to evaluate the wear performance of hip prostheses have simply measured the volumetric wear rate (6–8). There are very few groups who have also investigated the characteristics of the wear particles generated in *in vitro* simulations (9–11). The cellular response to prosthetic wear particles, and thus the functional biological activity of implant materials, is complex and is dependent not only on the wear volume, but also the mass distribution of particles as a function of size, their concentration, morphology, and chemistry (see the section, Biological Response of Wear Debris).

During the latter 1990s, methods were developed for the isolation and characterization of UHMWPE particles from

retrieved tissues and serum lubricants from simulators that allow discrimination between the particles generated in different patient samples and from different types of polyethylene tested *in vitro* (12–18). The basis of this method is to determine the mass distribution of the particles as a function of size. Determination of the number distribution as a function of size fails to discriminate between samples since the vast majority of the number of particles are invariably in the smallest size range detectable by the resolution of the imaging equipment.

In our laboratories we have pioneered cell culture studies with clinically relevant UHMWPE wear particles generated in experimental wear simulation systems operated under aseptic conditions (17–21). These studies have been extended to cell culture studies of clinically relevant metal (22), ceramic (23), and bone cement wear particles (24,25).

By combining volumetric wear determinations in hip joint simulations with experiments to determine the direct biological activity of the particles generated, we have developed novel methodologies to evaluate the functional biocompatibility of different materials used in prosthetic joint bearings. The functional biocompatibility can be used as a preclinical estimate of the *in vivo* performance of the material under test compared to historical materials. We have adopted two different approaches to determining functional biocompatibility. Our choice of method is dependent on the bearing material and the type of prosthesis.

The first approach is indirect, but can be applied to all materials and devices. It utilizes data obtained from the direct culture of UHMWPE wear particles in three different size ranges: 0.1–1, 1–10, and > 10 μm at different volumetric concentrations with human peripheral blood macrophages. Measurements of the biological activity for unit volumes of particles in the different size ranges are generated (20). The use of TNF- α as a determinant is justified since, in our experience the major cytokines concerned in osteolysis (TNF- α , IL-1, IL-6, GM-CSF) all show the same pattern of response to clinically relevant wear particles (19–21). By using our methods to determine the

Table 3. Typical Mechanical Properties in Terms of Elastic Modulus and Poisson's Ratio of the Bearing Materials for Artificial Hip Joints^a

Bearing Materials	Elastic Modulus, GPa	Poisson's Ratio
UHMWPE	0.5–1.	0.4
Cross-Linked UHMWPE	0.2–1.2 ^a	0.4
Stainless steel	210	0.3
CoCr	230	0.3
Zirconia	210	0.26
Alumina	380	0.26

^aSee Ref. 5.

volumetric concentration of particles generated in simulations as a function of size (see above), it is then possible to integrate the volume concentration and biological activity function to produce a relative index of specific biological activity (SBA) per unit volume of wear. The functional biological activity (FBA) has been defined as the product of volumetric wear and SBA (26). This has allowed us to compare the functional biological activity of different types of PE in hip joint simulators (27) and different types of bearing materials (23).

The second approach is to directly culture wear debris from wear simulators with primary macrophages. For metal and ceramic particles, we can directly culture wear particles from standard simulation systems after isolation, sterilisation, and removal of endotoxin by heat treatments (23). However, for PE this is not feasible since the heat treatment at elevated temperature required to remove endotoxin cannot be applied. For these materials, we have developed a sterile endotoxin free multidirectional wear simulator in which wear particles are generated in macrophage tissue culture medium. While this does not test whole joints, it allows the application of different kinematics to represent the hip and the knee. The advantage of this approach is that all the wear products are directly cultured with the cells, and there is no risk of modification during the isolation procedure. This method has recently been used to compare the biological reactivity of particles from PEs of different molecular weights and different levels of cross-linking. Higher molecular weight of GUR 1050 and higher levels of cross-linking of both GUR 1020 and 1050 produced particles that were more biologically reactive (18).

Tribology of Bearing Surfaces

Tribological studies of the bearing surfaces of artificial hip joints include friction, wear, and lubrication, which have been shown to mainly depend on the lubrication regimes involved. There are three lubrication regimes: boundary, fluid-film, and mixed. In the boundary lubrication regime, a significant asperity contact is experienced, and consequently both friction and wear are high. In the fluid film lubrication regime, where the two bearing surfaces are completely separated by a continuous lubricant, minimal friction and wear is expected. The mixed-lubrication regime consists of both fluid film lubricated and boundary contact regions. Friction and lubrication studies are usually performed to understand the wear mechanism involved in artificial hip joints. However, friction forces may be important in determining the stresses experienced at the interface between the implant and the cement bone (28) as well as temperature rise (29).

Friction in artificial hip joints is usually measured in a pendulum-like simulator with a dynamic load in the vertical direction and a reciprocating rotation in the horizontal direction. The coefficient of friction is usually expressed as a friction factor defined as

$$\mu = \frac{T}{w(d_{\text{head}}/2)} \quad (2)$$

where T is the measured friction torque and w is the load.

The measured coefficient of friction in a particular hip prosthesis itself can generally reveal the nature of the lubrication regime, since each mechanism is associated with broad ranges of the coefficient of friction. The variation in the coefficient of friction against a Sommerfeld number defined as, $S = (\eta u d_{\text{head}}/w)$, where η is viscosity and u velocity, can further indicate the lubrication regime. If the measured friction factors remain constant, fall or increase as the Sommerfeld number is increased, the associated modes of lubrication are boundary, mixed, or fluid-film, respectively (30).

Lubrication studies of artificial hip joints are generally carried out using both experimental and theoretical approaches. The experimental measurement is usually involved with the detection of the separation between the two bearing surfaces using a simple resistivity technique. A large resistance would imply a thick lubricant film, while a small resistance is attributed to the direct surface contact. Such a technique is directly applicable to metal-on-metal bearings as well as UHMWPE-on-metal and ceramic-on-ceramic bearings if appropriate coatings are used (31,32). The theoretical analysis is generally involved with the solution to the Reynolds equation, together with the elasticity equation subjected to the dynamic load and speed experienced during walking. The predicted film thickness (h_{min}) is then compared with the average surface roughness (Ra) using the following simple criterion.

$$\lambda = \frac{h_{\text{min}}}{[Ra_{\text{head}}^2 + Ra_{\text{cup}}^2]^{1/2}} \quad (3)$$

The lubrication regime is then classified as fluid film, mixed, or boundary if the predicted ratio is > 3 , between 1 and 3, or < 1 , respectively.

Wear of artificial hip joints has been investigated extensively, due to its direct relevance to biological reactions and clinical problems of osteolysis and loosening. Volumetric wear and wear particles can be measured using the following machines, among others:

- Pin-on-disk machines.
- Pin-on-plate machines.
- Joint simulators.

A unidirectional sliding motion is usually used in the pin-on-disc machine, and the reciprocating motion is added to the pin-on-plate machine. Both of these machines are used to screen potential bearing materials under well controlled, and often simplified conditions. Generally, it is necessary to introduce additional motion in order to produce a multidirectional motion. The next stage of wear testing is usually carried out in joint simulators with a varied degree of complexity of the 3D loading and motion patterns experienced by hip joints, while immersing the test joints in a lubricant deemed to be physically and chemically similar to synovial fluid. Wear can be evaluated by either dimensional or gravimetric means.

Contact mechanics analysis is often performed to predict the contact stresses within the prosthetic components and to compare with the strength of the material. However, other predicted contact parameters such as the contact

area and the contact pressure at the bearing surfaces have been found to be particularly useful in providing insights into friction, wear, and lubrication mechanisms. Contact mechanics can be investigated either experimentally using pressure-sensitive film and sensors, or theoretically using the finite element method.

Biological Response of Wear Debris

Our current understanding of the mechanisms of wear particle-induced osteolysis has developed from >30 years experience with UHMWPE-on-metal. The major factor limiting the longevity of initially well-fixed UHMWPE total joint replacements is osteolysis resulting in late aseptic loosening (33). There is extremely strong evidence from *in vivo* and *in vitro* studies that osteolysis is a UHMWPE particle related phenomenon.

Following total hip arthroplasty, a pseudocapsule forms around the joint and this may have a pseudosynovial lining. A fibrous interfacial tissue may also form at the bone–cement or bone–prosthesis interface that is normally thin with few vessels or cells (34–36). At revision surgery for aseptic loosening, the fibrous membrane is thickened, highly vascularized, and contains a heavy infiltrate of UHMWPE-laden macrophages and multinucleated giant cells (37,38). There is a correlation between the number of macrophages and the volume of UHMWPE wear debris in the tissues adjacent to areas of aggressive osteolysis (39–45). Analyses of interfacial membranes have demonstrated the presence of a multitude of mediators of inflammation including cytokines that may directly influence osteoclastic bone resorption: -TNF- α (46), IL-1 β (47), IL-6 (48), and M-CSF (49). There is a direct relationship between the particle concentration and the duration the implant, and there are billions of particles generated per gram of tissue (9,15,50,51). Osteolysis is likely to occur when the threshold of particles exceeds 1×10^{10} /g of tissue (45). Each milligram of PE wear has been estimated to generate 1.3×10^{10} particles (15).

The UHMWPE particles isolated from retrieved tissues vary in size and morphology, from large platelet-like particles, up to 250 μm in length, fibrils, shreds, and sub-micrometer globule-shaped spheroids 0.1–0.5 μm in diameter (15,52–54). The vast majority of the numbers of particles are the globular spheroids and the mode of the frequency distribution is invariably 0.1–0.5 μm , although the larger particles may account for a high proportion of the total volume of wear debris. Analysis of the mass distribution as a function of size is therefore necessary to discriminate between patient samples (15,55).

UHMWPE wear particles generated *in vitro* in hip joint simulators have a larger proportion of the mass of particles in the 0.01–1 μm sized range than those isolated from periprosthetic tissues (27,55). This may indicate that *in vivo*, the smaller particles are disseminated more widely away from the implant site. Recently, improvements to particle imaging techniques have revealed nanometer sized UHMWPE particles generated in hip joint simulators. These particles have yet to be identified *in vivo*. These nanometer size particles account for the greatest number of particles generated, but a negligible proportion of the total volume (18).

Studies of the response of macrophages to clinically relevant, endotoxin-free polyethylene particles *in vitro* have clearly demonstrated that particle stimulated macrophages elaborate a range of potentially osteolytic mediators (IL-1, IL-6, TNF- α , GM-CSF, PGE₂) and bone resorbing activity (19–21,56–58). Induction of bone resorbing activity in particle stimulated macrophage supernatants has been shown to be critically dependent on particle size and concentration with particles in the 0.1–1.0 μm size range at a volumetric concentration of 10–100 μm^3 /cell being the most biologically reactive (19,56). The importance of UHMWPE particle size has also been demonstrated in animal studies (59). These findings have enabled the preclinical prediction of the functional biological activity of different polyethylenes by analysis of the wear rate and mass distribution of the particles as a function of particle size (26,27). For a review of the biology of osteolysis, the reader is referred to Ingham and Fisher (60).

In metal-on-metal bearings in the hip, an abundance of small nanometer size particles are generated (61,62). It is believed that the majority of metal debris is transported away from the periprosthetic tissue. While only isolated instances of local osteolysis have been found around metal-on-metal hips, this is most commonly associated with high concentrations of metal debris and tissue necrosis. *In vitro* cell culture studies have shown that these nanometer size metal particles are highly toxic to cells at relatively low concentrations (22). These particles have a very limited capacity to activate macrophages to produce osteolytic cytokines at the volumes likely to be generated *in vivo* (63), however, metal particles are not bioinert and concerns exist regarding their potential genotoxicity (22).

Ceramic-on-ceramic prostheses have been shown to have extremely low wear rates. Ceramic wear particles generated in hip joint simulations under clinically relevant conditions in the hip joint simulator (64) and *in vivo* (65) have a bimodal size distribution with nanometer sized (5–20 nm) and larger particles (0.2–> 10 μm). Alumina ceramic particles have been shown to be capable of inducing osteolytic cytokine production by human mononuclear phagocytes *in vitro* (23). However, the volumetric concentration of the particles needed to generate this response was 100–500 μm^3 /cell. Given the extremely low wear rates of modern ceramic-on-ceramic bearings, even under severe conditions, it is unlikely that this concentration will arise in the periprosthetic tissues *in vivo* (60).

APPLICATIONS

UHMWPE-on-Metal and UHMWPE-on-Ceramic

The friction in UHMWPE hip joints has been measured using a pendulum-type simulator with a flexionsol–extension motion and a dynamic vertical load. The friction factor has been found to be generally in the range 0.02–0.06 for 28 mm diameter metal heads and UHMWPE cups (66), broadly representative of mixed lubrication, and this has been confirmed from the variation in the friction factor with the Sommerfeld number. These experimental observations are broadly consistent with the theoretical prediction of typical lubricant film thicknesses between 0.1 and

Table 4. Volumetric Wear Rate, % wear volume < 1 μm , SBA, and FBA for Nonirradiated and Irradiated UHMWPEs and Alumina Ceramic-on-Ceramic Hip Joint Prostheses^a

Material	Volumetric Wear rate, $\text{mm}^3/10^6$ cycles \pm 95% CL	% Volume < 1 μm	SBA	FBA

0.2 μm and the average surface roughness of UHMWPE bearing surface between 0.1 and 1 μm . Therefore, wear of UHMWPE acetabular cups is largely governed by the boundary lubrication mechanism. An increase in the femoral head diameter can lead to an increase in sliding distance and consequently wear (41). As a result, 28 mm diameter femoral heads appear to be a better choice. Furthermore, reducing the surface roughness of the metallic femoral head or using harder alumina to resist third-body abrasion and to maintain the smoothness is also very important. For example, the wear factor in UHMWPE-on-ceramic implants is generally 50% of that in UHMWPE-on-metal (67). The introduction of cross-linked UHMWPE has been shown to reduce wear significantly in simulator studies. However, the degree of wear reduction appears to depend on cross-linking, kinematics, counterface roughness, and bovine serum concentration (68). It should be pointed out that volumetric changes are often accompanied by morphology changes, which may have different biological reactions as discussed below.

First, let us consider the effect of irradiation and cross-linking on the osteolytic potential of UHMWPE bearings. Historically, UHMWPE acetabular cups were gamma irradiated in air until it became clear that oxidative degeneration of the PE was occurring. This oxidative damage was caused by the release of free radicals, which produced strand scission of the long PE chains. Research has indicated that deterioration to important mechanical properties such as tensile strength, impact strength, toughness, fatigue strength, and Young's modulus occurs (12). These time-dependent changes have been shown to affect the volumetric wear of the UHMWPE and typical values are in the region of 100 $\text{mm}^3/\text{million}$ cycles. In addition, UHMWPE that had been gamma irradiated in air produced a greater volumetric concentration of wear particles that were in the most biologically active size range, 0.1–1 μm (46% of the wear volume compared to 24% for nonirradiated UHMWPE). When the specific biological activity (biological activity per unit volume of wear; SBA) of the wear particles was calculated this gave an SBA that was 1.7-fold higher than the SBA of the nonirradiated material, which translated into a functional biological activity (FBA), which was 3.5-fold higher than the FBA of the nonirradiated material (Table 4).

Currently, UHMWPE is sterilized by gamma irradiation (2.5–4 Mrad) in an inert atmosphere. This material undergoes partial cross-linking as a result of this processing, and is often referred to as moderately cross-linked or stabilized PE. This material produces lower wear rates than the nonirradiated UHMWPE, but has a higher

volumetric concentration of wear particles < 1 μm compared to the nonirradiated material as shown in Table 4 (69). Consequently, the specific biological activity of the wear particles is higher at 0.5 compared to 0.32 for the nonirradiated material. However, as the wear volume is substantially lower, the FBA value for the stabilized UHMWPE is very similar to the nonirradiated material.

As the level of cross-linking increases, the wear volume decreases (69). The highly cross-linked UHMWPE is GUR 1050, irradiated at 10 Mrad and remelted, and has very low wear volumes at 8.6 \pm 3.1 $\text{mm}^3/\text{million}$ cycles. However, as can be seen from Table 4, 95% of the wear volume is comprised of particles in the most biologically active size range, leading to an extremely high SBA. However, as the wear volume is significantly lower than the other UHMWPEs, the FBA is one-half of those of the nonirradiated and stabilized materials (Table 4).

In addition, the wear particles from the cross-linked materials have increased biological activity per unit volume of wear (Fig. 2). A recent study by Ingram et al. (18) has shown that when worn against a scratched counterface, PE irradiated with 5 and 10 Mrad of gamma irradiation produced higher volumetric concentrations of wear particles in the 0.01–1.0 μm size range compared to noncross-linked material. This increased volumetric concentration of wear particles in the 0.01–1.0 μm size range meant that both cross-linked materials were able to stimulate the release of elevated levels of TNF- α , an osteolytic cytokine, at a 10-fold lower volumetric dose than the

Figure 2. TNF- α release (specific activity \pm 95% confidence limits) as a result of challenge with UHMWPE particles, which were noncross-linked (NXL), cross-linked with 5 Mrad of irradiation, cross-linked with 10 Mrad of irradiation compared to the cell only control.

noncross-linked polyethylene ($0.1 \mu\text{m}^3$ debris/cell compared to $1\text{--}10 \mu\text{m}^3$ debris/cell). So, while the cross-linked materials produced lower wear volumes, the particles produced from these materials were more reactive compared to the noncross-linked PE.

However, when the same materials were worn against a smooth counterface, analysis of the wear particles showed that both cross-linked and noncross-linked PE produced very high numbers of nanometer-sized wear particles. In addition, the cross-linked and noncross-linked materials produced similar low volumes of particles in the $0.1\text{--}1.0 \mu\text{m}$ size range, which resulted in wear debris that was only stimulatory at the highest volumetric dose of $50 \mu\text{m}^3$ debris/cell. This offers further explanation as to why the FBA or osteolytic potential of the highly cross-linked polyethylene's are lower than the moderately cross-linked and noncross-linked materials (Table 4).

Metal-on-Metal

The friction factor measured in metal-on-metal hip joints with different sizes and clearances in simple pendulum type machines is generally much higher than for UHMWPE-on-metal articulations, in the range between 0.1 and 0.2, indicating a mixed-boundary lubrication regime (66). However, the lubrication regime in metal-on-metal bearings has been shown to be sensitive to the surface roughness, loading and velocity, and design parameters (70–74). Consequently, different friction factors or wear factors are possible. Therefore, it is important to optimize the bearing system, in terms of the femoral head diameter, the clearance and the structural support (75,76). From a lubrication point of view, the femoral head diameter is the most important geometric parameter, since it is directly related to both the equivalent diameter defined in Eq. 1 and the sliding velocity (70). If the lubrication improvement is such that a fluid-film dominant lubrication regime is present, the increase in the sliding distance becomes unimportant. Such an advantage has been utilized in large-diameter metal-on-metal hip resurfacing prostheses (77). However, it should be pointed out that the lubrication improvement in large-diameter metal-on-metal hip resurfacing prostheses can only be realized with adequate clearances (78). A too large clearance can reduce the equivalent diameter, shifting the lubrication regime toward mixed-boundary regions. In addition, the increase in the sliding distance associated with the large diameter means that the bedding-in wear becomes important. The wear in optimised systems can be quite low, of the order of a few millimeters cubed.

The biological activity in terms of osteolytic potential of metal-on-metal hip prostheses is difficult to define. If macrophages and fibroblasts are challenged with clinically relevant cobalt chrome wear particles, there is some release of the osteolytic cytokine TNF- α (Fig. 3), however, this only takes place at very high levels of particulate load ($50 \mu\text{m}^3$ debris/cell), and the level of cytokine produced is at lower levels compared to UHMWPE particles [see Fig. 2(79)]. The predominant biological reaction is cytotoxicity or a reduction in cell viability (Fig. 4). Macrophage and fibroblast cell viability is significantly reduced when

Figure 3. TNF- α production by human peripheral blood mononuclear cells stimulated with clinically relevant cobalt–chromium particles.

challenged with 50 or $5 \mu\text{m}^3$ debris/cell (22). The specific biological activity of metal wear particles is difficult to assess as the cells may release cytokines, such as TNF- α as a consequence of cell death. In addition, the high levels of particulate load required to stimulate cytokine release

Figure 4. Effect of metal-on-metal cobalt–chromium wear particles on macrophage and fibroblast cell viability (*Significant ($p < 0.05$, ANOVA) reduction in cell viability).

Figure 5. Predicted functional biological activity or osteolytic potential of alumina ceramic-on-ceramic and highly cross-linked UHMWPE-on-metal hip prostheses.

may only be achieved *in vivo* if a pairing is particularly high wearing.

Ceramic-on-Ceramic

The friction factor in ceramic-on-ceramic hip implants is quite low, particularly when the nonbiological type lubricant is used (66). However, when biological lubricants such as bovine serum are tested, the friction factor can be quite high due to the complex interactions with proteins. The wear under normal ideal conditions is low, but can be increased substantially under adverse conditions such as microseparation (80). Despite this, the wear in ceramic-on-ceramic hip implants is generally the lowest among current hip prostheses available clinically.

The introduction of microseparation conditions into the *in vitro* simulation model replicates clinically relevant wear rates, wear patterns, and wear particles. Alumina wear particles have a lower biological activity than UHMWPE particles. A 10-fold higher concentration of alumina wear particles is required to stimulate the release of osteolytic cytokine TNF- α from macrophages compared to UHMWPE wear particles (23). It is questionable whether the volume of alumina wear particles will reach this threshold *in vivo* given the extremely low wear rates of ceramic-on-ceramic prostheses even under severe microseparation conditions. Consequently, alumina wear particles have a lower specific biological activity than UHMWPE particles (Table 4). When this lower SBA is integrated with the comparatively small volumetric wear rates that are produced by ceramic-on-ceramic couples compared to metal-on-polyethylene, a substantially lower functional biological activity or osteolytic potential is pro-

duced (Table 4; Fig. 5). In fact, alumina ceramic-on-ceramic couples produce a 20-fold lower FBA than the currently used highly cross-linked UHMWPEs.

Summary

Typical values of friction factor, wear factor, and biological reactions are summarized in Tables 5, 6, and 7 for various hip implants with different bearing couples.

FUTURE DEVELOPMENTS

Cross-Linked Polyethylene

The introduction of highly cross-linked PE into clinical use in the last 5 years has been extensive. Standard UHMWPE is irradiated at high dose levels (5–10 Mrad), which produces chain scission and cross-linking between the molecular chains. Subsequent heating and remelting recombines the free radicals producing a more stable material (81). The additional cross-links provide improved wear resistance, particularly during kinematic conditions with high levels of cross-shear as found in the hip. A number of early simulator studies showed no wear for these materials (81), while other studies demonstrated measurable wear (82). Initial clinical studies, however, do show penetration and wear (83). Wear and surface cracking has been identified in a few isolated retrievals. The wear rates reported more recently in simulator studies have been found to be in the range 5–10 mm³/million cycles, which is four to five times less than with conventional material (69). Recent work has also shown that cross-linked PE produces a greater proportion of smaller particles, per unit volume of wear debris and has been found to be up to three times more biologically active than conventional material (18). This leads to a functional reduction in osteolytic potential of about twofold compared to conventional PE. This improvement in functional osteolytic potential may not be sufficient for high demand patients, and in patients who require large head sizes. In these patients, larger diameter hard-on-hard, such as ceramic-on-ceramic or metal-on-metal, may be a more appropriate bearing choice.

Ceramic-on-Metal Bearing

Currently used hard-on-hard bearings are comprised of similar materials, such as alumina ceramic-on-ceramic or metal-on-metal. When lubrication conditions are depleted, like bearing materials can produce elevated adhesive friction and wear. The ceramic-on-metal hip was developed to produce a differential hardness hard bearing (84). Laboratory simulation studies have shown a reduction in wear of

Table 5. Typical Friction Factors and Lubrication Regimes in Various Bearings for Hip Implants^a

Bearing Couples	Friction Factor	Variation of Friction Factor Against Increasing Sommerfeld Number	Indicated Lubrication Regimes
UHMWPE-on-Metal	0.06–0.08	Constant/decreasing	Boundary/mixed
Metal-on-metal	0.22–0.27	Decreasing	Mixed
Ceramic-on-ceramic	0.002–0.2	Increasing	Fluid-film/mixed

up to 100-fold compared to metal on metal. The ceramic head does not wear and remains smooth, improving lubrication and reducing wear of the metallic cup. This new concept is currently entering clinical trials.

Surface Replacement Bearings

There is considerable interest in surface replacement solutions in the hip (85). In this approach, a large diameter metallic shell is placed over the reamed femoral head, preserving femoral bone stock, and this articulates against a large diameter acetabular cup. Both cobalt chrome cast and wrought alloys have been used in different bearing designs. The larger diameter head improves lubrication and reduces wear compared to smaller head sizes (70). However, it is important to maintain a low radical clearance between the components to ensure low bedding-in wear (78,86,87). Surface replacement metal on metal bearings are not suitable for all patients, due to the nature of the femoral bone, but are currently used in ~10% of patients receiving hip prostheses.

Surface Engineered Metal-on-Metal Bearings SUREHIP

Concerns still remain about wear particles in metal on metal bearings and elevated metal ion levels. Surface engineering solutions are an attractive option for reducing wear and metal ion levels, and can be readily applied to surface replacement hips. Recent research with thick AEPVD chromium nitride and chromium carbon nitride surface engineered coatings of thicknesses between 8 and 12 μm have shown a 30-fold reduction in wear and metal ion levels (88,89). These coatings are now undergoing product development in preparation for clinical studies.

Compliant Materials, Cushion Form Bearings

In recent years, the trend has been to move toward harder bearing materials that wear less, and away from the lower elastic modulus properties of articular cartilage. Compliant materials such as polyurethane have been investigated as bearing materials in acetabular cups. The cups have been formed as a composite structure with a higher modulus substrate to give structural support (90). The bearing has

shown improved lubrication and reduced wear compared to conventional polyethylene bearings. However, concerns remain about the long-term stability of these low modulus materials. More recently an experimental polyurethane surface replacement cup has been investigated (91).

Hemiarthroplasty and Hemisurface Replacements

Interest in more conservative bone preserving, and minimally invasive surgery has generated renewed interest in surgical treatments that replace only one side of the diseased joint or potentially just the diseased surface itself. In these scenarios, consideration has not only to be given to the biomaterial replacing the degenerated tissue, but also the function of the apposing articulating surface.

In the hip hemiarthroplasty using compliant materials has just entered clinical trials, where the femoral head covered with a layer of polyurethane articulates against the natural cartilage in the acetabulum (<http://www.impliant.com/home/index.html>). Future designs will focus on full or partial replacement of the diseased cartilage on one side of the joint.

SUMMARY

This article summarizes the biotribology of artificial hip joints and development over the last four decades. Although adequate solutions exist for the elderly less active patients > 65 years old with average life expectancies < 20 years, considerable technological advances are required to meet the demands and improved performance of younger patients. Recent moves toward large diameter heads to give greater function, stability and range of motion are placing greater demands on tribological performances and increasing use of the hard-on-hard bearings.

Nomenclature

d Diametral clearance

D Dearing diameter or equivalent diameter defined in Eq. 1

FBA Functional biological activity

h_{\min}	Minimum lubricant film thickness
PMMA	Poly(methyl methacrylate)
Ra	Average surface roughness
S	Summerfeld number
SBA	Specific biological activity
T	Frictional torque
u	Siding velocity
UHMWPE	Ultrahigh molecular weight polyethylene
w	Load
η	Viscosity
λ	Ratio defined in Eq.3
μ	Frictional factor defined in Eq. 2

Subscripts:

Head	Femoral head
Cup	Acetabular cup

HOME HEALTH CARE DEVICES

TOSHIYO TAMURA
Chiba University School of
Engineering
Chiba, Japan

INTRODUCTION

The increase in the size of the elderly population and the importance of preventing life-related diseases, such as

cancer, hypertension, and diabetes, all emphasize the importance of home healthcare. Generally, the purpose of home healthcare is to reduce the distance the patient must travel to receive care and to reduce the number of hospital admissions.

The devices used in home healthcare must be simple to use, safe, inexpensive, and noninvasive or minimum invasive so that they excessively disturb normal daily activities. Recent developments in home healthcare devices meet most of these specifications, but some still pose a problem in that they disturb the activities of normal daily life and the effectiveness of some other devices in monitoring particular health-related parameters has been questioned.

The requirements for the devices used in home healthcare depend on both their purpose and the subject's condition. Monitoring vital signs, such as heart rate, blood pressure, and respiration, is routinely done for elderly individuals and for patients with chronic disease or who are under terminal care. These cases require simple, non-invasive monitors. When patients are discharged from the hospital and continue to need these parameters monitored at home, the devices used are essentially no different from those used in the hospital.

For health management and the prevention of disease, an automatic health monitoring system has been considered. The onset of lifestyle-related diseases, such as hypertension, arteriosclerosis, and diabetes, is highly correlated with daily activities, such as physical exercise, including walking, as well as other habits, such as sleep and smoking. To prevent such diseases, daily monitoring will be important for achieving healthy living and improving the quality of life. Although the monitoring of daily activities is not well established in evidenced-based health research, there have been many attempts at installing sensors and transducers and monitoring daily life at home.

Evidenced-based health research directed at finding correlations between daily activity monitoring and the onset of disease, and identifying risk factors, is a major subject of epidemiology. In general, large population studies of daily living activities, including daily food intake, based on the history using interviews or questionnaires are required. If an automatic monitoring system can be applied, more reliable and objective data can be obtained.

Recently, many new home healthcare devices have been developed because many individuals have become motivated to maintain their health. This article discusses recently developed homecare devices, as well as expected laboratory-based devices.

BLOOD PRESSURE

Blood pressure is one of the most important physiological parameters to monitor. Blood pressure varies considerably throughout the day and frequent blood pressure monitoring is required in many home healthcare situations. Usually, a blood pressure reading just before the patient wakes in the morning is required. The success of home blood pressure readings is highly dependent on the patient's motivation. Blood pressure readings at home are also recommended because many patients have elevated

Figure 1. The standard blood pressure monitor. The device includes an inflatable cuff, a manometer, and a stethoscope. The bladder is inflated until the cuff compresses the artery in the arm; since no blood passes, the stethoscope detects no noise. Then, the cuff is deflated slowly, blood passes through the artery again, and the stethoscope perceives a noise, which is defined as the systolic pressure. The cuff continues to deflate and finally the stethoscope perceives no noise, defined as the diastolic pressure.

blood pressure readings in a clinical setting, the so-called "white-coat hypertension".

Medical doctors and nurses usually measure blood pressure using the auscultatory method as shown in Fig. 1, in which a pressure cuff is attached to the upper arm and inflated to compress the brachial artery to a value above the systolic pressure. Then, the cuff is gradually deflated while listening to the Korotkoff sounds through a stethoscope placed on the brachial artery distal to the cuff. The systolic and diastolic pressures are determined by reading the manometer when the sounds begin and end, respectively. However, this technique requires skill and it is difficult to measure blood pressure on some obese individuals using this method.

For home blood pressure monitoring, convenient automatic devices have been developed and are commercially available. The measurement sites are the upper arm, wrist, and finger.

The most common method is to attach the cuff to the upper arm, and the systolic and diastolic pressures are determined automatically (Fig. 2). The cuff is inflated by an electric pump and deflated by a pressure-released valve. To determine the pressures, two different methods are used: Korotkoff sounds and an oscillometric method.

A microphone installed beneath the cuff detects the Korotkoff sounds and when the systolic and diastolic pressures are detected, a pressure sensor measures the obtained sounds and pressure at the critical points. The advantage of this method is that this measurement principle follows the standard auscultatory method. When the cuff is attached correctly, a reliable reading can be obtained.

The size of the cuff is important. The cuff should accurately transmit pressure down to the tissue surrounding

Figure 2. Automatic blood pressure monitor using both auscultatory and oscillometric methods.

the brachial artery. A narrow cuff results in a larger error in pressure transmission. The effect of cuff size on blood pressure accuracy for the Korotkoff method has been studied experimentally (1).

The oscillometric method detects the pulsatile components of the cuff pressure as shown in Fig. 3. When the cuff pressure is reduced slowly, pulses appear in the systolic pressure and the amplitude of the pulses increases and then decreases again. The amplitude of these pulses is always maximal when the cuff pressure equals the mean arterial pressure. However, it is difficult to determine the diastolic pressure from the signal measured from the

Figure 3. Principle of the oscillometric method. The pulsations induced by the artery differ when the artery is compressed. Initially, no pulsation occurs, and then the pulsation starts. As the pressure decreases in the cuff, the oscillation becomes more significant, until the maximum amplitude of the oscillations defines the average blood pressure. Then, the oscillations decrease with the cuff pressure until they disappear.

Figure 4. Wrist-type home blood pressure monitor. The measurement site is the wrist and during the measurement, the wrist must be at heart level.

cuff pressure. In general, the diastolic pressure is determined indirectly in commercial devices. One simple method that is often used is to calculate the diastolic pressure from the mean arterial pressure and systolic pressure (2). Several algorithms for this calculation have been used in commercial blood pressure monitors. The oscillometric method can only measure the cuff pressure.

Blood pressure measurement is not restricted to the upper arm. It is possible to measure blood pressure at the wrist and on a finger. However, if the measurement site is changed from the upper arm, the errors due to gravitational force and the peripheral condition increase. Wrist-type blood pressure monitors are now common in home use (Fig. 4).

Home blood pressure monitors are tested for accuracy against two protocols: the Association for the Advancement of Medical Instruments (AAMI) and the International Protocol of the European Society of Hypertension. Reports of the accuracy of home blood pressure monitors have been published (3). In addition, a 24 h home blood pressure monitor has been evaluated (4).

A home blood pressure monitor using the pulse wave transit time has also been studied. The principle used in this approach is that the arterial pulse wave transit time depends on the elasticity of the arterial vessel wall and the elasticity depends on the arterial pressure. Therefore, arterial pressure affects the pulse wave transit time. However, vascular elasticity is also affected by vasomotor activities, which depend on external circumstances; so this method is not reliable. Even so, with intermittent calibration we can estimate the blood pressure from the pulse wave transit time (5). The pulse wave transit time can be non-invasively determined from the arrival time of the arterial pulse at the beginning of cardiac contraction, which is determined from the QRS complex in an electrocardiogram.

ELECTROCARDIOGRAM

The electrocardiogram (ECG) gives important cardiac information. Recording the ECG at home can assist physicians to make a diagnosis. When monitoring the ECG at home

Figure 5. Holter ECG recorder. The Holter recorder is used for 24 h ECG monitoring and a digital Holter recorder is commonly used.

during either recovery from an acute disease or when the patient has a chronic disease, long-term recording is essential in order to detect rarely occurring abnormalities.

The Holter ECG recorder as shown in Fig. 5, has been widely used. It is a portable recorder that records the ECG on two or more channels for 24 or 48 h, on either an ordinary audiocassette tape or in a digital memory, such as solid-state flash memory. Most Holter recorders are lightweight, typically weighing 300 g or less, including the battery. The ECG must be recorded on the chest and electrodes need to be attached by clinical staff. A physician should also be available to monitor the ECG. Aside from these limitations, the Holter recorder can be used without obstructing a patient's daily life.

There are some special ECG recordings that can be taken in the home. The ECG can be recorded automatically during sleep and bathing.

In bed, the ECG can be recorded from a pillow and sheets or beneath the leg using electroconductive textiles (Fig. 6) (6). Since the contact between the textile electrodes and the skin is not always secure, large artifacts occur with body movements. In our estimation, 70–80% of ECGs during sleep can be monitored.

The ECG can also be recorded while bathing. If electrodes are installed on the inside wall of the bathtub as shown in Fig. 7, an ECG can be recorded through the water (7,8). The amplitude of the ECG signal depends on the conductivity of the tap water. If the conductivity is high, the water makes a short circuit with the body, which serves as the voltage source, and consequently the amplitude is reduced. If the water conductivity is low, however, the signal amplitude remains at levels similar to those taken on the skin surface. Fortunately, the electrical conductivity of ordinary tap water is on the order of $10^{-2} \text{ S}\cdot\text{m}^{-1}$, which is within the acceptable range for measurement using a conventional ECG amplifier. However, such an ECG signal cannot be used for diagnostic purposes because of the attenuation of the signal at lower frequencies.

HEART AND PULSE RATES

The heart rate (HR) is a simple indicator of cardiac function during daily life and exercise. The HR is the number of

Figure 6. The ECG recorded from the bed. Electrodes are placed on the pillow and the lower part of the bed. An ECG signal can be obtained during sleep.

contractions of the heart per minute, and the pulse rate is defined as the number of arterial pulses per minute. Usually, both rates are the same. When there is an arrhythmia, some contractions of the heart do not produce effective ejection of blood into the arteries and this gives a lower pulse rate.

Figure 7. The ECG recorded from a bathtub. Silver–silver chloride electrodes are placed in the bathtub and the ECG signal can be obtained through the water.

The heart rate can be determined by counting the QRS complexes in an ECG or measuring the R–R interval when the cardiac rhythm is regular. In patients with an arrhythmia, the ECG waveforms are abnormal, and in this case detection algorithms with filtering are used. For accurate heart rate monitoring, electrodes are attached to the chest. Instead of surface electrodes, a chest strap is also available (Polar, Lake Success, NY)

The pulse rate can be obtained by detecting the arterial pulses using a photoplethysmograph, mechanical force measurements, vibration measurements, or an impedance plethysmograph. In photoplethysmography, the change in light absorption caused by the pulsatile change in the arterial volume in the tissue is detected. To monitor the pulse rate using photoplethysmography, the finger is commonly used. Light sources with wavelengths in the infrared (IR) region ~ 800 nm are adequate for this purpose, because tissue absorbance is low and the absorbance of hemoglobin at this wavelength does not change with oxygen saturation.

The pulse oximeter, described below, can monitor both oxygen saturation and pulse rate. The pulsatile component of light absorption is detected and the pulse rate can be determined from the signal directly. The ring-type pulse oximeter is the most commonly used type of pulse oximeter.

A wristwatch type pulse rate meter is also available. It consists of a reflection-type photoplethysmograph. To measure pulse rate, the subject puts their fingertip on the sensor. A flashing icon on the display indicates a detected pulse, and the rate is displayed within 5 s.

The pulse rate can also be monitored in bed. In this case, the pulse rate is obtained directly from an electroconductive sheet. Vibration of the bed is detected by a thin flexible electric film (BioMatt, Deinze, Belgium) or an air mattress with a pneumatic sensor. In either case, the pulse rate is obtained through signal processing.

BODY TEMPERATURE

Body temperature has been checked at home for many years to detect fever. Frequent body temperature measurements are required for homecare in many chronic diseases. Basal body temperature measurement is also required when monitoring the menstrual cycle.

Stand-alone mercury-in-glass clinical thermometers have long been used both in clinical practice and at home, although they have recently been replaced by electronic thermometers because mercury contamination can occur if they are broken (Fig. 8). The ordinary electronic clinical thermometer uses a thermistor as a temperature sensor. The body temperature is displayed digitally. There are two types of clinical thermometer: the prediction and the real-time type. The real-time type waits until a stable temperature value is obtained. The prediction type attempts to predict the steady-state temperature using an algorithm involving exponential interpolation. The response time of a real-time electronic thermometer is 3 min and the response time of a prediction-type electronic thermometer is < 1 min, when both are placed in the mouth.

Figure 8. The electric thermometer contains a thermistor. Both predicting and real-time types are sold.

The tympanic thermometer as shown in Fig. 9, has become popular for monitoring the body temperature in children and the elderly because of its fast response. The device operates on the principle of IR radiation. The sensor is either a thermopile or pyroelectric sensor and is installed

Figure 9. The tympanic thermometer. Either a thermopile or a pyroelectric sensor is used as the temperature sensor. This device has a faster response than an electric thermometer.

Figure 10. The principle of the tympanic thermometer. The sensor tip is inserted into the ear canal and the thermal distribution of tympanum is measured.

near the probe tip, as shown in Fig. 10. The probe tip is inserted into the auditory canal and the radiation from the tympanic membrane and surrounding tissue is detected. The tympanic temperature is close to the deep body temperature and the measurement can be made within a few seconds. Many studies have shown that when used properly, a tympanic thermometry is very accurate. However, IR tympanic thermometers produced measurements that were both less accurate and less reproducible when used by nurses who routinely used them in clinical practice (9,10).

A strip thermometer is sometimes used to monitor an acute fever. It is designed to be used once only and then discarded. It contains strips of thermosensitive liquid crystal that change color to indicate skin temperature, not body temperature. The color change is nonreversible. The strip is placed on the forehead and then read after 1 min. If a strip thermometer shows a high temperature, one should recheck the temperature with another type of thermometer.

BODY FAT

Body composition and body fat have both been proposed as indicators of the risk of chronic disease.

Body fat percentage is the proportion of fat in a person's body. Excess body fat was previously determined by measuring weight and comparing that value with height. Body fat is not always visible and cannot be measured on an ordinary scale. Obesity, which indicates a high degree of excess body fat, has been linked to high blood pressure, heart disease, diabetes, cancer, and other disabling conditions. To estimate the percentage of body fat, it is commonly derived from body density. The following equation gives an estimate of body density (D), which is then converted into the percent body fat (%BF) using the Siri equation:

$$\%BF = (495/D) - 450$$

Body density, measured by weighting an individual while immersed in a tank of water, is based on Archimedes' principle and is a standard technique. However, this is not

Figure 11. A scale with bioelectrical impedance analysis. This is a simple version of body impedance analysis using leg-to-leg bioimpedance analysis. The precision electronic scale has two footpad electrodes incorporated into its platform. The measurement is taken while the subject's bare feet are on the electrodes. The body fat percentage can be obtained from equations based on weight, height, and gender.

a convenient method for measurement in the home. Body volume can be determined from the air volume in an airtight chamber with the body inside by measuring the compliance of the air in the chamber (Bod Pod, Life Measurement Instruments, Concord, CA).

Body fat scales use the bioelectrical impedance analysis (BIA) technique. This method measures body composition using four electrodes, in which a constant alternating current (ac) of 50–100 kHz and 0.1–1 mA is applied between the outer electrode pair, and the alternating voltage developed between the inner electrode pair is detected (Fig. 11). Alternating current is applied between the toes of both feet, and the voltage developed between the electrodes at both feet is detected. The current passes freely through the fluids contained in muscle tissue, but encounters difficulty—resistance when it passes through fat tissue. This means that electrical impedance is different in different body tissues. This resistance of the fat tissue to the current is called bioelectrical impedance, and is accurately measured by body fat scales. Using a person's height and weight, the scales can then compute the body fat percentage. Recently, new commercial BIA instruments, such as the body segmental BIA analyzer, multifrequency BIA analyzer, lower body BIA analyzer, upper body BIA analyzer, and laboratory-designed BIA analyzers, have greatly expended the utility of this method (11). However, body composition differs by gender and race. Nevertheless, the impedance technique is highly reproducible for estimating the lean body mass (12).

The use of near-IR spectral data to determine body composition has also been studied (13). Basic data suggest that the absorption spectra of fat and lean tissues differ. The FUTREX-5000 (Zelcore, Hagerstown, MD) illuminates the body with near-IR light at very precise wavelengths (938 and 948 nm). Body fat absorbs the light, while lean body mass reflects the light. The intensity of back-scattered light is measured. This measurement provides an estimation of the distribution of body fat and lean body mass.

BLOOD COMPONENTS

In a typical clinical examination, the analysis of blood components is important. Medical laboratory generally use automatic blood analyzers for blood analysis. Usually, an invasive method is required to obtain a blood sample. Therefore, in a home healthcare setting, the monitoring and analysis of blood is uncommon, except for diabetic patients. In this section, we focus on the blood glucose monitor.

There are several commercial home blood glucose monitors. Self-monitoring of blood glucose (SMBG) is recommended for all people with diabetes, especially for those who take insulin. The role of SMBG has not been defined for people with stable type 2 diabetes treated with diet only. As a general rule, the American Diabetes Association (ADA) recommends that most patients with type 1 diabetes test glucose three or more times daily. Blood glucose is commonly measured at home using a glucose meter and a drop of blood taken from the finger (Fig. 12). A lancet device, which contains a steel needle that is pushed into the skin by a small spring, is used to obtain a blood sample. A small amount of blood is drawn into the lumen of the needle. The needle diameter is from 0.3 (30 G) to 0.8 (21 G) mm. In addition, laser lancing devices, which use a laser beam to produce a small hole by vaporizing the skin tissue, are available.

Once a small amount of blood is obtained, blood glucose can be analyzed using either a test strip or a glucose meter.

The blood glucose level can be estimated approximately by matching the color of the strip to a color chart. In electrochemical glucose meters for homecare, a drop of blood of 10 μL or less is placed in the sensor chip. The blood glucose is measured by an enzyme-based biosensor. Most glucose meters can read glucose levels over a broad range of values, from as low as 0 to as high as 600 mg-dL. Since the range differs among meters, it is important to interpret very high or low values carefully. Glucose readings are not linear over their entire range.

Home blood glucose meters measure the glucose in *whole blood*, while most lab tests measure the glucose in *plasma*. Glucose levels in plasma are generally 10–15% higher than glucose measurements in whole blood (and this difference is even larger after a person has eaten). Many commercial meters now give results as the “plasma equivalent”. This allows patients to compare their glucose measurements from lab tests with the values taken at home.

Minimally invasive and noninvasive blood glucose measurement devices are also sold. One of these uses near-IR spectroscopy to measure glucose. It is painless. There are increasing numbers of reports in the scientific literature on the challenges, strengths, and weaknesses of this and other new approaches to testing glucose without fingersticks (14,15).

The U.S. Food and Drug Administration (FDA) has approved minimally invasive meters and noninvasive glucose meters, but neither of these should replace standard glucose testing. They are used to obtain additional glucose values between fingerstick tests. Both devices require daily calibration using standard fingerstick glucose measurements.

The MiniMed system (Medtronic, Minneapolis, MN) consists of a small plastic catheter (a very small tube) inserted just under the skin. The catheter collects small amounts of liquid, which are passed through a biosensor to measure the amount of glucose present. The MiniMed is intended for occasional use and to discover trends in glucose levels during the day. Since it does not give readings for individual tests, it cannot be used for typical day-to-day

Figure 12. Glucose meter. This is used for self-monitoring blood glucose. The blood is taken from the fingertip and analyzed using a test strip.

Figure 13. GlucoWatch device (1) and principle of iontophoresis (2). This device provides non-invasive monitoring of glucose and uses reverse iontophoresis to extract glucose from the skin to monitor glucose. A low electric current is applied, which draws interstitial fluid through the skin. The glucose in this fluid is collected in a gel. A chemical process occurs, which generates an electrical signal that is converted into a glucose measurement.

monitoring. The device collects measurements over a 72 h period and then the stored values must be downloaded by the patient or healthcare provider.

GlucoWatch (Cygnus, Redwood City, CA) is worn on the arm like a wristwatch (Fig. 13). It pulls small amounts of interstitial fluid from the skin by iontophoresis and measures the glucose in the fluid without puncturing the skin. The device requires 3 h to warm up after it is put on the wrist. After this, it can measure glucose up to three times per hour for 12 h. The GlucoWatch displays results that can be read by the wearer, although like the MiniMed device, these readings are not meant to be used as replacements for fingerstick-based tests. The results are meant to show trends and patterns in glucose levels, rather than report any one result alone. It is useful for detecting and evaluating episodes of hyperglycemia and hypoglycemia. However, the values obtained must be confirmed by tests with a standard glucose meter before any corrective action is taken.

An elevated cholesterol level is one of the most important risk factors for coronary heart diseases. For home healthcare, a blood cholesterol test device is available. The test requires that a few drops of blood obtained from a finger stick sample be applied to the cholesterol strip, which contains cholesterol esterase and cholesterol oxidize. Total cholesterol, that is, the sum of free and esterified cholesterol, can be accurately and conveniently measured enzymatically using cholesterol oxidize and cholesterol esterase. The total amount of cholesterol is measured, and the results are obtained in 3–15 min.

URINE COMPONENTS

The analysis of urine components provides important diagnostic information for clinicians. Urine glucose and ketones

indicate diabetes and urine protein indicates kidney disease. However, the only tool available for such testing is the urine test strip. A urine test can be done using a test strip without pain or discomfort. No fully automatic urine test system available, but there have been some attempts to monitor urine components at home with minimum disturbance. The instrument shown in Fig. 14 has been developed. It can be installed in the toilet and measures the urine glucose after a button is pushed (TOTO, Tokyo). The urine collector protrudes, collects urine automatically from the urine stream, and analyzes urine glucose within 1 min using an enzyme glucose sensor. The sensor must be replaced every 4 months and a calibration solution must be replenished every 3 months. This system is useful for monitoring the urine glucose level in diabetic patients.

BODY WEIGHT

Body weight monitored at home is an essential parameter for health management. To use body weight for health management, data must be taken regularly and stored. A digital scale connected to a laptop computer, together with temperature and blood pressure monitors, and a bed-sensor system has been developed (16).

A device to weigh the body automatically for health monitoring based on measurements on the toilet seat has been developed (17). A precision load cell system was installed in the floor of the toilet, and the seat was supported so that the weight on the seat was transferred to the load cell. This system also allows the measurement of urine and feces volume, urine flow rate, and the number and times of urination and evacuation.

For health management, the body mass index is commonly used. This is defined as the weight divided by the

Figure 14. Urine glucose monitor installed in the toilet. A small nozzle collects urine and then a biosensor analyzes urine glucose automatically.

square of the height. Excess body weight increases the risk of death from cardiovascular disease and other causes in adults between 30 and 74 years of age. The relative risk associated with greater body weight is higher among younger subjects (18).

NUTRITION

To prevent cardiac disease, diabetes, and some cancers, it is important to control body weight. The most accurate method that currently exists is to weigh foods before they are eaten. Like many other methods, however, this method can be inaccurate, time-consuming, and expensive. There are two basic ways to monitor nutrition. One is to monitor food intake.

Food consumed is photographed using a digital camera and the intake calories are calculated from the photographs (19,20). Digital photography and direct visual estimation methods, estimates of the portion sizes for food selection, plate waste, and food intake are all highly correlated with weighed foods.

The resting metabolism rate (RMR) is an important parameter for controlling body weight. The RMR repre-

sents the calories the body burns in order to maintain vital body functions (heart rate, brain function, and breathing). It equals the number of calories a person would burn if they were awake, but at rest all day. The RMR can represent up to 75% of a person's total metabolism if they are inactive or lead a sedentary lifestyle. Since the RMR accounts for up to 75% of the total calories we need each day, it is a critical piece of information for establishing appropriate daily calorie needs, whether one is trying to lose or maintain weight. Most healthcare and fitness professionals recognize that metabolism is affected by a variety of characteristics, such as fever, illness, high fitness, obesity, and active weight loss. When managing a subject's nutritional needs and calorie requirements, knowledge of their RMR is critical. Since metabolism differs individually, estimating the RMR value can lead to errors, and inaccurate calorie budgets. Consequently, individuals can be unsuccessful at reaching their personal goals, due to over- or under-eating. As technology advances, professionals must reassess their practices. Caloric needs are assessed most accurately by measuring oxygen consumption and determining individual metabolism. Oxygen consumption estimates are obtained from the oxygen gas concentration and flow. Since it usually requires wearing a mask or mouthpiece, this measurement is difficult for some individuals. The BodyGem and MedGem (HealtheTech, Golden, CO) are devices that provide information vital for determining a personalized calorie budget, based on individual metabolism (Fig. 15). The BodyGem and MedGem consist of an ultrasound flow meter and fluorescence oxygen sensor with a blue LED excitation source, but the measurements are limited to an RMR monitor only. The RMR has been mentioned in the text.

We can also estimate the body's energy consumption from heat flow and acceleration measurements taken while an individual exercises (Body Media inc. Pittsburg, PA). For diabetes control, a pedometer with an accelerometer has been used and the energy consumption estimated using several algorithms.

Figure 15. A simple oxygen-uptake monitor. The subject wears the mask and a small ultrasonic flow meter measures the respiratory volume and a fluorescence oxygen monitor measures the oxygen concentration. This device is only used for measuring basal metabolism.

DAILY ACTIVITY

From the standpoint of health management, both the physical and mental health of an individual are reflected in their daily physical activities. The amount of daily physical activity can be estimated from the number of walking steps in a day, which are measured by a pedometer attached to the belt or waistband. To improve physical fitness 10,000 steps per day or more are recommended. For more precise measurement of physical activity, an accelerometer has been used. Behavior patterns, such as changes in posture and walking or running can be classified. The metabolic rate can be estimated from body acceleration patterns. The algorithms for calculating energy consumption differ for different pedometers. Each manufacturer has a different algorithm, and these have not been made public. However, the energy is likely evaluated using total body weight and walking time (21). This measurement requires attaching a device to the body, and requires continual motivation. An accelerometer equipped with a global positioning sensor has been developed and can monitor the distance and speed of daily activity (22).

There have been attempts to monitor daily activities at home without attaching any devices to the body. Infrared sensors can be installed in a house to detect the IR radiation from the body so that the presence or absence of a subject can be monitored, to estimate the daily activity at home, at least when the subject is living alone.

Other simple sensors, such as photointerrupters, electric touch sensors, and magnetic switches, can also be used to detect activities of daily living (23–25). The use of room lights, air conditioning, water taps, and electric appliances, such as a refrigerator, TV, or microwave oven, can be detected and used as information related to daily living. Habits and health conditions have correlated with these data to some extent, but further studies are required to give stronger evidence of correlations between sensor output and daily health conditions.

SLEEP

Sleep maintains the body's health. Unfortunately, in most modern industrial countries the process of sleep is disturbed by many factors, including psychological stress, noise, sleeping room temperature, and the general environment surrounding the bedroom. Insufficient sleep and poor sleeping habits can lead to insomnia. Another sleep problem is sleep apnea syndrome. In the laboratory, sleep studies aimed at the diagnosis of sleep apnea syndrome include polysomnography (PSG), electroencephalography (EEG), ECG, electromyography (EMG) pulse oximetry, and require chest and abdomen impedance belts. In the home, simple devices are required to evaluate sleep to determine if more detailed laboratory tests are needed.

A physical activity monitor actigraph (AMI, Ardsley, NY) can be used as a sleep detector. It is easy to wear and detects the acceleration of the wrist using a piezoelectric sensor. The wrist acceleration recorded by the actigraph accurately showed when the wearer was asleep (26).

Body movements during sleep can be measured without attaching sensors and transducers to the body using a pressure-sensitive sheet (BioMatt, VTT Electronics, Tampere, Finland). It consists of a 50 μm thick pressure-sensitive film, which can be installed under the mattress. This film is quite sensitive and not only detects body motions, but also respiration and heart rate. Therefore, it can be used as a sleep monitor for detecting insomnia and sleep disorders and as a patient monitor for detecting sleep apnea, heart dysfunctions, and even coughing and teeth grinding (27–29).

Body motion during sleep can also be monitored using a thermistor array installed on the bed surface at the waist or thigh level (30,31). The changes in temperatures show the body movement and sleep condition.

RESPIRATION THERAPY AND OXYGEN THERAPY

Respiration is the function of gas exchange between the air and blood in the body, and it consists of ventilation of the lung and gas transfer between the alveolar air and the blood in the pulmonary circulatory system. Lung ventilation can be monitored by either measuring the flow rate of the ventilated air or the volume change of the lung. Gas transfer is monitored by arterial blood oxygenation. Frequent respiratory monitoring is required for respiratory therapy at home.

Furthermore, many individuals have developed breathing difficulties as a consequence of increasing pollution, combined with an aging population.

For therapy, we use two types of respiration aid. One is for respiration related to cellular gas exchange. The other is for breathing difficulty, such as sleep apnea.

Reparatory therapy is included in the training of individuals involved in rehabilitation after thoracoabdominal surgery, in paraplegic or quadriplegic patients, and for patients requiring some form of mechanical ventilation. The fundamental parameters that must be monitored are the respiratory rate, respiratory amplitude, and respiratory resistance. Respiratory amplitude can be monitored using either airflow or lung movement.

For continuous monitoring of respiration in a home setting, it is inconvenient to use a mask or mouthpiece. Lung ventilation can be estimated by practice and from abdominal displacement. Inductance plethysmography has been used (32,33). This consists of two elastic bands placed at the rib cage and abdomen. Each band contains a zigzag coil and the inductance of this coil changes with its cross-sectional area. This system, Respitrace (Non-Invasive Monitoring Systems, North Bay Village, FL), gives the changes in volume of the rib cage and abdomen, tidal volume, and breathing rate. Respitrace was rated as the best noninvasive technology for the diagnosis of sleep-related breathing disorders by the American Academy of Sleep Medicine Task Force (1999).

Oxygen therapy, intermittent positive pressure breathing (IPPB) therapy, and respiratory assistance using a respirator can also be performed at home. In these situations, the arterial blood oxygenation must be monitored. Actually, there is a change in optical absorbance on the

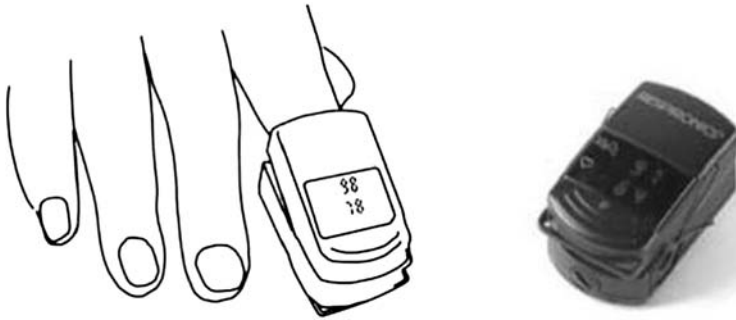

Figure 16. Pulse oximeter. A pulse oximeter is a simple noninvasive method of monitoring the percentage of hemoglobin (Hb) saturated with oxygen. It consists of a probe attached to the subject's finger. The device displays the percentage of Hb with oxygen together with an audible signal for each pulse beat and the calculated heart rate.

venous side that reflects changes in intrathoracic pressure due to breathing. Blood oxygenation is commonly monitored using a pulse oximeter, which can measure the oxygen saturation of arterial blood noninvasively from the light that is transmitted through a finger (Fig. 16).

The pulse oximeter is based on the principle that the pulsatile component in the transmitted light intensity is caused by the changes in the absorption of arterial blood in the light path while the absorption of the venous blood and tissue remains unchanged. The absorption spectrum of the blood changes with oxygen saturation, so the oxygen saturation of the arterial blood can be determined from the time-varying spectral components in the transmitted light. The oximeter contains two light-emitting diodes (LEDs), which emit light at two different wavelengths, and a photodiode to detect absorption changes at the two different wavelengths (Fig. 17). The measuring site is usually at a finger. However, a probe with a cable can sometimes disrupt the activities of daily life. A reflection-type probe that can be attached to any part of the body might be more convenient. Unfortunately, reflection-type probes are less reliable than transmission probes (34). A finger-clip probe without a cable (Onyx, Nonin Medical, Plymouth, MN) and a ring-type probe (35) are also available.

Recent advanced home healthcare devices are reviewed. These devices can be used effectively, not only for the elderly, but also for the middle-aged population and to establish home healthcare and telecare. Telecare and telemedicine are now popular for monitoring patients with chronic diseases and elderly people who live alone. The devices are placed in their homes and the data are transmitted to the hospital or a healthcare provider, who can check their clients' condition once every 12–24 h. Success-

ful application has been reported for oxygen therapy and respiratory therapy.

We have solved several problems for more practical use. The major problems are the standardization of these devices and the agreement between medical use and home healthcare. Standardization of monitoring is important. For example, the principle of body impedance analysis differs for each manufacturer. Therefore, the values differ for different devices. This confuses customers, who then think that the devices are not reliable; hence, nobody uses such devices. There are similar problems with pedometers. Pedometers use either a mechanical pendulum or an accelerometer. The manufacturers should mention their limitations and reliability briefly, although most customers find this information difficult to understand.

The next problem is more serious. Some home healthcare devices have not been approved by health organizations, such as the FDA. For blood pressure monitors, a physician still needs to measure blood pressure during clinical practice even if the subject measures blood pressure at home. If the home healthcare device was sufficiently reliable, the physician would be able to trust the blood pressure values. Both researchers and members of industry must consider ways to solve this problem in the near future. There are additional social problems, such as insurance coverage of home healthcare devices, costs, handling, and interface design. The development of home healthcare devices must also consider the psychological and environmental factors that affect users. In the future, preventative medicine will play an important role in medical diagnosis. Hopefully, more sophisticated, high quality home healthcare devices will be developed. Technology must solve the remaining problems in order to provide people with good devices.

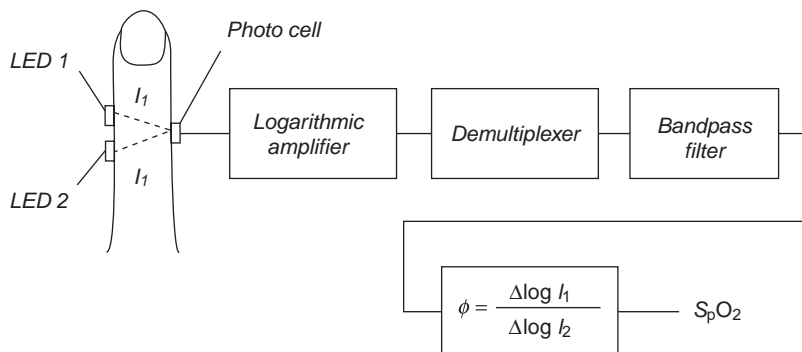

Figure 17. The principle of the oximeter. Hemoglobin absorbs light and the amount depends on whether it is saturated with oxygen. The absorption at two wavelengths (650 and 805 nm) is measured and used to calculate the proportion of hemoglobin that is oxygenated.

HUMAN FACTORS IN MEDICAL DEVICES

DANIEL W. REPPERGER
Wright-Patterson Air Force Base
Dayton, Ohio

INTRODUCTION

The human factors issues related to the use and design of medical devices has experienced significant paradigm shifts since this topic was addressed > 20 years ago (1). Not only has the technology innovation of the Internet

vastly affected how medical professionals both gather and report information, but also standards are now more easily established. In addition, technology in the healthcare industry has concomitantly made significant advances. The evolving characteristics of legal liability with medical devices have also changed. Concurrently, the skill and sophistication of users with computer-aided systems has significantly improved with more tolerance and acceptance of automation. The computer and microprocessor-based medical devices are now the pervasive means of humans dealing with mechanical–electrical systems. First, it is important to define the term Human Factors within the context of medical devices and biomedical engineering. The phrase human factors can be broadly characterized as the application of the scientific knowledge of human capabilities and limitations to the design of systems and equipment to generate products with the most efficient, safe, effective, and reliable operation. A modern expression to describe a systematic procedure to evaluate risk when humans use medical devices is termed human factors engineering (2). The U.S. Food and Drug Administration (FDA) is a strong proponent of the use of human factors engineering to manage risk, in particular with application to medical devices. The responsibility of the FDA is to guarantee the safety and efficacy of drugs and medical devices. Since, in the United States, the FDA is one of the leading authorities on medical standards, it is worthwhile to review (3,4) their interpretation on how human factors studies should be conducted with medical device use as perceived by this group. Other U.S. government organizations, such as the National Institute of Health (NIH) (5) and the Agency for Health Care Research and Quality (6), also offer their perspective on the application of human factors studies with respect to the manipulation of medical devices. Other sources of government information are found at (7–12). Also available online are a number of legal sources (13–15) related to injury issues and instrumentation affiliated with healthcare and how they perceive the relevance of human factors engineering. In these sources, there is a strong influence on how human factors procedures have some bearing on liability, abuse, misuse, and other troublesome issues associated with medical devices (16).

From an historical perspective, in the late 1980s, data collected by the FDA demonstrated that almost one-half of all medical device recalls resulted from design flaws. In 1990, the U.S. Congress passed the Safe Medical Devices Act, giving the FDA the ability to mandate good manufacturing practices. These practices involve design controls for manufacturers to use human factors engineering principles within medical device design.

In this article, we initially discuss human factors as defined by the FDA followed by three classic case studies. The ramifications of legal issues are then presented. Concurrent good human factors methods are then described, followed by some key topic areas including alarms, labeling, automation, and reporting. Future issues regarding human factors and medical devices are subsequently offered with conclusions and future directions of this field depicted.

First, it is instructive to review the present state of affairs on how the FDA defines human factors engineering

within the context of when humans interact with medical devices. The term human factors engineering is a persuasive term in the literature describing present FDA standards.

A HUMAN FACTORS ENGINEERING PERSPECTIVE FROM THE FDA

The goal of the FDA is to promote medical device designers to develop highly reliable devices. Human factors engineering is a phrase used to help understand and optimize how people employ and interact with technology. A host of literature describes human factors engineering in many eclectic areas (17–30). When medical devices fail or malfunction, this impacts patients, family members, and professional healthcare providers. A common term used to characterize the potential source of harm is a hazard. A hazard may arise in the use of a medical device due to the inherent risk of medical treatment, from device failures (malfunctions) and also from device use. Figure 1, from the FDA, displays possible sources of device failure hazards that impact the human factors issues in medical devices. Figure 1 may be deceptive in the presumption that equal hazards exist between use related and device failure. More correctly (3,4) the use contribution to the total medical devices hazards may far exceed those from the device failures. In fact, from an Institute of Medicine report (31), as many as 98,000 people die in any given year from medical errors that occur in hospitals. This is more than the number who die from motor vehicle accidents, breast cancer, or acquired immune deficiency syndrome (AIDS). A proportion of these errors may not directly be attributed to the medical device itself; however, the importance of incorporating human factors engineering principles into the early design and use of these important interfaces is a key concern. It is instructive to examine the two major types of errors (hazards) in Fig. 1 and how they are delineated. Risk analysis will refer to managing the forms of risks to be described herein. After the hazards are first clarified, the goal is for the hazards to be mitigated or controlled by modifying the device user interface (e.g., control or display characteristics, logic of operation, labeling) or the background of the users employing the device (training, limiting the use to qualified users). The power in the human factors approach is to help identify, understand, and address use-related problems as well as the original design problem with the physical device itself prior to its acceptance in the workplace of the healthcare professional. Some institutions have now developed in-house usability laboratories, in order to rigorously test any medical device

Figure 1. Hazards from device failure and use related.

Figure 2. Human factors consideration in medical device use.

before utilization. It is worthwhile to first elaborate on use related hazards as they are relevant in this area.

Use-Related Hazards

Addressing the hazards related to device use, the essential components include (1) device users (patient, caregiver, physician, family member, etc.); (2) typical and atypical device use; (3) characteristics of the environment for the application of the medical device; and (4) the interaction between users, devices, and use environments.

Figure 2 portrays an abstraction on all possible uses for a medical device.

Device Failure Hazards

When understanding hazards from the perspective of risk analysis, it is common to consider the following classes of hazards as they pertain to device design: (1) chemical hazards (e.g., toxic chemicals); (2) mechanical hazards (e.g., kinetic or potential energy from a moving object); (3) thermal hazards (high temperature components); (4) electrical hazards (electric shock, electromagnetic interference); (5) radiation hazards (ionizing and nonionizing); and (6) biological hazards (allergic reactions, bioincompatibility, and infection).

In an effort to address good human factors design when dealing with medical devices, it is instructive to now discuss three classic misadventures in the medical device arena when human factors procedures could have been modified to preclude untoward events. One usually thinks of medical errors occurring, for example, in surgery (wrong site surgery), as the amputation of the wrong appendage (32,33) or from chemotherapy overdoses (34). In 2005, it is now a common practice, in holding areas before surgery, for the surgeon and medical team to discuss with the patient the impending surgery and to have the patient mark on his body precisely where the surgery will be performed with a magic marker. This procedure assures the patient that no confusion may occur as a function of a patient mix-up, after the patient is under anesthesia. Three examples are now presented of untoward events that could have been prevented with improved human factors use methodologies. In the final analysis, the enemy of safety is complexity, which appears in these case studies. Complex systems fail because of the contribution of multiple small failures, each individual failure may be insufficient to cause an accident, but in combination, the results may be tragic.

EXAMPLES OF CASE STUDIES WHERE HUMAN FACTORS ISSUES ARISE

It is worthwhile to examine a few classic case studies where human factors procedures interacting with medical devices needed to be reevaluated. It is emphasized that the errors described herein may not be attributed to any one person or system. Rather, the complex interaction of humans with poorly defined procedures involving certain medical devices has given rise to events, which were not planned or expected. However, with a more structured interaction of humans with these systems, improved results could be obtained. The reference by Geddes (35) provides many interesting examples where enhanced human factors planning would have prevented errors in medical treatment.

Case Study 1 from Ref. 35 and Reported in the South African *Cape Times* (1996)

“For several months, our nurses have been baffled to find a dead patient in the same bed every Friday morning” a spokeswoman for the Pelonomi Hospital (Free State, South Africa) told reporters. “There was no apparent cause for any of the deaths, and extensive checks on the air conditioning system, and a search for possible bacterial infection, failed to reveal any clues.”

Although device failure could cause such deaths, why they occurred on Fridays is difficult to understand? The *Cape Times* later reported:

It seems that every Friday morning a cleaner woman would enter the ward, remove the plug that powered the patient’s life support system, plug her floor polisher into the vacant socket and then go about her business. When she had finished her chores, she would then replug the life support machine and leave, unaware that the patient was now dead. She could not, after all, hear the screams and eventual death rattle over the shirring of her polisher.

“We are sorry, and have sent a strong letter to the cleaner in question. Further, the Free State Health and Welfare Department is arranging for an electrician to fit an extra socket, so there should be no repetition of this incident. The inquiry is now closed.”

This example emphasizes that when unplanned influences or events interact with medical device operation, tragic results may occur. In a later section, we describe several human factors procedures and techniques that are now designed to help preclude these types of untoward events.

In Ref. 36, a second example shows how important (delicate) care is requisite to providing appropriate interaction of humans with medical devices.

Case Study 2 from Ref. 36

Besides putting patients at high risk for injury, clinicians who use a device they are not familiar with are placing themselves in legal jeopardy. The case of *Chin vs. St. Barnabos Medical Center* (160 NJ 454 [NJ 1999]) illustrates

this point. A patient died after gas inadvertently was pumped into her uterus during a diagnostic hysteroscopy. Evidence established that the two perioperative nurses implicated in the case had no experience with the new hysteroscope and used the wrong hook up for the procedure. They connected the exhaust line to the outflow port. The 45-year-old patient died from a massive air embolism. It was also discovered that the nurses never received any education regarding the device. The manufacturer was not found liable because records indicated that the device did not malfunction or break. Damages in the amount of \$2 million were awarded to the plaintiff and apportioned among the surgeon, nurses, and hospital. As discussed in the sequel, new training methods have been developed in the human factors area to preclude the occurrence of events of this type.

The last case study deals with a poor interface design. Usability Testing, to be discussed later, provides methods to preclude some of these difficulties encountered.

Case Study 3 from Ref. 37

"A 67 year-old man has ventricular tachycardia and reaches the emergency room. Using a defibrillator, nothing happens. The doctor suggests the nurse to start a fluid bolus with normal saline. The nurse opens the IV tubing wide open, but within minutes the patient starts seizing. The nurse then realizes that the xylocaine drip instead of the saline had been inadvertently turned up. The patient is then stabilized and the nurse starts her paperwork. She then realizes that the defibrillator was not set on the cardio version, but rather on an unsynchronized defibrillation. This is because the defibrillator she uses, every day, automatically resets to the nonsynchronized mode after each shock. The second shock must have been delivered at the wrong time during the cardiac cycle, causing ventricular fibrillation." By performing a usability study as described later, with better training, this type of event could have been prevented.

The changing effect of legal influences also has had its impact on human factor interactions of caregivers with medical devices. It is worthwhile to briefly describe some of these recent influences and how they impact on human dealings with medical devices.

NEW LEGAL INFLUENCES THAT AFFECT HUMAN FACTORS

As mentioned previously in Refs. 13–15, there have been a number of modifications in the legal system that affect how humans now interact with medical devices. It is not unusual in the year 2005 to hear prescription drugs advertised on television or on the radio with a disclaimer near the end of each commercial. The disclaimer lists major possible side effects and warns the user to discuss the drug with their physician. As the aging "baby boomers" of the post-World War II era now require more and more medications, the drug companies make major efforts and studies to ensure that safe and effective drugs are delivered to an ever increasing public audience. Experience from prior mistakes has significantly modified how the drug industry must deal with a larger, and more highly informed, popu-

lation base. Some major modifications that occur involving legal issues and medical device operation include

1. The legal profession (13) now recognizes the importance of human factors engineering [also known as usability engineering or ergonomics (a term used outside the United States)] in studying how humans interact with machines and complex systems. Ergonomics is a factor in the design of safe medical devices; A user-friendly device is usually a safe one (38).
2. Healthcare Institutions employ results of human factors engineering testing of devices in making key decisions in evaluation as well as major purchase judgments. If these components fail, but have been tested within a rigorous framework, the legal consequences are mitigated since standards were adhered to in the initial selection of the medical device and procedure of use.
3. Insurance premiums to Healthcare Institutions are correspondingly reduced if adherence to standards set forth by good human factors engineering principles are maintained. The insurance costs are directly related to the potential of legal expenses and thus sway the decisions on how medical devices are purchased and used.

A number of new ways of improving how human factor design with medical devices has evolved, which will now be discussed as pertinent to the prior discussion. These methods affect training, utilization procedures, design of the devices, testing, and overall interaction with caregivers in the workplace.

METHODS TO IMPROVE HUMAN FACTOR DESIGN AND MEDICAL DEVICES

Professionals working in the area of human factors have now devised a number of new means of improving how healthcare professionals can better deal with medical devices. We present some of the most popular methods in the year 2005, most of which now pervasively affect the development of a user's manual, training, and manner of use with respect to medical devices. Some of these techniques appear to have overlap, but the central theme of these approaches is to better assist the healthcare professional to mitigate untoward events. One of the most popular methods derived from human factors studies is cognitive task analysis (CTA). In short, the way that CTA works is that a primary task is subdivided up into smaller tasks that must be performed. It is necessary to specify the information needed to perform each subtask, and the decisions that direct the sequence of each subtask. Note, this type of task description is independent of the automation involved. For example, for the same tasks, information and decisions are required regardless of whether they are performed by a human or a machine. Also considered in this analysis are the mental demands that would be placed on the human operator while performing these selected subtasks.

Cognitive Task Analysis and How it Affects Human Factors and Medical Devices

The principle behind CTA is to take a large and complex task and divide it up into smaller subtasks (39). Each subtask should be attainable and reasonable within the scope of the user. If the subtask is not yet in the proper form, further subdivisions of that subtask are performed until the final subtask is in the proper form. The expression "proper form" implies the subtask is now attainable, sufficiently reasonable to perform, the proper information has been provided, and sufficient control is available to execute this subtask. An important aspect of CTA is to define if the user has the proper information set to complete his duties and also has the proper control means over the situation so that the task can be achieved adequately. Cognitive task analysis has great value in establishing a set of final subtasks that are both attainable and relevant to the overall mission. With this analysis, the caregiver can be provided better training and have an enhanced understanding of the role of each task within the overall mission. This procedure has been used in the nursing area for assessing risk of infants (40) and for patient-controlled analgesia machines (41). It has been noted (42) that 60% of the deaths and serious injuries communicated to the Medical Device Reporting system of the U.S. Food and Drug Administration (FDA) Center for Devices and Radiological Health have been attributed to operator error. Cognitive task analysis has evolved out of the original area of Critical Decision Methods (43) and is now an accepted procedure to analyze large and complex interactions of humans with machines.

A second popular method to shape procedures to interact with medical devices involves User Testing and Usability Engineering.

User Testing and How It Affects Human Factors and Medical Devices

User Centered Design has found popularity when humans have to interact with medical devices for ultrasound systems (44) and for people with functional limitations (45). Usability engineering methods are applied early in the system lifecycle to bridge the gap between users and technology. The ultimate goal is to design an easy to use system that meets the needs of its users. A basic principle of user-centered design is making design decisions based on the characteristics of users, their job requirements and their environments (46–50). It is often the complaint of human factors professionals that they are brought into the design process much too late to influence the construction of the overall system. It is all too common for the experimental psychologist to have to deal with an interface built without prior considerations of the human's limitations and preferences in the initial design construction. The usability engineering methods bring to light needs for users and tasks early on, and suggest specific performance testing prior to the recommendation of the final design of an interface.

A third method discussed here to influence how to work with medical devices involves Work Domain Analysis.

Work Domain Analysis and How It Affects Human Factors and Medical Devices

A third and popular method to better understand the interplay between human factors issues and medical devices is via an integrated method involving the technical world of physiological principles and the psychological world of clinical practice. This work domain analysis was originally proposed by Rasmussen et al. (51,52) and has found application in patient monitoring in the operating room (53). A variety of tables are constructed based on data to be utilized. Columns in the tables include a description of the task scenario and the relations between key variables of the work environment and the work domain. The tables portray interactions and different strategies that are elicited to help in monitoring and control.

As discussed earlier in Ref. 1, today many new advances have also been made in alarms. These inform the health-care provider of troublesome events and many innovative changes and studies have been instituted in this area that warrant discussion. Alarm deficiencies compromise the ability to provide adequate healthcare. For alarms, some research has focused on the identification of alarm parameters that improve or optimize alarm accuracy (i.e., to improve the ratio of true positives to false positives: the signal/noise ratio).

ALARMS AND HUMAN FACTORS ISSUES

Alarms are key to the detection of untoward events when humans interact with medical devices. One does not want to generate designs that invite user error. We cannot deal with confusing or complex controls, labeling, or operation. Many medical devices have alarms or other safety devices. If, however, these features can be defeated without calling attention to the fact that something is amiss, they can be easily ignored and their value is diminished (54). The efficacy of alarms may be disregarded because it is not attention getting. For example, if a multifunction liquid-crystal display (LCD) has a low battery warning as its message, but is not blinking, it does not call attention to itself. Alternatively, an improved design occurs in the case of a low battery alarm design commonly found in household smoke detectors. In this case, a low battery will cause the unit to chirp once a minute for a week, during which the smoke detector is still functional. The chirp may be confusing at first, but it cannot be ignored for a week. A battery test button is still available for the testing when the battery power is satisfactory. Adequate alarm systems are important to design in a number of analogous medical scenarios. For example, use of auditory systems (55) is preferable to a visual display, since this reduces the visual workload associated with highly skilled tasks that may occur, for example, in the operating room. For anesthesia alarms (56), care must be exercised to not have too many low level alarms that indicate, for example, that limits are exceeded or that the equipment is not functioning properly. The danger of false positives (alarms sounding when not necessary) provides an opportunity for the user to ignore information, which may be critical in a slightly different setting. An example where information of this type cannot be

ignored is in applications of human factors training to the use of automated external defibrillators. It is known that without defibrillation, survival rates drop by 10% for every minute that passes after cardiac arrest (57). A great deal of work still continues in the area of management of alarm systems in terms of their efficacy and utility (58,59).

Another significant issue with human factors is proper labeling. Medication misadventures are a very serious problem. We briefly summarize changes that impact how humans will interact with their prescriptions as well as medical devices in general and how they are influenced by their labeling constraints.

LABELING AND HUMAN FACTORS ISSUES

By government regulation and industry practice, instructions accompanying distribution of medical devices to the public are termed “labeling”. Medical device labeling comprises directions on how to use and care for such practices. It also includes supplementary information necessary for the understanding and safety, such as information about risks, precautions, warning, potential adverse reactions, and so on. From a human factors perspective, the instructions must have the necessary efficacy, that is, they must provide the correct information to the user. There are a number of standards on how the instructions must be displayed and their utility in the healthcare industry (60). For example, for prescription medications (61–64), they represent the most important part of outpatient treatment in the United States. This provides > 2 billion possible chances for patient error each year in the United States. To maximize the benefits and minimize the dangers of using these medications, users must comply with an often complex set of instructions and warnings. Studies show that seven specific system failures account for 78% of adverse drug events in hospitals. All seven of these failures could be corrected by better information systems that detect and correct for errors. The top seven system failures for prescription medications are (1) drug knowledge dissemination; (2) dose and identification checking; (3) patient

information availability; (4) order transcription error; (5) allergy defense; (6) medication order tracking; (7) improved interservice communication.

As mentioned previously, as computers and the Internet become more pervasive, patients, caregivers, doctors, and others become more tolerant and dependent on automation. The goal is to make a task easier, which is true most of the time. There are a number of issues with regard to automation that need to be addressed.

AUTOMATION ISSUES AND HUMAN FACTORS

As computers and microprocessor-based devices have become more ubiquitous in our modern age, there is increased tendency to foster automation (65) as a means of improving the interaction of users with medical devices. The original goal of automation was to reduce the workload (physical and mental) and complexity of a task to the user. This is specific to the desired response from the device of interest. There is an obvious downside of this concept. The idea that the automation has taken over and has a mind of its own is ghastly within human thinking. Also, if the automated system is too complex in its operation and the user is not comfortable in understanding its causality (input–output response characteristics), the trust in the device will decrease accordingly and the human–machine interaction will degrade. The classical work by Sheridan (66) defines eight possible levels of automation, as portrayed in Fig. 3. One easily sees the relationship of loss of control to increased automation. For medical device usage, this may be problematic to trade off simplicity of use to loss of control and eventual efficacy. Automation studies continue to be of interest (67–73).

REPORTING AND HUMAN FACTORS ISSUES

Reporting of failures of proper medical device operation has now commonly advanced to Web-based systems (3,74). The healthcare provider must be increasingly skilled with the use of computer systems. Sometimes the terms digital

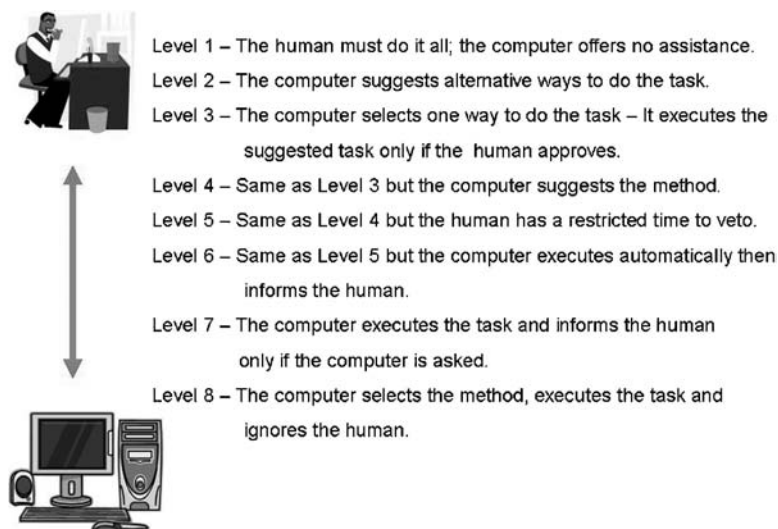

Figure 3. The eight levels of automation.

divide is employed to distinguish those that have the requisite computer skills from those that are not as competent in this area. This may be a consequence of human factors procedures instituted to deal with a more elderly patient group (75–82) who may not be comfortable with computers. Education is the best means to deal with this problem (83). It is important that modern healthcare givers who use medical devices in their work setting have the obligatory skills to accurately report failures and have the suitable computer training to make relevant reports to the necessary sources.

A number of new areas are growing and influence how human factors have been evolving with the interaction of medical devices. It is important to spend some time mentioning these contemporary and emergent areas.

NEW ISSUES INVOLVING HUMAN FACTORS AND MEDICAL DEVICES

With advances in technology, several new areas should be mentioned that seem to have relevance to novel advances in medical devices. The concept of telemedicine is now a developing field that certainly addresses the future uses of medical devices.

The Growth of Telemedicine

The term telemedicine literally means “medicine at a distance” (84) and is now an increasing and popular means of providing healthcare. The advantages are obvious in rural settings and numerous other scenarios (cf. Fig. 4). For example, having an expert physician or surgeon located at a remote and safe location, but performing a medical procedure on a person in a hazardous or distant environment provides a distinct advantage. The human at the hazardous environment may be placed in a battlefield in a combat situation, they may be in a space shuttle, or simply be in another country or distant location from the expert medical practitioner. Another simple example of telemedicine occurs in a simple endoscopic (colonoscopy) procedure or in a laparoscopic operation, for example, for knee surgery. For these procedures, a small insertion is made into

the patient and the process is carried out from a remote location with the physician observing the process on a television monitor. The advantages are obvious: (1) with smaller entrance incisions or openings into the patient, the trauma is significantly reduced; (2) recovery time is much quicker; and (3) the risk of infection is substantially mitigated. Some of the new human factors issues regarding medical devices used within this context include (1) Dealing with the time delay between observing and making actions and the associated instabilities that may occur in the closed loop interaction; (2) having the lack of a sense of presence about a remote environment; and (3) having a strong dependence on mechanical systems or automation at the end-effector of the device inside the patient. These methods have been advanced to the point where robots are now being used to perform heart surgery, and so on, and some operations have been conducted over the Internet. Recent applications of robots performing heart procedures on humans need only two very small incisions in the patient. This allows for much quicker recovery time to the patient (1 vs. 7 weeks for a typical open heart surgery). From the surgeon’s perspective, a significant advantage for the small incisions is that: It is not necessary to insert my hands inside the chest cavity. Thus the size of the incisions can be substantially reduced. One sees the disadvantage of traditional surgery in this area because *it is the size of the surgeon’s hands being required to be inside the chest cavity as the only reason for a large incision in the chest cavity*. When the surgeon’s hands no longer have to be inside the chest cavity, then the correspondingly two small incisions give rise to reduced possible infection, less trauma to the patient, and a shorter recovery time before the patient can return to normal work and living activities. This area of healthcare will only continue to advance as medical practices move more and more to this form of undertaking. In recent times, a number of studies in teleoperation have shown the efficacy of improving the sense of presence of the operator about the remote environment through “haptic” feedback. Haptic refers to forces reflected back on the physician (by various robotic interface devices) to improve their sense of presence about the remote environment, so the operator can “feel” the task much as they see it on a television monitor. A number of studies have shown both an improved sense of presence and performance about these teleoperation scenarios using haptic feedback (85–88). Auditory systems have also found analogous use in surgery (89). The problems in anesthesia are also well studied (90–93).

Another growth area includes more participation by the patient directly in their own healthcare.

The Growth of Increased Patient Participation in the Healthcare Process

As discussed previously, with the pervasive nature of automation, more and more of the healthcare responsibility and work will be performed by the patient, themselves. Modern insurance procedures also encourage additional homecare scenarios and many times without a trained caregiver. This saves expensive care at the hospital, but transfers the burden onto the patient or their family members to become the primary caregiver. A paradigm

Figure 4. The concept of telemedicine.

shift of this type is a consequence of present insurance reimbursement procedures requiring the patient to now spend much of their time away from the hospital. New human factors issues are consequently introduced when dealing with medical devices in this scenario. The design of the human computer interface (94–97) now becomes critical for the efficacy of the healthcare provided. Even in cancer treatment, the responsibility of the proper administration of radioisotopes may become the burden of the patient (98) or if they have to manipulate their own chemotherapy level. For pain treatment (99–101) the patient has to be proactive in the selection of the analgesia level of the device provided. Modern TENS (Transcutaneous Electrical Nerve Stimulator) units now have been constructed to be wireless and shown to have equivalent efficacy in terms of pain management as compared to long wired units that have been in existence for >40 years (102). The movement to more wireless medical devices is certainly in the future. For the TENS units, by eliminating the long and entangling wires, this provides more reliability, less chance of wires breaking or shorting, more efficient use of electric power, but different forms of control with these analgesia devices. For example, the physician or caregiver may use a remote control to program the voltage level of the TENS microprocessor in a wireless manner rather than making manual adjustments with the traditional, long wired, TENS devices.

A third area of modern concern is the impact of electromagnetic fields on the operation of other medical devices, especially if they are implanted.

The Growth of Electromagnetic Fields on the Operation of Other Medical Devices

The Geddes reference (35) describes numerous examples of documented problems when medical devices inadvertently interact with unexpected exposure to external electromagnetic fields. Electromagnetic interference (EMI) is used to describe the malfunction of a device exposed to electromagnetic waves of all types that propagate through space. The EMI can intervene with electrodes on a patient, it can bias results for EEG recording of generalized epileptiform activity, and can give false positives to alarm systems, Silbert et al. (103). Other cases where malfunctions can occur involve heart machines, apnea monitors, ventilator mishaps, and in drug infusion pumps. Pacemakers are known to be affected by low frequency EMI signals. There are many exogenous sources of EMI including, but not limited to, Electrostatic Discharge, arc welding, ambulance sirens, and other sources (104). The growth of EMI is only increasing and human factors professionals need to carefully consider sources of problems from EMI that may have to be dealt with.

A fourth area of potential problems of human factors interaction with medical devices occurs when two or more medical devices are simultaneously in operation, but their concurrent action may interact with each other in a destructive way.

The Potential Interaction of Multiple Medical Devices

As medical devices become more and more sophisticated, they may concurrently be in operation on the same patient

(105–109). The action of one medical device may produce an undesired response of another device, especially if it may be implanted. From Geddes (35): “Between 1979 and 1995, the Center for Devices and Radiological Health (CDRH) of the U.S. Food and Drug Administration (FDA) has received over one hundred reports alleging the electromagnetic interference (EMI) resulted in malfunction of electronic medical devices.” The source of the EMI was from one medical device treating the patient. The malfunction occurred in a second medical device, which was also, simultaneously, being used to treat the same patient.

“For example, about 100,000 cardiac pacemakers are implanted annually. These stimulators can be interrogated and programmed by an external device that uses a radio frequency link. Electro surgery, which also uses radio frequency electric current may interact with the pacemaker causing serious arrhythmias. Even though the two technologies are safe, when used alone, their simultaneous combination has resulted in injury.” More specifically, nowadays with the prevalence use of cellular telephones for both caregivers as well as the patients in care situations, there are documented cases of resulting injury to the patient. Cell phones have now been recognized to cause instances of malfunction of drug infusion pumps and patient monitors. These interactions have to be considered for new human factors interactions with medical devices in the future, Silbergberg (110) with increased interest in the errors created (111,112) and the specific technology used (113).

With the changing style of litigation with respect to the medical profession, there has been more public awareness of sources of human factor error induced by the medical professional working in a state of extreme fatigue.

Increased Public Awareness to Fatigue Issues and the Medical Professional

There has now been a substantial increased awareness of the general public to the fact that their medical professional may have compromised performance due to the fact that they are suffering from long hours of work. Fatigue studies continue to receive increased concern (114–120). This certainly has its influence on human factors procedures when dealing with medical devices and the overall success of the medical interaction. For example (115), it is known that physicians had demonstrated levels of daytime sleepiness worse than that of patients with narcolepsy or sleep apnea when required to perform long hours of duty.

Finally, since the publication of Ref. 1, the healthcare industry must now deal with a substantially larger population of acquired immune deficiency syndrome (AIDS) survivors who need medical, dental, and other types of interactions with healthcare professionals (121).

Changing Medical Procedures to Deal with Active Human Immunodeficiency Virus Patients

With the advent of advanced drug therapies, people with human immunodeficiency virus (HIV) are now living longer and longer. These same people need dental care, have medical attention requests, and require other types of consideration. The medical professional must exercise

forethought to not have exposure to body fluids and new procedures are in place to provide discrimination free care to these people. In the early days of public exposure to people with HIV, there were documented cases of health professionals refusing to give adequate care. For example, for resuscitation, fireman and others would avoid contact with individuals suspected of having HIV. New devices have now been constructed to keep body fluids and other contact more separated between the patient and the caregiver. There have been new laws passed to prevent discrimination to people suspected of having HIV in housing, in the workplace, and also in receiving adequate healthcare.

CONCLUSION

The modern human factors interactions with medical devices have been strongly influenced by the advent of new technologies including the Internet, microprocessors, and computers. People are becoming more accustomed to automation and dealing with other sophisticated means of delivering healthcare. One lesson that can be learned from the improvement of human factors interactions with medical devices is that we can create safety by anticipating and planning for unexpected events and future surprises. Another change in this new millennium is that the responsibility of the patient is now shifted more to the individual or their family to have a greater role and duty over their own therapies and venue, and perhaps work in their home setting. Telemedicine and wireless means of dealing with controls over the medical devices are certainly on the increase and will influence how the patient has to deal with their healthcare professional in the future.

INTRODUCTION

From a bioengineer's perspective, bio the spine involves an understanding of the interaction among spinal components to provide the desired function in a normal person. Thereafter, one needs to analyze the role of these elements in producing instability. Abnormal motion may be due to external environmental factors to which the spine is subjected to during activities of daily living (e.g., impact, repetitive loading, lifting) degeneration, infectious diseases, injury or trauma, disorders, and/or surgery. Furthermore, the field of spinal biomechanics encompasses a relationship between conservative treatments, surgical procedures, and spinal stabilization techniques. Obviously, the field of spinal biomechanics is very broad and it will not be practical to cover all aspects in one article. Consequently, this article describes several of these aspects, especially in the cervical and thoraco-lumbar regions of the human spine. A brief description of the spine anatomy follows since it is a prerequisite for the study of bio the human spine.

SPINE ANATOMY

The human spinal column consists of 33 vertebrae interconnected by fibrocartilaginous intervertebral disks (except the upper most cervical region), articular facet capsules, ligaments, and muscles. Normally, there are 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, and 5 fused sacral vertebrae, Fig. 1a (1). When viewed

in the frontal plane, the spine generally appears straight and symmetric while revealing four curves in the sagittal plane. The curves are anteriorly convex or lordotic in the cervical and lumbar regions, and posteriorly convex or kyphotic in the thoracic and sacrococcygeal regions. The center of gravity of the spinal column generally passes from the dens of the axis (C2) through the vertebra to the promontory of the sacrum (2,3). The ligamentous spine anatomy can be best described through a functional spinal unit (FSU, Fig. 1b), comprising the two adjacent vertebrae, the disk in between, and the other soft tissues structures. This segment can be divided into anterior and posterior columns. The anterior column consists of the posterior longitudinal ligament, intervertebral disk, vertebral body, and anterior longitudinal ligament. Additional stability is provided by the muscles that surround the ligamentous spine, Fig. 1c. The motion of this segment can be described as rotation about three axes and translation along the same axes, Fig. 2. In the following paragraphs, the anatomy of the cervical region is described in some detail followed by a descriptive section discussing the anatomy of the lumbar spine.

Cervical Spine Anatomy

The cervical spine usually is subdivided in two regions (upper and lower), based on the functional aspects and anatomical differences between the two regions. The lumbar region anatomy, in principle, is similar to the lower cervical region.

Upper Cervical Spine (C0-C1-C2)

The upper cervical spine has been commented to be the most complex combination of articulations in the human skeleton. This region is also commonly called the "cervicovertebral junction" or the "craniovertebral junction" (CVJ). It is composed of three bony structures: the occipital bone (C0), the atlas (C1), and the axis (C2, Fig. 3). The atlas (C1), serves to support the skull. The atlas is atypical of other cervical vertebrae in that it possesses neither a vertebral body nor a spinous process. The lateral masses of the atlas have both superior and inferior articular facets. The superior facets are elongated, kidney-shaped, and concave, and serve to receive the occipital condyles. The inferior facets are flatter and more circular and permit axial rotation. Transverse processes extend laterally from each lateral mass. Within each transverse process is a foramen that is bisected by the vertebral artery. The second cervical vertebra, or axis (C2), is also atypical of other cervical vertebrae due to its osseous geometry (5,6). The most noteworthy geometric anomaly is the odontoid process, or dens. The odontoid process articulates with the anterior arch of the atlas. Posterior and lateral to the odontoid process are the large, convex superior facets that articulate with the inferior facets of C1. The inferior facets of C2 articulate with the superior facets of C3. The axis contains a large bifid spinous process that is the attachment site delineating the craniovertebral and subaxial musculature and ligament anatomies.

Figure 1. The ligamentous human spine. (a) The side view showing the three curvatures. (b) The functional spinal unit (FSU) depicts the spinal elements that contribute to its stability. (c) Additional stability is provided by the muscles that surround the spine. (Taken from Ref. 1.)

The trabecular anatomy of weight bearing bones provides information about the normal loading patterns of the bones, fracture mechanisms, and fixation capabilities. According to Heggeness and Doherty (6) the medial, anterior cortex of the odontoid process (1.77 mm at the anterior promontory) was found to be much thicker than the anterolateral (1.00 mm), lateral (1.08 mm), and posterior (0.84 mm) aspects of the axis. These authors feel that this is suggestive of bending and torsional load carrying capabilities. The same was found for the vertebral body, with thinner cortices were noted in the anterolateral and posterior directions. The trabecular bone in the tip of the odontoid process was found to be dense, maximizing in the anterior aspect of the medullary canal. One observation made by the authors was an area of cortical bone density at the center near the tip, which would seem to indicate that this area experiences elevated external forces, perhaps due to local ligamentous attachments. The lateral masses immediately inferior to the facets demonstrated dense regions of trabecular bone, with individual trabeculas spanning from this region to the inferior end plate, suggestive of a major axial load path.

The ligamentous structures of the upper cervical spine form a complex architecture (Fig. 3) that serves to join the

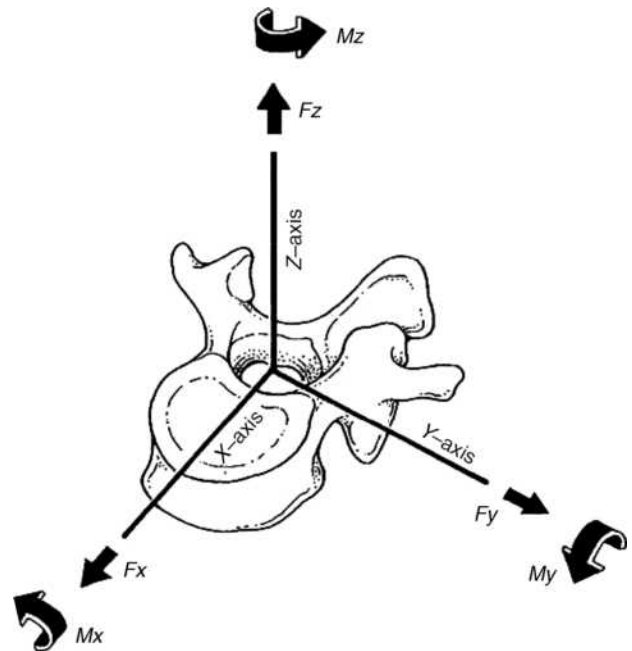

Figure 2. The spinal motion consists of six components (three translations and three rotations). (Adapted from Ref. 2.)

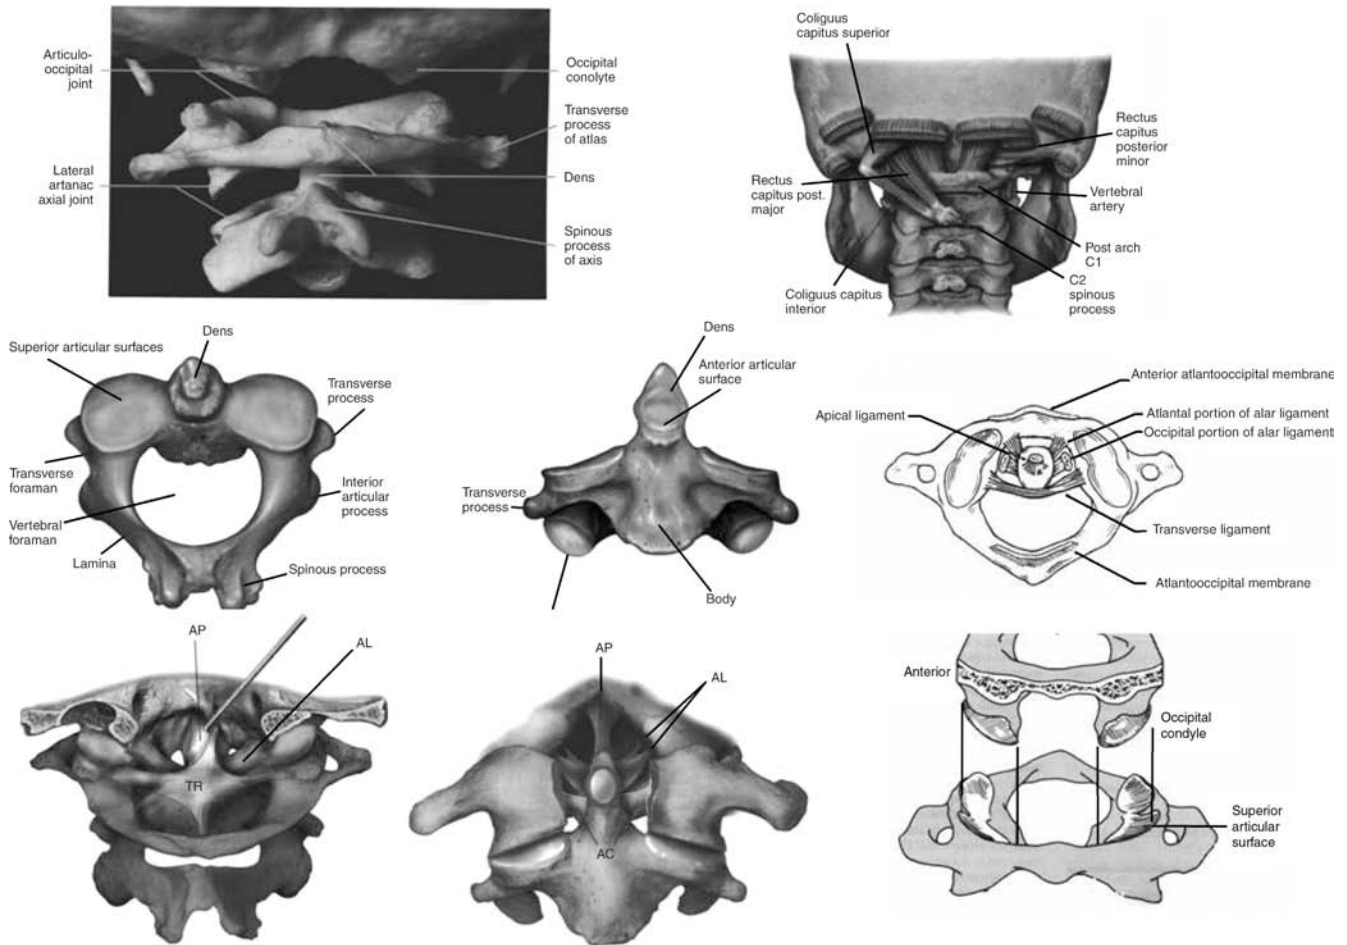

Figure 3. The anatomy of the upper region of the cervical spine C0 (occiput)-C1 (Atlanlanto)-C2 (Axial). (Taken from Ref. 4c.)

vertebras, allow limited motion within and between levels, and provide stability. The cruciform ligament as a whole consists of two ligaments: the atlantal transverse ligament and the inferior–superior fascicles. The transverse ligament attaches between the medial tubercles of the lateral masses of the atlas, passing posterior to the odontoid process. Attachment of the cervical spine to the skull is also achieved by the paired alar ligaments. These ligaments run bilaterally from the occipital condyles inferiolaterally to the tip of the odontoid process. The alar ligaments also contain fibers that run bilaterally from the odontoid process anterolaterally to the atlas. These ligaments have been identified as a check against overaxial rotation of the craniovertebral junction. Extending from the body of the axis to the inner surface of the occiput, the tectorial membrane is the most posterior ligament and actually represents the cephalad extension of the subaxial posterior longitudinal ligament. The tectorial membrane has been implicated as a check against extreme flexion motion. The apical dental ligament extends from the anterior portion of the magnum foramen to the tip of the odontoid process. The accessory atlantoaxial ligaments are bilateral structures that run between the base of the odontoid process and the lateral masses of the atlas. The most anterior of the major ligaments is the anterior longitudinal ligament.

This ligament extends inferiorly from the anterior margin of the foramen magnum to the superior surface of the anterior arch of the atlas at the anterior tuberosity. The ligament continues inferiorly to the anterior aspect of the axial body. The nuchal ligament (*ligamentum nuchae*) extends from the occiput to the posterior tubercle of the axis, continuing inferiorly to the spinous process of the subaxial vertebrae (7).

There are six synovial articulations in the occipitoatlantoaxial complex: the paired atlanto-occipital joints, the paired atlantoaxial joints, the joint between the odontoid process and the anterior arch of the atlas, and the joint formed by the transverse ligament and the posterior aspect of the odontoid process, Fig. 3. The bilateral atlanto-occipital joints are formed from the articulation of the occipital condyles with the superior facets of the atlas. These joints are relatively stable due to the high degree of congruence between the opposing surfaces and the marked rounding that is displayed by both sides. They allow flexion and extension, limited lateral bending, and almost no rotation. The lack of allowed rotation is thought to be due to the ellipsoid form of the joint itself. Bilateral articulation of the inferior facets of the atlas with the superior facets of the axis form the atlantoaxial joints. Relatively small contact areas and opposed convexity

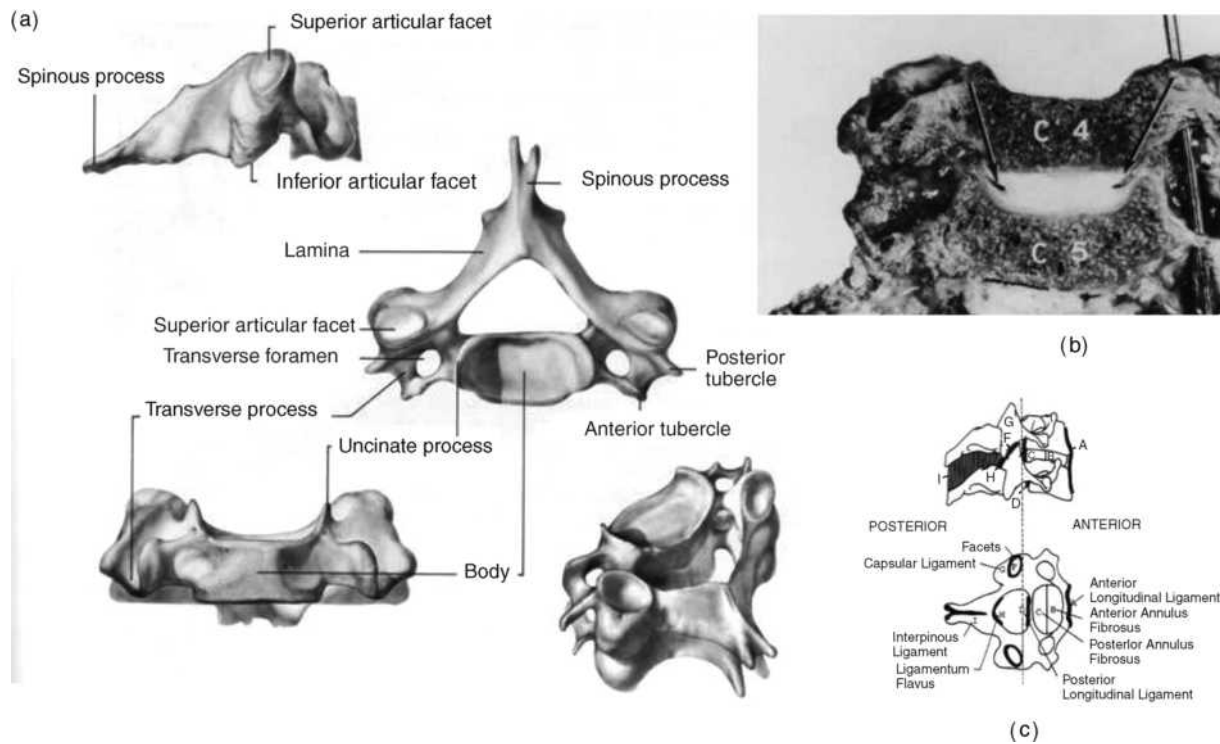

Figure 4. Anatomy of the lower cervical spine region. (Taken from Ref. 4d.)

result in a rather unstable joint. Movement is permitted in almost all six degrees of freedom: left and right axial rotation, flexion–extension, right and left lateral bending. Anteroposterior translation stability of this articulation is highly dependent on the transverse ligament. The odontoid process articulates anteriorly with the posterior aspect of the anterior atlantal ring. The joint is actually a bursal joint, with absence of specific capsular ligaments. The posterior aspect of the odontoid process and the transverse ligament form a joint via a bursa junction, creating the most unique articulation in the craniovertebral junction. This is necessitated by the large degree of axial rotation afforded at the atlantoaxial level.

Lower Cervical Spine (C3–C7). The lower cervical spinal vertebral column consists of osseous vertebrae separated by fibrocartilaginous intervertebral disks anteriorly, facet joint structures posteriorly, and a multitude of ligamentous structures that provide stability and serve as motion control. Motion between adjacent vertebrae is relatively limited due to these constraints, although overall motion of the lower cervical region is quite extensive. The lower cervical spine consists of five vertebrae (C3–C7).

Cervical Vertebrae (Fig. 4a): The vertebral body is roughly in the shape of an elliptical cylinder and has a concave superior surface (due to the uncinates) and a convex inferior surface. A thin cortical shell (~0.3 mm thick anteriorly and 0.2 mm thick posteriorly) surrounds the cancellous bone of the inner vertebral body, while the superior and inferior surfaces of the vertebral body form the cartilaginous endplates, to which the intervertebral disks are attached. The superior aspect of each

vertebra contains the uncinates or uncus, a dorso-lateral bilateral bony projection, which gives the body a concave shape superiorly in the coronal plane and allows for the vertebral body to fit around the convex inferior surface of the immediately superior vertebra. The height of these processes vary from level to level, but the highest uncinates are located at C5 and C6 (as high as 9 mm from the flat surface of the endplate) and the smallest are located at C3 and C7 (8–10). Vertebral bodies transmit the majority of load.

The transverse process of the vertebra contains the intervertebral foramen. The intervertebral foramen is elliptical or round in shape, and hides and protects the neurological and vascular structures of the cervical spine, specifically the vertebral artery. Also, the rostral side of each bilateral transverse process is grooved to allow space for the exiting spinal nerve root.

The bilateral diarthroidal facet (or zygapophyseal) joints are located posteriorly to the pedicles both superiorly and inferiorly. The average orientation for the C3–C7 facet joints is ~45° from the transverse plane, with steeper inclinations in the lower segments (11). This inclination allows far less axial rotation than occurs in the upper cervical spine. Together with the vertebral body (and intervertebral disks), the facets fulfill the primary role of load bearing in the spine. Typically a “three-column” aspect is applied to the cervical spine, consisting of bilateral facets and the anterior column (vertebral body plus intervertebral disk).

The pedicles, lamina, and spinous process of the cervical spine are made of relatively dense bone and, together with the posterior aspect of the vertebral body, form the spinal

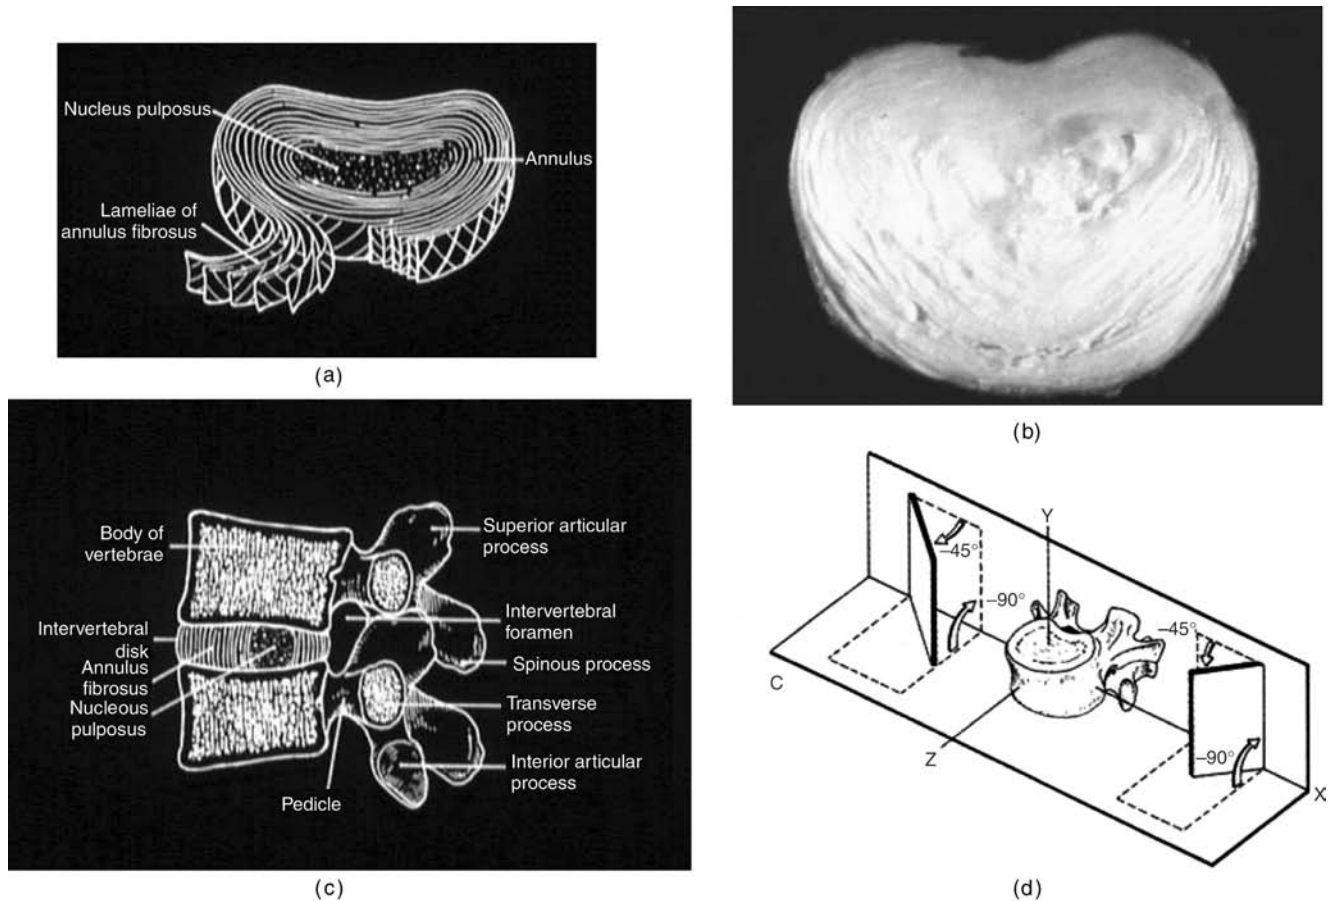

Figure 5. The anatomy of the lumbar spine. (a) and (b) show schematics of the disk and an actual disk (c) AFSU in the lumbar region. (d) The facet orientation in the lumbar region is more sagittal as compared to the other regions of the spine. (Adapted from Ref. 2.)

canal, within which lies the spinal cord. There are many ligament attachment points in this region and ligaments allow for resistance of flexion motion in the cervical spine.

The typical sagittal cervical spine alignment is thought to be a lordotic contour (11–15). The total average cervical lordosis was found to be $40 \pm 9.7^\circ$ for C0–C7, with the majority of this lordosis occurring at the C1–C2 level ($31.9 \pm 7.0^\circ$), and only 15% of the total lordosis occurring at the C4–C7 levels combined. The normal population seem to exhibit lordosis that ranges between 15 and 40° .

The Intervertebral Disk

Figure 5 forms the main articulation between adjacent vertebral bodies in the spine. It has the ability to transmit and distribute loads that pass between adjacent vertebral bodies. Its structure is a composite formation of outer layers of lamellas sheets called the annulus fibrosus, which surrounds the inner region of hydrophylic proteoglycan gel embedded in a collagen matrix called the nucleus pulposus. The material properties of the intervertebral disk appear to change markedly as a result of the aging process. The matrix in which collagen and elastin fibers are embedded is composed of proteoglycan aggregates formed from

proteoglycan subunits, hyaluronic acid, and link protein (16). In soft tissues, such as the intervertebral disk and cartilage, the proteoglycan aggregates are immobilized within a fibrous network and play a major biological role in the structure of collagen, in turn playing a major mechanical role in the intervertebral disk integrity. The viscoelastic properties of the intervertebral disk can be attributed to the interaction between the collagen fibrils and proteoglycan matrix composing the nucleus pulposus of the intervertebral disk. The proteoglycans function to attract fluids into the matrix, while the collagen fibers provide the tensile strength to the disk. As the human spine ages, the osmotic properties of the intervertebral disk decline, and the disks become dehydrated with age, causing a reduction in overall disk height.

The annulus fibrosus of the disk consists of a series of approximately twelve 1-mm thick lamellas sheets, each composed of collagen fibers. The anterior lamellas are generally thicker and more distinct than the posterior lamellas. According to a study by Pooni et al.(9), the collagen fibers running through a single laminar sheet are oriented at $\sim 65^\circ (\pm 2.5^\circ)$ with respect to the vertical axis. These fibers alternate direction in concentric lamellas to form a cross-pattern. The annulus fibrosus develops lesions as it ages.

The nucleus pulposus of the intervertebral disk consists of a hydrophilic proteoglycan gel embedded in a collagen matrix. The nucleus pulposus contains ~80–88% water content in a young adult spine and occupies ~30–50% of the total intervertebral disk volume (16,17). However, with aging the nucleus undergoes rapid fibrosis and loses its fluid properties such that, by the third decade of life, there is hardly any nuclear material distinguishable (18). In a normal healthy intervertebral disk, the nucleus pulposus is glossy in appearance.

Luschka's joints are something special in the cervical region. The human cervical intervertebral disk contains fissures, called Luschka's joints or uncovertebral joints that run along the uncinat process and radiate inward toward the nucleus (Fig. 4a and b). These fissures run through the annular lamellas and the adjacent annular fibers are oriented such that they run parallel to the fissure (19–21). These fissures appear within the latter part of the first decade of life and continue to grow in size as aging occurs (8). Although some argument exists as to the definition of the fissures as true joints or pseudojoints, the fissures have been shown to exist as a natural part of the aging process (19,20) and therefore are important aspects of biomechanical modeling of the human cervical intervertebral disks.

The ligaments of the cervical spine (Fig. 4c) provide stability and act to limit excessive motions of the vertebrae, thereby preventing injury during physiologic movement of the spine. Ligaments can only transmit tensile forces, impeding excessive motion, but do follow the principles of Wolff's law, where the tissue will remodel and realign along lines of tensile stress. The ligaments that are biomechanically relevant include the anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL), ligamentum flavum (LF), interspinous ligament (ISL), and the capsular ligaments (CAP). The ALL and PLL each traverse the length of the spine. The ALL originates at an insertion point on the inferior occipital surface and ends at the first segment of the sacrum. It runs along the anterior vertebral bodies, attached to the osseous bodies and loosely attached to the intervertebral disks as well. The ALL is under tension when the cervical spine undergoes extension. The PLL also runs the length of the spine down the posterior aspect of the vertebral bodies, originating at the occiput and terminating at the coccyx. Similar to the ALL, it is firmly attached to the osseous vertebral bodies and to the intervertebral disks. The PLL is under tension when the spine undergoes flexion. The ligamentum flavum couples the laminae of adjacent vertebrae. It is an extremely elastic ligament due to the higher percentage of elastin fibers (65–70%) as compared to other ligaments in the spine and any other structure in the human body. The LF resists flexion motion and lengthens during flexion and shortens during extension. The high elastin content minimizes the likelihood of buckling during extension. It is under slight tension when the spine is at rest and acts as a tension band in flexion. Torsion also places the ligamentum flavum under tension, and restraint of rotation may also be a significant function. The ISL insertion points lie between adjacent spinous processes. The ligament is typically slack when the head is in a neutral posture and only becomes

tensile when enough flexion motion has occurred such that other ligaments have undergone significant tension, such as the capsular ligaments, PLL and LF. Additionally, the ISL insertion points are such that it is ideal for resisting the larger flexion rotations that can occur as a result of excessive flexion loading. The capsular ligaments (CAPs) enclose the cervical facet joints and serve to stabilize the articulations of these joints and limit excessive motions at these joints. Generally, the fibers are oriented such that they lie perpendicular to the plane of the facet joints. These ligaments potentially also serve to keep the facets aligned and allow for the coupled rotations.

Lumbar Spine Anatomy

The basic structural components of the lumbar spine are the same as that of the lower cervical spine with differences in size, shape, and orientation of the structures due to functional requirements being different from that of the cervical region, Fig. 5. For example, the lumbar vertebrae are bigger in size, because of the higher axial loads they carry. With regard to the peripheral margin of the intervertebral disk, annulus fibrosus is composed of 15–20 layers of collagenous fibrils obliquely running from one cartilage end plate to the other and crossing at 120° angles. As one progresses from the cervical into the thoracic region, the facet joints gradually orient themselves parallel with the frontal plane. The transition from the thoracic region into the lumbar region is indicated by a progressive change from the joints in the frontal plane to a more sagittal plane (4,22). This transition in facet orientation from the thoracic to the lumbar spine creates a different series of degenerative complications and disorders in the spine. Sagittal alignment of the facet joints increases the risk of subaxial and spondylolisthesis of the lumbar spine.

CLINICAL BIOMECHANICS OF THE NORMAL SPINE

The three basic functions of the spine are to protect the vital spinal cord, to transmit loads, and to provide the flexibility to accomplish activities of daily living. Components that provide stability to the spine are divided into four groups as follows:

1. **Passive stabilizers:** Passive stabilization is provided by the shape and size of vertebrae and by the size, shape, and orientation of the facet joints that link them.
2. **Dynamic stabilizers:** Dynamic stabilization is provided by viscoelastic structures, such as the ligaments, capsules, and annulus fibrosus. The cartilage of the facet joints also acts as a damper.
3. **Active stabilizers:** Active voluntary or reflex stabilization is provided by the muscular system that governs the spine, Fig. 1c.
4. **Hydrodynamic stabilizer:** Hydrodynamic stabilization is due to the viscous nucleus pulposus.

The combination of these elements generates the characteristics of the entire spine. The discussion of the kinematics will begin by further analyzing spinal elements as

either passive or active. It will then progress into the effect these stabilizers have on the different portions of the spine.

Passive Elements

The vertebral body acts to passively resist compressive force. The size, mineral content, and orientation of the cancellous bone of each vertebral body increase—change as one descends in the caudal direction, which is a morphologic response to the increasing weight it must bear (4). The cortical shell on the vertebral body serves as the chief load path. The shell also provides a rigid link in the FSU, and a platform for attachment of the intervertebral disk, muscles, and the anterior and posterior longitudinal ligaments. The transition area of the motion segment is the endplate. This serves to anchor the intervertebral disk to the vertebral body. Note that the endplate starts out as growth cartilage and transitions into bone as aging occurs (22). The disk acts as both a shock absorber and an intervertebral joint because the relative flexibility of the intervertebral disk is high when compared to the vertebral body. The intervertebral disk resists compression, tension, shear, bending, and torsion (4). It is relatively resistant to failure in axial compression while its annular portions fail in axial torsion first (23).

Dynamic Stabilizers

Although bone is viscoelastic in nature, it serves more as a structural component within the spine that passively resists axial forces and can transmit forces along the spinal column. The soft tissue spinal structures (ligamentous, capsules, annulus fibrosis) are far more elastic as compared to bone behavior and stabilize the spine in a dynamic manner, where rapid vamping of oscillatory motions occur. The main function of the facet joints is to pattern the motions of the spine so that during activities of daily living the neural elements are not strained beyond the physiological limits. Therefore, they play a major role in determining the range of motion across a joint and as a damper to any possible dynamic loading. The amount of stability provided by the facet joints depends on extent of the capsular ligaments, their shape, orientation, and level within the spine (2). For example, the thoracic facets have a limited capsular reinforcement and facilitate axial rotation, which is in contrast to the lumbar region where the facet ligaments are more substantial and the joint plane is configured to impede axial motion (24).

From a biomechanical perspective, the ligaments respond to tensile forces only (1). The effectiveness of a ligament depends on the morphology and the moment arm through which it acts. That is, not only the strength, but also the longer lever arm a ligament has, the more it participates in the stabilization of the spine (4). Ligaments also obey Wolff's law. The ligaments also undergo remodeling along the lines of applied tensile stresses in response to chronic loads, just like bones. The ligamentum flavum acts as a protective barrier for the entire spine.

Active Stabilizers

Muscles contribute significantly to maintain the stability of the spinal column under physiological conditions. Decreasing the muscle forces acting on a FSU, increases the motion

and loading of the ligaments. A thoracolumbar (T1-sacrum) spinal column that is devoid of musculature is an unstable structure, with a load-carrying capacity of $< 25 \text{ N}$ (24). However, with properly coordinated muscle action, the spine can sustain large loads, which is exemplified by the action of weight lifters (24).

The internal force resisted by the muscle depends on factors such as cross-section and length at the initiation of contraction. The maximum force develops at approximately 125% of muscle resting length. In contrast, at approximately one-half of its resting length, the muscle develops very low force. The muscle stress (the maximum force per unit area) ranges from 30 to $90 \text{ N} \cdot \text{cm}^{-2}$ (25,26). Macintosh et al. (27) performed a modeling study based on radiographs from normal subjects to determine the effects of flexion on the forces exerted by the lumbar muscles. They found that the compressive forces and moments exerted by the back muscles in full flexion are not significantly different from those in the upright posture.

The remainder of this section is devoted to the biomechanics of the individual sections of the spinal column in a normal healthy person. Various methods for recording data with varying degrees of accuracy and repeatability are used ranging from the use of different types of goniometers, radiographs, *in vitro* cadaver based studies, magnetic resonance imaging (MRI) to visual estimation of motion. Although the value of assessing the ROM is not yet documented, the understanding and knowledge of normal age- and sex-related values of ROM is the basis for analysis of altered and possibly pathologic motion patterns as well as decreased or increased ROM (23,28). The issue of spinal instability (stability), although controversial in its definition, has immense clinical significance in the diagnosis and treatment of spinal disorders. Maintaining a normal range of motion in the spine is linked to spinal stability. The spine needs to maintain its normal range of motion to remain stable and distribute forces while bearing loads in several directions. The typical motion, for example, in response to the flexion—extension loads, as determined using cadaver testing protocols, is shown in Fig. 6. The two motion

Figure 6. The load-displacement response of a FSU in flexion and extension. Two of the motion components are major and the other four are minor (or coupled). The range-of-motion and neutral zones, two of the terms used to describe the motion behavior of a segment, are also shown. (Adapted from Ref. 1.)

components (Flexion/extension rotation- R_x , and A-P translation- T_{zH}) are an order of magnitude higher than the other four. The two larger components are called the major-main motions and other four are the secondary-coupled motions. Range of motion, highlighted in the figure, will depend on the maximum load exerted on the specimen during testing. Likewise, the *in vivo* ranges of motion data will vary depending on the level of external force applied, that is, active or passive (2).

Biomechanics of the Occipital-Atlantoaxial Complex (C0-C1-C2)

As a unit, the craniovertebral junction accounts for 60% of the axial rotation and 40% of the flexion-extension behavior of the cervical spine (29,30).

Flexion-Extension. Large sagittal plane rotations have been attributed to the craniovertebral junction (Tables 1 and 2). Panjabi et al. (31) reported combined flexion-extension of C0-C1 and C1-C2 of 24.5 and 22.4°, respectively, confirming flexion-extension equivalence at the two levels. They also found that the occipitoatlantal joint level demonstrated a sixfold increase in extension as compared to flexion (21.0 vs. 3.5°), whereas the atlantoaxial level equally distributed its sagittal plane rotation between the two rotations, 11.5 (flexion) versus 10.9° (extension). Goel et al. (32) documented coupling rotations that occur with flexion and extension. They reported one-side lateral bending values of 1.2 and 1.4° for flexion and extension, respectively, at the C0-C1 level. In addition, they found C1-C2 coupled lateral bending, associated with flexion and extension movents, were lower than seen at the C0-C1 level. The largest axial rotation reported was 1.9°, which was an outcome of a C0-C1 extension of 16.5°. Note that the values reported by this study do not represent range of motion data, but rather intermediate rotation due to submaximal loading. Displacement coupling occurs between the translation of the head and flexion-extension of the occipitoatlanto-axial complex. Translation of the occiput with respect to the axis produces flexion-extension movements in the atlas. Anterior translation of the head extends the occipitoatlantal joints, with posterior motion resulting in converse flexion of the joint. This is postulated to occur due

to the highly contoured articular surfaces of the atlanto-occipital joint.

Lateral Bending. As is shown in Tables 1 and 2, early studies have shown that occipitoatlantal lateral bending dominates the overall contribution of this motion in the occipitoatlanto-axial complex. However, this is not the finding of the most recent study. Almost all other studies indicate a significantly greater contribution from the C0-C1 joint. Lateral flexion also plays an important role in rotation of the head. Rotation of the lower cervical spine (C2-T1) results in lateral flexion of this region.

Axial Rotation. Almost all of the occipitoatlanto-axial contribution to axial rotation occurs in the atlantoaxial region. Atlantoaxial rotation occurs about an axis that passes vertically through the center of the odontoid process. This axis remains halfway between the lateral masses of the atlas in both neutral and maximal rotation. In maximal rotation, there is minimal joint surface contact, and sudden overrotation of the head can lead to interlocking of the C1-C2 facets, making it impossible to rotate the head back to neutral. Table 2 lists the amount of rotation found in the atlantoaxial joint by various researchers. Although these studies have produced widely varying results, there seems to be a consensus among the more recent studies that one side axial rotation at the atlantoaxial level falls somewhere in the range of 35-45°. The findings in Table 1 demonstrate that there is a relatively small contribution from the C0-C1 joint, with researchers finding between 0 and 7.2° of rotation. One interesting anatomical note concerning axial rotation is the behavior of the vertebral artery during rotation. The vertebral artery possess a loop between the atlas and axis, thus affording it over-length. Upon atlantoaxial rotation, the slack is taken up in the loop and it straightens, thus preventing overstretching and possible rupture during maximal rotation.

The instantaneous axes of rotation (IARs) for the C0-C1 articulation pass through the center of the mastoid processes for flexion-extension and through a point 2-3 cm above the apex of the dens for lateral bending. There is a slight axial rotation at C0-C1. The IARs for the C1-C2 articulation are somewhere in the region of the middle third of the dens for flexion-extension and in the center of the dens for axial rotation. Lateral bending of C1-C2 is

controversial at the most 5–10° (4). During lateral bending, the alar ligament is responsible for the forced rotation of the second vertebra.

Middle and Lower Cervical Spine (C2-C7)

In the middle and lower cervical regions, stability and mobility must be provided; while, the vital spinal cord and the vertebral arteries must be protected. There is a good deal of flexion–extension and lateral bending in this area, Tables 3–6.

Flexion–Extension. Most of the flexion–extension motion in the lower cervical spine occurs in the central region, with the largest range of motion (ROM) generally occurring at the C5-C6 level. Except for extension, the orientation of the

cervical facets (on average, ~45° in the sagittal plane) does not excessively limit spinal movements in any direction or rotation. Flexion–extension rotations are distributed throughout the entire lower cervical spine for total rotations typically in the range of 60–75° and sagittal A/P translation is usually in the range of ~2–3 mm at all cervical levels (1). There is relatively little coupling effect that occurs during flexion–extension due to the orientation of the facets. There have been many published *in vivo* and *in vitro* studies reporting “normal” rotations at the various cervical spinal levels. These studies are in general agreement, although there appears to be a wide variation within ROM at all levels of the cervical region.

An *in vitro* study by Moroney et al.(33) averaged rotations among 35 adult cervical motion segments and found that average rotations (±SD) in flexion and extension

under an applied 1.8-N·m moment with 73.6-N preload (applied axially through the center of the vertebral bodies) were 5.55° (1.84) and 3.52° (1.94), respectively. These results demonstrate a total ROM in flexion–extension of ~ 9.02°. Although generally lower than the reported data in Tables 3–6, probably due to the effect of averaging across cervical levels, the measurements are within the range of motion for all levels discussed above.

Lateral Bending. Lateral bending rotations are distributed throughout the entire lower cervical spine for total rotations typically in the range of 10–12° for C2-C5 and 4–8° for C7-T1 (1). Unlike flexion–extension motion, where coupling effects are minimal, lateral bending is a more complicated motion involving the cervical spine, mainly due to the increased coupling effects. The coupling effects, probably due to the spatial locations of the facet joints at each level, are such that the spinous processes are rotated in the opposite direction of the lateral bending direction. The degree of coupling that occurs at separate levels of the cervical region has been described (33). There is a gradual decrease in the amount of axial rotation coupled with lateral bending as one traverses from C2 to C7. At C2, for every 3° of lateral bending there is ~ 2° of coupled axial rotation, a ratio of 0.67. At C7, for every 7.5° of lateral bending there is ~ 1° of coupled axial rotation, a ratio of 0.13.

Axial Rotation. Most cervical rotation occurs about the C1-C2 level, in the range of 35–45° for unilateral axial rotation: ~ 40% of the total rotation observed in the spine (1). In the lower cervical spine, axial rotation is in the range of 5.4–11.0° per level. Again, as in the main motion of lateral bending, there exists a coupling effect with lateral bending when axial rotation is the main motion of the cervical spine. This coupling effect is in the range of 0.51–0.75° of lateral bending per degree of axial rotation (34). The effects of aging and gender on cervical spine motion have been investigated by numerous researchers. The average values for age decades for each motion, as well as average for the gender groups along with significant differences are shown in Table 7. Significantly less motion in the active tests was evident in comparison of lateral bending and axial rotation. Generally, for passive tests, the SD was lower. Women showed greater ROM in all these motions. In the age range of 40–49 years, women again showed significantly greater ROM in axial rotation and rotation at maximal flexion. There were no significant differences between gender groups for the group aged 60+ years. The well-established clinical observation that motion of the cervical spine decreases with age has been confirmed. An exception to this finding was the surprising observation that the rotation of the upper cervical spine, mainly at the atlantoaxial joint (tested by rotating the head at maximum flexion of the cervical spine that presumably locks the other levels)

did not decrease with age. The measurement data for rotation out of maximum flexion suggests that the rotation of the atlantoaxial joint does not decrease with age, but rather remains constant or increases slightly perhaps to compensate for the reduced motion of the lower segments.

Lumbar Spine

The lumbar spine is anatomically designed to limit anterior translation and permit considerable flexion-extension and lateral bending, Tables 8A, B, and C. The unique characteristic of the spine is that it must support tremendous axial loads. The lumbar spine and the hips contribute to the considerable mobility of the trunk (34,35). The facets play a crucial role in the stability of the lumbar spine. The well-developed capsules of these joints play a major part in stabilizing the FSU against axial rotation and lateral bending. Lumbar facet joints are oriented in the sagittal plane, thereby allowing flexion-extension and lateral bending but limiting torsion (4).

In flexion-extension, there is usually a cephalocaudal increase in the range of motion in the lumbar spine. The L5-S1 joint offers more sagittal plane motion than the other joints, due to the unique anatomy of the FSU. The orientation of the facet becomes more parallel to the frontal plane

as the spinal column descends toward S1. Both this facet orientation and the lordotic angle at this motion segment contribute to the differences in the motion at this level. For lateral bending, each level is about the same except for L5-S1, which shows a relatively small amount of motion. The situation is the same for axial rotation, except that there is more motion at the L5-S1 joint.

There are several coupling patterns that have been observed in the lumbar spine. Pearcy (36) observed coupling of 2° of axial rotation and 3° of lateral bending with flexion-extension. In addition, there is also a coupling pattern, in which axial rotation is combined with lateral bending, such that the spinous processes point in the same direction as the lateral bending (22). This pattern is the opposite of that in the cervical spine and the upper thoracic spine (34).

The rotation axes for the sagittal plane of the lumbar spine have been described in several reports. In 1930, Calve and Galland (37) suggested that the center of the intervertebral disk is the site of the axes for flexion-extension; however, Rolander (38) showed that when flexion is simulated starting from a neutral position, the axes are located in the region of the anterior portion of the disk. In lateral bending, the axes fall in the region of the right side of the disk with left lateral bending, and in the region of the left side of the disk with right lateral bending. For axial

rotation, the IARs are located in the region of the posterior nucleus and annulus (4,36).

BIOMECHANICS OF SPINAL INSTABILITY: ROLE OF VARIOUS FACTORS

The causes of spinal instability have been hypothesized to include environmental factors that contribute to spinal degeneration and host of other variables (39). For example, some diseases can lead to spinal instability without being the direct cause. Chronic spondylolisthesis can lead to permanent deformation of the annulus that increases the probability of instability, Fig. 7. Essentially, any damage to any of the components of the motion segment or neural elements can contribute to instability. Instability can result from ruptured ligaments, fractured facets, fractured endplates, torn disks, or many other causes. However, the elements within the spine that seem to contribute more to stability and can therefore be major sources of instability are the facet joints, the intervertebral disks, and the ligaments (40). Both *in vivo* investigations in humans and animals and *in vitro* investigations of ligamentous spinal segments have been undertaken to accumulate biomechanical data of clinical significance.

Role of Environmental Factors in Producing Instability–Injury

Upper Cervical Spine. High speed impact loads that may be imposed on the spine are one of the major causes of

spinal instability in the cervical region, especially in the upper region. To quantify the likely injuries of the atlas, Oda et al. (39,40) subjected upper cervical spine specimens to high speed axial impact by dropping 3–6 kg weights from various heights. The load produced axial compression and flexion of the specimen. Both bony and soft tissue injuries, similar to Jefferson fractures, were observed. The bony fractures were six bursting fractures, one four-part fracture without a prominent bursting, and one posterior arch fracture. The major soft tissue injury involved the transverse ligament. There were five bony avulsions and three midsubstance tears. The study was extended to determine the three-dimensional (3D) load displacements of fresh ligamentous upper cervical spines (C0–C3) in flexion, extension, and lateral bending before and following the impact loading in the axial mode. The largest increase in flexibility due to the injury was in flexion–extension: ~42%. In lateral bending, the increase was on the order of 24%; in axial rotation it was minimal: ~5%. These increases in motion are in concordance with the actual instabilities observed clinically. In patients with burst fractures of the atlas, Jefferson noted that the patients could not flex their heads, but could easily rotate without pain (41).

Heller et al. (42) tested the transverse ligament attached to C1 vertebra by holding the C1 vertebra and pushing the ligament in the middle along the AP direction. The specimens were loaded with an MTS testing device at varying loading rates. Eleven specimens failed within the substance of the ligament, and two failed by bone avulsion.

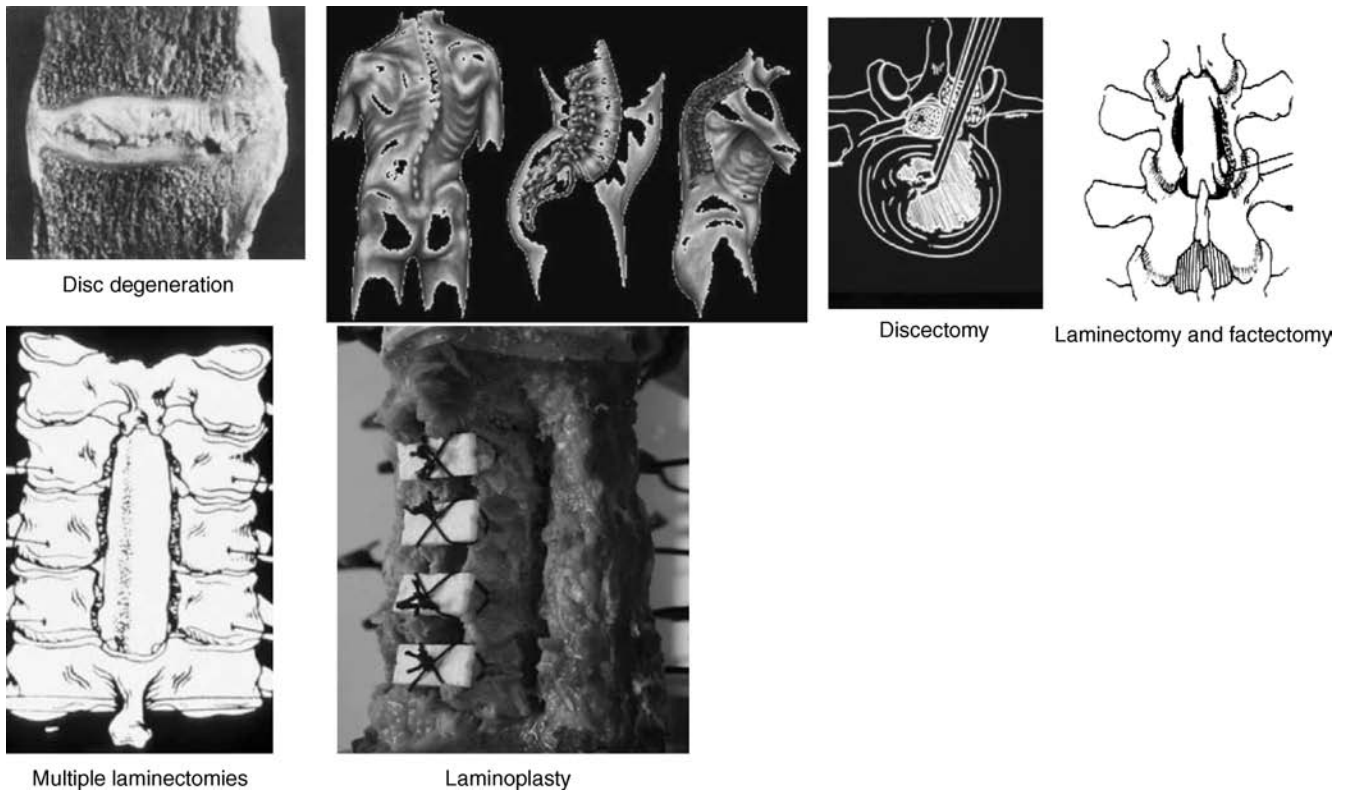

Figure 7. Various spinal disorders and surgical procedures that may lead to spinal instability. Such procedures are common for all of the spine regions.

The mean load to failure was 692 N (range 220–1590 N). The displacement to failure ranged from 2 to 14 mm (mean 6.7 mm). This study, when compared with the work of Oda et al. (39,40) suggests that (a) anteroposterior (AP) translation of the transverse ligament with respect to the dens is essential to produce its fracture; (b) rate of loading affects the type of fracture (bony versus ligamentous) but not the displacement at failure; and (c) even “axial” impact loads are capable of producing enough AP translation to produce a midsubstance tear of the ligament, as reported by Oda et al. (39).

The contribution to stabilization by the alar ligament of the upper cervical spine is of particular interest in evaluation of the effects of trauma, especially in the axial rotation mode. Goel and associates (43), in a study of occipitoatlantoaxial specimens, determined that the average values for axial rotation and torque at the point of maximum resistance were 68.1° and 13.6 N·m, respectively. They also observed that the value of axial rotation at which complete bilateral rotary dislocation occurred was approximately the point of maximal resistance. The types of injuries observed were related to the magnitude of axial rotation imposed on a specimen during testing. Soft tissue injuries (such as stretch–rupture of the capsular ligaments, subluxation of the C1–C2 facets) were confined to specimens rotated to or almost to the point of maximum resistance. Specimens that were rotated well beyond the point of maximum resistance also showed avulsion fractures of the bone at the points of attachment of the alar ligament or fractures of the odontoid process inferior to the level of alar ligament attachment. The alar ligament did not rupture in any of the specimens. Chang and associates (44) extended this study to determine the effects of rate of loading (dynamic loading) on the occipitoatlantoaxial complex. The specimens were divided into three groups and tested until failure at three different dynamic loading rates: $50^\circ/\text{s}$, $100^\circ/\text{s}$, and $400^\circ/\text{s}$ as compared to the quasi-static ($4^\circ/\text{s}$) rate of loading used by Goel et al. (43). The results showed that at the higher rates of loading, (a) the specimens became stiffer and the torque required to produce “failure” increased significantly (e.g., from 13.6 N·m at $4^\circ/\text{s}$ to 27.9 N·m at $100^\circ/\text{s}$); (b) the corresponding right angular rotations ($65\text{--}79^\circ$) did not change significantly; and (c) the rates of the alar ligament midsubstance rupture increased and that of “dens fracture” decreased. No fractures of the atlas were noted. This is another example of the rate of load application affecting the type of injury produced.

Fractures of the odontoid process of the second cervical vertebra comprise 7–13% of all cervical spine fractures (45). Most published reports involving odontoid fracture use the classification system detailed by Anderson and D’Alonzo (46). They described three types of odontoid process fracture (Fig. 8). Type I is an oblique fracture near the superior tip of the odontoid process and is thought to involve an avulsion defect associated with the alar–apical complex. Fracture of the odontoid process at the juncture of the process and vertebral body in the region of the accessory ligaments (Type II) is the most common osseous injury of the atlas. Fractures of this type lead to a highly unstable cervicovertebral region, commonly threatening the spinal

Figure 8. Fractures of the odontoid process. Taken from Ref. 46.

canal, and are often accompanied by ligamentous insult. Many of these fractures result in pseudoarthrosis if not properly treated. Type III fractures involve the junction of the odontoid process and the anterior portion of the vertebral body. These fractures are thought to be more stable than the Type I and Type II fractures. Type III fractures have high union rates owing to the cancellous bone involvement and the relatively high degree of vascularity (46,47).

Forces required to produce various types of dens fractures have been documented by Doherty et al. (45) who harvested the second cervical vertebra from fresh human spinal columns. Force was applied at the tip of the dens until failure occurred. The direction of the applied force was adjusted to exert extension bending or combined flexion and lateral bending on the tip of the dens. Extension resulted in type III fractures, and the combined load led to type II fractures of the dens. Furthermore, dynamic loading modes are essential to produce midsubstance ligament ruptures as opposed to dens fractures, especially in a normal specimen. Odontoid fractures have been implicated as being the result of high energy traumatic events. Indeed, there have been numerous accounts as to the events that lead to odontoid fracture. Schatzker et al. (47) reported that 16 of the 37 cases they reviewed were due to motor vehicle accidents and 15 cases were the result of high energy falls. Clark and White (48) report that all Type II (96 patients) and Type III (48 patients) fractures they reviewed were attributable to either motor vehicle accidents (~70%) or

falls. Alker et al. (19) examined postmortem radiographs of 312 victims of fatal motor vehicle accidents. The cohort exhibited 98 injuries of the cervical spine, of which 70 were seen in the craniovertebral junction. The authors, although not quantifying the degree of dens fractures, hypothesized that odontoid fractures were probably due to hyperextension because of the posterior displacement of the fracture pieces.

There is considerable controversy as to the major load path that causes odontoid fractures. A review of the clinical and laboratory research literature fails to designate a consensus on this issue. Schatzker et al. (47) reviewed clinical case presentations and concluded that odontoid fractures are not the result of simple tension and that there must exist a complex combination of forces needed to produce these failures. Althoff (49) performed a cadaver study, whereby he applied various combinations of compression and horizontal shear to the head via a pendulum. Before load onset the head was placed in neutral, extension or flexion. The position of the load and the angle of impact, determining the degree of compression with shear, was changed for each experiment. The results indicated that an impact in the sagittal plane (anterior or posterior) produced fractures that involved the C2 body (Type III). As the force vector moved from anterior to lateral, the location of the fracture moved superiorly, with lateral loading producing Type I fractures. This led the author to propose a new hypothesis: impact loading corresponding to combined horizontal shear and compression results in odontoid fractures. Althoff dismissed the contributions of sagittal rotation (flexion and extension) to the production of resultant odontoid fracture.

Mouradian et al. (50) reported on a cadaver and clinical model of odontoid fracture. In their opinion, "it seems reasonable to assume that shearing or bending forces are primarily involved." The cadaver experimentation involved anterior or lateral translation of the occiput as well as lateral translation of the atlantal ring. In forward loading, the odontoid was fractured in 9 of the 13 cases, with 8 Type III fractures and 1 Type II fracture. The lateral loading specimens evidenced similar patterns of odontoid fracture regardless of the point of load application (on the occiput or on the atlas). In 11 specimens, lateral loading resulted in 10 Type II fractures and 1 Type III fracture. The clinical model involved reviewing 25 cases of odontoid fracture. They reported that 80% of these cases resulted from flexion or flexion-rotation injuries. They pointed out that the clinical data does not reflect the lateral loading cadaver experimentation results. In fact, they state that "a pure lateral blow probably did not occur in any [clinical] case". However, their clinical data indicated that the remaining 20% of the odontoid injuries could be ascribed to extension injuries. The technical difficulties precluded cadaver experimentation of this possible mechanism. Experimental investigations dealing with the pathogenesis of odontoid fractures have failed to produce a consensus as to the etiology of these fractures. These findings may actually reflect the diversity of causal mechanisms, suggesting the various mechanical factors are coincident in producing these fractures. It is difficult to discern if this is the case or if this is due to the inhomogeneity of cadaver

experiment methodology. That is, some of the boundary and loading conditions used by the surveyed studies are vastly different and have produced divergent results. In addition, the anatomical variants of the craniovertebral osteo-ligamentous structures could also be integral to the cadaver study outcomes. The purpose of the study undertaken by Puttlitz et al. (51) was to utilize of the finite element method, in which the loading and kinematic constraints can be exactly designated, for elucidating the true fracture etiology of the upper cervical spine. Previous laboratory investigations of odontoid process failure have used cadaver models. However, shortcomings associated with this type of experimentation and the various loading and boundary conditions may have influenced the resulting data. Utilization of the FE method for the study of odontoid process failure has eliminated confounding factors often seen with cadaveric testing, such as interspecimen anatomic variability, age-dependent degeneration, and so on. This has allowed us to isolate changes in complex loading conditions as the lone experimental variable for determining odontoid process failure.

There are many scenarios, that are capable of producing fracture of the odontoid process. Force loading, in the absence of rotational components, can reach maximum von Mises stresses that far exceed 100 MPa. Most of these loads are lateral or compressive in nature. The maximum stress obtained was 177 MPa due to a force directed in the posteroinferior direction. The net effect of this load vector and its point of application, the posterior aspect of the occiput, is to produce a compression, posterior shear, and extension due to the load's offset from the center of rotation. This seems to suggest that extension and compression can play a significant role in the development of high stresses, and possibly failure, of the odontoid. The location of the maximum stress for this loading scenario was in the region of a Type I fracture. The same result, with respect to laterally loading, was obtained by Althoff (49). However, he dismissed the contribution of sagittal plane rotation to development of odontoid failures. The results of this study disagree with that finding. Posteroinferior loading with extension produced a maximum von Mises stress in the axis of 226 MPa. As stated above, the load vector for this case intensifies the degree of extension, probably producing hyperextension. The addition of the extension moment did not change the location of the maximum stress, still identifiable in the region of a Type I fracture. The clinical study by Moradian et al. (50) suggested that almost 20% of the odontoid fracture cases they reviewed involved some component of extension. The involvement of extension in producing odontoid process failures can be explained by its position with respect to the atlantal ring and the occiput. As extension proceeds, the contact force produced at the atlanto-dental articulation increases, putting high bending loads on the odontoid process. The result could be failure of the odontoid. Increasing tension of the alar ligaments as the occiput extends could magnify these bending stress via superposition of the loads, resulting in avulsion failure of the bone (Type I).

While the FE model predicted mostly higher stresses with the addition of an extension moment, the model showed that, in most cases, flexion actually mitigates

the osseous tissue stress response. This was especially true for compressive (inferior) force application. Flexion loading with posterior application of an inferior load vectorally decreases the overall effect of producing extension on the occiput. None of the studies surveyed for this investigation pinpointed flexion, per se, as a damage mechanism for odontoid failure. The findings of this study supported the lack of evidence in support of flexion as being a causal mechanism for failure. In addition, the data suggested that flexion can act as a preventative mechanism against odontoid fracture.

Once again, the lateral bending results support the hypothesis of extension being a major injury vector in odontoid process failure. Inferior and posteroinferior loads with lateral rotation resulted in the highest maximal von Mises stress in the axis. Lateral loading also intensified the maximal stress in compression, suggesting rotations that incorporate a component of both lateral and extension motion may cause odontoid failures. Many of the lateral bending scenarios resulted in the maximum von Mises stress being located in the Type II and Type III fracture regions. In fact, the only scenarios that lead to the maximum stress in the Type I area was when there was an inferior or posterior load applied with the lateral bending. This is, again, suggestive that the extension moment, produced by these vectors and their associated moment arms (measured from the center of rotation), can result in more superiorly-located fractures.

Overall, this investigation has indicated that extension and the application of extension via force vector application, causes the greatest risk of superior odontoid failure. The hypothesis of extension as a causal mechanism of odontoid fracture includes coupling of this motion to other rotations. Flexion seems to provide a protective mechanism against force application that would otherwise cause a higher risk of odontoid failure.

Middle and Lower Cervical Spine. In the C2-T1 region of the spine, as in the upper cervical region, instabilities in a laboratory setting have been produced in an effort to understand the dynamics of traumatic forces on the spine (19). In one study, fresh ligamentous porcine cervical spine segments were subjected to flexion-compression, extension-compression, and compression-alone loads at high speeds (dynamic-impact loading) (19). The resultant injuries were evaluated by anatomic dissection. The results that the severity of the injuries were related mostly to the addition of bending moments to high speed axial compression of the spine segment, since compression alone produced the least amount of injury and no definite pattern of injuries could be identified. Other investigators have reported similar results (19).

Lumbar Spine. The onset of low back pain is sometimes associated with a sudden injury. However, it is more often the result of cumulative damage to the spinal components induced by the presence of chronic loading on the spine. Under chronic loading, the rate of damage may exceed the rate of repair by the cellular mechanisms, thus weakening the structures to the point where failure occurs under mildly abnormal loads. Chronic loading to structures may

occur under a variety of conditions (52,53). One type of loading is heavy physical work prevalent among blue collar workers. Lifting not only induces large compressive loads across the segment, but tends to be associated with bending and twisting (54). Persons with jobs requiring the lifting of objects of $> 11.3 \text{ kg}$ > 25 times/day have over three times the risk for acute disk prolapse than people whose jobs do not require lifting (55). If the body is twisted during lifting, the risk is even higher with less frequent lifting. The other major class of loading associated with low back pain is posture related, for example, prolonged sitting-sedentary activities, and posture that involve bending over while sitting. Prolonged sitting may be compounded by vibration, such as observed in truck drivers (52,56,57).

The effects of various types of cyclic loads on the specimen behavior have been investigated (52,55). For example, Liu et al. subjected ligamentous motion segments to cyclic axial loads of varying magnitudes until failure or 10,000 cycles, whichever occurred first (53). Test results fell in to two categories, stable and unstable. In the unstable group, fracture occurred within the 6000 cycles of loading. The radiographs in the unstable group revealed generalized trabecular bony microfailure. Cracks were found to propagate from the periphery of the subcondral bone. After the removal of the organic phase, the unstable group specimens disintegrated into small pieces, as opposed to stable group specimens. This suggests that microcrack initiation occurs throughout the inorganic phase of the subchondral bone as a result of axial cyclic loading. In response to cyclic axial twisting of the specimens, Liu et al. noticed a discharge of synovial fluid from the articular joints (58). Specimens that exhibited an initial angular displacement of $< 1.5^\circ$, irrespective of the magnitude of the applied cyclic torque, did not show any failures. On the other hand, specimens, exhibiting initial rotations $< 1.5^\circ$, fractured before reaching 10,000 cycles. These fractures included bony failure of facets and/or tearing of the capsular ligaments.

Chronic vibration exposure and prolonged sitting are also known to lead to spinal degeneration. Spinal structures exhibit resonance between 5 and 8 Hz (56-59). *In vivo* and *in vitro* experimental and analytical studies have shown that the intradiscal pressure and motion increase when spinal structures experience vibration, such as during driving cars-trucks, at the natural resonant frequency (59). Prolonged sitting alone or in conjunction with chronic vibration exposure is also a contributing factor to spinal degeneration. A finite element-based study revealed that prolonged sitting led to an increase in disk bulge and the stresses in the annulus fibers located at the outer periphery (59,60).

Lee et al. (61) quantitatively analyzed occlusion of the dural-sac in the lumbar spine was quantitatively analyzed by utilizing a finite element lumbar spine model. In the static analysis, it was found that $< 2 \text{ kN}$ of compressive load could not produce dural-sac occlusion, but the compression together with extension moment was more likely to produce the dural-sac occlusion. The 7.4% of occlusion was obtained when the $8 \text{ N}\cdot\text{m}$ of extension moment was added to 2 kN of compressive load that alone did not create any occlusion. The magnitude of occlusions was increased

to 10.5% as the extension moment increased to 10 N·m with the same 2 kN of compressive load. In creep analysis, 10 N·m extension, kept for 3600 s, induced 6.9% of occlusion, and 2.4% of volume reduction in the dural-sac. However, flexion moment did not produce any occlusion in the dural-sac, but increased the volume instead because it caused stretching of the dural-sac coupled with vertebral motion. As a conclusion, occlusions resulted mainly from the slackening of the ligamentum flavum and disk bulging. Furthermore, the amount of occlusion was strongly dependent with loading conditions and the viscoelastic behavior of materials as well.

Changes in Motion due to Degeneration–Trauma

The degenerative process can effect all of the spinal elements and trauma can lead to partial or full destruction of the spinal elements. As such the motion behavior of the segment will change.

Cervical Spine Region. The rotation-limiting ability of the alar ligament was investigated by Dvorak et al. (62,63). A mean increase of 10.8° or 30% (divided equally between the occipitoatlantal and atlantoaxial complexes) in axial rotation was observed in response to an alar lesion on the opposite side. Oda et al. (39,40) determined the effects of alar ligament transections on the stability of the joint in flexion, extension, and lateral bending modes. Their main conclusion was that the motion changes occurred subsequent to alar ligament transection. The increases, however, were directional-dependent. Crisco et al. (64) compared changes in 3D motion of C1 relative to C2 before and after the capsular ligament transections in axial rotation. Two groups of cadaveric specimens were used to study the effect of two different sequential ligamentous transections. In the first group ($n=4$), transection of the left capsular ligament was followed by transection of the right capsular ligament. In the second group ($n=10$), transection of the left capsular ligament preceded transection of left and right alar and transverse ligaments. The greatest changes in motion occurred in axial rotation to the side opposite the transection. In the first group, transection of left capsular ligaments resulted in a significant increase in axial rotation ROM to the right of 1°. After the right capsular ligament was transected, there was a further significant increase of 1.8° to the left and of 1.0° to the right. Lateral bending to the left also increased significantly by 1.5° after both ligaments were cut. In the second group, with the nonfunctional alar and transverse ligaments, transection of the capsular ligament resulted in greater increases in ROM: 3.3° to the right and 1.3° to the left. Lateral bending to the right also increased significantly by 4.2°. Although the issue is more complex than this, in general these studies show that the major function of the alar ligament is to prevent axial rotation to the contralateral side. Transection of the ligament increases the contralateral axial rotation by ~15%.

The dens and the intact transverse ligament provide the major stability at the C1-C2 articulation. The articular capsules between C1 and C2 are loose, to allow a large amount of rotation and provide a small amount of stability.

Although the C1-C2 segment is clinically unstable after failure of the transverse ligament, resistance against gross dislocation is probably provided by the tectorial membrane, the ala, and the apical ligaments. With transection of the tectorial membrane and the ala ligaments, there is an increased flexion of the units of the occipital–atlantoaxial complex and a subluxation of the occiput (4h). It was also demonstrated that transection of the ala ligament on one side causes increased axial rotation to the opposite side by ~30%.

Fielding et al. (65) performed a biomechanical study investigating lesion development in rheumatoid arthritis. Their study tested 20 cadaveric occipitoatlanto–axial specimens for transverse ligament strength by application of a posterior force to the atlantal ring. They found atlantoaxial subluxation of 3–5 mm and increased atlas movement on the axis after rupture of the transverse ligament. From this study, Fielding et al. were able to conclude that the “transverse ligament represents a strong primary defense against anterior shift of the first cervical vertebra.” Puttlitz et al. (66) developed an experimentally validated ligamentous, nonlinear, sliding contact 3D finite element (FE) model of the C0-C1-C2 complex generated from 0.5-mm thick serial computed tomography scans (Fig. 9). The model was used to determine specific structure involvement during the progression of RA and to evaluate these structures in terms of their effect on clinically observed erosive changes associated with the disease by assessing changes in loading patterns and degree of AAS (see Table 9 for terminology). The role of specific ligament involvement during the development and advancement of AAS was evaluated by calculating the AADI and PADI after reductions in transverse, ala, and capsular ligament stiffness. (The stiffness of transverse, alar, and capsular ligaments was sequentially reduced by 50, 75, and 100% of their intact values.) All models were subjected to flexion moments, replicating the clinical diagnosis of RA using full flexion lateral plane radiographs. Stress profiles at the transverse ligament-odontoid process junction were monitored. Changes in loading profiles through the C0-C1 and C1-C2 lateral articulations and their associated capsular ligaments were calculated. Posterior atlantodental interval (PADI) values were calculated to correlate ligamentous destruction to advancement of AAS. As an isolated entity, the model predicted that the transverse ligament had the greatest effect on AADI in the fully flexed posture. Without transverse ligament disruption, both ala and capsular ligament compromise did not contribute significantly to the development of AAS. Combinations of ala and capsular ligament disruptions were modeled with transverse ligament removal in an attempt to describe the interactive effect of ligament compromise, which may lead to advanced AAS. Ala ligament compromise with intact capsular ligaments markedly increased the level of AAS (Table 9). Subsequent capsular ligament stiffness loss (50%) with complete ala ligament removal led to an additional decrease in PADI of 0.92 mm. Simultaneous resection of the transverse, ala, and capsular ligaments resulted in a highly unstable situation. The model predicted stresses at the posterior base of the odontoid process greatly reduced, with transverse ligament compromise beyond 75%

Figure 9. Finite element models of the upper cervical spine used to study the biomechanics of rheumatoid arthritis. (Taken from Ref. 66.)

(Fig. 10). Decreases through the lateral C0-C1 and C1-C2 articulations were compensated by their capsular ligaments. The data indicate that there may be a mechanical component (in addition to enzymatic degradation) associated with the osseous resorption seen during RA. Specifically, erosion of the base of the odontoid may involve Wolff's law unloading considerations. Changes through

Table 9. Combinations of Ligament Stiffness Reductions with the Resultant Degree of AAS, as Indicated by the AADI and PADI Values at Full Flexion (1.5 N · m moment)^a

Reduction in Ligament Stiffness, %			Criteria, mm	
Transverse	Alar	Capsular	AADI	PADI
0	0	0	2.92	15.28
100	0	50	5.77	12.43
100	0	75	6.21	11.99
100	50	0	7.42	10.79
100	75	0	7.51	10.71

^aZero (0) ligament stiffness values represent completely intact ligament stiffness, "100" corresponds to total ligament destruction (via removal). (Taken from Ref. 66.) AAS = anterior atlantoaxial subluxation, AADI = anterior atlantodental interval, PADI = posterior atlantodental interval.

the lateral aspects of the atlas suggest that this same mechanism may be partially responsible for the erosive changes seen during progressive RA. The PADI values indicate that complete destruction of the transverse ligament coupled with alar and/or capsular ligament compromise exist if advanced levels of AAS are present.

Figure 10. (a) Anterior atlantodental interval (AADI) (b) and posterior atlantodental interval (PADI) calculated for the intact model and models with stiffness reductions of the transverse, alar, and capsular ligaments at the fully flexed posture (1.5 N · m moment load). Each ligament's stiffness was altered while holding the other two at the baseline value (completely intact). (Taken from Ref. 66.)

In vitro studies to determine the feasibility of the “stretch test” in predicting instability of the spine in the cervical region were performed by Panjabi et al. (67). Four cervical spines (C1-T1; ages 25–29) were loaded in axial tension in increments of 5 kg to a maximum of one third of the specimen’s body weight. The effects of sequential AP transection of soft tissues of a motion segment on the motion in one group and of posterior–anterior transections in another group were investigated. The intact cervical spine went into flexion under axial tension. Anterior transection produced extension. Posterior transection produced opposite results. Anterior injuries creating displacements of 3.3 mm at the disk space (with a force equal to one-third body weight) and rotation changes of $\sim 3.8^\circ$ were considered precursors to failure. Likewise, posterior injuries resulting in 27 mm separation at the tips of the spinous process and an angular increase of 30° with loading were considered unstable. This work supports the concept that spinal failure results from transection of either all the anterior elements or all the posterior plus at least two additional elements.

In a study by Goel et al. (68,69), the 3D load-displacement motion of C4–C5 and C5–C6 as a function of transection of C5–C6 ligaments was determined. Transection was performed posteriorly, starting with the supraspinous and interspinous ligaments, followed by the ligamentum flavum and the capsular ligaments. With the transection of the capsular ligaments, the C5–C6 motion segment (injured level) showed a significant increase in motion in extension, lateral bending, and axial rotation. A significant increase in flexion resulted when the ligamentum flavum was transected.

A major path of loading in the cervical spine is through the vertebral bodies, which are separated by the intervertebral disk. The role of the cervical intervertebral disk has received little attention. A finite element model of the ligamentous cervical spinal segment was used to compute loads in various structures in response to clinically relevant loading modes (70). The objective was to predict biomechanical parameters, including intradiskal pressure, tension in ligaments, and forces across facets that are not practical to quantify with an experimental approach. In axial compression, 88% of the applied load passed through the disk. The interspinous ligament experienced the most strain (29.5% in flexion, and the capsular ligaments were strained the most (15.5% in axial rotation). The maximum intradiskal pressure was 0.24 MPa in flexion with an axial compression mode (1.8 N·m of flexion moment + 73.6 N of compression). The anterior and posterior disk bulges increased with an increase in axial compression (up to 800 N). The results provide new insight into the role of various elements in transmitting loads.

This model was further used to investigate the biomechanical significance of uncinata processes and Luschka joints (71). The results indicate that the facet joints and Luschka joints are the major contributors to coupled motion in the lower cervical spine and that the uncinata processes effectively reduce motion coupling and primary cervical motion (motion in the same direction as load application), especially in response to axial rotation and lateral bending loads. Luschka joints appear to increase primary cervical

motion, showing an effect on cervical motion opposite to that of the uncinata processes. Surgeons should be aware of the increase in motion accompanied by resection of the uncinata processes.

Cervical spine disorders such as spondylotic radiculopathy and myelopathy are often related to osteophyte formation. Bone remodeling experimental–analytical studies have correlated biomechanical responses, such as stress and strain energy density, to the formation of bony outgrowth. Using these responses of the spinal components, a finite element study was conducted to investigate the basis for the occurrence of disk-related pathological conditions. An anatomically accurate and validated intact element model of the C4–C5–C6 cervical spine was used to simulate progressive disk degeneration at the C5–C6 level. Slight degeneration included an alteration of material properties of the nucleus pulposus representing the dehydration process. Moderate degeneration included an alteration of fiber content and material properties of the annulus fibrosus representing the disintegrated nature of the annulus in addition to dehydrated nucleus. Severe degeneration included decrease in the intervertebral disk height with dehydrated nucleus and disintegrated annulus. The intact and three degenerated models were exercised under compression, and the overall force-displacement response, local segmental stiffness, annulus fiber strain, disk bulge, annulus stress, load shared by the disk and facet joints, pressure in the disk, facet and uncovertebral joints, and strain energy density and stress in the vertebral cortex were determined. The overall stiffness (C4–C6) increased with the severity of degeneration. The segmental stiffness at the degenerated level (C5–C6) increased with the severity of degeneration. Intervertebral disk bulge and annulus stress and strain decreased at the degenerated level. The strain energy density and stress in vertebral cortex increased adjacent to the degenerated disk. Specifically, the anterior region of the cortex responded with a higher increase in these responses. The increased strain energy density and stress in the vertebral cortex over time may induce the remodeling process according to Wolff’s law, leading to the formation of osteophytes.

Thoracolumbar Region. The most common vertebral levels involved with the thoracolumbar injuries are T12–L1 (62%) and L1–L2 (24%) (22,25). The injuries, depending on the severity of the trauma, have included disruption of the posterior ligaments, fracture and dislocation of the facets, and fracture of the vertebral bodies with and without neural lesions. Operative intervention is often suggested to restore spinal stability. These involve use of spinal instrumentation, vertebroplasty, and host of other procedures which have been described elsewhere in this article.

For ease in description of these injuries, conceptually the osteoligamentous structures of the spine have been grouped into three “columns”; anterior, middle, and posterior. The anterior column consists of the anterior longitudinal ligament, anterior annulus fibrosus, and the anterior part of the vertebral body. The middle column consists of the posterior longitudinal ligament, posterior annulus

fibrosus, and the posterior vertebral body wall. The posterior column contains the posterior bony complex or arch (including the facet joints), and the posterior ligamentous complex composed of the supraspinous ligament, interspinous ligament, facet joint capsules, and ligamentum flavum.

As per this classification, a compression fracture is a fracture of the anterior column with the middle and posterior columns remaining intact. In severe cases, there may also be a partial tensile failure of the posterior column, but the vertebral ring, consisting of the posterior wall, pedicles, and lamina, remains totally intact in a compression fracture. A burst fracture is a fracture of the anterior and middle columns under compression; the status of the posterior column can vary. In the burst fracture, there is fracture of the posterior vertebral wall cortex with marked retropulsion of bone into the spinal canal, obstructing, on average, 50% of the spinal canal cross-section. There may be a tilting and retropulsion of a bone fragment into the canal from one or both endplates. In contrast to the compression fracture, there is loss of posterior vertebral body height in a burst fracture. The seat-belt type injuries feature failure of the middle and posterior columns under tension, and either no failure or slight compression failure of the anterior column. In fracture dislocations, the anterior, middle, and posterior columns all fail, leading to subluxation or dislocation. There may be "jumped facets" or fracture of one articular process at its base or at the base of the pedicle. There is also disruption of the anterolateral periosteum and anterior longitudinal ligament. If the separation goes through the disk, there will be some degree of wedging in the vertebral body under the disk space. However, the fracture cleavage may pass through the vertebral body itself, resulting in a "slice fracture".

There are four mechanisms of fracture that have been hypothesized in the literature to explain why the thoracolumbar region experiences a higher frequency of injury than adjacent regions. The hypotheses state that a thoracolumbar fracture sequence can be put into motion by stress concentrations arising from (1) spinal loading conditions; (2) material imperfections in spine; (3) differences in spinal stiffness and physiological range of motion characteristics between the thoracic and lumbar regions; and (4) abrupt changes in spinal anatomy, especially facet orientations. As always, there is no consensus for these mechanisms.

A few of the experimental investigations that have attempted to reproduce the clinical fracture patterns are as follows: In one study, cadaver motion segments were subjected to loads of different magnitude and direction: compression, flexion, extension, lateral flexion, rotation, and horizontal shear to reproduce all varieties of spinal injury experimentally by accurately controlled forces. For a normal disk, increases of intradiskal pressure and bulging of the annulus occur under application of axial compressive load. With increased application of force, the end-plate bulges and finally cracks, allowing displacement of nuclear material into the vertebral body. Continued loading of the motion segment results in a vertical fracture of the vertebral body. If a forward shear component of force accompanies the compression force, the line of fracture of the

vertebral body is not vertical but is oblique. Different forms of fracture could be produced by axial compressive loading if the specimens were from older subjects (i.e., the nucleus was no longer fluid), or if the compressive loading was asymmetrical. Under these conditions, the transmission of load mainly through the annulus is responsible for the (1) tearing of the annulus, (2) general collapse of the vertebra due to buckling of the sides (cortical wall), and (3) marginal plateau fracture.

Thoracolumbar burst fractures in cadaver specimens have also been produced by dropping a weight such that the prepared column is subjected to axial-compressive impact loads. The potential energies of the failing weights used by these researchers have been 200 and 300 N·m. Fracture in four of the seven specimens apparently started at the nutrient foramen. The nutrient foramen may perhaps be viewed as a local area of material imperfection where stresses may be concentrated during loading, leading to fracture. Other researchers are apparently unable to consistently produce burst fractures *in vitro* without first creating artificial "stress raisers" in the vertebral body by means of cuts or slices into the bone.

Panjabi et al. (3) conducted *in vitro* flexibility tests of 11 T11-L1 specimens to document the 3D mechanical behavior of the thoracolumbar junction region (see section on Construct Testing for an explanation). Pure moments up to 7.5 N·m were applied to the specimens in flexion-extension, left-right axial torque, and right-left lateral bending. The authors reported the average flexibility coefficients of the main motions (range of motion divided by the maximum applied load). For extension moment, the average flexibility coefficient of T11-T12. ($0.32^\circ/\text{N}\cdot\text{m}$) was significantly less than that of T12-L1 ($0.52^\circ/\text{N}\cdot\text{m}$). For axial torque, the average flexibility coefficient of T11-T12 ($0.24^\circ/\text{N}\cdot\text{m}$) was significantly greater than that of T12-L1 ($0.16^\circ/\text{N}\cdot\text{m}$). The authors attributed these biomechanical differences to the facet orientation. They speculated that thoracic-type facets would offer greater resistance to extension than the more vertically oriented lumbar-type facets while the lumbar-type facets would provide a more effective stop to axial rotation than thoracic-type facets. No other significant biomechanical differences were detected between T11-T12 and T12-L1. In addition to these observations, authors found that for flexion torque, the average flexibility coefficients of the lumbar spine (e.g., L1-L2, $0.58^\circ/\text{N}\cdot\text{m}$; L5-S1, $1.00^\circ/\text{N}\cdot\text{m}$) were much greater than those of both T11-T12 ($0.36^\circ/\text{N}\cdot\text{m}$) and T12-L1 ($0.39^\circ/\text{N}\cdot\text{m}$). They identified this change in flexion stiffness between the thoracolumbar and lumbar regions as a possible thoracolumbar injury risk factor.

Lumbar Spine Region. The porosity of the cancellous bone within the vertebral body increases with age, especially in women. The vertebral body strength is known to decrease with increase in porosity of the cancellous bone, a contributing factor to the kyphosis normally seen in an elderly person (4). As the trabeculae reduce in size and number, the cortical shell must withstand greater axial load, thus increasing the thickness of the shell obeying the principles of Wolff's law. Edwards et al. (72) demonstrated cortical shell thickening of osteoporotic vertebral bodies

compared to that of normal vertebral bodies. Furthermore, there was increased incidence of osteophytic development along the cortical shell in the regions of highest stress within the compromised osteoporotic vertebrae.

The normal disk consists of a gel-like nucleus encased in the annulus. In a normal healthy person, the disk acts like a fluid filled cavity. With age, the annulus develops radial, circumferential and rim lesions, and the nucleus becomes fibrous. Using a theoretical model in which cracks of varying lengths were simulated, Goel et al. found that the interlaminar shear stresses (and likewise displacements) were minimal until the crack length reached 70% of the annulus depth (73). Likewise, dehydration of the nucleus (extreme case totally ineffective like in a total nucleotomy) also was found to lead to separation of the lamina layers and an increase in motion (74). Thus, the results support the observation that the increase in motion really occurs in moderately degenerated disks.

Posner et al. investigated the effects of transection of the spinal ligaments on the stability of the lumbar spine (75). The ligaments were transected in a sequential manner, either anterior to posterior or posterior to anterior. While cutting structures from the anterior to posterior portion of the spine, extension loading caused a significant residual deformation after the anterior half of the disk was cut. Cutting from the posterior to anterior region, flexion loading caused significant residual motion upon facet joint transection. The role of ligaments becomes more prominent in subjects whose muscles are not fully functional. Using a

finite element model in which the muscular forces during lifting were simulated, Kong et al. found that a 10% decrease in the muscle function increased loads borne by the ligaments and the disks (76). The forces across the facet joint decreased.

The orientation of facet becomes more parallel to the frontal plane as one goes down from L1 to S1 (77). Other factors can also contribute to changes in facet orientation in a person. The facet orientation, especially at L4-5 and L5-S1, plays a role in producing spondylolisthesis. Kong et al. using a finite element of the ligamentous lumbar segment (Fig. 11a) found that as the facet orientation becomes more sagittal, the A-P translation across the segment, increases in response to the load applied, Fig. 11b. The increase in flexion angle was marginal.

Changes in Motion Due to Surgical Procedures

Cervical Region. *In vivo* "injuries" result in disk degeneration and may produce osteophytes, ankylosed vertebrae, and changes in the apophyseal joints (78). The effects of total discectomy on cervical spine motions are of interest (79). Schulte and colleagues reported a significant increase in the motion after C5-C6 discectomy (80). Motion between C5-C6 increased in flexion (66.6%), extension (69.5%), lateral bending (41.4%), and axial rotation (37.9%). In previous studies, Martins (81) and Wilson and Campbell (82) could not detect increases in motion roentgenographically and deemed the spines functionally stable.

Figure 11. The finite element of a lumbar segment used to predict the effect of facet orientations on the motion and loads in various spinal components in a motion segment. (Taken from Ref. 77.)

The reasons for this discrepancy in results are not apparent. The experimental designs were quite different as were the methods of motion measurement. However, the disk obviously is a major structural and functional component of the cervical spine.

The contribution of facet and its capsule to the stability of the cervical spine has been well documented using both *in vitro* laboratory models (83–85) and mathematical models (70,86,87,88). Facet joints play an integral part in the biomechanical stability of the cervical spine. Cusick et al. (89) found that total unilateral and bilateral facetectomies decreased compression-flexion strength by 31.6 and 53.1%, respectively. Facetectomy resulted in an anterior shift of the IAR, resulting in increased compression of the vertebral body and disk. This work confirmed the findings of Raynor et al. (63,64) who reported that bilateral facetectomy of as much as 50% did not significantly decrease shear strength; however, with a 75% bilateral facetectomy, a significant decrease in shear strength was noted. One should take great care when exposing an unfused segment to limit facet capsule resection to < 50%. With resection of > 50% of the capsule, postoperative hypermobility can occur and may require stabilization.

In contrast, studies that focused on the effects of laminectomy alone have been few and still unclear. Goel et al. were the first to evaluate the effects of cervical laminectomy with *in vitro* spine models (83,90). They found 10% increase of motion in flexion-extension using 0.3 N·m after a two level laminectomy. Zdeblick et al. did not find motion changes in flexion-extension after one level laminectomy under 5 N·m (84,85). Cusick et al. successfully showed that three level cervical laminectomy (C4-C6) induces a significant increase in total column flexibility using physiologic compression-flexion forces (86,87). Nevertheless, it seems difficult to estimate the instantaneous combination of physiologic compression and flexion forces. Therefore, quantitative evaluation might be difficult with this model. Our results indicate significant increase of spinal column motion in flexion (24.5%), extension (19.1%), and axial rotation (23.7%) using 1.5 N·m after a four level (C3-C6) laminectomy. Cervical vertebral laminae may transmit loads. Laminectomies result in the removal of part of this loading path and the attachment points for the ligamentum flavum, interspinous ligament, and the supraspinous ligament. It is not surprising that total laminectomy results in significant modifications in the motion characteristics of the cervical spine, especially in children. For example, Bell et al. (91) reported that multiple-level cervical laminectomy can lead to increase in postoperative hyperlordosis or kyphosis in children. However, there was no correlation between diagnosis, sex, location, or number of levels decompressed and the subsequent development of deformity. Postlaminectomy spinal deformity in the cervical spine, however, is rare in adults, probably owing to stiffening of the spine with age and changes in facet morphology. Goel et al. (89) removed the laminae of multisegmental cervical spines (C2-T2) at the level of C5 and C6 (total laminectomy); in flexion-extension mode, demonstrating an increase in motion of ~ 10%.

In another *in vitro* study, the effects of multilevel cervical laminoplasty (C3-C6) and laminectomy with

increasing amounts of facetectomy (25% and more) on the mechanical stability of the cervical spine were investigated (88). Cervical laminoplasty was not significantly different from the intact control, except for producing a marginal increase in axial rotation. However, cervical laminectomy with facetectomy of 25% or more resulted in a highly significant increase in cervical motion as compared with that of the intact specimens in flexion, extension, axial rotation, and lateral bending. There was no significant change in the coupled motions after either laminoplasty or laminectomy. The researchers recommended that concurrent arthrodesis be performed in patients undergoing laminectomy accompanied by > 25% bilateral facetectomy. Alternatively, one may use laminoplasty to achieve decompression if feasible. More recently, the effect of laminoplasty on the spinal motion using *in vivo* testing protocols have also been investigated (92–94). Kubo et al. (95) undertook an *in vitro* 3D kinematic study to quantify changes after a double door laminoplasty. Using fresh cadaveric C2-T1 specimens, sequential injuries were created in the following order: intact, double door laminoplasty (C3-C6) with insertion of hydroxyapatite (HA) spacers, laminoplasty without spacer, and laminectomy. Motions of each vertebra in each injury status were measured in six loading modes: flexion, extension, right and left lateral bending, and right and left axial rotation. Cervical laminectomy showed significant increase in motion compared to intact control in flexion (25%: $P < 0.001$), extension (19%: $P < 0.05$), and axial rotation (24%: $P < 0.001$) at maximum load. Double door laminoplasty with HA spacer indicated no significant difference in motion in all loading modes compared to intact. Laminoplasty without spacer showed intermediate values between laminoplasty with spacer and laminectomy in all loading modes. Initial slack of each injury status showed similar trends that of maximum load although mean % changes of laminectomy and laminoplasty without spacer were greater than that of maximum load. Double door laminoplasty with HA spacer appears to restore the motion of the decompressed segment back to its intact state in all loading modes. The use of HA spacers well contribute to maintain the total stiffness of cervical spine. In contrast, laminectomy seems to have potential leading postoperative deformity or instability.

Kubo et al. (96) undertook another study with the aim to evaluate the biomechanical effects of multilevel foraminotomy and foraminotomy with double door laminoplasty as compared to foraminotomy with laminectomy. Using fresh human cadaveric specimens (C2-T1), sequential injuries were created in the following order: intact, bilateral foraminotomies (C3/4, C4/5, C5/6), laminoplasty (C3-C6) using hydroxyapatite spacer, removal of the spacers, and laminectomy. Changes in the rotations of each vertebra in each injury status were measured in six loading modes: flexion-extension, right-left lateral bending, and right-left axial rotation. Foraminotomy alone, and following laminoplasty showed no significant differences in motion compared to the intact with the exception of axial rotation. After removal of the spacers and following a laminectomy, the motion increased significantly in flexion and axial rotation. The ranges of initial slack showed similar trends when compared to the results at

maximum load. Clinical implications of these observations are presented.

Lumbar Region. The spine is naturally shaped to properly distribute and absorb loads, therefore, any surgical technique involving dissection of spinal components can disrupt the natural equilibrium of the spinal elements and lead to instability. The amount and origin of pain within the spine usually determines the type of surgical procedure for a patient. Such procedures include the removal of some or all of the laminae, facets, and/or disks. A certain increase in the range of motion within the spine can be attributed to each procedure. The increased range of motion can also lead to more pain, as noted by Panjabi and others, who used an external fixator to stabilize the spine (97,98). The fixator decreased the range of motion for flexion, extension, lateral bending, and axial rotation. The pain experienced by the patients who had the external fixator applied was significantly reduced. For these reasons, it is essential to learn the effects of various surgical procedures on the stability of the spine. In particular, we need to consider when procedures may lead to increase in motion to a point leading to instability.

Much of the debate surrounding laminectomy and instability involves the use of fusion after the laminectomy. The possibility that fusion will be necessary to stabilize the spine after a laminectomy is largely case specific and depends on the purpose of the surgery. In a study by Goel et al., the results did not indicate the presence of instability after a partial laminectomy (99).

The facets are particularly important because they contribute to strength and resist axial rotation and extension. Subsequently, facetectomies can potentially be linked to instability. Abumi et al. developed some conclusions regarding partial and total facetectomies (2). They found that, although it significantly increased the range of motion, a partial facetectomy of one or both facets at a single level did not cause spinal instability. However, the loss of a complete facet joint on one or both sides was found to contribute to instability. Total facetectomy produced an increase of 65% in flexion, 78% in extension, 15% in lateral bending, and 126% in axial rotation compared with intact motion. Goel et al. also found similar results regarding partial facetectomy (99). Another study indicated that facetectomy performed within animals resulted in a large decrease in motion *in vivo* even though the increase in range of motion occurred acutely (2).

Goel et al. reported a significant increase in the range of motion for all loading modes except extension when a total discectomy was performed across L4-5 level (99). A significant, but smaller increase in range of motion for subtotal disk removal was also observed, however, the postoperative instability was minimal. Both partial and total discectomies produced a significant amount of intervertebral translational instability in response to left lateral bending at the L3-L4 and L4-L5 levels. They attributed the one-sided instability to the combination of injuries to the annulus and the right capsular ligament. Studies have also shown that more significant changes to the motion of the spine occur with removal of the nucleus pulposus as opposed to the removal of the annulus (4d). Discectomy

by fenestration and minimal resection of the lamina did not produce instability either.

BIOMECHANICS OF STABILIZATION PROCEDURES

Stability (or instability) retains a central role in the diagnosis and treatment of patients with back pain. Several studies have been carried out that help to clarify the foundation for understanding stability in the spine, as summarized above. In recent years, to restore stability across an abnormal segment, surgeons have well-accepted surgical stabilization and fusion of the spine using instrumentation, Figs. 12 and 13. The types and complexity of procedures (e.g., posterior, anterior, interbody) (100–105) have produced novel design challenges, requiring sophisticated testing protocols. In addition, most contemporary implant issues of stabilization and fusion of the spine are mostly mechanical in nature. [Biologic factors related to the adaptive nature of living tissue further complicate mechanical characterization (103,105)] Accordingly, it becomes essential to understand the biomechanical aspects of various spinal instrumentation and their effectiveness in stabilizing the segment. Properly applied spinal instrumentation maintains alignment and shares spinal loads until a solid, consolidated fusion is achieved. With few exceptions, these hardware systems are used in combination with bone grafting procedures, and may be augmented by external bracing systems.

Spinal implants typically follow loosely standardized testing sequelae during the design and development stage and in preparation for clinical use. The design and development phase goal, from a biomechanical standpoint, seeks to characterize and define the geometric considerations and load-bearing environment to which the implant will be subjected. Various testing modalities exist that elucidate which components may need to be redesigned. Not including the testing protocols for individual components of a device, plastic vertebrae (corpectomy) models are one of the first-stage tests that involves placing the assembled device on plastic vertebral components in an attempt to pinpoint which component of the assembled device may be the weakest mechanical link in the worst-case scenario, vertebrectomy. The *in vivo* effectiveness of the device may be limited by its attachment to the vertebrae (fixation). Thus, testing of the implant-bone interface is critical in determining the fixation of the device to biologic tissue. Construct testing on cadaveric specimens provides information about the effectiveness of the device in reducing intervertebral motion across the affected and adjacent segments during quasiphysiologic loading. Animal studies provide insight with respect to the long-term biologic effects of implantation. Analytic modeling, such as the finite element method, is an extremely valuable tool for determining how implants and osseous loading patterns change with varying parameters of the device design. This type of modeling may also provide information about temporal changes in the bone quality due to the changing loading patterns as bone adapts to the implant (e.g., stress shielding-induced bone remodeling). After a certain level of confidence in the implant's safety and effectiveness is

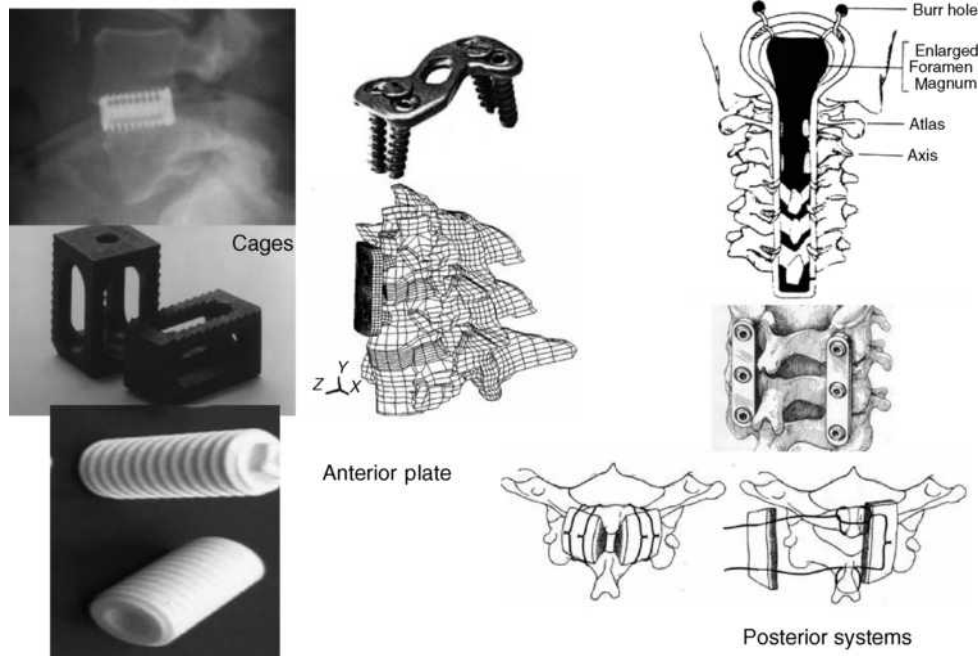

Figure 12. Devices used for stabilizing the cervical spine using the anterior and posterior approaches. Cages used both for the lumbar and cervical regions are also shown.

established via all or some of the aforementioned tests, controlled clinical trials allow for the determination of an implant's suitability for widespread clinical use. The following sections discuss each of these testing modalities, with specific examples used to illustrate the type of information that different tests can provide.

Implant-Bone Interface

Depending on the spinal instrumentation, the implant-bone interface may deal with the interface, where the spinal

instrumentation abuts, encroaches, or invades the bone surface. It may include bony elements, such as the laminas, pedicles, the vertebral body itself, or the vertebral endplates.

Interlaminar Hooks. Interlaminar hooks are used as a means for fixing the device to the spine. Hook dislodgment, slippage, and incorrect placement have led to loss of fixation, however, resulting in nonfusion and pseudoarthrosis. Purcell et al. (106) investigated construct stiffness as a function of hook placement with respect to affected level in a thoracolumbar cadaver model. The failure moment was

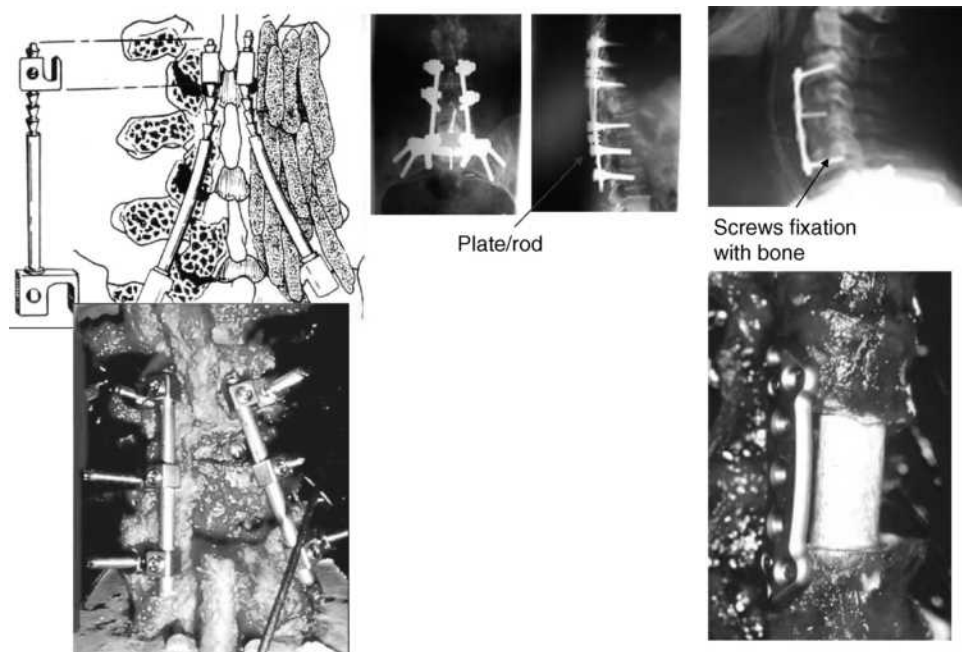

Figure 13. Examples of spinal instrumentation used in the lumbar region. Figure on the bottom right is an anterior plate.

found to be a function of the location of the hook placement with regard to the “injured” vertebra. The authors recommended hook placements three levels above and two levels below the affected area. This placement reduced vertebral tilting (analogous to intervertebral motion) across the stabilized segment, where fusion is to be promoted. Furthermore, the three-above, two-below surgical instrumentation strategy avoids the construct ending at the apex of a spinal deformity. Shortened fixation in this manner tends to augment a kyphotic deformity and cause continued progressive deformation. Overall, the use of hook fixation is a useful surgical stabilization procedure in patients with poor bone quality, where screw fixation is not an ideal choice for achieving adequate purchase into the bone.

Transpedicular Screws. Proper application of screw based anterior or posterior spinal devices requires an understanding of screw biomechanics, including screw characteristics and insertion techniques, as well as an understanding of bone quality, pedicle and vertebral body morphometries, and salvage options (107–109). This is best illustrated by the fact that the pedicle, rather than the vertebral body, contributes ~80% of the stiffness and ~60% of the pull out strength across the screw–bone interface (107).

Carlson et al. (110) evaluated the effects of screw orientation, instrumentation, and bone mineral density on screw translation, rotation at maximal load, and compliance of the screw–bone interface in human cadaveric bones. An inferiorly directed load was applied to each screw, inserted either anteromedially or anterolaterally,

until failure of the fixation was perceived. Anteromedial screw placement with fully constrained loading linkages provided the stiffest fixation at low loads and sustained the highest maximal load. Larger rotation of the screws, an indication of screw pull out failure, was found with the semi-constrained screws at maximal load. Bone mineral density directly correlated with maximal load, indicating that bone quality is a major predictor of bone–screw interfacial strength. A significant correlation between BMD and insertional torque ($p < 0.0001$, $r = 0.42$), BMD and pullout force ($p < 0.0001$, $r = 0.54$), and torque and pullout force has been found (109–112).

Since the specimens used for pull-out strength studies primarily come from elderly subjects, Choi et al. used foams of varying densities to study the effect of bone mineral density on the pull out strength of several screws (112). Pedicle screws (6.0 × 40 mm, 2 mm pitch, Ti alloy) of several geometric variations used for the study included the buttress (B), square (S), and V-shape (V) screw tooth profiles. For each type of tooth profile, its core shape (i.e., minor diameter) also varied, either the straight (i.e., cylindrical, core diameter = 4.0 mm) or tapered (i.e., conical, core diameter = 4.0/2.0 mm). In addition, for the cylindrical screws the major diameter was kept straight or tapered. The conical screws had its major diameters tapered only. Therefore, screws with a total of nine different geometries were prepared and tested (Fig. 14a). The screws were implanted in the rigid polyurethane foams of three different grades. The pullout strengths for various screw designs are shown in Table 10. The highest purchasing power in any screw design was observed in foams with

Figure 14. (a) Types of screws used in the foam model to determine the pull-out strength. The nomenclature used is as follows: Square = S, Buttress = B, V-shape = V. Screw diameters were SS = straight major diameter on straight core, ST = straight major diameter on tapered core, TT = tapered major diameter on tapered core. (b) Regression analysis. The maximum and minimum values from pull-out test for each foam grade were used regardless of tooth or core profiles. (Taken from Ref. 112.)

Table 10. Axial Pull Out Strength (N) Data for Different Types of Screws, Based on a Foam Model of Varying Densities

Foam Grade	Body Profile	Tooth Profile(Mean \pm SD)		
		Square	Buttress	V-shape
10	SS ^a	591 \pm 22	497 \pm 80	615 \pm 36
	ST ^b	622 \pm 43	598 \pm 25	634 \pm 19
	TT ^c	525 \pm 36	547 \pm 30	568 \pm 74
12	SS	864 \pm 50	769 \pm 56	987 \pm 55
	ST	956 \pm 30	825 \pm 108	1005 \pm 92
	TT	811 \pm 41	808 \pm 25	944 \pm 32
15	SS	1397 \pm 93	1303 \pm 126	1516 \pm 78
	ST	1582 \pm 82	1438 \pm 36	1569 \pm 79
	TT	1197 \pm 43	1352 \pm 88	1396 \pm 68

the highest density (Grade 15). Exponential increase in pullout strength was seen when the foam density increased from Grade 10–15 (Fig. 14b). Overall, results demonstrated that the conical screws were consistently more effective against the pullout than the cylindrical designs. This was especially evident when the major diameter of the screw was kept straight. In this case, the contact area between the screw thread and surrounding foam was large. Although no consistent statistical superiority was found with the tooth profiles, results did suggest that the V-shape tooth screws ranked highest in many statistical comparisons and the buttress types showed comparatively lower pullout strength than the other types. This finding may be somewhat different from the literature. This can be due to the absence of the cortical purchase in the foam model used in this study. On the other hand, the square-tooth screws fared well in terms of pullout strength when the major diameter was kept straight but did not do so when tapered. Results also suggested that as the density of host site was decreased no clear choice of tooth profile could be found.

Lim et al. investigated the relationship between the bone mineral density of the vertebral body and the number of loading cycles to induce loosening of an anterior vertebral screw (113). (Screw loosening was defined as 1 mm displacement of the screw relative to bone). The average number of loading cycles to induce screw loosening was significantly less for specimens with bone mineral density $< 0.45 \text{ g} \cdot \text{cm}^{-2}$, compared to those with bone mineral density $> \text{or} = 0.45 \text{ g} \cdot \text{cm}^{-2}$. These findings suggest that bone mineral density may be a good predictor of anterior vertebral screw loosening as well, just like the pedicle screws.

Since BMD seems to play a crucial role in the loosening of fixation screws, their use with osteoporotic bone is a contraindication. Alternatives have been proposed, including the use of bone cement to augment fixation and use of hooks along with pedicle screws (114,115).

The above findings related to increased pullout strength, number of cycles to failure, and tightening torque with BMD, are not fully corroborated with the corresponding *in vivo* work. For example, moments and forces during pedicle screw insertion were measured *in vivo* and *in vitro* and correlated to bone mineral density, pedicle size, and other screw parameters (material, diameter) (116). The mean *in vivo* insertion torque (1.29 N·m) was significantly

greater than the *in vitro* value (0.67 N·m). The linear correlation between insertion torque and bone mineral density was significant for the *in vitro* data, but not for the *in vivo* data. No correlation was observed between insertion torque and pedicle diameter. However, another investigation that clinically evaluated 52 patients who underwent pedicle screw fixation augmenting posterior lumbar interbody fusion (PLIF) supports the *in vitro* findings. The BMD was measured using DEXA and radiographs were assessed for detecting loosening, and so on at the screw bone interface. Bone mineral density was found to have a close relation with the stability of pedicle screw *in vivo*, and BMD values $< 0.674 \pm 0.104 \text{ g} \cdot \text{cm}^{-2}$ suggested a potential increased risk of “non-union”.

Cages. Total disk removal alone or in combination with other surgical procedures invariably leads to a loss of disk height and an unstable segment. Both allo- and autologous bone grafts have been used as interbody spacers (103,117–120). Associated with the harvest and use of autogenous bone grafts are several complications: pain, dislodgment of the anterior bone graft, loss of alignment, and so on. Recently, the use of inserts, fabricated from synthetic materials (metal or bone-biologic), have gained popularity. These may be implanted through an anterior or posterior approach. Interbody devices promote fusion by imparting immediate postoperative stability, and by providing axial load-bearing characteristics, while allowing long-term fusion incorporation of the bone chips packed inside and around the cage (121,122). Many factors influence the performance of an interbody cage. The geometry, porosity, elastic modulus, and ultimate strength of the cage is crucial to achieving a successful fusion. An ideal fixation scenario should be to utilize the largest cross-sectional footprint of a cage in the interbody space so that the cortical margin can be captured by the fixation to decrease the risk of endplate subsidence. A modulus of elasticity close to bone is often an ideal choice to balance the mechanical integrity at the endplate–implant interface. A cage that has a large elastic modulus and high ultimate strength increases the risk to endplate subsidence and/or stress-shielding issues. Finally, cage design must possess a balance between an ideal porosity to augment bony fusion through the cage and mechanical strength to bear axial loads.

Steffen et al. undertook a human cadaveric study with the objectives to assess the axial compressive strength of an implant with peripheral endplate contact as opposed to full surface contact, and to assess whether removal of the central bony endplate affects the axial compressive strength (120). Neither endplate contact region nor its preparation technique affected yield strength or ultimate compressive strength. Age, bone mineral content, and the normalized endplate coverage were strong predictors of yield strength ($P < 0.0001$; $r^2 = 0.459$) and ultimate compressive strength ($P < 0.0001$; $r^2 = 0.510$). An implant with only peripheral support resting on the apophyseal ring offers axial mechanical strength similar to that of an implant with full support. Neither supplementary struts nor a solid implant face has any additional mechanical advantage, but reduces graft–host contact area. Removal of the central bony endplate is recommended because it does not affect the compressive strength and promotes graft incorporation. There are drawbacks to using threaded cylindrical cages (e.g., limited area for bone ingrowth, subsidence issues, and metal precluding radiographic visualization of bone healing). To somewhat offset these drawbacks, several modifications have been proposed, including changes in shape and material (123–125). For example, the central core of the barbell shaped cage can be wrapped with collagen sheets infiltrated with bone morphogenetic protein. The femoral ring allograft (FRA) and posterior lumbar interbody fusion (PLIF) spacers have been developed as biological cages that permit restoration of the anterior column with a machined allograft bone (123).

Wang et al. (126) looked at *in vitro* load transfer across standard tricortical grafts, reverse tricortical grafts, and fibula grafts, in the absence of additional stabilization. Using pressure sensitive film to record force levels on the graft, the authors found the greatest load on the graft occurred in flexion. As expected, the anterior portion of the graft bore increased load in flexion and the posterior portion of the graft bore the higher loads in extension. The authors did not supplement the anterior grafting with an anterior plate. Cheng et al. (127) performed an *in vitro* study to determine load sharing characteristics of two anterior cervical plate systems under axial compressive loads: the Aesculap system (Aesculap AGT, Tuttlingen, Germany) and the CerviLock system (SpineTech Inc., Minneapolis, MN). The percent loads carried by the plates at a 45 N applied axial load were as follows: Aesculap system $-6.2\% \pm 9.2\%$ and the CerviLock system $-23.8\% \pm 12.7\%$. Application of 90 N loads produced similar results to those of the 45 N loads. The authors stated that the primary factor in load transfer characteristics of the instrumented spine was a difference in plate designs. The study contained several limitations. Loading was performed solely in axial compression across a single functional spinal unit (FSU). The study did not simulate complex loading, such as flexion combined with compression. In the physiologic environment, load sharing in multisegmental cervical spine could be altered since the axial compressive load will produce additional flexion–extension moments, due to the lordosis. The upper and lower vertebrae of the FSU tested were constrained in the load frame, whereas in

reality they are free to move, subject to anatomic constraints.

Rapoff et al. (128) recently observed load sharing in an anterior CSLP plate fixed to a three level bovine cadaveric spinal mid-thoracic segment under simple compression of 125 N. A Smith–Robinson discectomy procedure was performed at the median disk space to a maximum distraction of 2 mm prior to plate insertion and loading. Results showed that at 55 N of load, mean graft load sharing was 53% ($\pm 23\%$) and the plate load sharing was 57% ($\pm 23\%$). This study was limited in several aspects, including the fact that no direct measurement of plate load was made, the spines were not human, and the loading mode was simplified and did not incorporate more complex physiologic motions, such as coupled rotation and bending or flexion/extension.

A recent study by An et al. (129) looking at the effect of endplate thickness, endplate holes, and BMD on the strength of the graft–endplate interphase of the cervical spine found that there existed a strong relationship between BMD and load to failure of the vertebrae, demonstrating implications for patient selection and choice of surgical technique. There was a significantly larger load to failure in the endplate intact group compared to the endplate resected group studied, suggesting that an intact endplate may be a significant factor in prevention of graft subsidence into the endplate. Results of an FE model observing hole patterns in the endplate indicated that the hole pattern only significantly affected the fraction of the upper endplate that was exposed to fracture stresses at 110 N loading. A large central hole was found to be best for minimization of fracture area and more effective at distribution of the compressive load across the endplate area.

Dietl et al. pulled out cylindrical threaded cages (Ray TFC Surgical Dynamics), bullet-shaped cages (Stryker), and newly designed rectangular titanium cages with an endplate anchorage device (Marquardt) used as posterior interbody implants (130). The Stryker cages required a median pullout force of 130 N (minimum, 100 N; maximum, 220 N), as compared with the higher pullout force of the Marquardt cages (median, 605 N; minimum, 450 N; maximum, 680 N), and the Ray cages (median, 945 N; minimum, 125 N; maximum, 2230 N). Differences in pullout resistance were noted depending on the cage design. A cage design with threads or a hook device provided superior stability, as compared with ridges. The pyramid shaped teeth on the surfaces and the geometry of the implant increased the resistance to expulsion at clinically relevant loads (1053 and 1236 N) (124,125).

Construct Testing

Spinal instrumentation needs to be applied to a spine specimen to evaluate its effectiveness. As a highly simplified model, two plastic vertebrae serve as the spine model. Loads are applied to the plastic vertebrae and their motions and applied loads to failure are measured. This gives some idea of the rigidity of the instrumentation. However, a truer picture is obtained by attaching the device to the cadaveric spine specimen.

Plastic Vertebra (Corpectomy) Models. Clinical reviews of failure modes of the devices indicate that most designs satisfactorily operate in the immediate postoperative period. Over time, however, these designs can fail because of the repeated loading environment to which they are subjected. Thus, fatigue testing of newer designs has become an extremely important indicator of long-term implant survivorship. Several authors have tested thoracolumbar instrumentation systems in static and fatigue modes using a plastic vertebral model (131–133). For example, Cunningham et al. compared 12 anterior instrumentation systems, consisting of 5 plate and 7 rod systems in terms of stiffness, bending strength, and cycles to failure (132). The stiffness ranged from $280.5 \text{ kN} \cdot \text{m}^{-1}$ in the Synthes plate (Synthes, Paoli, PA) to $67.9 \text{ kN} \cdot \text{m}^{-1}$ in the Z-plate (Sofamor-Danek, Memphis, TN). The Synthes plate and Kaneda SR titanium (AcroMed, Cleveland, OH) formed the highest subset in bending strength of 1516.1 and 1209.9 N, respectively, whereas the Z plate showed the lowest value of 407.3 N. There were no substantial differences between plate and rod devices. In fatigue, only three systems: Synthes plate, Kaneda SR titanium, and Olerud plate (Nord Opedic AB, Sweden) withstood 2 million cycles at 600 N. The failure mode analysis demonstrated plate or bolt fractures in plate systems and rod fractures in rod systems.

Clearly, studies, such as these involving missing vertebral (corpectomy) artificial models, reveal the weakest components or linkages of a given system. Results must be viewed with caution since these results do not shed light on the biomechanical performance of the device. Furthermore, we do not know the optimum strength of a fixation system. These protocols do not provide any information about the effects the device implantation may have on individual spinal components found *in vivo*. For these data, osteoligamentous cadaver models need to be incorporated in the testing sequelae and such studies are more clinically relevant.

Osteoligamentous Cadaver Models. For applications, such as fusion and stabilization, initial reductions in intervertebral motion are the primary determinants of instrumentation success, although the optimal values for such reductions are not known and probably not needed to determine relative effectiveness. Thus, describing changes in motion of the injured and stabilized segments in response to physiologic loads is the goal of most cadaver studies. Many times, these data are compared with the intact specimen, and the results are reported as the instrumentation's contribution to providing stability (134). To standardize, the flexibility testing protocol has been suggested (135). Here a load is applied and resulting unconstrained motions are measured. However, there are several issues pertaining to this type of testing, as described below.

More recently nonfusion devices have come on the market. These devices try to restore motion of the involved segment. With the paradigm shift from spinal fusion to spinal motion, there are dramatically different criteria to be considered in the evaluation of nonfusion devices. While fusion devices need to function for a short period and are differentiated primarily by their ability to provide rigid

fixation, nonfusion devices must function for much longer time periods and need to provide spinal motion, functional stability, and tolerable facet loads. The classic flexibility testing protocol is not appropriate for the understanding of the biomechanics of the construct for the nonfusion devices, at the adjacent levels (136,137). However, constant pure moments are not appropriate for measuring effects of implants, like the total disk replacements, at adjacent levels. The pure moments distribute evenly down a column and are thus not effected by perturbation at a level(s) in a longer construct. Further, the net motion of a longer construct is not similar if only pure moments are applied: fusions will limit motion and other interventions may increase motion, a reflection of the change in stiffness of the segment. This may have shortcomings for clinical applications. For example, with forward flexion, there are clinical demands to get to ones shoes to tie them, to reach a piece of paper fallen to the floor, and so on. It would thus be advantageous to use a protocol that would achieve the same overall range of motion for the intact specimen and instrumented construct by applying pure moments that distribute evenly down the column.

Another issue is that the ligamentous specimens cannot tolerate axial compressive loads, specimens in the absence of the muscles will buckle. Thus, methods have been developed to apply preloads on the ligamentous spines during testing, since these indirectly simulate the effects of muscles on the specimens. A number of approaches have been proposed with one that stands out and is getting accepted by the research community. It is termed the follower-load concept (137).

It could be reasoned that coactivation of trunk muscles (e.g., the lumbar multifidus, longissimus pars lumborum, iliocostalis pars lumborum) could alter the direction of the internal compressive force vector such that its path followed the lordotic and kyphotic curves of the spine, passing through the instantaneous center of rotation of each segment. This would minimize the segmental bending moments and shear forces induced by the compressive load, thereby allowing the ligamentous spine to support loads that would otherwise cause buckling and providing a greater margin of safety against both instability and tissue injury. The load vector described above is called a "follower load".

Additionally, most of these studies involve quasistatic loading; however, short-term fatigue characteristics have also been investigated. Both posterior and anterior-instrumentation employed for the promotion of fusion and non fusion have been evaluated. The following are examples of such devices, which are discussed within the context of these testing modalities.

Cervical Spine Stabilization and Fusion Procedures

There are a variety of techniques that are utilized for spinal fusion in the lower cervical spine, among which are spinal wiring techniques (138–144), posterior plating (145–154), anterior plating, and (more recently) cervical interbody fusion devices. While fusions are effective in a majority of cases, they do have documented biomechanical shortcomings, particularly at the segments adjacent to the

fusion. Some of these problems include observations of excessive motion (sometimes due to pseudoarthrosis) (155–164), degenerative changes (165,166), fracture dislocation (167), screw breakage or plate pullout (160,168–170), and risks to neural structures. These problems are typically minimal when only one or two segments are involved in the injury. However, when the number of segments involved in the reconstruction increases to three or more, the incidence of failed fusion, screw breakage, and plate pullout increases dramatically.

Upper Cervical Spine Stabilization. Stabilization of the craniovertebral junction is not common; however, its importance for treating rheumatoid arthritis associated lesions, fractures and tumors cannot be underestimated. Currier et al. (171) studied the degree of stability provided by a rod-based instrumentation system. They compared this new device to the Ransford loop technique and a plate system using C2 pedicle screws. Transverse and alar ligament sectioning and odontoidectomy destabilized the specimen. All three-fixation systems significantly reduced motion as compared to intact and injured spines in axial rotation and extension. The new device did not significantly reduce motion at C1-C2 in flexion, and none of the devices were able to produce significant motion reductions in C1-C2 lateral bending. The authors claimed, based on these findings, that the new system is equivalent or superior to the other two systems for obtaining occipito-cervical stability. Oda et al. (172) investigated the comparative stability afforded by five different fixation systems. Type II odontoid fractures were created to simulate instability. The results indicate that the imposed dens fracture decreased construct stiffness as compared to the intact case. Overall, the techniques that utilized screws for cervical anchors provided greater stiffness than the wiring techniques. Also, the system that utilized occipital screws with C2 pedicle screw fixation demonstrated the greatest construct stiffness for all rotations. Puttlitz et al. (1c) have used the finite element model of the C0-C1-C2 complex to investigate the biomechanics of a novel hardware system (Fig. 15). The FE models representing combinations of

cervical anchor type (C1-C2 transarticular screws versus C2 pedicle screws) and unilateral versus bilateral instrumentation were evaluated. All models were subjected to compression with pure moments in flexion, extension, or lateral bending. Bilateral instrumentation provided greater motion reductions than the unilateral hardware. When used bilaterally, C2 pedicle screws approximate the kinematic reductions and hardware stresses (except in lateral bending) that are seen with C1-C2 transarticular screws. The FE model predicted that the maximum stress was always located in the region where the plate transformed into the rod. Thus, the authors felt that C2 pedicle screws should be considered as an alternative to C2-C1 transarticular screw usage when bilateral instrumentation is applied.

Other strategies to fix the atlantoaxial complex can be found in the literature. Commonly available fixation techniques to stabilize the atlantoaxial complex are posterior wiring procedures (Brooks fusion, Gallie fusion) (169), interlaminar clamps (Halifax) (170), and transarticular screw (Magerl technique), either alone or in combination.

Posterior wiring procedures and interlaminar clamps are obviously easier to accomplish. However, these do not provide sufficient immobilization across the atlantoaxial complex. In particular, posterior wiring procedures and place the patient at risk of spinal cord injury due to sublaminar passage of wires into the spinal canal (172). Interlaminar clamps offer the advantage of avoiding the sublaminar wire hazard and have more rigid biomechanical stiffness than posterior wiring procedures (173).

Transarticular screw fixation (TSF), on the other hand, affords a stiffer atlantoaxial arthrodesis than posterior wiring procedures and interlaminar clamps. The TSF does have some drawbacks including injury of vertebral artery, malposition, and screw breakage (174). Furthermore, body habitus (obesity or thoracic hyperkyphosis) may prohibit achieving the low angle needed for screw placement across C1 and C2. Recently, a new technique of screw and rod fixation (SRF) that minimizes the risk of injury to the vertebral artery and allows intraoperative reduction has been reported (175,176). The configuration of this technique, which achieves rigid fixation of the atlantoaxial

Figure 15. The finite element model showing the posterior fixation system and the stress plots in the rods. (Taken from Ref. 4c.)

Max stress:
132.5 MPa in lateral bending,
C2 pedicle, injury, compressed.

complex, consists of lateral mass screws at C1 and pedicle screws at C2 linked via longitudinal rods with constrained coupling devices.

One recent study compared the biomechanical stability impaired to the atlantoaxial complex by either the TSF or SRF technique and to assess how well these methods withstand fatigue in a cadaver model (177).

The results of this study suggested that in the unilateral fixations, the SRF group was stiffer than the TSF group in flexion loading, but there were no evident differences in other directions. In the bilateral fixations, SRF was more stable than TSF, especially in flexion and extension. These results were similar to those reported by Melcher et al. (178) and Richter et al. (179), yet different from Lynch et al. (180). The instrumentation procedure (screw length, type of constrained coupling device, etc.), the destabilization technique, and the condition of the specimens might have an influence on the results. In this study, when stabilizing the atlantoaxial segments, all screws were placed bicortically in both techniques in accordance with procedures by Harms and Melcher (181). Previous work has demonstrated that bicortical cervical vertical screws are superior to unicortical screws in terms of pullout strength and decreased wobble (182,183). Most surgeons, however, prefer unicortical screwing at C1 and C2 levels to reduce the risk of penetration during surgery. This could affect the outcome. They initially connected the screw to the rod using the oval shape constrained coupling device recommended for use in C1 and C2 vertebrae. However, the stability was not judged adequate, so they altered the procedure to use the stiffer circle shape constrained coupling device. With regards to the destabilization procedure, there are three typical methods: sectioning of intact ligaments, odontoid fracture, and odontoidectomy. The atlantoaxial complex was destabilized by ligament transection to simulate ligamentous instability, while Lynch et al. (180) used odontoidectomy. Furthermore, the bone quality of specimens affects the screw-bone interface stability. These factors were possibly reflected in other results. However, both results were not statistically different between TSF and SRF, so they could be interpreted equivalent in terms of effective stabilization when compared with the intact specimen.

In unilateral TSF and SRF, the fixed left lateral atlantoaxial joint acted as a pivot in left axial rotation and as a fulcrum in left lateral bending, thus leading to an increase in motion. This motion could be observed with the naked eye.

Stability in flexion and extension of the bilateral TSF group was inferior to that of SRF group. Henriques et al. (184) and Naderi et al. (182) also reported similar tendency. Henriques et al. (184) felt that this was most likely due to the transarticular screws being placed near the center of motion between C1 and C2. This was judged as another reason that the trajectory of the screws is consistent with the motion direction of flexion and extension. So, if TSF is combined with some posterior wiring procedures, the stability in flexion and extension will increase.

Lower Cervical Spine

Anterior Plating Techniques for Fusion. The anterior approach in order to achieve arthrodesis of the cervical

spine has become a widely utilized and accepted approach. However, many of these techniques rely on insertion of a bone graft only anteriorly and the use of an external immobilization device, such as a halo vest, or posterior fixation in order to allow for sufficient fixation. Problems encountered with these methods include dislodging of the bone graft (potentially causing neural compromise), loss of angular correction, and failure to maintain spinal reduction (185,186). The use of anterior plates has recently become popular partially because they address some of the complications stated above. The main reasons typically cited for the use of anterior plates are (1) advantage of simultaneous neural decompression via an anterior as opposed to posterior approach, (2) improved fusion rates associated with anterior cervical fusion (187,188), (3) help in reduction of spinal deformities, (4) provides for rigid segmental fixation, and (5) prevents bone graft migration. However, the efficacy of anterior plates alone is still debated by some authors, particularly in multilevel reconstruction techniques, due to the high rates of failure observed, up to 50% in some cases (189–192). Thus, more biomechanical research must be accomplished to delineate the contributions of anterior plates to load sharing mechanics in the anterior approach.

There have been several *in vitro* studies examining the efficacy of anterior plates for use in a multitude of procedures involving cervical spine stabilization. Grubb et al. (151) performed a study involving 45 porcine and 12 cadaveric specimens to study anterior plate fixation. Phase I of the study involved intact porcine specimens which were subjected to nondestructive testing in flexion, lateral bending, and axial rotation loading modes to determine structural stiffness. Maximum moments applied included 2.7 N·m for flexion and lateral bending and 3.0 N·m for axial rotation testing. After completion of the nondestructive testing, a flexion-compression injury was introduced by performing a C5 corpectomy and inserting an iliac strut bone graft in the resulting space. An anterior plate was then introduced across C4–C6. Three different anterior plates were tested, including a Synthes CSLP (cervical spine locking plate) with unicortical fixation, a Caspar plate with unicortical fixation, and a Caspar plate with bicortical fixation. Each instrumented specimen was then tested again nondestructively in flexion, lateral bending, and axial rotation. Finally, destructive testing in each loading mode was performed on particular specimens in each plated group. Phase II of the study involved intact cadaver specimens that were subjected to nondestructive testing in flexion, lateral bending, and axial rotation loading modes to determine structural stiffness. Maximum moments applied included 2.0 N·m for flexion, lateral bending, and axial rotation. After completion of the nondestructive testing, a flexion-compression injury was introduced by performing a C5 corpectomy and inserting an iliac strut bone graft in the resulting space. An anterior plate was then introduced across C4–C6. Two different anterior plates were tested: a Synthes CSLP (cervical spine locking plate) with unicortical fixation and a Caspar plate with bicortical fixation. Each instrumented specimen was then tested again nondestructively in flexion, lateral bending, and axial rotation. Finally, destructive testing in flexion

was performed on each specimen. Results of the study demonstrated that each of the stabilized specimens had stiffness characteristics greater than or equal to their paired intact test results. The CSLP was found to have a significantly higher stiffness ratio (plated: intact), higher failure moment, lower flexion neutral zone ratio, and higher energy to failure than the Caspar plates.

A study by Clausen et al. (193) reported the results of biomechanical testing of both the CSLP system with unicortical locking screws and Caspar plate system with unlocked bicortical screws. Fifteen cadaveric human spines were tested intact in flexion, extension, lateral bending, and axial rotation loading modes to determine stiffness characteristics. A C5-C6 instability was then introduced, consisting of a C5-C6 discectomy with complete posterior longitudinal ligament (PLL) disruption. An iliac crest bone graft was then introduced into the C5-C6 disk space and the spine was instrumented with either the CSLP or Caspar system. Once instrumented, each of the spines were further destabilized through disruption of the interspinous and supraspinous ligaments, the *ligamentum flavum*, facet capsules, and lateral annulus. The specimens were then retested for stiffness. After initial postinstrumented testing was done, biomechanical stability of the specimens was reassessed following cyclic fatigue for 5000 cycles of flexion-extension. Finally, failure testing of each specimen was performed in flexion. Results of the study demonstrated that both devices stabilized the spine before but not after fatigue and that only the Caspar plate stabilized the spine significantly before and after fatigue. Failure moment did not differ between the two systems. Biomechanical stability discrepancy between the two devices was attributed to differences in bone-screw fixation. Kinematic testing of 10 cervical spines following single level (C5-C6) discectomy and anterior plate insertion was studied by Schulte et al. (194). Results showed that the use of an anterior plate in addition to the bone graft provided significant stabilization in all loading modes. Traynelis et al. (195) performed biomechanical testing to compare anterior plating versus posterior wiring in an cadaver instability model involving a simulated C5 teardrop fracture with posterior disruption and fixation across C4-C6. Study results showed that bicortical anterior plating provided significantly more stability than posterior wiring in extension and lateral bending, and was slightly more stable than posterior wiring in flexion. Both provided equivalent stability in axial rotation. A variety of anterior constructs exist in the market today, typically using either bicortical screws or unicortical locking screws. Several studies have evaluated the purchase of unicortical versus bicortical screws in the cervical spine (195-197).

Wang et al. (198) looked at *in vitro* load transfer across standard tricortical grafts, reverse tricortical grafts, and fibula grafts, in the absence of additional stabilization. Using pressure sensitive film to record force levels on the graft, the authors found the greatest load on the graft occurred in 10° of flexion (~20.5 N) with a preload on the spine of 44 N. As expected, the anterior portion of the graft bore increased loading in flexion and the posterior portion of the graft bore the highest loads in 10° extension. The authors did not supplement the anterior grafting with an

anterior plate. Cheng et al. (127) performed an *in vitro* study to determine load-sharing characteristics of two anterior cervical plate systems under axial compressive loads: the Aesculap system (Aesculap AGT, Tuttlingen, Germany) and the CerviLock system (SpineTech Inc., Minneapolis, MN). The percent loads carried by the plates at a 45 N applied axial load were as follows: Aesculap system $-6.2\% \pm 9.2\%$ and the CerviLock system $-23.8\% \pm 12.7\%$. Application of 90 N loads produced similar results to those of the 45 N loads. The authors stated that the primary factor in load transfer characteristics of the instrumented spine was a difference in plate designs. The study contained several limitations. Loading was performed solely in axial compression across a single FSU. The study did not simulate complex loading, such as flexion combined with compression. In the physiologic environment, load sharing in multisegmental cervical spine could be altered since the axial compressive load will produce additional flexion-extension moments, due to the lordosis. The upper and lower vertebrae of the FSU tested were constrained in the load frame, whereas in reality they are free to move, subject to anatomic constraints. Foley et al. also performed *in vitro* experiments to examine the loading mechanics of multilevel strut grafts with anterior plate augmentation (199). The results of the study showed that application of an anterior plate in a cadaver corpectomy model unloads the graft in flexion and increases the loads borne by the graft under extension of the spine. The increase in load borne by the graft in the presence of the plate should increase the graft subsidence, a finding that is contrary to clinical follow-up studies, as stated earlier.

Finite element (FE) analysis has been used by our group on a C5-C6 motion segment model to determine load sharing in an intact spine under compressive loading and more clinically relevant combined loading of flexion-extension and compression (4b). Similarly, using the FE approach, stresses in various graft materials (titanium core, titanium cage, iliac crest, tantalum core, and tantalum cage), the adjacent disk space, and vertebra have been investigated by Kumareson et al. (200). These authors found that angular stiffness decreased with decreasing graft material stiffness in flexion, extension, and lateral bending. They also observed the stress levels in the disk and vertebral bodies as a whole due to the presence of a graft, but did not focus on the graft itself or the endplate regions, superior and inferior to the graft. The effects of anterior plates on load sharing were not investigated.

Scifert et al. (4d) developed an experimentally validated C4-C6 cervical spine finite element model was developed to examine stress levels and load sharing characteristics in an anterior plate and graft. Model predictions demonstrated good agreement with the *in vitro* data. The rotations across the stabilized segment significantly decreased in the presence of a plate as compared to graft alone case. Much like the *in vitro* studies, the model also predicted that the compressive load in the graft increased in extension in the presence of plate, as compared to graft alone case. Depending on the load type, stresses in graft were concentrated in its anterior or posterior region in the graft alone case and became more uniformly distributed in the presence of the plate. The predicted load-displacement data

and load sharing results reveal that plate is very effective in maintaining the alignment. Increase in load borne by the graft in the presence of a plate in the extension mode suggests that pistoning of the graft is a possible outcome. However, the stress data reported in the present study, and something that the *in vitro* studies are unable to quantify, show that pistoning of the graft is not likely to happen due to stresses being low, an observation in agreement with the clinical outcome data. For an optimal healing, the stress results suggest the placement of the tricortical bone graft with its cortical region towards the canal when a plate is used. For the graft case alone, this parameter does not seem to be that critical. A more uniform stress distribution in the graft in the presence of the plate would tend to promote bone fusion in a more uniform fashion, as compared to the graft alone case. In the later case fusion may initiate in a selective region.

Lower Cervical Spine

Posterior Plating Techniques for Fusion. The posterior approach in order to achieve cervical spine arthrodesis has been a widely utilized and accepted approach to dealing with cervical spine trauma, such as posterior trauma involving the spinous processes or facet dislocation or injury, and disease, such as degenerative spondylosis or ossification of the posterior longitudinal ligament. Recently, however, posterior fixation using cervical screw plates affixed to the lateral masses has gained acceptance due to a variety of factors, including the fact that they do not rely on the integrity of the lamina or spinous processes to allow for fixation, bone grafting is not always necessary to allow for long-term stability, greater rotational stability is achieved at the facets (201,202), and it eliminates the need for external immobilization such as halo vests. Problems encountered with these posterior methods include (1) risk to nerve roots, vertebral arteries, facets, and spinal cord (168); (2) screw loosening and avulsion (203); (3) plate breakage; (4) and loss of reduction. Additionally, contraindications exist where the patient has osteoporosis, metabolic bone disease, or conditions where the bone is soft (i.e., ankylosing spondylitis) (204). There also exists controversy as to the advantages of using posterior plating techniques when posterior cervical wiring techniques can be used (205). In theory, anterior stabilization of the spine in cases of vertebral body injury is superior to posterior plating. However, in practice, posterior plates are an effective means of stabilizing vertebral body injuries, and their application is easier than the anterior approach involving corpectomy, grafting, and anterior plating.

In addition to clinical *in vivo* studies, there have been several *in vitro* studies examining the efficacy of posterior plates for use in cervical spine stabilization. Roy-Camille et al. (202) utilized a cadaveric model to compare posterior lateral mass plating to spinous process wiring. They found that posterior plates increased stability by 92% in flexion and 60% in extension, while spinous process wiring enhanced flexion stability by only 33% and did not stabilize in extension at all. Coe et al. (201) performed biomechanical testing of several fixation devices, including Roy-Camille posterior plates, on six human cadaveric spines. Complete

disruption of the supraspinous and interspinous ligaments, *ligamentum flavum*, posterior longitudinal ligament, and facet joints was performed. They found no significant difference in static or cyclic loading results between the posterior wiring and posterior plates, although the posterior plating was stiffer in torsion. Overall, the authors recommended the Bohlmann triple wire technique for most flexion distraction injuries. In experimental studies performed in our lab on 12 cervical spines, Scifert et al. (202) found that posterior plates were superior to posterior facet wiring in almost every loading mode tested in both the stabilized and cyclic fatigue testing modes, excluding the cyclic extension case. Smith et al. (153) performed biomechanical tests on 22 spines to evaluate the efficacy of Roy-Camille plates in stabilization of the cervical spine following simulation of a severe fracture dislocation with three-column involvement caused by forced flexion-rotation of the head. Results of the study indicated that the posterior plating system decreased motion significantly compared to the intact spine, specifically by a factor of 17 in flexion-extension and a factor of 5 units in torsion. Raftopoulos et al. (203) found that both posterior wiring and posterior plating resulted in significant stability following severe spinal destabilization, although posterior plating provided superior stability compared to that of interfacet wiring. Similar to the results of anterior plates, Gill et al. (204) found that bicortical lateral posterior plate screw fixation provided greater stability than unicortical fixation. However, Grubb et al. (151) found that unicortical fixation of a destabilized spine using a cervical rod device provided equivalent stability in torsion and lateral bending as bicortical fixation using an AO lateral mass plate. Effectiveness of 360° plating techniques for fusion.

As stated previously, both anterior and posterior plating procedures contain inherent difficulties and drawbacks. Some authors have examined the utilization of both techniques concomitantly to ensure adequate stabilization. Lim et al. (205) examined both anterior only, posterior only, and combined techniques *in vitro* to determine efficacy of these techniques in stabilizing either a C4-C5 flexion-distraction injury or an injury simulating a C5 burst fracture involving a C5 corpectomy. The AXIS and Orion plates were used for posterior and anterior stabilization, respectively. In the C4-C5 flexion-distraction injury, both posterior and combined fixation reduced motion significantly from intact in flexion. Only the combined procedure was able to reduce motion effectively in extension. In lateral bending and axial rotation, posterior fixation alone and combined fixation were able to significantly reduce motion compared to intact. In the C5 corpectomy model, all constructs exhibited significantly less motion compared to intact in flexion, although the combined fixation was the most rigid. In extension, all constructs except the posterior fixation with bone graft were able to reduce motion significantly compared to intact. In lateral bending, only the posterior fixation and combined fixation were able to provide enhanced stability compared to intact. In axial rotation, only the combined fixation was able to significantly reduce motion compared to intact. Thus, the authors concluded that combined fixation provided the most rigid

stability for both surgical cases tested. In a clinical study of multilevel anterior cervical reconstruction surgical techniques, Doh et al. (190) found a 0% pseudoarthrosis rate for the combined fixation system only.

Although combined fixation almost certainly allows for the most rigid fixation in most unstable cervical spine injuries, there are other factors to consider, such as the necessity for an additional surgery, possibility of severely reduced range of motion, and neck pain, Jonsson et al. (206) found a propensity for 22 out of 26 patients with combined fixation to have pain related to the posterior surgery. Additionally, patients with the combined fixation were found to have considerably restricted motion compared to normal. These and other factors must be weighed with the additional advantages of almost assured stability with the combined fixations.

Interbody Fusion Cage Stabilization for Fusion

Interbody fusion in the cervical spine has traditionally been accomplished via the anterior and posterior methods, incorporating the use of anterior or posterior plates, usually with the concomitant use of bone grafts. However, recently, interbody fusion cages using titanium mesh cages packed with morselized bone have been reported for use in the cervical spine. Majid et al. (163) performed channeled corpectomy on 34 patients, followed by insertion of a titanium cage implant packed with autogenous bone graft obtained from the vertebral bodies removed in the corpectomy. The authors then performed additional anterior plating on 30 of the 34 patients that involved decompression of two or more levels. Results of the study indicated a 97% radiographic arthrodesis rate in the patient population, with a 12% complication rate including pseudoarthrosis, extruded cage, cage in kyphosis, and radiculopathy. The authors concluded that titanium cages provide immediate anterior column stability and offer a safe alternative to autogenous bone grafts.

Two recent studies examined the biomechanics of anterior cervical interbody cages. Hacker et al. (207) conducted a randomized multicenter clinical trial looking at three different study cohorts of anterior cervical discectomy fusions: instrumented with HA-coated BAK-C, instrumented with noncoated BAK-C, and uninstrumented, bone graft only (ACDF) fusions. There were a total of 488 patients in the trial, with 288 included in the 1 year follow up and 140 in the 2 year follow up. There were 79.9% one-level fusions and 20.1% two-level fusions performed. Results showed no significant differences between the coated or noncoated BAK-C devices, leading the authors to combine these groups for analysis. Complication rate with the BAK-C group of 346 patients was 10.1% and the ACDF group of 142 patients demonstrated an overall complication rate of 16.2%. The fusion rates for the BAK-C and ACDF fusions at 12 months for one level were 98.7 and 86.4%, respectively; for two levels, 80.0 and 80.0%, respectively. The fusion rates for the BAK-C and ACDF fusions at 24 months for one level were 100 and 96.4%, respectively; for two levels, 91.7 and 77.8%, respectively. Overall, the authors found that the BAK-C cage performed comparably to conventional, uninstrumented, bone graft

only anterior discectomy and fusion. In an *in vitro* comparative study, Yang et al. (208) compared the initial stability and pullout strength of five different cervical cages and analyzed the effect of implant size, placement accuracy, and tightness of the implant on segmental stability. The cages analyzed included (1) SynCage-C Curved, (2) SynCage-C Wedged, (3) Brantigan I/F, (4) BAK-C, and (5) ACF Spacer. Overall, 35 cervical spines were used, with a total number of 59 segments selected for the study. Flexibility testing was performed under 50 N preload and up to 2 N·m in flexion, extension, lateral bending, and axial rotation. After quasistatic load tests were completed, the cages were subjected to an anterior pull-out test. Direct measurement on the specimen and biplanar radiographs allowed for quantification of distractive height, change in segmental lordosis, cage protrusion, and cage dimensions normalized to the endplate. Results from the study indicated that, in general, the cages were effective in reducing ROM in all directions by approximately one-third, but failed to reduce the neutral zone (NZ) in flexion/extension and axial rotation. Additionally, differences in implants were not significant and only existed between the threaded and nonthreaded designs. The threaded BAK-C was found to have the highest pullout force. Pullout force and lordotic change were both identified as significant predictors of segmental stability, a result the authors underscored as emphasizing the importance of a tight implant fit within the disk space.

RHAKOSS C synthetic bone spinal implant (Orthovita Inc., Malvern, PA) is trapezoidal in shape with an opening in the center for bone graft augmentation, and is fabricated from a bioactive glass/ceramic composite. *In vitro* testing conducted by Goel et al. (209) was conducted to evaluate the expulsion and stabilizing capabilities of the cervical cage in the lower cervical spine; C6/7 and C4/5 motion segments. from five of the spinal donors were used for the expulsion testing. All specimens received the "Narrow Lordotic" version of the Rhakoss C design. The cages were implanted by orthopedic surgeons following manufacturer recommendations. Specimens were tested in various modes; intact, destabilized with the cage in place, cage plus an anterior plate (Aline system, Surgical Dynamics Inc., Norwalk, CT), and again with the cage and plate after fatigue loading of 5000 flexion–extension cycles of 1.5 N·m. The results of the expulsion testing indicate that BMD and patient age are good predictors of implant migration resistance ($r = 0.8$). However, the high BMD/age correlation in the specimens makes it difficult to distinguish the relative importance of these two factors. The stability testing demonstrated the ability of a cage with a plate construct to sufficiently stabilize the cervical spine. However, BMD and specimen age play a major role in determining the overall performance of the cervical interbody cage.

Totribe (210) undertook a biomechanical comparison of a new cage made of a forged composite of unsintered-hydroxyapatite particles–poly-L-lactide (F-u-HA-PLLA) and the Ray threaded fusion cage. The objective was to compare the stability imparted to the human cadaveric spine by two different threaded cervical cages, and the effect of cyclic loading on construct stability. Threaded cages have been developed for use in anterior cervical

interbody fusions to provide initial stability during the fusion process. However, metallic instrumentation has several limitations. Recently, totally bioresorbable bone fixation devices made of F-u-HA/PLLA have been developed, including a cage for spinal interbody fusion. Twelve fresh ligamentous human cervical spines (C4-C7) were used. Following anterior discectomy across C5-C6 level, stabilization was achieved with the F-u-HA/PLLA cage in six spines and the Ray threaded fusion cage in the remaining six. Biomechanical testing of the spines was performed with six degrees of freedom before and after stabilization, and after cyclic loading of the stabilized spines (5000 cycles of flexion–extension at 0.5 N·m). The stabilized specimens (with F-u-HA/PLLA cage or the Ray cage) were significantly more stable than the discectomy case in all directions except in extension. In extension, both groups were stiffer, although not at a significant level ($P > 0.05$). Following fatigue, the stiffness, as compared to the pre-fatigue case, decreased in both groups, although not at a significant level. The Ray cage group exhibited better stability than the F-u-HA/PLLA cage group in all directions, although a significant difference was found only in right axial rotation.

Lumbar Spine

Anterior and Posterior Spinal Instrumentation. The stability analysis of devices with varying stiffness is best exemplified by a study of Gwon et al. (211) who tested three different transpedicular screw devices: spinal rod-transpedicular screw system (RTS), the Steffee System (VSP), and Crock device (CRK). All devices provided statistically significant ($P < 0.01$) motion reductions across the affected level (L4-L5). The differences among the three devices in reducing motion across L4-L5, however, were not significant. Also, the changes in motion patterns of segments adjacent to the stabilized level compared with the intact case were not statistically significant. These findings have been confirmed by Rohlmann and associates who used a finite element model to address several implant related issues, including this one (212).

In an *in vitro* study, Weinhoffer et al. (213) measured intradiskal pressure in lumbosacral cadaver specimens subjected to constant displacement before and after applying bilateral pedicle screw instrumentation across L4-S1. They noted that intradiskal pressure increased in the disk above the instrumented levels. Also, the adjacent level effect was confounded in two-level instrumentation compared with single-level instrumentation. Other investigators, in principle, have reported similar results. Completely opposite results, however, are presented by several others (212). Results based on *in vitro* studies must be interpreted with caution, being dependent on the testing mode chosen (displacement or load control) for experiments. In the displacement control-type studies, in which applied displacement is kept constant during testing of intact and stabilized specimens, higher displacements and related parameters (e.g., intradiskal pressure) at the adjacent segments are reported. This is not true for the results based on the load control-type studies, in which the applied loads are kept constant.

Lim et al., assessed the biomechanical advantages of diagonal transfixation compared to horizontal transfixation (214). Diagonal cross-members yielded more rigid fixation in flexion and extension, but less in lateral bending and axial rotational modes, as compared to horizontal cross-members. Furthermore, greater stresses in the pedicle screws were predicted for the system having diagonal cross members. The use of diagonal configuration of the transverse members in the posterior fixation systems did not offer any specific advantages, contrary to the common belief.

Biomechanical cadaver studies of anterior fusion promoting and stabilizing devices (214–217) have become increasingly more common in the literature, owing to this procedure's rising popularity (105). *In vitro* testing was performed using the T9-L3 segments of human cadaver spines (218). An L-1 corpectomy was performed, and stabilization was achieved using one of three anterior devices: the ATLP in nine spines, the SRK in 10, and the Z-plate in 10. Specimens were load tested. Testing was performed in the intact state, in spines stabilized with one of the three aforementioned devices after the devices had been fatigued to 5000 cycles at ± 3 N·m, and after bilateral facetectomy. There were no differences between the SRK- and Z-plate-instrumented spines in any state. In extension testing, the mean angular rotation (\pm standard deviation) of spines instrumented with the SRK ($4.7 \pm 3.2^\circ$) and Z-plate devices ($3.3 \pm 2.3^\circ$) was more rigid than that observed in the ATLP-stabilized spines ($9 \pm 4.8^\circ$). In flexion testing after induction of fatigue, however, only the SRK ($4.2 \pm 3.2^\circ$) was stiffer than the ATLP ($8.9 \pm 4.9^\circ$). Also, in extension post-fatigue, only the SRK ($2.4 \pm 3.4^\circ$) provided more rigid fixation than the ATLP ($6.4 \pm 2.9^\circ$). All three devices were equally unstable after bilateral facetectomy. The SRK and Z-plate anterior thoracolumbar implants were both more rigid than the ATLP, and of the former two the SRK was stiffer. The results suggest that in cases in which profile and ease of application are not of paramount importance, the SRK has an advantage over the other two tested implants in achieving rigid fixation immediately post-operatively.

Vahldiek and Panjabi investigated the biomechanical characteristics of short-segment anterior, posterior, and combined instrumentations in lumbar spine tumor vertebral body replacement surgery (219). The L2 vertebral body was resected and replaced by a carbon-fiber cage. Different fixation methods were applied across the L1 and L3 vertebrae. One anterior, two posterior, and two combined instrumentations were tested. The anterior instrumentation, after vertebral body replacement, showed greater motion than the intact spine, especially in axial torsion (range of motion, 10.3 vs. 5.5°; neutral zone, 2.9 vs. 0.7°; $P < 0.05$). Posterior instrumentation provided greater rigidity than the anterior instrumentation, especially in flexion–extension (range of motion, 2.1 vs. 12.6°; neutral zone, 0.6 vs. 6.1°; $P < 0.05$). The combined instrumentation provided superior rigidity in all directions compared with all other instrumentations. Posterior and combined instrumentations provided greater rigidity than anterior instrumentation. Anterior instrumentation should not be used alone in vertebral body replacement.

Oda et al. nondestructively compared three types of anterior thoracolumbar multisegmental fixation with the objective to investigate the effects of rod diameter and rod number on construct stiffness and rod–screw strain (220). Three types of anterior fixation were then performed at L1–L4: (1) 4.75 mm diameter single rod, (2) 4.75 mm dual-rod, and (3) 6.35 mm single-rod systems. A carbon fiber cage was used for restoring intervertebral disk space. Single screws at each vertebra were used for single-rod and two screws for dual-rod fixation. The 6.35 mm single-rod fixation significantly improved construct stiffness compared with the 4.75 mm single rod fixation only under torsion ($P < 0.05$). The 4.75 mm dual rod construct resulted in significantly higher stiffness than did both single-rod fixations ($P < 0.05$), except under compression. For single-rod fixation, increased rod diameter neither markedly improved construct stiffness nor affected rod–screw strain, indicating the limitations of a single-rod system. In thoracolumbar anterior multisegmental instrumentation, the dual-rod fixation provided higher construct stiffness and less rod–screw strain compared with single-rod fixation.

Lumbar Interbody Cages. Cage related biomechanical studies range from evaluations of cages as stand alone devices to use of anterior or posterior instrumentation for additional stabilization. The changes in stiffness and disk height of porcine FSUs by installation of a threaded interbody fusion cage and those by gradual resection of the annulus fibrosus were quantified (117). Flexion, extension, bending, and torsion testing of the FSUs were performed in four sequential stages: stage I, intact FSU; stage II, the FSUs were fitted with a threaded fusion cage; stage III, the FSUs were fitted with a threaded fusion cage with the anterior one-third of the annulus fibrosus excised, including excision of the anterior longitudinal ligament; and stage IV, in addition to stage III, the bilateral annulus fibrosus was excised. Segmental stiffness in each loading in the four stages and a change of disk height induced by the instrumentation were measured. After instrumentation, stiffness in all loading modes ($p < 0.005$) and disk height ($p = 0.002$) increased significantly. The stiffness of FSUs fixed by the cage decreased with gradual excision of the annulus fibrosus in flexion, extension, and bending. These results suggest that distraction of the annulus fibrosus and posterior ligamentous structures by installation of the cage increases the soft-tissue tension, resulting in compression to the cage and a stiffer motion segment. This study explains the basic mechanism through which the cages may provide the stability in various loading modes.

Three posterior lumbar interbody fusion implant constructs (Ray Threaded Fusion Cage, Contact Fusion Cage, and PLIF Allograft Spacer) were tested for stability in a cadaver model (221). None of the standalone implant constructs reduced the neutral zone (amount of motion in response to minimal load application). The constructs decreased the range of motion in flexion and lateral bending. The data did not suggest any implant construct to behave superiorly. Specifically, the PLIF Allograft Spacer is biomechanically equivalent to titanium cages and is devoid of the deficiencies associated with metal cages. Therefore, the PLIF Allograft Spacer is a valid alternative to conventional cages.

The lateral, and other cage orientations within the disk have been increasingly used for fusion (222). In one study, 14 spines were randomized into the anterior group (anterior discectomy and dual anterior cage—TFC placement) and the lateral group (lateral discectomy and single transverse cage placement) for load-displacement evaluations. Segmental ranges of motion were similar between spines undergoing either anterior or lateral cage implantation. Combined with a decreased risk of adjacent structure injury through a lateral approach, these data support a lateral approach for lumbar interbody fusion. When used alone to restore stability, the orientation of the cage (oblique vs. posterior) effected the outcome (223). Likewise, in flexion, both the OBAK (Oblique placement of one cage) and CBAK (Conventional posterior placement of two cages) orientations provided significant stability. In lateral bending, CBAK orientation was found to be better than OBAK. In axial mode, CBAK orientation was significantly effective in both directions while OBAK was effective only in right axial rotation. Owing to the differences in the surgical approach and the amount of dissection, the stability for the cages when used alone as a function of cage orientation was different.

The high elastic modulus of the cages causes the structures to be very stiff and may lead to stress-shielded environments within the devices with potential adverse effect on growth of the cancellous bone within the cage itself (224). Using a calf spine model, a study was designed to compare the construct stiffness afforded by 11 differently designed anterior lumbar interbody fusion devices: four different threaded fusion cages: (BAK device, BAK Proximity, Ray TFC, and Danek TIBFD); five different nonthreaded fusion devices (oval and circular Harms cages, Brantigan PLIF and ALIF cages, and InFix device); two different types of allograft (femoral ring and bone dowel); and to quantify their stress-shielding effects by measuring pressure within the devices. Prior to testing, a silicon elastomer was injected into the cages and intra cage pressures were measured using pressure needle transducers. No statistical differences were observed in construct stiffness among the threaded cages and nonthreaded devices in most of the testing modalities. Threaded fusion cages demonstrated significantly lower intracage pressures compared with nonthreaded cages and structural allografts. Compared with nonthreaded cages and structural allografts, threaded fusion cages afforded equivalent reconstruction stiffness but provided more stress-shielded environment within the devices. (This stress shielding effect may further increase in the presence of supplementary fixation devices.)

It is known that micromotion at the cage–endplate interface can influence bone growth into its pores. Loading conditions, mechanical properties of the materials, friction coefficients at the interfaces, and geometry of spinal segments would affect relative micromotion and spinal stability. In particular, relative micromotion is related closely to friction at bone–implant interfaces after arthroplasty. A high rate of pseudarthrosis and a high overall rate of implant migration requiring surgical revision has been reported following posterior lumbar interbody fusion using BAK threaded cages (225). This may be due to poor fixation

of the implant, in addition to the stress shielding phenomena described above. Thus, Kim developed an experimentally validated finite element model of an intact FSU and the FSU implanted with two threaded cages to analyze the motion of threaded cages in posterior lumbar interbody fusion (226). Motion of the implants was not seen in compression. In torsion, a rolling motion was noted, with a range of motion of 10.6° around the central axis of the implant when left–right torsion (25 N·m) was applied. The way the implants move within the segment may be due to their special shape: the thread of the implants cannot prevent the BAK cages rolling within the disk space. However, note that the authors considered too high a value of torsional load; such values may not be clinically relevant. Relative micromotion (slip distance) at the interfaces was obvious at their edges under axial compression. The slip occurred primarily at the anterior edges under torsion with preload, whereas it occurred primarily at the edges of the left cage under lateral bending with preload. Relative micromotion at the interfaces increased significantly as the apparent density of cancellous bone or the friction coefficient of the interfaces decreased. A significant increase in slip distance at the anterior annulus occurred with an addition of torsion to the compressive preload. Relative micromotion was sensitive to the friction coefficient of the interfaces, the bone density, and the loading conditions. A reduction in age-related bone density was less likely to allow bone growth into surface pores of the cage. It was likely that the larger the disk area the more stable the interbody fusion of the spinal segments. However, the amount of micromotion may change in the presence of a posterior fixation technique, an issue that was not reported by the authors.

Almost every biomechanical study has shown that interbody cages alone, irrespective of their shapes, sizes, surface type, material, and approach used for implantation, does not stabilize the spine in all of the modes. It is suspected that this may be caused by the destruction of the appropriate spinal elements like the anterior longitudinal ligament, and anterior annulus fibrosus, or facets. Thus, use of additional instrumentation to augment cages seems to have become a standard procedure.

The 3D flexibility in ligamentous human lumbar spinal units have been investigated after the anterior, anterolateral, posterior, or oblique insertion of various types of interbody cages with supplemental fixation using anterior or posterior spinal instrumentation (227). With the supplementary fixation using transfacet screws, the differences in stability due to the orientations were not noticeable at all, both before and after; underscoring the importance of using instrumentation when cages are used.

Patwardhan et al. (228) tested the hypothesis that the ability of the ALIF cages to reduce the segmental motions in flexion and extension will be significantly affected by the magnitude of the compressive preload. Fourteen human lumbar spine specimens (L1–sacrum) were tested intact, and after insertion of two threaded cylindrical cages at L5–S1. They were tested in flexion–extension with progressively increasing magnitude of compressive preload from 0 to 1200 N applied along the follower load path (described earlier). The stability of the stand-alone cage construct was

significantly affected by the amount of compressive preload applied across the operated segment. In contrast to the extension instability reported in the literature, the two-cage construct exerted a stabilizing effect on the motion segment (reduction in segmental motion) in extension under physiologic compressive preloads. The cages provided substantially more stability, both in flexion and in extension, at larger preloads (800–1200 N) corresponding to standing and walking activities as compared to the smaller preloads (200–400 N) experienced during supine and recumbent postures. The compressive preload due to muscle activity likely plays a substantial role in stabilizing the segment with interbody cages.

The function of the interbody fusion cages is to stabilize the spinal segment primarily by distracting them as well as allowing bone ingrowth and fusion (122). An important condition for efficient formation of bone tissue is achieving adequate spinal stability. However, the initial stability may be reduced due to repeated movements of the spine during activities of daily living. Before and directly after implantation of a Zientek, Stryker, or Ray posterior lumbar interbody fusion cage, 24 lumbar spine segments were evaluated for stability analyses. The specimens were then loaded cyclically for 40,000 cycles at 5 Hz with an axial compression load ranging from 200 to 1000 N. The specimens were tested again in the spine tester. Generally, a decrease in motion in all loading modes was noted after insertion of the Zientek and Ray cages and an increase after implantation of a Stryker cage. In all three groups, greater stability was demonstrated in lateral bending and flexion then in extension and axial rotation. Reduced stability during cyclic loading was observed in all three groups; however, loss of stability was most pronounced in Ray cage group. Authors felt that this may be due to the damage of the cage: bone interface during cyclic loading that was not the case for the other two since they have a flat brick type interface. In order to reduce the incidence of stress risers at the bone–implant interface, it is essential that interbody fusion implants take advantage of the cortical periphery of the vertebral endplates. A larger cross-sectional footprint to the implant design will aid in dispersing the axial forces of spinal motion over a larger surface area and minimize the risk of stress risers, which may result in endplate fractures.

Animal Models

An approximation of the *in vivo* performance of spinal implants in humans can be attained by evaluation in animal models (229). Specifically, animal models provide a dynamic biologic and mechanical environment in which the implant can be evaluated. Temporal changes in both the host biologic tissue and instrumentation can be assessed with selective incremental sacrificing of the animals. Common limitations of animal studies include the method of loading (quadruped versus biped) and the size adjustment of devices needed such that proper fit is achieved in the animals.

Animal studies have revealed the fixation benefits of grouting materials in the preparation of the screw hole (230). The major findings were that the HA grouting of

the screw hole bed before insertion significantly increased fixation (pullout) of the screws. Scanning electron microscopy analysis revealed that HA plasma spraying had deleterious effects on the screw geometry, dulling the self-tapping portion of the screw and reducing available space for bony in-growth.

An animal model of anterior and posterior column instability was developed by McAfee et al. (231–233) to allow *in vivo* observation of bone remodeling and arthrodesis after spinal instrumentation. An initial anterior and posterior destabilizing lesion was created at the L5–6 vertebral levels in 63 adult Beagle dogs. Observations 6 months after surgery revealed a significantly improved probability of achieving a spinal fusion if spinal instrumentation had been used. Nondestructive mechanical testing after removal of all metal instrumentation in torsion, axial compression, and flexion revealed that the fusions performed in conjunction with spinal instrumentation were more rigid. Quantitative histomorphometry showed that the volumetric density of bone was significantly lower (i.e., device-related osteoporosis occurred) for fused versus unfused spines. In addition, a linear correlation occurred between decreasing volumetric density of bone and increasing rigidity of the spinal implant; device-related osteoporosis occurred secondary to Harrington, Cotrel-Dubousset, and Steffee pedicular instrumentation. However, the stress-induced changes in the bone quality found in the animal models is not likely to correlate well with the actual changes in the spinal segment of a patient. In fact, it is suggested that the degeneration in a patient may be determined more by individual characteristics than by the fusion itself (234).

In long bone fractures, internal fixation improves the union rate, but does not accelerate the healing process. Spinal instrumentation also improves the fusion rate in spinal arthrodesis. However, it remains unclear whether the use of spinal instrumentation expedites the healing process of spinal fusion (235,236). Accordingly, an *in vivo* sheep model was used to investigate the effect of spinal instrumentation on the healing process of posterolateral spinal fusion. Sixteen sheep underwent posterolateral spinal arthrodeses at L2-L3 and L4-L5 using equal amounts of autologous bone. One of those segments was selected randomly for further augmentation with transpedicular screw fixation (Texas Scottish Rite Hospital spinal system). The animals were killed at 8 or 16 weeks after surgery. Fusion status was evaluated through biomechanical testing, manual palpation, plain radiography, computed tomography, and histology. Instrumented fusion segments demonstrated significantly higher stiffness than did uninstrumented fusions at 8 weeks after surgery. Radiographic assessment and manual palpation showed that the use of spinal instrumentation improved the fusion rate at 8 weeks (47 vs. 38% in radiographs, 86 vs. 57% in manual palpation). Histologically, the instrumented fusions consisted of more woven bone than the uninstrumented fusions at 8 weeks after surgery. The 16-week-old fusion mass was diagnosed biomechanically, radiographically, and histologically as solid, regardless of pedicle screw augmentation. The results demonstrated that spinal instrumentation created a stable mechanical environment to enhance the early bone healing of spinal fusion.

Human Clinical Models

Loads in posterior implants were measured in 10 patients using telemeterized internal spinal fixation devices (237–239). Implant loads were determined in up to 20 measuring sessions for different activities, including walking, standing, sitting, lying in the supine position, and lifting an extended leg while in the supine position. Implant loads often increased shortly after anterior interbody fusion was performed. Several patients retained the same high level even after fusion had taken place. This explains the reason why screw breakage sometimes occurs more than half a year after implantation. The time of fusion could not be pinpointed from the loading curves. A flexion bending moment acted on the implant even when the body was in a relaxed lying position. This meant that already shortly after the anterior procedure, the shape of the spine was not neutral and unloaded, but slightly deformed, which loaded the fixators. In another study, the same authors used the telemeterized internal spinal fixation devices to study the influence of muscle forces on the implant loads in three patients before and after anterior interbody fusion. Contracting abdominal or back muscles in a lying position was found to significantly increase implant loads. Hanging by the hands from wall bars as well as balancing with the hands on parallel bars reduced the implant loads compared with standing; however, hanging by the feet with the head upside down did not reduce implant loads, compared with lying in a supine position. When lying on an operating table with only the foot end lowered so that the hips were bent, the patient had different load measurements in the conscious and anesthetized states before anterior interbody fusion. The anesthetized patient evidenced predominately extension moments in both fixators, whereas flexion moments were observed in the right fixator of the conscious patient. After anterior interbody fusion had occurred, the differences in implant loads resulting from anesthesia were small. The muscles greatly influence implant loads. They prevent an axial tensile load on the spine when part of the body weight is pulling, for example, when the patient is hanging by their hands or feet. The implant loads may be strongly altered when the patient is under anesthesia.

The above review clearly shows that a large number of fusion enhancement instrumentation are available to surgeons. However, none of the instrumentation is totally satisfactory in its performance and there is room to improve the rate of fusion success, if fusion is the goal. Naturally, alternative fusion approaches (mechanical, biological) are currently being pursued.

The rigidity of a spinal fixation device and its ability to share load with the fusion mass are considered essential for the fusion to occur. If the load transferred through the fusion mass, is increased without sacrificing the rigidity of the construct, a more favorable environment for fusion may be created. To achieve this objective, posterior as well as anterior “dynamized” systems have been designed (240–242). One such posterior system consists of rods and pedicle screws and has a *hinged* connection between the screw head and shaft compared with the rigid screws (Fig. 16a). Another example of the dynamized anterior system (ALC) is shown in Fig. 16b. Load-displacement

(a)

(b)

Figure 16. The two different types of dynamized systems used in a cadaver model to assess their stability characteristics. The data were compared with the corresponding “rigid” systems. (a) Posterior system and (b) anterior system. (Taken from Refs. 242 and 241.)

tests were performed to assess the efficacy of these devices in stabilizing a severely destabilized spinal segment. The hinged and rigid posterior systems provided significant stability across the L2-L4 segment in flexion, extension, and lateral bending as compared with the intact case ($P < 0.5$). The stabilities imparted by the hinged-type and its alternative rigid devices were of similar magnitudes. The ALC dynamized and rigid anterior systems also provided significant stability across the L3-L5 segment in flexion, extension, and lateral bending ($P < 0.5$). The stability imparted by the Dynamized ALC and its alternate rigid system did not differ significantly.

Dynamic stabilization may provide an alternative to fusion for patients suffering from early degenerative disk disease (DDD). The advantages of using a dynamic system are, preservation of the disk loading, allowing some physiologic load sharing in the motion segment. A finite element (FE) study was done to understand the effect of a commercially available dynamic system (DYNESYS, Zimmer Spine) compared to a rigid system on the ROM and disk stresses at the instrumented level (243). An experimentally validated 3-D FE model of intact L3-S1 spine was modified to simulate rigid and dynamic systems across L4-L5 level with the disk intact. The DYNESYS spacer and ligament were modeled with truss elements, with the “no tension” and “no compression” options, respectively. The ROM and disk stresses in response to a 400 N axial compression and 10.6-N·m flexion–extension moment were calculated. The ROM and disk stresses of the adjacent levels with rigid and DYNESYS systems had no significant change when compared to the intact. At the instrumented level in flexion–extension the decrease in motion when

compared to the intact was 68/84% for rigid system and 50/56% for DYNESYS. The peak Von Mises disk stresses at the instrumented segment reduced by 41/80% for the rigid system, 27/45% for the DYNESYS system for flexion–extension loading condition. The predicted motion data for the dynamic system was in agreement with the experimental data. From the FE study it can be seen that the DYNESYS system allows more motion than the rigid screw-rod system, and hence allows for partial disk loading. This partial disk loading might be advantageous for a potential recovery of the degenerated disk, thus making dynamic stabilization systems a viable option for patients in early stages of DDD.

An anterior bone graft in combination with posterior instrumentation has been shown to provide superior support because the graft is in line with axial loads and the posterior elements are left intact. However, employing posterior instrumentation with anterior grafting requires execution of two surgical procedures. Furthermore, use of a posterior approach to place an interbody graft requires considerable compromise of the posterior elements, although it reduces the surgery time. It would be advantageous to minimize surgical labor and structural damage caused by graft insertion into the disk space via a posterior approach. Authors have addressed this issue by preparing an interbody bone graft using morselized bone (244–246). This device is a gauze bag of Dacron that is inserted into the disk space, filled with morselized bone, and tied shut, Fig. 17. *In vitro* testing measured the rotations of each vertebral level of mechanically loaded cadaver lumbar spines, both in intact and several experimental conditions. With the tension band alone, motion was restored to the

Figure 17. The Bag system developed by Spineology Inc. The increases and decreases in motion with respect to intact segment for bag alone and bag with a band are also shown. (Taken from Ref. 244.)

intact case, except in extension where it was reduced. With the graft implant, motion was restored to intact in all of the loading modes, except in flexion where it was reduced. With the tension band and graft, motion was again restored to intact except in flexion and extension where it was reduced. *In vitro* results suggest that a tension band increases stability in extension, while the bag device alone seems to provide increased stability in flexion. The implanted bag filled with morselized bone in combination with a posterior tension band, restores intact stiffness. Postcyclic results in axial compression suggest that the morselized bone in the bone-only specimens either consolidates or extrudes from the cavity despite confinement. Motion restoration or reduction as tested here is relevant both to graft incorporation and segment biomechanics. The posterior interbody grafting method using morselized bone is amenable to orthoscopy. It produces an interbody graft without an anterior surgical approach. In addition, this technique greatly reduces surgical exposure with minimal blood loss and no facet compromise. This technique would be a viable alternative to current 360° techniques pending animal tests and clinical trials.

Bone grafting is used to augment bone healing and provide stability after spinal surgery. Autologous bone graft is limited in quantity and unfortunately associated with increased surgical time and donor-site morbidity. Recent research has provided insight into methods that may modulate the bone healing process at the cellular level in addition to reversing the effects of symptomatic disk degeneration, which is a potentially disabling condition, managed frequently with various fusion procedures. Alternatives to autologous bone graft include allograft bone, demineralized bone matrix, recombinant growth factors, and synthetic implants (247,248). Each of these alternatives could possibly be combined with autologous bone marrow or various growth factors. Although none of the presently available substitutes provides all three of the fundamental properties of autograft bone (osteogeneticity,

osteoconductivity, and osteoinductivity), there are a number of situations in which they have proven clinically useful. A literature review indicates that alternatives to autogenous bone grafting find their greatest appeal when autograft bone is limited in supply or when acceptable rates of fusion may be achieved with these substitutes. For example, bone morphogenetic proteins have been shown to induce bone formation and repair.

Relatively little research has been undertaken to investigate the efficacy of OP-1 in the above stated role (249,250). Grauer et al. performed single-level intertransverse process lumbar fusions at L5-L6 of 31 New Zealand White rabbits. These were divided into three study groups: autograft, carrier alone, and carrier with OP-1. The animals were killed 5 weeks after surgery. Five (63%) of the 8 in the autograft group had fusion detected by manual palpation, none (0%) of the 8 in the carrier-alone group had fusion, and all 8 (100%) in the OP-1 group had fusion. Biomechanical testing results correlated well with those of manual palpation. Histologically, autograft specimens were predominantly fibrocartilage, OP-1 specimens were predominantly maturing bone, and carrier-alone specimens did not show significant bone formation. OP-1 was found to reliably induce solid intertransverse process fusion in a rabbit model at 5 weeks. Smoking interferes with the success of posterolateral lumbar fusion and the above authors extended the investigation to study the effect of using OP-1 to enhance fusion process in patients who smoke. Osteoinductive protein-1 was able to overcome the inhibitory effects of nicotine in a rabbit posterolateral spine fusion model, and to induce bony fusion reliably at 5 weeks.

Finally, another study performed a systematic literature review on non-autologous interbody fusion materials in anterior cervical fusion, gathering data from 32 clinical- and ten laboratory studies. Ten alternatives to autologous bone were compared: autograft, allograft, xenograft, poly(methyl methacrylate) (PMMA), biocompatible osteoconductive polymer (BOP), Hydroxyapatite compounds, bone

morphogenic protein (BMP), Carbon fiber, metallic devices and ceramics. The study revealed that autologous bone still provides the golden standard that other methods should be compared to. The team concluded that the results of the various alternative fusion options are mixed, and comparing the different methods proved difficult. Once a testing standard has been established, reliable comparisons could be conducted.

Finite Element Models

In vitro investigations and *in vivo* animal studies contain numerous limitations, including that these are both time consuming and monetarily expensive. The most important limitations of *in vitro* studies are that muscle contributions to loading are not usually incorporated and the highly variable quality of the cadaver specimens. As stated earlier, *in vivo* animal studies usually involve quadruped animals, and the implant sizes usually need to be scaled according to the animal size. In an attempt to compliment the above protocols, several FE models of the ligamentous spine have been developed (251–257).

Goel et al. (255) generated osteoligamentous FE models of intact lumbar one segment (L3-L4) and two segments (L3-L5). Using the L3-L4 model, they simulated fusion with numerous techniques in an attempt to describe the magnitude and position of internal stresses in both the biologic tissue (bone and ligament) and applied hardware. Specifically, the authors modeled bilateral fusion using unilateral and bilateral plating. Bilateral plating models showed that cancellous bone stresses were significantly reduced with the instrumentation simulated in the immediate postoperative period. Completely consolidated fusion mass case, load transmission led to unloading of the cancellous bone region, even after simulated removal of the device. Thus, this model predicted that removal of the device would not alleviate stress shielding-induced osteopenia of the bone and that this phenomenon may truly be a complication of the fusion itself. As would be expected, unilateral plating models revealed higher trabecular bone stresses than were seen in the bilateral plating cases. The degree of stability afforded to the affected segment, however, was less. Thus, a system that allows the bone to bear more load as fusion proceeds may be warranted. Several solutions have been proposed to address this question.

For example, a fixation system was developed that incorporated polymer washers in the load train (Steffee variable screw placement, VSP). The system afforded immediate postoperative stability and reduced stiffness with time as the washers underwent stress relaxation (a viscoelastic effect) (256). The FE modeling of this system immediately after implantation showed that internal bony stresses were increased by ~20% over the same system without the polymeric material. In addition, mechanical property manipulation of the washers simulating their *in vivo* stress relaxation revealed these stresses were continuously increasing, promoting the likelihood that decreased bone resorption would occur. The other solution is the use of dynamized fixation devices, as discussed next.

The ability of a hinged pedicle screw-rod fixation (dynamized, see next section for details) device to transmit more

loads across the stabilized segment compared with its rigid equivalent system was predicted using the FE models (240). In general, the hinged screw device allowed for slightly larger axial displacements of L3, while it maintained flexion rotational stability similar to the rigid screw device (Table 11). Slightly larger axial displacements may be sufficient enough to increase the load through the graft since the stiffness of the disk was increased by replacing it (shown as the “nucleus” in the tables) with a cancellous, cortical, or titanium interbody device to simulate the fusion mass in the model (Table 12).

The FE modeling coupled with adaptive bone remodeling algorithms has been used to investigate temporal changes associated with interbody fusion devices. Grossland et al. predicted the change in bone density distribution after implantation of the BAK device (Fig. 18) (257). The major findings included hypertrophy of bone directly in the load train (directly overlying and underlying the implant) and lateral atrophy secondary to the relatively high stiffness of the implant. The model also predicted that bone growth into and around the larger holes in the implant, resulting in sound fixation of the device.

Nonfusion Treatment Alternatives

Various methods have been employed in the characterization of device effectiveness for which spinal fusion is indicated. Because of nonphysiological nature of fusing the spinal segments that are supposed to provide motion-flexibility, adjacent-level degeneration, and other complications associated with the fusion process, alternatives to fusion have been proposed.

Ray Nucleus

In 1988, Ray presented a prosthetic nuclear replacement consisting of flexible woven filaments (Dacron) surrounding an internal semipermeable polyethylene membranous sac filled with hyaluronic acid and a thixotropic agent (i.e.,

Alc= anterior longitudinal ligament completely removed/cut, Alp= partially cut, and Ali= intact; and (b) Percentage change in density of the bone surrounding the BAK cage. (Taken from Refs. 32,33, and 257.)

a hydrogel) (244,258,259). As a nucleus replacement, the implant can be inserted similar to a thoracolumbar interbody fusion device, either posteriorly or transversely. Two are inserted per disk level in a partly collapsed and dehydrated state, but would swell due to the strongly hygroscopic properties of the hyaluronic acid constituent. The designer expects the implant to swell enough to distract the segment while retain enough flexibility to allow a normal range of motion. An option is to include therapeutic agents in the gel that would be released by water flow in and out of the prosthesis according to external pressures.

Recent reports on biomechanical tests of the device show that it can produce some degree of stabilization and distraction. Loads of 7.5 N·m and 200 N axial were applied to six L4-L5 specimens. Nucleotomized spines increased rotations by 12–18% depending on load orientation, but implanted spines (implant placed transversely) showed a change of –12% to +2% from the intact with substantial reductions in neutral zone. Up to 2 mm of disk height was recovered by insertion. The implant, however, was implanted and tested in its no hydrated form. The biomechanics of the hydrated prosthesis may vary considerably from that of its desiccated form.

In Situ Curable Prosthetic Intervertebral Nucleus (PIN)

The device (Disc Dynamics, Inc, Minnetonka, MN) consists of a compliant balloon connected to a catheter (Fig. 19) (244,260). This is inserted and a liquid polymer injected into the balloon under controlled pressure inflating the balloon, filling the cavity, and distracting the interverteb-

ral disk. Within 5 min the polymer is cured. Five fresh-frozen osteoligamentous three-segment human lumbar spines, screened for abnormal radiograph and low bone density, were used for the biomechanical study. The spines were tested under four conditions: intact, denucleated, implanted, and fatigued. Fatiguing was produced by cyclic loading from 250 to 750 N at 2 Hz for at least 100,000 cycles. Nuclectomy was performed through a 5.5 mm trephine hole in the right middle lateral side of the annulus. The device was placed in the nuclear cavity as described earlier. Following biomechanical tests, these specimens were radiographed and dissected to determine any structural damage inflicted during testing. Middle segment rotations generally increased with diskectomy, but were restored to the normal intact range with implantation. After fatiguing, rotations across the implanted segment increased. However, these were not more than, and often less than the intact adjacent segments. During polymer injection under compressive load the segment distracted as much as +1.8 mm (av) at the disk center as determined by the surrounding gauges. Over 1.6 mm was maintained during polymer cure with compression. The immediate goals of a disk replacement system are to restore disk height and provide segment mobility without causing instability. This study showed that PIN device could reverse the destabilizing effects of a nuclectomy and restore normal segment stiffness. Significant increases in disk height can also be achieved. Implanting the majority of disk replacement systems requires significant annulus removal, this device requires minimal surgical compromise and has the potential to be performed arthroscopically.

Figure 19. In situ curable prosthetic intervertebral nucleus (PIN) developed by Disc Dynamics, Inc. (Taken from Ref. 244.)

Artificial Disk

One of the most recent developments for nonfusion treatment alternatives is replacement of the intervertebral disk (244,261,262). The goal of this treatment alternative is to restore the original mechanical function of the resected disk. One of the stipulations of artificial disk replacement is that the remaining osseous spinal and paraspinal soft tissue components are not compromised by pathologic changes. Bao et al. (263) have classified the designs of total disk replacements into four categories: (1) low friction sliding surface; (2) spring and hinge systems; (3) contained fluid-filled chambers; and (4) disks of rubber and other elastomers. The former two designs seek to take advantage of the inherently high fatigue characteristics that all-metal designs afford. The latter two designs attempt to incorporate some of the viscoelastic and compliant properties that are exhibited by the normal, healthy intervertebral disk. Hedman et al. (264) outlined the major design criteria for intervertebral disk prosthesis: The disk must be able to maintain its mechanical integrity out to approximately 85 million cycles; consist of biocompatible materials; exist entirely within the normal disk space and maintain physiologic disk height; restore normal kinematic motion wherein the axes of each motion, especially sagittal plane motion, is correctly replicated; duplicate the intact disk stiffness in all three planes of rotation and compression; provide immediate and long-term fixation to bone; and, finally, provide *failsafe* mechanisms such that if an individual component of the design fails, catastrophic failure is not immediately imminent, and it does not lead to peri-implant soft tissue damage. This is certainly one of the greatest design challenges that bioengineers have encountered to date. In the following, some of the methods are discussed that are being employed in an attempt to meet this rigorous challenge.

One of the available studies dealt iterative design of the artificial disk replacement based on measured biomechanical properties. Lee, Langrana and co-workers (265,266) looked at incorporating three different polymers into their prosthetic intervertebral disk design and tried to represent the separate components (annulus fibrosis and nucleus) of the normal disk in varying proportion. They loaded their designs under 800 N axial compression and in compression-torsion out to 5°. The results indicated that disks fabricated from homogeneous materials exhibited isotropy that could not replicate the anisotropic behavior of the normal human disk. Thus, 12 layers of fiber reinforcement were incorporated in an attempt to mimic the actual annulus fibrosis. This method did result in more closely approximating the mechanical properties of the normal disk. Through this method of redesign and testing, authors claim that eventually “a disk prosthesis that has mechanical properties comparable to the natural disk could be manufactured.”

The FE analyses have also been recruited in an effort to perturbate design with an eye toward optimizing the mechanical behavior of artificial disks. Goel and associates modified a previously validated intact finite element model to create models implanted with a ball-and-cup and slip core-type artificial disk models via an anterior approach, Figs. 20 and 21 (244,245,261). To study surgical variables, small and large windows were cut into the annulus, and the implants were placed anteriorly and posteriorly within the disk space. The anterior longitudinal ligament was also restored. Models were subjected to either 800 N axial compression force alone or to a combination of 10 N·m flexion–extension moments and 400 N axial preload. Implanted model predictions were compared with those of the intact model. The predicted rotations for the two disk implanted models were in agreement with the experimental data.

Figure 20. The intact finite element model of a ligamentous segment was modified to simulate the ball and socket type artificial disk implant. (Taken from Refs. 244,245.)

For the ball and socket design disk facet loads were more sensitive to the anteroposterior location of the artificial disk than to the amount of annulus removed. Under 800-N axial compression, implanted models with an anteriorly placed artificial disk exhibited facet loads 2.5 times greater than loads observed with the intact model, whereas posteriorly implanted models predicted no facet loads in compression. Implanted models with a posteriorly placed disk exhibited greater flexibility than the intact and implanted models with anteriorly placed disks. Restoration of the anterior longitudinal ligament reduced pedicle stresses, facet loads, and extension rotation to nearly intact levels. The models suggest that, by altering placement of the artificial disk in the anteroposterior direction, a surgeon can modulate motion-segment flexural stiffness and posterior load sharing, even though the specific disk replacement design has no inherent rotational stiffness.

The motion data, as expected, differed between the two disk designs (ball and socket, and slip core) and as compared to the intact as well, Fig. 22. Similar changes were observed for the loads on the facets, Fig. 23.

The experimentally validated finite element models of the intact and disk implanted L3-L5 segments revealed that both of these devices do not restore motion and loads across facets back to the intact case. (These design restore the intact biomechanics in a limited sense.) These differences are not only due to the size of the implants but the inherent design differences. Ball and socket design has a more “fixed” center of rotation as compared to the slip core design in which the COR undergoes a wider variation. Further complicating factor is the location of the disk within the annular space itself, a parameter under the control of the surgeon. Thus, it will be difficult to restore biomechanics of the segment back to normal using such designs. Only clinical follow up studies will provide the effects of such variations on the changes in spinal structures as a function of time.

More Recent and Future Initiatives

Although many of the well-accepted investigation techniques and devices have been discussed above, other

Figure 21. The intact finite element model of a ligamentous segment was modified to simulate the slip core type artificial disk implant. (Taken from Ref. 244.)

Figure 22. Predicted rotations for the two disk designs, shown in Figs. 20 and 21, as compared to the intact. (Taken from Ref. 244.)

techniques for the stabilization–fusion of the spine and nonfusion approaches are currently being investigated. These concepts are likely to play a significant role in future and are discussed. One such technique is vertebroplasty. Painful vertebral osteoporotic compression fractures leads to significant morbidity and mortality (263). Kyphoplasty and vertebroplasty are relatively new techniques that help decrease the pain and improve function in fractured vertebrae.

Vertebroplasty is the percutaneous injection of PMMA cement into the vertebral body (263–269). While PMMA has high mechanical strength, it cures fast and thus allows only a short handling time. Other potential problems of using PMMA injection may include damage to surrounding tissues by a high polymerization temperature or by the unreacted toxic monomer, and the lack of long-term biocompatibility. Bone mineral cements, such as calcium carbonate and CaP, have longer working time and low thermal effect. They are also biodegradable while having

a good mechanical strength. However, the viscosity of injectable mineral cements is high, and the infiltration of these cements into vertebral body has been questioned. Lim et al. evaluated the compression strength of human vertebral bodies injected with a new calcium phosphate (CaP) cement with improved infiltration properties before compression fracture and also for vertebroplasty in comparison with PMMA injection (268). The bone mineral densities of 30 vertebral bodies (T2–L1) were measured using dual-energy X-ray absorptiometry. Ten control specimens were compressed at a loading rate of 15 mm/min to 50% of their original height. The other specimens had 6 mL of PMMA ($n = 10$) or the new CaP ($n = 10$) cement injected through the bilateral pedicle approach before being loaded in compression. Additionally, after the control specimens had been compressed, they were injected with either CaP ($n = 5$) or PMMA ($n = 5$) cement using the same technique, to simulate vertebroplasty. Loading experiments were repeated with the displacement control of 50% vertebral

Figure 23. Predicted facet loads for the two disk designs, shown in Figs. 20 and 21, as compared to the intact. (Taken from Ref. 244.)

height. Load to failure was compared among groups and analyzed using analysis of variance. Mean bone mineral densities of all five groups were similar and ranged from 0.56 to 0.89 g · cm⁻². The size of the vertebral body and the amount of cement injected were similar in all groups. Load to failure values for PMMA, the new CaP, and vertebroplasty PMMA were significantly greater than that of control. Load to failure of the vertebroplasty CaP group was higher than control but not statistically significant. The mean stiffness of the vertebroplasty CaP group was significantly smaller than control, PMMA, and the new CaP groups. The mean height gains after injection of the new CaP and PMMA cements for vertebroplasty were minimal (3.56 and 2.01%, respectively). Results of this study demonstrated that the new CaP cement can be injected and infiltrates easily into the vertebral body. It was also found that injection of the new CaP cement can improve the strength of a fractured vertebral body to at least the level of its intact strength. Thus, the new CaP cement may be a good alternative to PMMA cement for vertebroplasty, although further *in vitro*, *in vivo* animal and clinical studies should be done. Furthermore, the new CaP may be more effective in augmenting the strength of osteoporotic vertebral bodies, and for preventing compression fractures considering our biomechanical testing data and the known potential for biodegradability of the new CaP cement. Belkof et al. (266) found that the injection of either Orthocomp or Simplex P resulted in vertebral body strengths that were significantly greater than initial strength values. Vertebral bodies augmented with Orthocomp recovered their initial stiffness; and, vertebral bodies augmented with Simplex P were significantly less stiff than they were in their initial condition. However, these biomechanical results have yet to be substantiated in clinical studies.

Previous biomechanical studies have shown that injections of 8–10 mL of cement during vertebroplasty restore or increase vertebral body strength and stiffness; however, the dose-response association between cement volume and restoration of strength and stiffness is unknown. Belkof et al. (266) investigated the association between the volume of cement injected during percutaneous vertebroplasty and the restoration of strength and stiffness in osteoporotic vertebral bodies. Two investigational cements were studied: Orthocomp (Orthovita, Malvern, PA) and Simplex 20 (Simplex P with 20% by weight barium sulfate). Compression fractures were experimentally created in 144 vertebral bodies (T6-L5) obtained from 12 osteoporotic spines harvested from female cadavers. After initial strength and stiffness were determined, the vertebral bodies were stabilized using bipedicular injections of cement totaling 2, 4, 6, or 8 mL and recompressed, from which post-treatment strength and stiffness were measured. Strength and stiffness were considered restored when post-treatment values were not significantly different from initial values. Strength was restored for all regions when 2 mL of either cement was injected. To restore stiffness with Orthocomp, the thoracic and thoracolumbar regions required 4 mL, but the lumbar region required 6 mL. To restore stiffness with Simplex 20, the thoracic and lumbar regions required 4 mL, but the thoracolumbar region required 8 mL. These data provide

guidance on the cement volumes needed to restore biomechanical integrity to compressed osteoporotic vertebral bodies.

Liebschner et al. undertook a finite element based biomechanical study to provide a theoretical framework for understanding and optimizing the biomechanics of vertebroplasty, especially the effects of volume and distribution of bone cement on stiffness recovery of the vertebral body, just like the preceding experimental study (269). An experimentally calibrated, anatomically accurate finite-element model of an elderly L1 vertebral body was developed. Damage was simulated in each element based on empirical measurements in response to a uniform compressive load. After virtual vertebroplasty (bone cement filling range of 1–7 cm³) on the damaged model, the resulting compressive stiffness of the vertebral body was computed for various spatial distributions of the filling material and different loading conditions. Vertebral stiffness recovery after vertebroplasty was strongly influenced by the volume fraction of the implanted cement. Only a small amount of bone cement (14% fill or 3.5 cm³) was necessary to restore stiffness of the damaged vertebral body to the predamaged value. Use of a 30% fill increased stiffness by > 50% compared with the predamaged value. Whereas the unipedicular distributions exhibited a comparative stiffness to the bipedicular or posterolateral cases, it showed a medial-lateral bending motion (toggle) toward the untreated side when a uniform compressive pressure load was applied. Only a small amount of bone cement (15% volume fraction) is needed to restore stiffness to predamage levels, and greater filling can result in substantial increase in stiffness well beyond the intact level. Such overfilling also renders the system more sensitive to the placement of the cement because asymmetric distributions with large fills can promote single-sided load transfer and thus toggle. These results suggest that large fill volumes may not be the most biomechanically optimal configuration, and an improvement might be achieved by use of lower cement volume with symmetric placement. These theoretical findings support the experimental observations described in the preceding paragraph, except these authors did not analyze the relationship between cement type and volume needed to restore strength.

Hitchon et al. compared the stabilizing effects of the HA product, with PMMA in an experimental compression fracture of L1 (268). No significant difference between the HA and PMMA cemented-fixated spines was demonstrated in flexion, extension, left lateral bending, or right- and left-axial rotation. The only difference between the two cements was encountered before and after fatiguing in right lateral bending ($p \leq 0.05$). The results of this study suggest that the same angular rigidity can be achieved by using either HA or PMMA. This is of particular interest because HA is osteoconductive, undergoes remodeling, and is not exothermic.

Advances in the surgical treatment of spinal etiologies continues to evolve with the rapid progression of technology. The advent of robotics, Microelectromechanical systems (MEMS) (270), novel biomaterials, and genetic and tissue engineering are revolutionizing spinal medicine. Novel biomaterials, also termed “smart biomaterials” that are capable of conforming or changing their mechanical

properties in response to different loading paradigms are being investigated for their use in spinal implant design. The rapidly advancing field of tissue engineering opens new possibilities to solving spine problems. By seeding and growing intervertebral disk cells, it could be possible to grow a new bioartificial disk, to be implanted in to the spine. Studies are in progress at a number of centers, including our own (269).

CONCLUSION

The stability (or instability) of the human spine is integral to the diagnosis and treatment of patients with low back pain. The stability of the lumbar spine as portrayed by its motion characteristics can be determined through the use of clinical and radiographic criteria or other methods of determining the orientation of one spinal vertebra with respect to another. The instability can be the result of injury, disease, and many other factors, including surgery. Therefore, it is necessary to become familiar with recent findings and suggestions that deal with the instability that can result from such procedures. The prevalence of spinal fusion and stabilization procedures to restore spinal stability and host of other factors is continuously increasing. This article has presented many of the contemporary biomechanical issues germane to stabilization and fusion of the spine. Because of the wide variety of devices available, various testing protocols have been developed in an attempt to describe the mechanical aspects of these devices. These investigations reveal comparative advantages (and disadvantages) of the newer designs to existing hardware. Subsequent *in vivo* testing, specifically animal models, provides data on the performance of the device in a dynamic physiologic environment. All of the testing, *in vitro* and *in vivo*, helps to build confidence that the instrumentation is safe for clinical trial. Future biomechanical work is required to produce newer devices and optimize existing ones, with an eye toward reducing the rates of nonfusion and pseudoarthrosis. In addition, novel devices and treatments that seek to restore normal spinal function and loading patterns without fusion continue to necessitate advances in biomechanical methods. These are the primary challenges that need to be incorporated in future biomechanical investigations. Finally, one has to gain understanding of the effects of devices at the cellular level and one must undertake outcome assessment studies to see if the use of instrumentation is warranted for the enhancement of the fusion process.

ACKNOWLEDGMENTS

Manuscript is based on the work sponsored by various funding agencies over the last 20 years. Thanks also to a large number of coinvestigators who have contributed to the original work reported in this article.

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

LIST OF ARTICLES

ALLOYS, SHAPE MEMORY
AMBULATORY MONITORING
ANALYTICAL METHODS, AUTOMATED
ANESTHESIA MACHINES
ANESTHESIA, COMPUTERS IN
ANGER CAMERA
ANORECTAL MANOMETRY
ARRHYTHMIA ANALYSIS, AUTOMATED
ARTERIES, ELASTIC PROPERTIES OF
AUDIOMETRY
BIOCOMPATIBILITY OF MATERIALS
BIOELECTRODES
BIOFEEDBACK
BIOHEAT TRANSFER
BIOIMPEDANCE IN CARDIOVASCULAR MEDICINE
BIOINFORMATICS
BIOMAGNETISM
BIOMATERIALS, ABSORBABLE

ABBREVIATIONS AND ACRONYMS

AAMI	Association for the Advancement of Medical Instrumentation	ALS	Advanced life support; Amyotropic lateral sclerosis
AAPM	American Association of Physicists in Medicine	ALT	Alanine aminotransferase
ABC	Automatic brightness control	ALU	Arithmetic and logic unit
ABET	Accreditation board for engineering training	AM	Amplitude modulation
ABG	Arterial blood gases	AMA	American Medical Association
ABLB	Alternative binaural loudness balance	amu	Atomic mass units
ABS	Acrylonitrile–butadiene–styrene	ANOVA	Analysis of variance
ac	Alternating current	ANSI	American National Standards Institute
AC	Abdominal circumference; Affinity chromatography	AP	Action potential; Alternative pathway; Anteroposterior
ACA	Automated clinical analyzer	APD	Anterioposterior diameter
ACES	Augmentative communication evaluation system	APL	Adjustable pressure limiting valve; Applied Physics Laboratory
ACL	Anterior chamber lens	APR	Anatomically programmed radiography
ACLS	Advanced cardiac life support	AR	Amplitude reduction; Aortic regurgitation; Autoregressive
ACOG	American College of Obstetrics and Gynecology	Ara-C	Arabinosylcytosine
ACR	American College of Radiology	ARD	Absorption rate density
ACS	American Cancer Society; American College of Surgeons	ARDS	Adult respiratory distress syndrome
A/D	Analog-to-digital	ARGUS	Arrhythmia guard system
ADC	Agar diffusion chambers; Analog-to-digital converter	ARMA	Autoregressive-moving-average model
ADCC	Antibody-dependent cellular cytotoxicity	ARMAX	Autoregressive-moving-average model with external inputs
ADCL	Accredited Dosimetry Calibration Laboratories	AS	Aortic stenosis
ADP	Adenosine diphosphate	ASA	American Standards Association
A-D-T	Admission, discharge, and transfer	ASCII	American standard code for information interchange
AE	Anion exchange; Auxiliary electrode	ASD	Antisiphon device
AEA	Articulation error analysis	ASHE	American Society for Hospital Engineering
AEB	Activation energy barrier	ASTM	American Society for Testing and Materials
AEC	Automatic exposure control	AT	Adenosine-thiamide; Anaerobic threshold; Antithrombin
AED	Automatic external defibrillator	ATA	Atmosphere absolute
AEMB	Alliance for Engineering in Medicine and Biology	ATLS	Advanced trauma life support
AES	Auger electron spectroscopy	ATN	Acute tubular necrosis
AESC	American Engineering Standards Committee	ATP	Adenosine triphosphate
AET	Automatic exposure termination	ATPD	Ambient temperature pressure dry
AFO	Ankle-foot orthosis	ATPS	Ambient temperature pressure saturated
AGC	Automatic gain control	ATR	Attenuated total reflection
AHA	American Heart Association	AUC	Area under curve
AI	Arterial insufficiency	AUMC	Area under moment curve
AICD	Automatic implantable cardiac defibrillator	AV	Atrioventricular
AID	Agency for International Development	AZT	Azido thymidine
AIDS	Acquired immune deficiency syndrome	BA	Biliary atresia
AL	Anterior leaflet	BAEP	Brainstem auditory evoked potential
ALG	Antilymphocyte globulin	BAPN	Beta-amino-propionitril
		BAS	Boston anesthesia system
		BASO	Basophil
		BB	Buffer base
		BBT	Basal body temperature

BCC	Body-centered cubic	CCTV	Closed circuit television system
BCD	Binary-coded decimal	CCU	Coronary care unit; Critical care unit
BCG	Ballistocardiogram	CD	Current density
BCLS	Basic cardiac life support	CDR	Complimentary determining region
BCRU	British Committee on Radiation Units and Measurements	CDRH	Center for Devices and Radiological Health
BDI	Beck depression inventory	CEA	Carcinoembryonic antigen
BE	Base excess; Binding energy	CF	Conversion factor; Cystic fibrosis
BET	Brunauer, Emmett, and Teller methods	CFC	Continuous flow cytometer
BH	His bundle	CFR	Code of Federal Regulations
BI	Biological indicators	CFU	Colony forming units
BIH	Beth Israel Hospital	CGA	Compressed Gas Association
BIPM	International Bureau of Weights and Measurements	CGPM	General Conference on Weights and Measures
BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMI	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDT	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCM1	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength
RTT	Revised token test	SISI	Short increment sensitivity index
r.v.	Random variable	SL	Surgical lithotomy
RV	Residual volume; Right ventricle	SLD	Sublethal damage
RVH	Right ventricular hypertrophy	SLE	Systemic lupus erythemotodes
RVOT	Right ventricular outflow tract	SMA	Sequential multiple analyzer
RZ	Return-to-zero	SMAC	Sequential multiple analyzer with computer
SA	Sinoatrial; Specific absorption	SMR	Sensorimotor
SACH	Solid-ankle-cushion-heel	S/N	Signal-to-noise
SAD	Source-axis distance; Statistical Analysis System	S:N/D	Signal-to-noise ratio per unit dose
SAINT	System analysis of integrated network of tasks	SNP	Sodium nitroprusside
SAL	Sterility assurance level; Surface averaged lead	SNR	Signal-to-noise ratio
SALT	Systematic analysis of language transcripts	SOA	Sources of artifact
SAMI	Socially acceptable monitoring instrument	SOAP	Subjective, objective, assessment, plan
SAP	Systemic arterial pressure	SOBP	Spread-out Bragg peak
SAR	Scatter-air ratio; Specific absorption rate	SP	Skin potential
SARA	System for anesthetic and respiratory gas analysis	SPECT	Single photon emission computed tomography
SBE	Subbacterial endocarditis	SPL	Sound pressure level
SBR	Styrene-butadiene rubbers	SPRINT	Single photon ring tomograph
SC	Stratum corneum; Subcommittees	SPRT	Standard platinum resistance thermometer
SCAP	Right scapula	SPSS	Statistical Package for the Social Sciences
SCE	Saturated calomel electrode; Sister chromatid exchange	SQUID	Superconducting quantum interference device
SCI	Spinal cord injury	SQV	Square wave voltammetry
SCRAD	Sub-Committee on Radiation Dosimetry	SR	Polysulfide rubbers
SCS	Spinal cord stimulation	SRT	Speech reception threshold
SCUBA	Self-contained underwater breathing apparatus	SS	Stainless steel
SD	Standard deviation	SSB	Single strand breaks
SDA	Stepwise discriminant analysis	SSD	Source-to-skin distance; Source-to-surface distance
SDS	Sodium dodecyl sulfate	SSE	Stainless steel electrode
S&E	Safety and effectiveness	SSEP	Somatosensory evoked potential
SE	Standard error	SSG	Solid state generator
SEC	Size exclusion chromatography	SSP	Skin stretch potential
SEM	Scanning electron microscope; Standard error of the mean	SSS	Sick sinus syndrome
SEP	Somatosensory evoked potential	STD	Source-tray distance
SEXAFS	Surface extended X-ray absorption fine structure	STI	Systolic time intervals
SF	Surviving fraction	STP	Standard temperature and pressure
SFD	Source-film distance	STPD	Standard temperature pressure dry
SFH	Stroma-free hemoglobin	SV	Stroke volume
SFTR	Sagittal frontal transverse rotational	SVC	Superior vena cava
SG	Silica gel	SW	Standing wave
SGF	Silica gel fraction	TAA	Tumor-associated antigens
SGG	Spark gap generator	TAC	Time-averaged concentration
SGOT	Serum glutamic oxaloacetic transaminase	TAD	Transverse abdominal diameter
SGP	Strain gage plethysmography; Stress-generated potential	TAG	Technical Advisory Group
SHE	Standard hydrogen electrode	TAH	Total artificial heart
SI	Le Système International d'Unités	TAR	Tissue-air ratio
		TC	Technical Committees
		TCA	Tricarboxylic acid cycle
		TCD	Thermal conductivity detector
		TCES	Transcutaneous cranial electrical stimulation

TCP	Tricalcium phosphate	UHMWPE	Ultra high molecular weight polyethylene
TDD	Telecommunication devices for the deaf	UL	Underwriters Laboratory
TDM	Therapeutic drug monitoring	ULF	Ultralow frequency
TE	Test electrode; Thermoplastic elastomers	ULTI	Ultralow temperature isotropic
TEAM	Technology evaluation and acquisition methods	UMN	Upper motor neuron
TEM	Transmission electron microscope; Transverse electric and magnetic mode; Transverse electromagnetic mode	UO	Urinary output
TENS	Transcutaneous electrical nerve stimulation	UPTD	Unit pulmonary oxygen toxicity doses
TEP	Tracheoesophageal puncture	UR	Unconditioned response
TEPA	Triethylenephosphoramidate	US	Ultrasound; Unconditioned stimulus
TF	Transmission factor	USNC	United States National Committee
TFE	Tetrafluorethylene	USP	United States Pharmacopeia
TI	Totally implantable	UTS	Ultimate tensile strength
TICCIT	Time-shared Interaction Computer-Controlled Information Television	UV	Ultraviolet; Umbilical vessel
TLC	Thin-layer chromatography; Total lung capacity	UVR	Ultraviolet radiation
TLD	Thermoluminescent dosimetry	V/F	Voltage-to-frequency
TMJ	Temporomandibular joint	VA	Veterans Administration
TMR	Tissue maximum ratio; Topical magnetic resonance	VAS	Visual analog scale
TNF	Tumor necrosis factor	VBA	Vaginal blood volume in arousal
TOF	Train-of-four	VC	Vital capacity
TP	Thermal performance	VCO	Voltage-controlled oscillator
TPC	Temperature pressure correction	VDT	Video display terminal
TPD	Triphasic dissociation	VECG	Vectorelectrocardiography
TPG	Transvalvular pressure gradient	VEP	Visually evoked potential
TPN	Total parenteral nutrition	VF	Ventricular fibrillation
TR	Temperature rise	VOP	Venous occlusion plethysmography
tRNA	Transfer RNA	VP	Ventriculoperitoneal
TSH	Thyroid stimulating hormone	VPA	Vaginal pressure pulse in arousal
TSS	Toxic shock syndrome	VPB	Ventricular premature beat
TTD	Telephone devices for the deaf	VPR	Volume pressure response
TTI	Tension time index	VSD	Ventricular septal defect
TTR	Transition temperature range	VSWR	Voltage standing wave ratio
TTV	Trimming tip version	VT	Ventricular tachycardia
TTY	Teletypewriter	VTG	Vacuum tube generator
TUR	Transurethral resection	VTS	Viewscan text system
TURP	Transurethral resections of the prostate	VV	Variable version
TV	Television; Tidal volume; Tricuspid valve	WAIS-R	Weschler Adult Intelligence Scale-Revised
TVER	Transscleral visual evoked response	WAK	Wearable artificial kidney
TW	Traveling wave	WAML	Wide-angle mobility light
TxB ₂	Thromboxane B ²	WBAR	Whole-body autoradiography
TZ	Transformation zone	WBC	White blood cell
UES	Upper esophageal sphincter	WG	Working Groups
UP	Urea-formaldehyde	WHO	World Health Organization; Wrist hand orthosis
UffIS	University Hospital Information System	WLF	Williams-Landel-Ferry
UHMW	Ultra high molecular weight	WMR	Work metabolic rate
		w/o	Weight percent
		WORM	Write once, read many
		WPW	Wolff-Parkinson-White
		XPS	X-ray photon spectroscopy
		XR	Xeroradiograph
		YAG	Yttrium aluminum garnet
		ZPL	Zero pressure level

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

§Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
cfm (cubic foot per minute)	cubic meter per second (m ³ /s)	4.72 × 10 ⁻⁴
cubic inch	cubic meter (m ³)	1.639 × 10 ⁻⁴
cubic foot	cubic meter (m ³)	2.832 × 10 ⁻²
cubic yard	cubic meter (m ³)	0.7646
curie	becquerel (Bq)	3.70 × 10 ^{10†}
debye	coulomb-meter (C·m)	3.336 × 10 ⁻³⁰
degree (angle)	radian (rad)	1.745 × 10 ⁻²
denier (international)	kilogram per meter (kg/m)	1.111 × 10 ⁻⁷
	tex	0.1111
dram (apothecaries')	kilogram (kg)	3.888 × 10 ⁻³
dram (avoirdupois)	kilogram (kg)	1.772 × 10 ⁻³
dram (U.S. fluid)	cubic meter (m ³)	3.697 × 10 ⁻⁶
dyne	newton(N)	1.0 × 10 ^{-6†}
dyne/cm	newton per meter (N/m)	1.00 × 10 ^{-3†}
electron volt	joule (J)	1.602 × 10 ⁻¹⁹
erg	joule (J)	1.0 × 10 ^{-7†}
fathom	meter (m)	1.829
fluid ounce (U.S.)	cubic meter (m ³)	2.957 × 10 ⁻⁵
foot	meter (m)	0.3048†
foot-pound force	joule (J)	1.356
foot-pound force	newton meter (N·m)	1.356
foot-pound force per second	watt(W)	1.356
footcandle	lux (lx)	10.76
furlong	meter (m)	2.012 × 10 ²
gal	meter per second squared (m/s ²)	1.0 × 10 ^{-2†}
gallon (U.S. dry)	cubic meter (m ³)	4.405 × 10 ⁻³
gallon (U.S. liquid)	cubic meter (m ³)	3.785 × 10 ⁻³
gilbert	ampere (A)	0.7958
gill (U.S.)	cubic meter (m ³)	1.183 × 10 ⁻⁴
grad	radian	1.571 × 10 ⁻²
grain	kilogram (kg)	6.480 × 10 ⁻⁵
gram force per denier	newton per tex (N/tex)	8.826 × 10 ⁻²
hectare	square meter (m ²)	1.0 × 10 ^{4†}
horsepower (550 ft·lbf/s)	watt(W)	7.457 × 10 ²
horsepower (boiler)	watt(W)	9.810 × 10 ³
horsepower (electric)	watt(W)	7.46 × 10 ^{2†}
hundredweight (long)	kilogram (kg)	50.80
hundredweight (short)	kilogram (kg)	45.36
inch	meter (m)	2.54 × 10 ^{-2†}
inch of mercury (32 °F)	pascal (Pa)	3.386 × 10 ³
inch of water (39.2 °F)	pascal (Pa)	2.491 × 10 ²
kilogram force	newton (N)	9.807
kilopond	newton (N)	9.807
kilopond-meter	newton-meter (N·m)	9.807
kilopond-meter per second	watt (W)	9.807
kilopond-meter per min	watt(W)	0.1635
kilowatt hour	megajoule (MJ)	3.6†
kip	newton (N)	4.448 × 10 ²
knot international	meter per second (m/s)	0.5144
lambert	candela per square meter (cd/m ²)	3.183 × 10 ³
league (British nautical)	meter (m)	5.559 × 10 ²
league (statute)	meter (m)	4.828 × 10 ³
light year	meter (m)	9.461 × 10 ¹⁵
liter (for fluids only)	cubic meter (m ³)	1.0 × 10 ^{-3†}
maxwell	weber (Wb)	1.0 × 10 ^{-8†}
micron	meter (m)	1.0 × 10 ^{-6†}
mil	meter (m)	2.54 × 10 ^{-5†}
mile (U.S. nautical)	meter (m)	1.852 × 10 ^{3†}
mile (statute)	meter (m)	1.609 × 10 ³
mile per hour	meter per second (m/s)	0.4470

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
millibar	pascal (Pa)	1.0×10^2
millimeter of mercury (0 °C)	pascal (Pa)	$1.333 \times 10^{2\dagger}$
millimeter of water (39.2 °F)	pascal (Pa)	9.807
minute (angular)	radian	2.909×10^{-4}
myriagram	kilogram (kg)	10
myriameter	kilometer (km)	10
oersted	ampere per meter (A/m)	79.58
ounce (avoirdupois)	kilogram (kg)	2.835×10^{-2}
ounce (troy)	kilogram (kg)	3.110×10^{-2}
ounce (U.S. fluid)	cubic meter (m ³)	2.957×10^{-5}
ounce-force	newton (N)	0.2780
peck (U.S.)	cubic meter (m ³)	8.810×10^{-3}
pennyweight	kilogram (kg)	1.555×10^{-3}
pint (U.S. dry)	cubic meter (m ³)	5.506×10^{-4}
pint (U.S. liquid)	cubic meter (m ³)	4.732×10^{-4}
poise (absolute viscosity)	pascal second (Pa·s)	0.10 [†]
pound (avoirdupois)	kilogram (kg)	0.4536
pound (troy)	kilogram (kg)	0.3732
poundal	newton (N)	0.1383
pound-force	newton (N)	4.448
pound per square inch (psi)	pascal (Pa)	6.895×10^3
quart (U.S. dry)	cubic meter (m ³)	1.101×10^{-3}
quart (U.S. liquid)	cubic meter (m ³)	9.464×10^{-4}
quintal	kilogram (kg)	$1.0 \times 10^{2\dagger}$
rad	gray (Gy)	$1.0 \times 10^{-2\dagger}$
rod	meter (m)	5.029
roentgen	coulomb per kilogram (C/kg)	2.58×10^{-4}
second (angle)	radian (rad)	4.848×10^{-6}
section	square meter (m ²)	2.590×10^6
slug	kilogram (kg)	14.59
spherical candle power	lumen (lm)	12.57

University of Illinois at Chicago
Chicago, Illinois

INTRODUCTION

Epidemiology

A congenital form of hydrocephalus occurs in roughly 50 in 100,000 live births (6). Hydrocephalus may also be acquired later in life as a result of a brain tumor, following meningitis, trauma, or intracranial hemorrhage. It has been estimated that prevalence of shunted hydrocephalus is about 40/100,000 population in the United States (7). Untreated hydrocephalus has a poor natural history with a mortality rate of 20–25% and results in severe physical and mental disabilities in survivors (8,9). There has been a significant reduction in mortality and morbidity with use of shunting. However, shunting is associated with a high failure rate; a 40% failure rate occurs within the first year after shunting (10). Advances in the technology have led to the development of a diverse type of shunt systems to circumvent problems related to long-term shunting, such as obstruction, infection, and overdrainage. Yet, studies done to evaluate these devices have not shown a significant long- or short-term benefit from their use compared with the conventional devices (10). It is estimated that, during the year 2000, the cost associated with shunting exceeded one billion dollars in the United States alone (11). Shunt replacement accounted for 43% of shunt procedures. Endoscopic surgery has provided an alternative strategy in patients with obstructive hydrocephalus. However, limited data in the literature suggest that long-term survival of third ventriculostomy is not significantly superior to that of a shunt (12).

Physiology

The CSF flow in the craniospinal system is influenced by two separate processes: (1) the circulation of the CSF from its formation sites to its absorption sites (i.e., bulk flow) and (2) an oscillatory (back and forth) flow during the cardiac cycle (pulsatile flow). The first process governs the overall volume of CSF and thereby influences intracranial pressure (ICP). The second process, the oscillatory movement of the CSF within the craniospinal compartments, is caused by the pulsatile blood flow entering and leaving the intracranial compartment during the cardiac cycle. These two processes occur over different time scales; circulation and replenishing of CSF occurs over minutes, whereas the time scale of the pulsatile CSF flow is milliseconds.

CSF Circulation. Unlike other organ systems, the brain and the spinal cord are unique in being bathed in a clear fluid called cerebrospinal fluid. The exact role that it plays in maintaining the necessary environment for the functioning of the nervous system is unclear. It has been ascribed a role in providing nutrition, removing excess waste, circulating neurotransmitters, maintaining the necessary electrolyte environment, and acting as a shock absorber against trauma.

The distribution of nutrients, or neurotransmitters, and removal of waste products of metabolism, is an unlikely function of CSF, because these chemicals are present in very low concentrations in the CSF. The main function of CSF is to provide buoyancy to support the brain and act as a cushion against trauma. The normal brain weighs about 1500 g; however, supported by the buoyancy of the CSF, its apparent weight is reduced to about 50 g in the cranium. Support for its role in cushioning the brain and spinal cord against trauma comes from clinical conditions like severe spinal canal stenosis. The CSF cushion around the site of stenosis is markedly reduced. As a result, spinal cord injury often occurs even with minor trauma as the shock waves are directly transmitted from the bone to the spinal cord.

Cerebrospinal fluid is made through a complex process that occurs in the cells of the choroid plexus, which lines the margin of the four fluid-filled spaces in the brain called the ventricles. First, an ultrafiltrate of plasma is formed in the connective tissue surrounding the choroidal capillaries. Next, this is converted into a secretion by carbonic anhydrase enzyme present in the choroids epithelium. The CSF is made at a fairly constant rate of about 10 mL/h. Most of the CSF is made in the choroids plexus of the lateral ventricles. Roughly, 20% of the CSF comes from the ventricular walls. As most CSF is made in the lateral ventricles, it is traditionally believed that the CSF bulk flow occurs from the lateral ventricles to the third ventricle, fourth ventricle, and then through the foramen of Magendie and Lushka into the cerebello-pontine cistern and on to the surface of the brain and spinal cord (Fig. 1). A fifth of the CSF runs down around the spinal cord and then back to the cranial subarachnoid space.

The CSF is absorbed by the cells of the arachnoid granulations (13). These are present in the superior sagittal sinus. The process involves pinocytosis of a small quanta of CSF, on the subarachnoid side of the granulations, and discharge into the blood on the venous side. The process is driven by a pressure difference of at least 5 mm Hg between the subarachnoid CSF and the superior sagittal sinus. A small proportion of CSF is also absorbed along the perivascular spaces and along the nerve sheaths exiting the spinal canal (14).

This traditional view has been recently challenged. Johnston et al. in experimental and cadaveric studies have demonstrated that a large amount of CSF is present around the olfactory nerve and the cribriform plate area

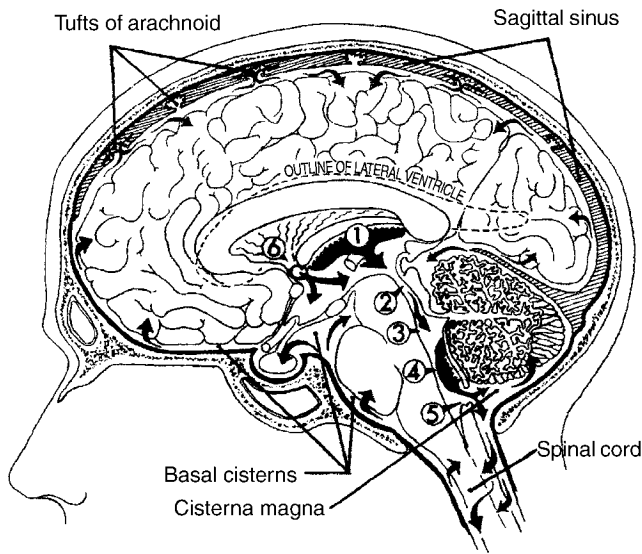

Figure 1. CSF is mainly formed by the choroids plexus in the lateral, third (1), and fourth (4) ventricles. The fluid flows (in the direction of the arrows) from lateral ventricles through the foramen of Monro (6) into the third ventricle. CSF then passes through the aqueduct of Sylvius (2) into the fourth ventricle (3) and exits the fourth ventricle through the foramen of Luschka and Magendie (5) into the cisterna magna and the basal cisterns. The flow is then into the subarachnoid space over the surface of the brain and about the spinal cord. Finally, the fluid is absorbed through the tufts of arachnoid (arachnoid villi) into the sagittal sinus.

and drains into the lymphatic system of the face (15,16). Others believe that CSF may be absorbed directly at the level of the capillaries and perivascular spaces (17).

CSF Pulsations. The pulsatile back and forth movement of CSF between the cranium and the spinal canal with each heartbeat plays a role in modulating the pulsatile cerebral blood flow. Blood flow in the arteries leading blood to the brain is pulsatile, whereas the pulsatility of blood flow in the cerebral veins is considerably attenuated. The displacement of CSF into the spinal canal during the systolic phase helps accommodate the temporary increase in blood volume in the intracranial space, which otherwise has only a limited capacity to accommodate additional volume due to the limited compliance of the intracranial compartment. Reducing the pulsatility of the blood flow through the brain may play a role in diffusion of nutrients to the brain cells from the blood and of waste products from the brain cell to the blood through a less pulsatile flow at the level of the capillaries. As discussed later, MRI measurements of the pulsatile arterial, venous, and CSF flows, to and from the cranium, can now be used to measure intracranial compliance and pressure (ICP), noninvasively. As one of the main roles of shunting is to protect the brain from increased ICP, diagnostic noninvasive measurement of ICP may aid in management decisions in hydrocephalus.

Pathophysiology

Hydrocephalus occurs if there is a mismatch between the CSF production and the absorption. Accumulation of CSF

can occur from obstruction to the egress of CSF from the ventricles. This is referred to as obstructive or noncommunicating hydrocephalus. It may also result from impairment of absorption of the CSF at the level of the arachnoid villi or increased resistance to the flow of CSF in the subarachnoid spaces from fibrosis and scarring related to meningitis or previous subarachnoid hemorrhage. This is referred to as communicating hydrocephalus. Irrespective of the cause, the accumulation of CSF has two consequences. It results in an increase in the pressure in the cranium and may cause dilation of the ventricles (ventriculomegaly).

- **Increase in Intracranial Pressure:** Maintaining normal intracranial pressure is important for the functioning of the brain. The pressure in the intracranial cavity increases exponentially with an increase in the total volume of its content (brain tissue, blood, and the CSF) (18). Therefore, increase in intracranial volume, due to uncompensated accumulation of CSF, increases ICP and reduces intracranial compliance. Compliance quantifies the ability of a compartment to accommodate increase in volume for a given increase in pressure and is defined as the ratio of the changes in volume and pressure:

$$\text{Compliance} = \frac{\Delta v}{\Delta p} \quad (1)$$

where, Δv is change in volume and, Δp is the change in pressure. Intracranial compliance decreases with increased ICP because of the exponential relationship between ICP and intracranial volume (ICV).

Normal ICP is about 1–5 mm Hg in an infant and up to 20 mm Hg in an adult. It is measured by inserting a needle into the spinal canal and recording the pressure using a manometer or by placing a catheter with miniature strain gauge transducer at its distal tip (Codman, Raynham, MA; Camino, Integra LifeSciences, Plainsboro, NJ) directly into the brain parenchyma or the ventricles through a small twist drill hole in the skull. Noninvasive means for measurement of ICP would be important for diagnosis and management of hydrocephalus. Over the last several decades, different approaches have been attempted (19). A method based on measurements of CSF and blood flows to and from the brain by MRI is described in more detail in this article. Increase in ICP can affect the brain in two ways. First, it reduces perfusion of blood into the brain due to the reduced cerebral perfusion pressure (i.e., arterial pressure minus ICP). Depending on the severity and duration, it may result in chronic ischemia causing impairment in higher mental functions, developmental delay in children, or an acute ischemic injury and stroke. Second, rise in pressure in any one of the compartments in the cranium, formed by the tough dural falx in the midline and the tentorium between the cerebral hemispheres superiorly and the cerebellum inferiorly, forces the brain to herniate. This often leads to infarction of the brain stem and death.

- **Symptoms:** Clinically, patients who have elevated ICP generally present with typical symptoms. Headache is the most common. It occurs especially in the

early hours of the morning in initial stages. Low respiratory rate during sleep results in buildup of blood CO₂ and vasodilation. This aggravates the increased ICP in the early stages of the disease. Vomiting is the next common symptom and probably results either from the distortion of the brain stem vomiting center or its ischemia. Vomiting is often associated with retching and rapid respiration that lowers the blood CO₂ level. This in turn leads to vasoconstriction and lowers the ICP and often results in a transient relief in headaches. Diplopia or double vision is also commonly encountered in a setting of increased ICP. It is a result of stretch of the sixth cranial nerve, which controls the abduction of the eyes. Weakness of ocular abduction disturbs the normal axial alignment of the two eyes resulting in defective fusion of the two images by the brain. Blurring of vision and visual loss may occur in patients with long-standing intracranial hypertension. This results from edema of the optic nerve head as the axoplasmic flow in the neurons of the optic nerve is impaired by the high ICP that is transmitted to the nerve through the patent nerve sheath. Hearing deficits related to similar effect on the cochlea are, however, less frequent. Lethargy or sleepiness is frequently observed in patients with high ICP and is probably from a combination of decreased cerebral perfusion and distortion of the brain stem.

- **Ventricular Enlargement:** Depending on the pathophysiology of hydrocephalus, CSF may accumulate only in the ventricles as in obstructive hydrocephalus or in both the ventricles and the subarachnoid space in communicating hydrocephalus. The increased pressure within the ventricle is transmitted to the periventricular region and results, over time, in loss of neurons, increase in periventricular interstitial fluid, and subsequent gliosis with loss of white matter (20).

When onset of hydrocephalus occurs early in infancy, before the skull sutures have closed, the enlarging ventricles are associated with a progressive increase in head circumference and developmental delay. In later childhood and adults, the increasing ventricular size is associated with symptoms of increased ICP. However, ventricular enlargement may also occur with normal mean ICP, in the elderly patients (21). This is referred to as normal pressure hydrocephalus (NPH). The enlarging ventricle stretches the periventricular nerve fibers. The patient presents not with signs of increase in ICP but with progressive gait ataxia, bladder incontinence, and dementia. Similar presentation may also be observed in adolescents with aqueductal stenosis and obstructive hydrocephalus. These patients with compensated long-standing hydrocephalus have been referred to as long-standing hydrocephalus of adults (LOVA) (22).

It is not clear why the ventricles enlarge preferentially, compared with the subarachnoid space, even though the pressure distributes equally in a closed system. It has been argued that, rather than the actual mean ICP, it is the pulse pressure that determines ventricular dilation. Di Rocco et al. (23) have shown that ventricular enlargement could be induced by an intraventricular pulsatile balloon with a high

pulse pressure, despite the mean ICP being normal. It may be argued that in a pulsatile system, it is the *root mean square* (RMS) of the pressure, rather than the mean pressure, that is the cause of enlarged ventricles. It has been suggested that, in communicating hydrocephalus, decrease in compliance may be responsible for preferential transmission of the pulsations to the ventricles (24,25). However, others have shown that in acute or chronic communicating hydrocephalus, the pulse pressure and the pressure waveforms in the SAS and the ventricles are similar (26,27). Alternative explanations offered are that the pia over the cortical surface is more resilient than ependyma that lines the ventricular wall; the venous pressure in the periventricular region is lower, making it more deformable than the subcortical area (28).

DIAGNOSTIC METHODS

Measurement of Resistance to CSF Reabsorption

The hydrodynamics of the craniospinal system is governed by patient-specific properties like CSF formation rate, CSF reabsorption resistance (historically termed as outflow resistance), venous pressure in the sinus, and craniospinal compliance. Together with the periodic variations in ICP, due to blood volume variation from the heartbeat and vasomotion, these properties describe the CSF dynamics, which provide the working environment of the brain. When this environment is disturbed, it affects the function of the brain resulting in the clinical symptoms of hydrocephalus. After shunting, symptoms are often eliminated or reduced. It shows that a clinical improvement can be accomplished by actively changing the brain's working environment. This link among CSF dynamics, brain function, symptoms, and shunting has made researchers look for CSF dynamical means to identify patients that would benefit from a shunt surgery. Outflow resistance has been suggested as a strong predictive parameter in communicating hydrocephalus. Invasive infusion tests in conjunction with a mathematical model of the craniospinal system can be used to estimate CSF absorption rate. The most accepted model for the system hydrodynamics has been proposed by Marmarou (29).

The basic assumptions for the model are as follows:

- CSF reabsorption rate is linearly dependent on the difference between the intracranial and venous pressures (the outflow resistance describes this linear relationship)
- A pressure-dependent compliance
- A constant formation rate of CSF, independent of ICP

The model can be displayed as an electrical analogy (Fig. 2). The model is described mathematically as a differential equation of the time-dependent ICP as a function of external infusion and the governing physical parameters:

$$\frac{dP_{IC}(t)}{dt} + \frac{K}{R_{out}} [P_{IC}(t)]^2 - \left(K \cdot I_{infusion}(t) + \frac{K \cdot P_r}{R_{out}} \right) P_{IC}(t) = 0 \quad (2)$$

Figure 2. Model of the dynamics of the CSF system. $I_{\text{formation}}$ is the CSF formation rate, C is the pressure-dependent compliance described by the elastance parameter K , R_{out} is outflow resistance, P_{sinus} is the venous pressure in the sinus, and P_{IC} is the intracranial pressure. I_{infusion} is the option of external infusion of artificial CSF.

where R_{out} is outflow resistance, P_{IC} is the intracranial pressure, P_r is the ICP at rest, and K is the elastance.

Estimation of CSF outflow resistance and the other system parameters requires perturbation of the system steady state by infusion of fluid into the craniospinal system, either through a lumbar or a ventricular route. Typically, one or two needles are placed in the lumbar canal. When two needles are used, one is connected to a pressure transducer for continuous recording of the dynamic changes in ICP following the infusion, and the other one for infusion and/or withdrawal of the fluid. Different protocols of infusion will lead to unique mathematical solutions. In addition to the resting pressure (also referred to as opening pressure), which always is determined during these investigations, it is generally believed that the outflow resistance is the clinically most important parameter, but compliance has also been proposed as a predictor for outcome after shunting.

Bolus Infusion. An example of ICP recoding during the bolus infusion test is shown in Fig. 3. The approach is to first determine the compliance from the ratio of the injected volume and the magnitude of pressure increase (30). A pressure volume index (PVI), which describes compliance, is calculated through the expression:

$$\text{PVI} = \frac{\Delta V}{\log(P_p/P_0)} \quad (3)$$

Figure 3. ICP curve from a bolus injection of 4 mL. Figure from Marmarou et al. (30).

where ΔV is the infused volume, P_p is the peak pressure and P_0 is the initial pressure just before the infusion. The next step is to determine R_{out} from the spontaneous relaxation curve when the ICP returns toward the resting pressure (Fig. 3). Solving the differential equation for the relaxation phase after the bolus infusion gives the following expression for R_{out} as a function of time (31):

$$R_{\text{out}} = \frac{tP_0}{\text{PVI} \log \left[\frac{(P_t/P_p)(P_p - P_0)}{P_t - P_0} \right]} \quad (4)$$

where t is the time in seconds after the bolus and P_t is the measured pressure at time t on the relaxation curve. From each bolus, a number of values of R_{out} are calculated and averaged, for example at $t = 1$ min, 1.5 min, and 2 min. The bolus procedure is usually repeated a couple of times for increased measurement reliability.

Constant Pressure Infusion. In this infusion protocol, several constant ICP levels are created. This is done by using a measurement system that continuously records the ICP and regulates it by controlling the pump speed of an infusion pump (Fig. 4) (32). The net infusion rate needed to sustain ICP at each pressure level is determined, and a flow versus pressure curve is generated (Fig. 4). Using linear regression, the outflow resistance is then determined from the slope of that curve (33), because at steady state, the differential equation reduces to

$$I_{\text{inf}} = \frac{1}{R_{\text{out}}} P_{\text{IC}} - \frac{P_r}{R_{\text{out}}} \quad (5)$$

where P_{IC} is the mean intracranial pressure on each level, P_r is the resting pressure, and I_{inf} is the net infusion flow at each level.

The constant pressure method can also be used to estimate the CSF formation rate. This is done by lowering the ICP beneath the venous pressure, i.e., below 5 mm Hg. At that ICP, no CSF reabsorption should take place. Therefore, the net withdrawal of CSF needed to sustain that constant pressure level should equal the formation rate.

Constant Flow Infusion. In this method, both the static and the dynamic behavior of the CSF system can be used to estimate outflow resistance (34). In a steady-state analysis R_{out} can be calculated from the stable ICP value associated with a certain constant infusion rate. R_{out} is then estimated by the following expression:

$$R_{\text{out,stat}} = \frac{P_{\text{level}} - P_r}{I_{\text{inf}}} \quad (6)$$

where $R_{\text{out,stat}}$ is a static estimation of R_{out} , P_{level} is the new equilibrium pressure obtained at the constant infusion rate, P_r is the resting pressure, and I_{inf} is the infusion rate (Fig. 5).

R_{out} can also be estimated from the dynamic phase during the pressure increases toward the new equilibrium (Fig. 5). This procedure will also give an estimate of the craniospinal compliance (elastance). The differential equation is now solved for a condition of a constant infusion rate, and the solution is fitted against the recorded pressure

Figure 4. Pressure and flow curves for the constant pressure method. Left graph shows typical data for ICP and infused CSF volume versus time. Right graph shows the mean pressure and flow points determined from each steady-state level. Outflow resistance corresponds to the inverse of the slope.

curve. The time-dependent pressure increase is described by the following expression:

$$P(t) = \frac{\left(I_{\text{inf}} + \frac{P_r - P_0}{R_{\text{out,dyn}}}\right) \cdot (P_r - P_0)}{\frac{P_r - P_0}{R_{\text{out,dyn}}} + I_{\text{inf}} \left[e^{-K \left(\frac{P_r - P_0}{R_{\text{out,dyn}}} + I_{\text{inf}} \right) t} \right]} + P_0 \quad (7)$$

where K is the elastance and P_0 is a reference pressure that is suggested to be equal to venous sinus pressure. Fitting against data will result in estimations of the unknown parameters $R_{\text{out,dyn}}$, K , and P_0 .

In summary, CSF infusion tests are conducted to reveal parameters describing the hydrodynamics of the craniospinal system. An active infusion of artificial CSF is performed, and the resulting ICP response is recorded, and parameters such as outflow resistance, compliance, formation rate, and the venous sinus pressure are then estimated based on a proposed mathematical model. Outflow resistance values determined with the bolus method are usually lower than the values determined with the constant infusion and constant pressure methods. The reason for this difference is not well understood at this time. Determina-

tion of R_{out} is often used as a predictive test in hydrocephalus, and it has been stated that if the outflow resistance exceeded a certain threshold, it is an excellent predictor of clinical improvement after shunting (35). In a recent guideline for idiopathic normal pressure hydrocephalus, measurement of R_{out} is included as a supplementary test for selecting patients suitable for shunt surgery (36).

DIAGNOSIS WITH IMAGING

Cross-sectional imaging is routinely used in the diagnosis of hydrocephalus. CSF spaces are well visualized with CT and MRI. In CT images, CSF spaces appear darker due to the lower atomic density of the CSF compared with that of brain tissue. MRI provides an excellent soft-tissue contrast resolution and is considered the primary imaging modality for brain imaging. With MRI, CSF spaces can appear either darker or brighter compared with its surrounding tissues depending on the imaging technique. An example of a CT image and MRI images demonstrating abnormally large CSF spaces is shown in Fig. 6. Cross-sectional imaging enables quantitative assessment of the CSF spaces as well

Figure 5. ICP data from a constant infusion investigation. Figure modified from Czosnyka et al. (34).

Figure 6. An example of a (a) CT image and (b and c) MRI images demonstrating abnormally large CSF spaces. The appearance of CSF in MRI depends on the technique used to acquire the images; its (b) dark with a T1 technique and (c) bright with a T2 technique.

as 3D reconstruction of the geometry of the ventricular system. The 3D model is obtained by segmentation of the CSF spaces in each of the 2D slices. An example of 3D models of the ventricular system from MRI data demonstrating normal size ventricles and enlarged ventricles are shown in Fig. 7a and b, respectively.

MRI-based motion-sensitive techniques capable of imaging flow are gaining an important role in the diagnosis of hydrocephalus. In particular, dynamic phase-contrast techniques provide images of velocities (velocity-encoded images). The degree of brightness in these images is proportional to the direction and the speed of the moving fluid or tissue. Dynamic (cine) phase contrast images are used to visualize the back and forth flow through the different CSF pathways. The cine phase contrast MRI (PCMRI) technique is also used to derive quantitative parameters such as CSF volumetric flow rate through the aqueduct of Sylvius, from which the CSF production rate in the lateral ventricles can be estimated (37), and intracranial compliance and pressure (19,30).

MRI-Based Measurement of Intracranial Compliance and Pressure

The noninvasive measurement of compliance and pressure uses the cardiac pulsations of the intracranial volume and

pressure (30,38). This method is the noninvasive analogs to the measurement of intracranial compliance with the previously described bolus infusion method where the volume and pressure changes are calculated from the MRI measurements of CSF and blood flows to and from the brain. Intracranial elastance, i.e., a change in pressure due to a small change in volume, or the inverse of compliance, is derived from the ratio of the magnitudes of the changes in volume and pressure, and the pressure is then derived through the linear relationship between elastance and pressure. The MRI method measures the arterial, venous, and CSF flows into and out of the cranial vault. A small-volume change, on the order of 1 mL, is calculated from the momentary differences between inflow and outflow at each time points in the cardiac cycle. The pressure change is proportional to the pressure gradient change, which is calculated from time and spatial derivatives of the CSF velocities using fluid dynamics principles.

A motion-sensitive MRI technique, cine phase contrast, provides a series of images where the value at each picture element is proportional to the velocity at that location. The phase contrast MRI technique is based on the principle that the precession frequency of the protons is proportional to the magnetic field strength. Therefore, velocity can be phased-encoded by varying the magnetic field in space and time, i.e., generating magnetic field

Figure 7. Volume rendering of the CSF spaces inside the brain (i.e., ventricles) generated using segmented MRI data from a (left) healthy volunteer and from a (right) hydrocephalic patient.

Figure 8. (a) Anatomical mid-sagittal T1-weighted MR image showing the location of the axial plane used for CSF flow measurement (dark line). (b and c) Phase-contrast MRI images of CSF flow in the spinal canal. (b) CSF flow during systole. (c) CSF flow during diastole. The pixel values in these images are proportional to velocities in a direction perpendicular to the image plane. Gray-static tissue, white-outward flow (caudal direction), and black-inward flow (cranial direction). (d) A 3D plot of the CSF velocities during systole.

gradients. When a gradient field is applied along an axis for a short time, the proton's phase will change based on its location along that axis. When a bipolar (positive and then negative) gradient field is applied, the phase of the stationary protons will increase during the positive portion (lobe) of the bipolar gradient and then will decrease during the negative lobe. If the lobes were of equal area, no net phase change would occur. However, moving protons, such as those in the blood or CSF, will experience different field strength during each lobe due to their

change in position; this will result in a net phase change proportional to the proton velocity.

Examples of MRI phase contrast images of CSF and blood flow are shown in Figs. 8 and 9, respectively. The oscillatory CSF flow between the cranial and the spinal compartments is visualized in images taken in a transverse anatomical orientation through the upper cervical spinal canal. The location of this plane is indicated on a mid-sagittal scout MR image shown in Fig. 8a. Fig. 8b depicts outflow (white pixels) during systole, and Fig. 8c depicts

Figure 9. (a) A blood vessel MRI scout image showing the location of the axial plane for blood flow measurement (dash line). (b) A phase contrast MRI image of blood flow through that location. Black pixels indicate arterial inflow, and white are venous outflow. (c) A 3D plot of the blood flow velocities.

Figure 10. The volumetric flows into and out of the cranial vault during the cardiac cycle derived from the MRI phase contrast scans. Total arterial inflow (filled circles), venous outflow (open), and the cranial-to-spinal CSF volumetric flow rate (diamonds) during the cardiac cycle. Note that arterial inflow is greater than venous outflow during systole.

inflow (black pixels) during diastole. Fig 9d depicts a 3D plot of the velocities in a region of interest containing the CSF space and an epidural vein. The CSF flow is imaged with a low-velocity encoding, and the faster blood flow through the neck arteries and veins is imaged using high-velocity encoding. The location of the imaging plane used for blood flow measurement is shown in Fig. 9a, and a velocity encoded image of blood flow is shown in Fig. 9b. Fig 9c depicts a 3D plot of the velocities in a region of interest containing the internal carotid and vertebral arteries and the jugular vein.

Volumetric flow rates are obtained by integration of the velocities throughout a lumen cross-sectional area. The total volumetric arterial flow rate—that is, total cerebral blood flow—is calculated directly from the sum of the volumetric flow through the four vessels carrying blood to the brain (internal carotid and vertebral arteries). The venous blood outflow is obtained by summation of the flow through the jugular veins, and through secondary venous outflow channels such as the epidural, vertebral, and deep cervical veins when venous drainage occurs through these veins. An example of the volumetric flow waveforms for CSF, arterial inflow, and venous outflow measured in a healthy volunteer is shown in Fig. 10.

The rate of the time-varying intracranial volume change (net transcranial volumetric flow rate) is obtained by sub-

tracting outflow rates from inflow rates at each time point. The intracranial volume change (delta of volume from a given reference point) is obtained by integrating that waveform with respect to time. Waveforms of the net transcranial volumetric flow rate and the change in the intracranial volume are shown in Fig. 11.

The magnitude of the change in intracranial pressure during the cardiac cycle (pulse pressure) is proportional to that of the CSF pressure gradient waveform. A method to measure pressure gradient of pulsatile flow in tubes with MRI was reported by Urchuk and Plewes (39). Pulsatile pressure gradients are derived from the MRI velocity-encoded phase contrast images using the Navier–Stokes relationship between pressure gradient and temporal and spatial derivatives of the fluid velocity for incompressible fluid in a rigid tube (40). Pressure traces from invasive recordings obtained invasively in patients with low and elevated ICP with an intraventricular pressure transducer and the corresponding CSF pressure gradient waveforms derived from the MRI measurements of the CSF velocities at low- and high-pressure states are shown in Fig 12. The ratio of the magnitude of the pressure and volume changes, i.e., intracranial elastance, is then expressed in terms of MR-ICP based on the linear relationship between elastance and ICP.

DEVICES FOR TREATMENT

Despite significant advances in understanding of the pathophysiology of hydrocephalus, the gold standard for the treatment of hydrocephalus still continues to be CSF diversion through a tube shunt to another body cavity. Unfortunately, treatment with CSF shunts is associated with multiple complications and morbidity. The rate of shunt malfunction in the first year of shunt placement is 40%, and, thereafter, about 10% per year. The cumulative risk of infection approaches 20% per person although the risk of infection per procedure is only 5–8% (41). The technological advances in shunt valve designs and materials have had only a marginal impact on the rate of complications. Third ventriculostomy has become popular in recent years for management of obstructive hydrocephalus, but many questions about its long-term permanence remain controversial. Choroid plexectomy (42,43) aimed at arresting hydrocephalus by reducing CSF production or pharmacotherapy with similar intentions have had very limited success in selected patients.

Figure 11. (Left) The MRI-derived net transcranial volumetric flow rate waveform. (Right) The intra cranial volume change during the cardiac cycle derived by integrating the net transcranial volumetric flow waveform on the left. Note that the maximal volume change in this subject is 0.5 mL.

Figure 12. Invasive pressure traces (top) obtained with an intra-ventricular catheter from two patients with (left) low and (right) elevated ICP. The corresponding MRI-derived CSF pressure gradients are shown at the bottom.

Nonobstructive Hydrocephalus

No treatment other than CSF diversion has been effective in management of this form of hydrocephalus. The CSF may be diverted from the ventricles through a catheter that runs in the subcutaneous tissue into the abdominal cavity where it is absorbed by the peritoneum (*ventriculo-peritoneal shunt*) (Fig. 13). It may also be diverted from the spinal subarachnoid space by a lumbar shunt that diverts it to the peritoneum (*Lumbar-peritoneal shunt*). Lumbar CSF diversion avoids the potential risk of brain injury by the ventricular catheter. Lumbar shunts have a lower risk of obstruction and infection (44) but are more prone to malfunction from mechanical failures (45), and, the development of hind brain herniation, over a period of time, has been well documented (46,47). Evaluation of a lumbar shunt for function is more cumbersome than that of a ventricular shunt. The lumbar shunt is usable in patients with communicating hydrocephalus, small ventricles, and patients who have had multiple ventricular shunt malfunctions.

In patients who cannot absorb CSF from the peritoneum due to scarring from previous operations or infections, the CSF may be diverted to the venous system through a

catheter placed at the junction of superior vena cava and the right atrium (*ventriculo/lumbar-atrial shunt*).

A typical shunt system consists of three parts (Fig. 14). First, the proximal catheter, i.e. the catheter, is inserted into the ventricle or the lumbar subarachnoid space. Second, the valve controls the amount of CSF that flows through the shunt system, and third, the distal catheter drains the CSF from the valve to the peritoneum or the atrium.

Proximal Catheter

Three basic types of proximal catheter designs are available: simple with multiple perforations (Codman, Raynham, MA; PS Medical, Goleta, CA), simple Flanged (Heyer-Schulte), Integra, Plainsboro, NJ; Anti-Blok (Phoenix Vygon Neuro, Valley Forge, PA) with recessed perforations. The last two have been designed to minimize the growth of choroid plexus into the perforations and causing obstruction. There is no controlled study to suggest that these two designs are in any way superior to simple perforations. The flanged catheters can get stuck, as choroid plexus grows around it, making removal of an obstructed catheter difficult (48).

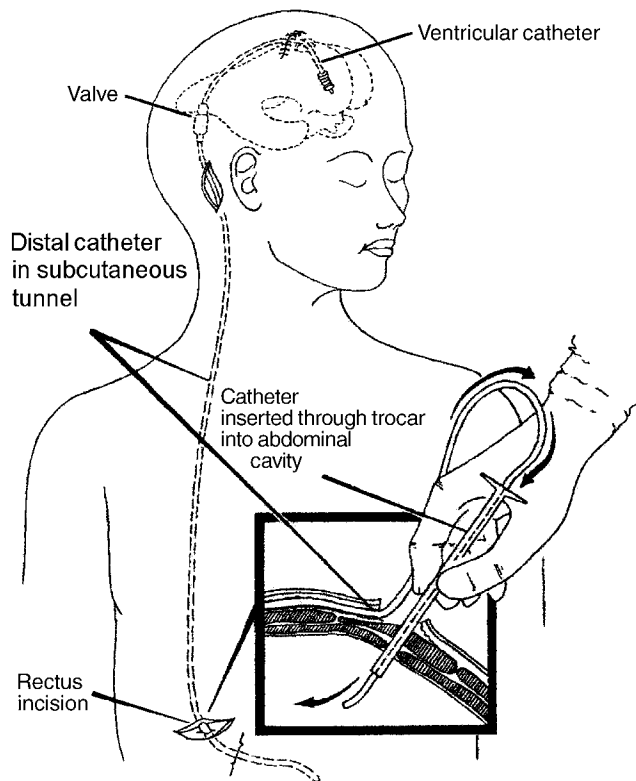

Figure 13. The shunt consists of three parts. The ventricular catheter enters the skull through a burr hole in the skull and passes through the brain into the lateral ventricle. It is connected to the valve that is placed in the subcutaneous tissue of the scalp. The valve in turn is connected to the distal catheter that runs in the subcutaneous tissue to enter the peritoneal cavity of the abdomen as shown in the inset (*ventriculo-peritoneal shunt*) or into the jugular vein and through it to the superior vena cava (*ventriculo-atrial shunt*).

Placement of the proximal catheter has generated considerable controversy in the literature (48–51). More recently, endoscopic placement of the proximal catheter into the frontal horn, away from the choroid plexus, has been advocated to minimize proximal malfunction (3,52,53). Again no controlled study has been done to confirm whether placement of the proximal catheter into frontal or occipital horn is superior to placement in the body of the lateral ventricle. Often catheters that are grossly malpositioned may continue to work, whereas those that are well positioned may fail. The choice of the site, frontal or parietal, may be made on the basis of the above although some studies have suggested a higher incidence of seizure with catheters placed via a frontal burr-hole (49). A study to evaluate use of endoscope to place the shunt catheter in the frontal horn failed to show any benefit (54). This suggests that no matter where the catheter is placed, the flow of CSF toward the catheter causes the choroids plexus to creep toward the catheter, ultimately causing ingrowth and obstruction of the catheter (55).

To remove an obstructed catheter, intraluminal coagulation of the choroid plexus is done using a stylet and low-voltage diathermy, at the time of shunt revision (56–58). Massive intraventricular hemorrhage may occur if the

choroid plexus is torn while forcefully removing the catheter. Delayed subarachnoid hemorrhage from rupture of pseudoaneurysm resulting from diathermy of a catheter close to anterior cerebral artery has been reported (59). At times, if the ventricular catheter is severely stuck, it is advisable to leave it in position but occlude it by a ligature and clip. This may become necessary as sometimes an occluded catheter may become unstuck over time and begin to partially function, resulting in formation of subgaleal CSF collection. Replacing a new catheter into the ventricle in patients with small or collapsed ventricles can be sometimes challenging. In most instances, after removal of the old catheter, the new catheter can be gently passed into the ventricle through the same tract. Frameless stereotaxis (StealthStation, Medtronic, Goleta, PA) is now available and may offer an alternative to cumbersome and time-consuming frame-based stereotactic catheter placement (52).

Valve

The valve regulates the amount of CSF that is drained. The aim is to maintain normal ICP. The simplest valves are differential pressure valves. The CSF drainage in these valves is based on the pressure difference between the proximal and the distal ends. Three major configurations are available (Fig. 14): diaphragm, slit valve, and ball-spring mechanism in different pressure ranges (low, medium, and high). Recently, valves in which the pressure setting can be changed with a magnetic wand have become available. These programmable valves allow pressure changes over different pressure ranges based on the manufacturer. The pressure setting on the valve can be ascertained by X ray of the head in the Medos valve (Codman, Raynham, MA) or using a magnetic wand in the Strata valve (Medtronic, Goleta, CA). To prevent inadvertent changes in the valve setting by stray magnetic fields, the Polaris valve (Sophysa, Costa Mesa, CA) has an ingenious locking mechanism that allows changes only if the magnetic field has a certain configuration.

Slit valves tend to be the most inaccurate in their performance followed by ball and spring valves. The diaphragm valves proved to be most stable in long-term tests. Most valves, like the slit valves, ball-spring, and diaphragm valves, offer a lower resistance (<2.5 mm Hg/mL/min) than the normal physiological CSF outflow of 6–10 mm Hg/mL/min. The standard distal tubing of 110 cm increases the overall resistance to 50–80% of the physiological value (60).

Standard differential pressure valves are available in different pressure ranges. It is unclear whether it makes a difference in an ambulatory patient to use a low-, medium-, or high-pressure valve because in the upright position irrespective of the rating the hydrostatic column converts all differential pressure valves into “negative” pressure valves (61). The overdrainage results in persistent headaches from low ICP, ventricular collapse, and increased risk of shunt obstruction. Long-term changes in cerebrovenous physiology cause acute and severe increase in ICP without enlargement of ventricles at the time of shunt malfunction (62). To circumvent the overdrainage in the

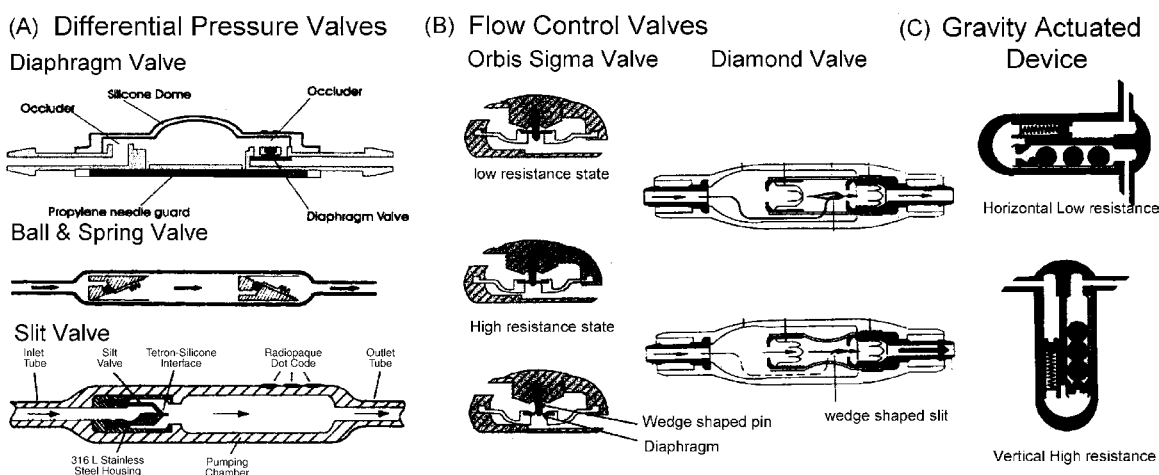

Figure 14. Three major types of valve designs are available. (a) Differential pressure valves allow flow in proportion to the pressure difference between the proximal catheter and the distal catheter. Configurations are a simple diaphragm, ball and spring, or slit valve. Programmable differential pressure valves can be programmed to a pressure setting using a magnetic wand. In the upright position, due to a negative pressure from the hydrostatic column of fluid in the distal catheter, these valves tend to overdrain causing negative pressure symptoms. (b) Flow control valves have the ability to limit overdrainage from a negative hydrostatic pressure gradient. The Orbis-Sigma Valve has a wedge-shaped pin over which the orifice of the diaphragm (arrows) rests. When the distal pressure becomes negative in the upright position, the diaphragm slides downward on the pin narrowing the drainage channel and hence reducing the flow rate. The Diamond valve has a wedge-shaped slit in the construct (arrows) that narrows as the distal pressure becomes increasingly negative again reducing the flow rate. (c) Gravity actuated devices reduce drainage in the upright position by increase in resistance to flow of CSF from the weight of metal balls in the drainage channel.

upright position, ingenious devices, also referred to as devices for reducing siphoning (DRS), have been developed (Fig. 14). The Anti-Siphon device (Integra LifeSciences) has a flexible diaphragm that mechanically senses atmospheric pressure and shuts off the drainage channel if the hydrostatic pressure in the fluid column becomes negative. Flow control valves (Orbis Sigma Valve, Integra LifeSciences and Diamond Valve, Vygon Neuro, Valley Forge, PA) have a drainage channel that narrows as the differential pressure increases in the upright position to reduce the flow. Gravity actuated devices (Gravity Compensating Accessory, Integra LifeSciences, CA, Chabbra Shunt) have metal balls that fall over one another in the upright position to increase resistance to flow. Double channel devices (Dual Switch Valve, Christoph Miethke GmbH & Co KG; SiphonGuard, Codman) have two channels; the low-resistance channel is shut off by a gravity actuated ball in the upright position.

There is no evidence to suggest that use of one type of valve is superior to the other, and several valve designs are available in the market today. A recent multicentric study, evaluating three basis types of valves, failed to confirm the utility of flow control or anti-siphon valves in children and infants over the differential pressure valves (10). Similarly, studies have failed to show that programmable devices are superior to fixed pressure valves (63). Over a period of time, the ventricle tended to become small irrespective of the type of valve used. The rate of proximal malfunction in a patient with flow control valves was 6.5% compared with 42–46% for the other two valves, although the overall rate of malfunction and shunt survival was not statistically

different. The design of the flow control valves with a narrow orifice makes it sensitive to malfunction (64). Certainly, revising a valve has less morbidity and risk of neurological injury than revising the proximal catheter, especially in patients with slit ventricles. There is evidence that a significant number of patients do not tolerate flow control valves and, despite a radiologically functioning shunt, have high intracranial pressure from underdrainage through the valve. In patients with limited pressure–volume compensatory reserve, there can be an excessive increase in intracranial pressure during cardiovascular fluctuations, especially at night and be responsible for nighttime or early morning headaches, in patients with flow control devices (60). Self-adjusting diaphragm valves like the Orbis-Sigma (Integra LifeSciences), on bench test, have proved to be inaccurate and unstable at perfusion rates of 20–30 mL/h, which is the most important physiological range, leading to pre-valve pressures rapidly changing between 4 and 28 mm Hg. During long-term perfusion, these may resemble ICP pressure waves (60).

Diaphragm-based anti-siphon devices are prone to obstruction from encapsulation as has been shown in experimental animals and is often encountered in patients who have had recurrent malfunctions (65). Some patients are more prone to develop heavy scarring around the shunt system. Again, there is no evidence that using an open (ASD, Anti Siphon device, Integra LifeSciences) has any advantage over using a closed system that opens when the pressure exceeds the negative hydrostatic pressure (SCD, Siphon Control Device, Medtronic), although theoretically malfunctions in an open system would only result in loss of

anti-siphon function without obstruction to the flow of CSF. In the open system (ASD), the flow through the valve stops only after the intracranial pressure has become negative in the upright position, which is more physiological, than with SCD, in which the flow stops once the pressure reaches zero. In the multicentric shunt study, the incidence of overdrainage was 7.8% in the SCD group and 2.6% in the Standard valve group. The study suggests that diaphragm-based anti-siphon devices may not be any superior to differential pressure valves in reducing overdrainage (10). Considerable controversy also revolves around the most optimum site for placement for the anti-siphon devices (66,67). The classic position is at the level of the skull base; however, the bench test suggests a marked tendency to overdrain if the SCD is below the level of the proximal catheter. These factors may be minor when considered in light of the excessive sensitivity of the SCD to external pressure from scar or when the patient is lying on the device (64).

The gravity actuated device (GAD) is used in conjunction with a differential pressure valve to limit overdrainage (68). It is similar to the horizontal vertical valve used in lumbar shunts but constructed to fit in-line with a ventriculoperitoneal shunt. There is no literature to prove or disprove its utility; however, in individual cases, we have found it effective. Experimental evidence suggests that motion and vibration (35) make the mechanism of these devices ineffective although clinical studies are lacking. The position of the GAD device is critical for optimum functioning. Slight angulation of the device to vertical can cause underdrainage in the horizontal position and overdrainage in the vertical position. Examples of pressure flow characteristics of a standard differential pressure valve, a flow control valve, and a valve containing a GAD are shown in Fig. 15.

Distal Catheter

Distal shunt malfunction is reported to occur in 12% to 34% of shunts (51,69). Three types of distal catheters have been used: the closed ended with side slits, open ended with side slits, and open ended. A higher incidence of distal catheter obstruction has been noted in catheters with side slits whether closed ended or open ended (51,70). Omental ingrowth is responsible for the peritoneal catheter obstruction;

possibly the distal slits act as collection points for the debris and provide a channel for trapping the omentum. It is unclear whether using open-ended distal catheters increases the likelihood of small ventricle malfunction. Use of extended length catheters (110–120 cm) is not associated with an increase in the complications and eliminates the need to lengthen the peritoneal catheter for growth of the patient (71). However, care must be taken to identify patients who may have enough length of tubing in the abdomen but may underdrain due to a narrow and taught segment of tubing from subcutaneous tethering as a result of scarring and calcification.

It is difficult to justify use of atrial over the peritoneal site for distal absorption (72,73). Data on 887 patients suggested that atrial shunts have a higher rate of malfunction although some studies have not shown a significant difference. However, when the same information was stratified by age, shunt type, and time period, there was no significant difference in shunt durability. Cardio-pulmonary complication, such as irreversible pulmonary hypertension, endocarditis, and glomerulonephritis, are some of the more serious complications that may occur with atrial shunts (73). Alternative sites, like pleura, may result in significant negative pressures in the shunt system (74). Poor absorption from the pleura may result in large pleural effusions in small children (74). The gall bladder has also been effectively used in patients in whom peritoneal, atrial, or pleural sites have been exhausted (75,76). Potential complications of these shunts, notably biliary ventriculitis and biliary meningitis, have been reported in the literature (77,78). The ventriculo-femoral shunt may be tried in patients with a difficult access to the atrium from the subclavian or jugular route (79). Trans-diaphragmatic placement of the distal catheter in the sub-hepatic space worked successfully in one reported patient with poor peritoneal access due to scarring (80).

Shunt Material

Ideal shunt material should be completely biocompatible, be easy to handle, flexible, resistant to infection, and non-metallic but radio-opaque (metals interfere with MRI imaging). From a manufacturing standpoint, it should be easy

Figure 15. Pressure flow characteristics of (a). Standard differential pressure valve; note that with increasing differential pressure, such as from upright posture, there is an increase in the flow rate. (b) The flow control valve has a sigmoid flow-pressure relationship; in the upright position, the valve works at the high resistance stage and maintains a relatively steady flow rate despite increase in differential pressure. (c) Gravity actuated device, in vertical position acts as a very high-resistance differential pressure valve (depending on the number of balls in the device) and as a low-resistance differential pressure valve in the supine position.

to mold into tubing and making valve components. Silicone polymer is probably the best available material for this purpose.

Some studies have suggested development of silicone allergy in some patients with ventricular shunts (81–84). It is unclear whether it represents a true immunological reaction or a nonspecific foreign body type granulomatous reaction (85). In patients with suspected or documented silicone allergy, use of polyurethane (86) or, more recently CO₂ extracted silicone catheters has been postulated but not proven to offer some advantage in reducing risk of recurrent malfunctions.

Subcutaneous location of the distal catheters makes them susceptible to degradation from a foreign-body reaction mounted by the body (87). Scarring around the catheter, calcification, and stress fractures are long-term consequences of this reaction (88,89). Unless there is some amount of surface degradation, the adhesions to the subcutaneous tissues do not occur (87). Evidence suggests that barium used in the silicone catheters is probably not an important factor in promoting calcification and degradation (90). Use of barium-free catheters, however, makes it difficult to evaluate a shunt system on radiological imaging.

To minimize colonization of shunt catheters and infection, recently antibiotic-coated catheters have become available. The catheters are available coated with rifampin and minocycline (Medtronic, Goleta, CA) and another with rifampin and clindamycin (Bactiseal, Codman, Raynham, MA). The antibiotic is most active against *Staph epidermidis*, which is the cause of shunt infection in most patients. The antibiotic gradually leaches out of the catheter over a 30–60 day period providing added advantage. Control studies have shown a significant reduction in rate of infection with use of these catheters (91,92). The major drawback is the excessive cost of the antibiotic-coated catheters.

Shunt Malfunction

About 30–40% of the shunts malfunction within the first year of placement (10) and 80% of malfunctions are proximal malfunctions. Although most patients with a malfunctioning shunt will present with the classic features of raised pressure, headache, and vomiting, in 20%, there may be no signs of raised pressure (93). Instead, this group of patients present with a subtle change in behavior, decline in school performance, gait disturbances, and incontinence. Some patients may present with aggravation in the signs and symptoms of Chiari malformation or syringomyelia. Parents are often more sensitive to these subtle changes. In a study comparing the accuracy of referral source in diagnosing shunt malfunction, parents were more likely to be correct about the diagnosis as compared with a hospital or general practitioner (94).

At examination, a tense fontanelle, split sutures, and swelling at the shunt site are very strongly suggestive of a malfunctioning shunt. Shunt pumping has a positive predictive value of only 20% (95). A shunt valve that fails to fill up in 10 minutes is very strongly suggestive of shunt malfunction. Radiological assessment may demonstrate a fracture or dislocation. Presence of double-backing of the distal catheter, wherein the distal catheter tip loops out of

the peritoneal through the same spot that it enters it, is diagnostic of distal malfunction (96). The shunt tap gives useful information about the proximal and distal shunt system. The absence of spontaneous flow and poor drip rate indicate proximal malfunction, whereas a high opening pressure is suggestive of distal malfunction (97). The presence of increase in size of the ventricles on CT scan confirms a malfunctioning shunt; however, a large number of patients with long-standing shunt have altered brain compliance and may not dilate the ventricles at the time of presentation. In children, similar symptoms occur in the common illnesses like otitis media; gastroenteritis of viral fevers often confound the diagnosis. Radiological assessment of shunt flow using radionuclide or iodide contrast media injected into the shunt may help (2,98–100). Unfortunately, although some studies have shown an accuracy of 99% with combined pressure and radionuclide evaluation (98,101), others have shown a 25–40% incidence of deceptive patency when evaluated by radionuclide cisternogram (97). This could stem from a partial but inadequately functioning shunt, intermittent malfunction, or presence of isolated ventricle. Similar problems are encountered with an iodide contrast-based shuntogram or shunt injection tests. In the absence of normative data with regard to adequate flow in the shunt, which may vary significantly with the individual, time of the day, and activity (102), use of Doppler-based flow devices, flow systems that work based on differential temperature-gradient or MRI-based flow systems becomes irrelevant for an individual patient. Lumbar infusion tests and shunt infusion tests to assess the outflow resistance through the shunt are cumbersome and require a laboratory-based setup and may not be possible in an ER setting (103–105). Infusion through a reservoir to assess outflow resistance through the shunt suggests a cutoff of less than 12 mm Hg/mL/min as reliable for distinguishing a clinically suspected high probability of malfunction from those with a low probability of shunt malfunction (104). However, this is the group of patients who may not really need the test, and patients who have a questionable malfunction on clinical grounds often have equivocal results on the infusion study.

In childhood hydrocephalus, ICP is the only accurate guide to shunt function other than the symptoms (105). Again the ability to measure ICP through the valve tap becomes unreliable with a partial proximal malfunction. A similar problem may be encountered with in-line telemetric ICP monitors (106,107). In addition, the telemetric transducers may develop a significant drift over time. In difficult cases, the only way to resolve the issue may be to explore the shunt, to measure ICP through a lumbar puncture if the patient has communicating hydrocephalus, or to place an ICP monitor. Noninvasive monitoring of ICP is going to have a major role in assessment of these patients. For patients who have a very compliant brain, ventricular dilation on the CT scan easily confirms inadequate shunt function.

Despite advances in shunt technology, the incidence of shunt malfunction has not changed over the last 50 years. Nulsen and Becker (3) reported a rate of malfunction of 44%, in 1967, which is similar to that reported in recent studies. To improve on the existing shunt systems, it is

Figure 16. Third ventriculostomy is useful in patients with obstructive hydrocephalus such as observed with aqueductal stenosis (arrows). An endoscope is passed through a small hole in the skull into the frontal horn of the ventricle and navigated into the third ventricle. The floor of the third ventricle is then perforated under vision (arrow, in the inset) so as to bypass the obstruction at the aqueduct. Iohexol, a nonionic iodinated dye, is then instilled into the ventricle to demonstrate good communication between the ventricles and the subarachnoid space.

important to understand the factors that reduce shunt survival. Although the location of the proximal catheter has not been clearly shown to influence shunt survival (50,51), the presence of a small amount of fluid around the proximal catheter is associated with longer shunt survival. In a study that looked at shunt over a 11 year period, statistically significant differences were noted in shunt survival in patients with tumor versus post-hemorrhagic and aqueductal stenosis; shunts in infants and the pediatric age group survive shorter than in adults; shunt after multiple revisions survive shorter, and additional shunts placed for isolated ventricles have shorter survival (70,108). Chronic inflammatory changes of granular ependymitis often seen at the time of endoscopic shunt placement in patients with multiple revisions probably contribute to recurrent malfunction and progressive shortening of the interval between revisions as the number of surgeries increase (108).

The nature of the valve clearly influences the risk of proximal catheter malfunction. It is much lower with flow control valves (10,109). Overdrainage from the differential pressure valves pulls the choroid plexus toward the proximal catheter and may promote malfunction (55). However, the increased rate of valve malfunction in flow control devices balances out this advantage (10).

THIRD VENTRICULOSTOMY

In patients with an obstructive type of hydrocephalus, third ventriculostomy offers an alternative to shunt. The procedure involves making an opening in the relatively

thin membrane of the floor of the third ventricle. This is accomplished by passing an endoscope through the lateral ventricle and guiding it through the foramen of Munro to the floor of the third ventricle (Fig. 16). The opening allows CSF to bypass the obstruction at the level of the aqueduct or the fourth ventricle and directly enter the subarachnoid space.

Although third ventriculostomy has been recommended as a procedure of choice for obstructive hydrocephalus; data from some prospective studies have failed to show an improved cure rate (110,111). A retrospective analysis of ventriculographic versus endoscopic third ventriculostomy in 213 cases does show the superiority of the endoscopic procedure over the ventriculographic operation both in terms of reduced risk and improved survival of the procedure (112). Despite the theoretical advantages, evidence suggests that third ventriculostomy may not be effective in controlling raised intracranial pressure in all patients (112,113). Early failures in a radiologically proven case of obstructive hydrocephalus may relate to multifactorial etiology of hydrocephalus; associated absorption defects, obliteration of subarachnoid space from long-standing ventricular dilatation, and unidentified infectious cause of aqueductal stenosis may be responsible. Late failures may relate to gliotic scarring over the ventriculostomy, which has been visually confirmed by endoscope in some cases. Does the ventriculostomy close from scarring, or is it a secondary response to lack of flow through the ventriculostomy due to poor absorption, therefore, a lack of gradient between the ventricle and the subarachnoid space, is unclear. In a small prospective study comparing the shunt failure rate with the failure rate of third ventriculostomy,

no statistical difference was found between the two (12). Likewise, no controlled study has compared laser, blunt, or sharp fenestration of the floor or demonstrated usefulness of balloon dilatation of the fenestration. The success rate of third ventriculostomy of 49–100%, as reported in the literature, may not be a true representative of the efficacy of third ventriculostomy (12). Evaluation after third ventriculostomy and defining success is difficult in the absence of documented reduction in ICP or improvement on neuropsychological tests. This is so because the ventricles may not reduce in size, and to and from motion through the patent fenestration may still be observed on MRI CSF flow studies even though the patient may be symptomatic. In the absence of clear evidence in literature, third ventriculostomy is often advocated for patients with obstructive hydrocephalus, and if failures occur, shunting is preferred over repeat fenestration.

It is hoped that close collaboration between the industry and medicine will help develop “smart shunts” that would be able to mimic physiological CSF dynamics. These devices will possibly incorporate nanotechnology and would be superior to the presently available devices. It is likely that better understanding of CSF drainage mechanism in the future may help develop alternatives such as drugs that improve drainage of CSF through lymphatic/arachnoidal venous channels or promote proliferation of new lymphatic/arachnoidal venous channels. Until that time, it seems that shunts are the best available alternative for management of communicating hydrocephalus.

INTRODUCTION

The goal of hyperbaric oxygen (HBO) therapy is to deliver high concentrations of oxygen under pressure to increase the amount of dissolved oxygen in the blood. The physiologic repercussions of this increased plasma oxygen have widespread effects that translate into a variety of clinical applications. Initially, the use of hyperbaric medicine surrounded acute decompression illness and gas embolism. Later, the increased oxygen under pressure was shown to have use in a variety of clinical situations. The delivered pressure can be two to six times ambient atmospheric pressure (ATM) or atmospheres absolute (ATA) depending on the indication. The current Undersea and Hyperbaric Medical Society approved uses of HBO are shown in Table 1, and many of these indications will be discussed individually.

Table 1. Approved Uses for Hyperbaric Oxygen Therapy

acute decompression illness
gas embolism
carbon monoxide poisoning
clostridial gas gangrene
necrotizing soft tissue infections
compromised skin grafts and skin flaps
crush injury
compartment syndrome
acute traumatic ischemias
radiation tissue damage
refractory osteomyelitis
selected problem wounds
acute exceptional blood loss anemia
acute thermal burns
intracranial abscess

HBO in the treatment of these conditions is supported by controlled medical trials published in peer-reviewed journals and, as such, is evidence-based. Numerous other experimental uses exist for HBO, such as for stroke and for cardiac ischemia, but these uses have not yet been sufficiently proven to be supported by the Undersea and Hyperbaric Medicine Society or by the American College of Hyperbaric Medicine. The goal of this chapter is to outline the physical principles underlying the use of HBO therapy, to discuss its medical indications for HBO, and to familiarize the reader with the mechanical, safety, and regulatory issues involved in operating a hyperbaric medicine program.

HISTORICAL BACKGROUND

British physician and clergyman Henshaw was the first to use alteration in atmospheric pressure to treat medical conditions when he used his domicilium chamber in 1862. Hyperbaric medicine also surrounded diving and diving medicine. Triger, in 1841, gave the first human description of decompression sickness (1). In 1934, U.S. Naval Submarine Officer Dr. Albert Behnke was the first to use oxygen recompression to treat decompression sickness in naval divers (2). Later, in 1943, Gagnon and Cousteau invented SCUBA (self-contained underwater breathing apparatus). Dr. Boerma, a Dutch thoracic surgeon, removed the blood cells from pigs in 1955 and found they could survive with the oxygen dissolved in plasma by use of HBO. An upsurge in hyperbaric surgery followed in 1956, when Boerma performed cardiovascular surgery in a hyperbaric chamber, which along with hypothermia, allowed for periods of circulatory arrest of 7–8 min. The large chamber developed at Wilhelmina Gasthuis in Amsterdam in 1959, headed by Boerma, allowed a wide variety of research to be carried out on the uses of HBO therapy on many diseases (3). By 1966, it was indicated for the treatment of protection during induced circulatory arrest, homotransplantation, clostridial infection, acute arterial insufficiency, chronic arterial insufficiency, and hypovolemic shock. Shortly thereafter, the advent of cardiopulmonary bypass obviated hyperbaric chambers for cardiac protection. In 1967, the Undersea Medical Society was founded by the U.S. Navy diving and submarine medical officers. This organization originally focused on undersea and diving medicine but, later, came to include clinical hyperbaric medicine. In 1986, the name was changed to the Undersea and Hyperbaric Medical Society or UHMS with more than 2500 physician and scientist members in 50 countries. More recently, the American College of Hyperbaric Medicine has come to offer board certification to U.S. physicians in the specialty of hyperbaric medicine.

PHYSICS

To understand HBO therapy, one must understand a few basic laws of physics, namely, Boyle's law, Charles law, Dalton's law, and Henry's law. Boyles law explains how gas volume shrinks with increasing pressure. Charles law explains that the volume of a gas decreases with decreasing temperature. Dalton's law explains that each gas in a

mixture exerts its own partial pressure independently of the others. Henry's law explains that the number of gas molecules that will dissolve in a liquid depends on the partial pressure of the gas as well as on the mass of the liquid. These laws themselves will be explained in the first part of this section and the application of the laws to each area of hyperbaric medicine will be explained in the respective section.

Boyle's Law

Boyles law states if the temperature remains constant, the volume of a gas is inversely proportional to the pressure.

Boyle's law is stated as $PV = K$ or $P = K/V$, where P is pressure, V is volume, and K is a constant.

Thus, as in Table 2, the volume of a bubble at 1 Atmosphere or sea level shrinks to one-half of its original volume at 33 feet below sea level (10 m or 2 atmospheres). It shrinks to one-third of its original size at 66 feet below sea level (20 m or 3 atmospheres). Conversely, if a diver were to hold his breath at depth and then ascend, the air in his lungs will expand to three times the volume it occupied at 66 feet below sea level.

Charle's Law

Charles' law states that if the pressure remains constant, the volume of a fixed mass of gas is directly proportional to absolute temperature. The volume increases as the temperature increases. For example, a balloon has a volume of 1 L at 20 °C and its volume would expand to 1.1 L at 50 °C.

Charles' law is stated as $V/T = K$ or $V1/T1 = V2/T2$, where V is volume of gas 1 or 2, T is temperature in Kelvin of gas 1 or 2, and K is a constant.

Dalton's Law

Dalton's law states that each gas in a mixture exerts its partial pressure independently, which is important in understanding human physiology and HBO. For example, if a patient is given a high concentration of oxygen and a lower concentration of nitrogen, these gasses will diffuse across membranes and act in the body independently of each other.

Dalton's law is stated as $P(t) = P1+P2+P3$, where $P(t)$ is total pressure and $P1$, $P2$, and $P3$ are the individual gas pressures. Gases try to equalize their concentrations across a membrane, which explains how breathing a higher oxygen, lower nitrogen mixture can help nitrogen leave the blood through the lungs as nitrogen gas.

Henry's Law

Henry's law states that at a given temperature, the amount of gas dissolved in a solute is directly proportional to the pressure of the gas above the substance.

Table 2. Pressure vs. Volume at Depth

Depth (feet sea water)	Pressure (ATA) atmospheres	Gas Volume (%)
0(sea level)	1	100
33	2	50
66	3	33
165	6	17

Henry's law illustrates that when a liquid is exposed to a gas, some of the gas molecules dissolve into it. The number of moles that will dissolve in the liquid depends on the mass of the liquid, the partial pressure of the gas, its solubility in the liquid, the surface area of contact, and the temperature (as that changes with the partial pressure). Thus, more gas, oxygen, or nitrogen will dissolve in tissue fluid at a higher pressure because the partial pressure of each gas increases at a higher pressure.

Henry's law is stated as $p = Kc$, where p is the partial pressure of the gas 1, c is its molar concentration, and K is the Henry's law constant, which is temperature-dependent.

An example of Henry's law is dissolved carbon dioxide in soda, which bubbles out of solution as the pressure decreases. Another example is exemplified by water when it is heated. Long before it boils, bubbles of air form on the side of the pan, which is an example of the gas coming out of solution as the temperature is raised.

For treatment of decompression illness (DCI) and gas embolism (GE), increased pressure alone as well as the increased oxygen pressure facilitate treatment. Both of these conditions are a result of gas bubbles in the tissues or gas bubbles in the blood causing blockage of vessels or ischemia of tissues. Therefore, shrinking the bubbles with increased pressure allows them to be removed or minimized by the body, which is the principle of Boyle's law, that the volume of a gas varies inversely with pressure. If one has a bubble occluding an important vessel or lodged in a joint, it will shrink as the pressure increases as in Table 2. The blood can accommodate an increased amount of dissolved gas with increased atmospheric pressure as explained by Henry's law. Henry's law states that the amount of gas that will dissolve in a liquid is proportional to the partial pressure of the gas in contact with that liquid as well as to the atmospheric pressure. Atmospheric pressure at sea level is 760 mmHg, and the normal atmosphere consists of 21% oxygen and 79% nitrogen. (see Fig. 1) (4). The pressure of a gas dissolved in plasma relates to its solubility in a liquid as well as to its partial pressure. A gas bubble caught in the tissues or in the systemic circulation either because of an air embolus or because of decompression sickness is significantly decreased under hyperbaric conditions, as illustrated by Table 3. By Boyles law, the pressure alone shrinks the bubble to a fraction of its' original size. Dalton's law states that total pressure of a mixture of gases is equal to the sum of the pressures of each gas. Each gas is acting as if it alone were present, which explains how the oxygen under pressure creates a situation whereby the higher dissolved oxygen surrounds the bubble and causes the diffusion of nitrogen out of the bubble, called nitrogen washout. Simply put, each gas attempts to have equal concentration of particles, in this case, nitrogen and oxygen on each side of the gas bubble. Nitrogen, therefore, diffuses out of the bubble and shrinks in size. Hyperbaric oxygen enables treatment of the two conditions where air or nitrogen bubbles become lodged in the tissues.

PHYSIOLOGY

Hyperbaric oxygen therapy oxygen enters the systemic circulation through the alveoli in the lungs, and the

Table 3. Oxygen Levels During Hyperbaric Oxygen Treatment Breathing Air (4)

5	3800			
6	4560			

diffusion is mediated by the pressure differential between the alveolar oxygen content and the oxygen content of venous blood. Alveolar oxygen content is 100 mmHg and venous oxygen content is 40 mm Hg (5). Normally, 97% of oxygen is carried in the arterial blood bound to hemoglobin molecules and only 3% of the oxygen is dissolved in plasma, illustrated by the formula for oxygen content in arterial blood. $CaO_2 = (1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)$, where CaO_2 is oxygen content, Hb is Hemoglobin in grams, and SaO_2 is arterial O₂ saturation expressed as a fraction not a percentage (0.95, not 95%). 1.34 is the realistic binding capacity of hemoglobin, although 1.39 is the actual binding capacity. 0.003 times the PaO_2 is the amount of oxygen soluble in plasma at normal atmospheric pressure. With hyperbaric oxygen, the amount of oxygen dissolved in arterial blood is dramatically increased. Conversely, the amount carried by hemoglobin remains about the same as that achieved by inspiring oxygen at 1 atmosphere absolute (ATA) (4). As measured in ml O₂ per deciliter of whole blood, the oxygen content increases significantly under hyperbaric conditions as shown in Table 3. The oxygen content of blood increases from 0.31 at 1 atmosphere to 6.80ml/dl vol% at 3 atmospheres. Note that 100% oxygen is not used at pressures greater than 3 ATA to minimize the risk of oxygen toxicity. The alveolar type 1 cells in the lungs and the neurons in the brain are sensitive to excessive concentrations of oxygen. Again, to prevent oxygen toxicity, which can lead to alveolar damage or seizure, 100% oxygen is not given at pressures greater than 3 ATA. Even in these pressure ranges, air breaks are given to patients and they breathe air as opposed to concentrated oxygen under pressure for 10 minutes during many of the protocols, which in theory, gives the xanthine oxidase system a chance to deal with the current load of free radicals in the lungs and tissues and the Gaba amino buteric acid (GABA) depletion in the brain a chance to normalize. As mentioned, the blood's ability to carry more dissolved oxygen molecules under higher atmospheric pressure is a function of Henry's law. It states that the amount of gas that will dissolve in a liquid is propor-

tional to the partial pressure of the gas in contact with that liquid as well as to the atmospheric pressure. Thus, more gas, oxygen, or nitrogen will dissolve in tissue fluid at higher atmospheric pressure. %X is the percentage of gas X dissolved in the liquid, $P(t)$ is the atmospheric pressure, and $P(X)$ is the partial pressure of gas X.

TRANSCUTANEOUS OXYMETRY (TcPO₂ OR TCOM)

In order for the patient to benefit from HBO therapy, they must have adequate perfusion of blood to the affected area. This perfusion can be assessed prior to hyperbaric oxygen therapy by checking transcutaneous oxygen tension, TcPO₂. Transcutaneous oxygen tension values of less than 40, which increase to more than 100 mmHg while breathing 100% oxygen or to more than 200 during HBO therapy, will likely benefit from hyperbaric oxygen therapy (6). The detailed mechanisms by which the elevated oxygen tension is felt to improve wound healing and the body's ability to combat bacterial pathogens will be discussed under each indication for HBO therapy. Briefly, Hunt and Pa: (7) showed, in 1976, that increased oxygen tension stimulated collagen synthesis and fibroblast proliferation. Then, studies revealed improved ability of leukocytes to clear infected wounds of bacteria with hyperbaric oxygen (8,9). Then, in 1989, Zamboni et al. (10) showed that HBO therapy in the reduction of tissue flap necrosis was a systemic phenomenon that involved inhibition of neutrophil adherence and prevention of arteriolar vasoconstriction thought to be via a nitric oxide-mediated mechanism. In addition, it increases platelet-derived growth factor Beta (PDGF B), vascular endothelial growth factor (VEGF), Epidermal growth factor (EGF), and other factors.

APPROVED INDICATIONS

The following indications are approved uses of hyperbaric oxygen therapy as defined by the Hyperbaric Oxygen

Therapy Committee of the Undersea and Hyperbaric Medical Society (Table 1). Most of these indications are also covered by Medicare and many are covered by major insurance companies. The indications include air or gas embolism, decompression illness, carbon monoxide poisoning, Clostridial myositis and myonecrosis (gas gangrene), crush injury, compartment syndrome and other acute traumatic ischemias, decompression sickness, problem wounds, exceptional blood loss anemia, intracranial abscess, necrotizing soft tissue infections, refractory osteomyelitis, delayed radiation injury, compromised skin grafts and flaps, and thermal burns. Many of these indications will be specifically discussed in the following sections.

HYPERBARIC CHAMBER BASICS

Hyperbaric oxygen therapy is a feature offered in many hospitals, medical centers, and in specialty situations such as diver rescue stations and oil rigs. Over 500 hyperbaric chambers exist in the United States alone. When a patient is referred for one of the listed emergent or nonemergent indications to undergo hyperbaric oxygen therapy, a complete workup of the patient should be performed if possible prior to hyperbaric oxygen therapy. Emergency situations may necessitate an abbreviated exam. The patient should wear only cotton medical-center-provided clothing to prevent static electricity, which could cause a spark and a fire. All foreign appliances should be removed, including hearing aids, lighters, and jewelry. Internal appliances such as pacemakers are usually safe under hyperbaric conditions. The patient will then be premedicated with a benzodiazapine such as valium if needed for anxiety. Hyperbaric oxygen therapy can be administered through monoplace or multiplace chambers. Monoplace chambers accommodate a single patient within a pressurized environment of 100% oxygen (Fig. 1). These chambers are often constructed as acrylic cylinders with steel ends and can withstand pressures of up to 3 ATA. Multiplace chambers are usually constructed of steel and can withstand pressures up to 6 ATA (Fig. 2). They can accommodate two or more people and often have the capacity to treat ventilated or critically ill patients. Some are even large enough to accommodate operating teams, and the 100% oxygen is delivered to the patient via face mask, hood, or endotracheal tube. Depending on the indication, patients will require from 1 to 60 treatments. Most commonly, treatments are delivered to the patient for 60–90 min at 2.8–3.0 ATA five days a week for the protocol duration.

CONTRAINDICATIONS

Six absolute contraindications exist to hyperbaric oxygen therapy.

1. Untreated pneumothorax – An untreated pneumothorax can be converted to a tension pneumothorax with administration of HBO.
2. History of spontaneous pneumothorax.

Figure 1. Relative composition of air.

3. Bleomycin – History of the chemotherapy agent Bleomycin, which can cause pneumonitis, especially if the patient is exposed to HBO.
4. Doxyrubicin.
5. Disulfiram – (antibuse) Blocks production of superoxide dismutase, which protects the patient from oxygen toxicity.
6. Cisplatin/Carboplatin – An anticancer agent that interferes with DNA synthesis.
7. Mefenide (Sulfamyelone) – It is a topical ointment for burns and wounds that is a carbonic anhydrase inhibitor and increases the risk of seizure during HBO therapy.

The relative considerations and contraindications are many. In these patients, the hyperbaric physician should consider each patient individually, including their history of thoracic surgery, seizure disorder, obstructive lung disease, congestive heart failure, pulmonary lesions on X-ray or CT scan, seizure disorder, upper respiratory infections

Figure 2. Fire risk.

Table 4. Arterial and Venous Air Embolism Etiology

Etiology of Air Embolism	
<i>Arterial Air Embolism</i>	<i>Venous Air Embolism</i>
Pulmonary Overpressure	Central Venous Catheters
Open Lung Biopsy	Infusion Pumps
Arterial Catheter	Neurosurgery
Angiography	Laparoscopy
Surgery	Liver Transplantation
Penetrating Chest Trauma	Neurosurgery
Pneumothorax	Pelvic Surgery
	Trendelenburg Position
Cardiopulmonary Bypass	Necrotizing Enterocolitis
Dialysis	Lumbar Spine Spine Surgery
Autotransfusion	Air Contrast Salpingogram
Neonatal Respiratory	Umbilical Venous Catheters
Distress Syndrome	
Paradoxical, Patent	
Foramen Ovale	

(due to risk of barotraumas to the ears), acute viral infections, uncontrolled high fever (as it increases CNS sensitivity to oxygen), reconstructive ear surgery, congenital spherocytosis, history of optic neuritis, recent retinal repair, claustrophobia, acidosis, nicotine, alcohol, and many others.

AIR EMBOLISM

Air embolism is a medical emergency. In the diving community, it is the main cause of death following diving accidents. Early diagnosis followed by definitive treatment are critical in determining the eventual outcome. Treatment is based on compression of the air bubbles by Boyle’s law as well as oxygenation of ischemic tissues and treatment of ischemia reperfusion injury with hyperbaric oxygen. Air embolism can occur in the hospital setting by introduction of air into the systemic circulation by central venous and arterial catheters and other invasive procedures. Interestingly, the first report of a death from air embolism was from France in 1821. The patient was undergoing surgery on his clavicle when the surgeon noted a hissing sound in the area of operation and the patient yelled “my blood is falling into my heart- I’m dead” (11). The patient likely died of a venous air embolism obstructing the systemic circulation.

Air entry in the systemic circulation occurs following violation of the systemic circulation by any number of mechanisms (Table 4), which can be either by introduction of air into the arterial circulation, as in a lung biopsy, chest trauma, and pulmonary overpressure (diving), or into venous circulation, as in air introduction via central venous catheters, liver transplantation, and neurosurgery. Venous air emboli are more common, whereas arterial emboli are tend to be more serious. Physiologically, the air bubble forms or is introduced into the circulation. The lung usually serves as an excellent filter for air emboli, and can protect the embolism from traveling to the brain. This protective filter may be bypassed by a patent foramen ovale. Approximately 30% of patients have a foramen ovale that is patent by probe. The lung as a filter may be overwhelmed by large quantities of air. The bubble can then lodge in the smaller arteries of the brain causing obstruction. An air embolism is immediately identified as a foreign body, and platelets are activated, which leads to an inflammatory cascade. Hypoxia then develops distal to the obstruction with associated swelling. The embolism is eventually absorbed by the body, but the fibrin deposition at the embolism site may prevent return of blood flow. In order to diagnose an air embolism, it needs to have a high index of suspicion. If air embolism is suspected, the patient should receive a number of immediate measures, including ACLS or ATLS protocols. The patient should be placed on the left side and one should consider draining air from the right atrium with a central venous catheter. Air in the heart can cause a machinery murmur. 100% oxygen should be administered via a face mask or endotracheal tube, and the patient should be hydrated to preserve intravascular volume. Per Dalton’s law, administration of high oxygen will cause nitrogen to diffuse out of the air bubble and shrink in size. Dalton’s law states that total pressure of a mixture of gases is equal to the sum of the pressures of each gas. Each gas acts as if it alone were present. Dalton’s law is stated as $P(t) = P1 + P2 + P3$. The inspired 100% oxygen will also maximize oxygenation of the tissues as much as possible under normal atmospheric pressure. Next, the patient should be emergently treated with hyperbaric oxygen. If a chamber is available that can provide compression to 6 ATA with air or a mixture of 50% nitrogen and 50% air, treatment should immediately be performed following the U.S. Navy protocol (Fig. 3).

Figure 3. U.S. Navy decompression treatment.

DECOMPRESSION ILLNESS

By definition, decompression illness (DCI), also called bends or caisson disease, occurs when gas bubbles exit in the blood or body tissues. At depth, more gas can dissolve in the tissues than in the blood. When the diver ascends too quickly, the gas comes out of solution and forms bubbles in the tissues and in the blood, much like popping a soda can and releasing its pressure causes the carbon dioxide bubbles to come out of the solution. In 1994, Diver’s Alert Network (DAN) recorded 1164 diving-related injuries and 97 diving-related deaths, many related to DCI (12). The severity of DCI depends on the volume and location of gas bubbles. The range of symptoms is from vague constitutional complaints or limb pain to cardiopulmonary arrest and coma, the pathophysiology of which is explained by Henry’s law. As previously explained, Henry’s law is $p = Kc$, where p is the partial pressure of the gas 1, c is its molar concentration, and K is the Henry’s law constant, which is temperature-dependent. Thus, simply stated, more inert gas can be dissolved in a liquid at higher atmospheric pressure and, conversely, less under lower atmospheric pressure, which occurs on decompression when gas must be removed from tissues, and rapid decompression leads to bubble formation. Using the Henry’s law equation, one can calculate the estimated amount of nitrogen a diver must clear from the bloodstream (about 5 L) in rising from 100 ft to the surface. The amount would be approximately 750 ml nitrogen assuming room temperature, which is a significant volume of nitrogen that must be eliminated from the divers bloodstream. The onset of symptoms is usually rapid and 75% of patients experience symptoms within 1 h of decompression and 90% within 12 h of decompression (13). A small number of patients may present even later, particularly if they have flown in commercial aircraft after diving and not followed the recommendation of the major diving organizations not to fly within 24 hours of one’s last dive. Interestingly, up to 10% of the inert gas that is absorbed in the tissues is released as bubbles after the diver’s decompression (14). Patients experience symptoms depending on the location and concentration of the

bubbles (see Table 5). Bubbles forming in or near joints cause the joint pain of a classical “bend.” These musculoskeletal effects are called type 1 DCS. When these effects occur in the spinal cord or brain, numbness, paralysis, and disorders of higher cerebral function may result. If large numbers of bubbles enter the venous bloodstream, congestive symptoms in the lung and circulatory shock can then occur. These pulmonary and neurologic effects are termed type 2 DCS. Treatment should involve immediate administration of 100% oxygen, which facilitates nitrogen washout by the previously explained principles of Dalton’s law. Rehydration as well as advanced cardiac or trauma life-support protocols should be followed by transfer to a hyperbaric facility emergently. The patient should be treated with hyperbaric oxygen following U.S. Navy guidelines (Fig. 3), even if the inspired oxygen and rehydration alone have improved the patient’s signs and symptoms because tiny bubbles may be left that can cause tissue necrosis. Hyperbaric oxygen shrinks the size of the mostly nitrogen-filled bubbles by the principles of Boyle’s law, and the increased pressure also increases the partial pressure of the gas by Dalton’s law, hastening complete elimination of the bubble (Table 2). If the U.S. Navy (Fig. 3) recompression regimen fails to lead to symptom resolution, the Diver’s Alert Network or a medical expert on DCI should be contacted, and one of a number of recompression tables may be followed.

PROBLEM WOUNDS

The management of problem wounds should always include infection control, debridement, aggressive wound care, and correction of perfusion and oxygenation deficiencies. When an oxygenation deficiency of the wound is found, in the face of nonreconstructable vascular disease, hyperbaric oxygen should be considered as an adjunctive therapy. An increase in tissue oxygen tension by HBO therapy enhances wound healing by increasing neutrophil bactericidal capacity, inhibiting toxin formation in and even killing some anaerobes, encouraging fibroblast activity, and promoting angiogenesis (15). In normal physiology, the oxygen gradient across a wound is essential to stimulate these components of healing. Oxygen consumption is relatively low in wounds, and microvasculature damage and peripheral vasoconstriction increase diffusion distances. Partial pressure via Dalton’s law is the driving force of diffusion. Hyperbaric oxygen creates a steep tissue oxygenation gradient, providing a stronger stimulus than lactate or moderate hypoxia, to initiate and facilitate wound healing (16,17). These stimulated factors are thought to include platelet-derived growth factor B (PDGF-B), Vascular endothelial growth factor (VEGF), Epidermal growth factor, and others. Several clinical studies support the use of hyperbaric oxygen to promote wound healing. Perhaps the studies involving diabetic lower extremity wounds have been most informative. Several studies have shown an increased number of healed wounds, decreased wound size, and decreased rates of amputation among patients receiving hyperbaric

Table 5. Signs and Symptoms of Decompression Illness

Symptoms of Decompression Illness	Signs of Decompression Illness
Unusual fatigue	Blotchy skin rash
Skin itching	Paralysis, muscle weakness
Pain in joints/ muscles of arms, legs or torso	Difficulty urinating
Dizziness	Confusion, personality changes, bizarre behavior
Vertigo	Amnesia,
Ringing in the ears, (Tinnitus)	Staggering
Numbness, tingling and paralysis	Coughing up bloody, frothy sputum
Shortness of breath (Dyspnea)	Collapse or unconsciousness Tremors

oxygen therapy as an adjunctive treatment (18,19). Baroni et al. reported in a controlled study that a significant number of subjects receiving HBO went on to heal their wounds and fewer required amputation when compared with subjects not receiving HBO (20). In another study involving 151 diabetic patients with wounds of the lower extremity, Oriani et al. showed that 130 of these patients completely healed their wounds with adjunctive HBO (21). When compared with conventionally treated wounds, HBO-treated patients had an accelerated rate of healing, reduced rate of amputation, and an increased rate of completely healed wounds on a long-term basis (21). Transcutaneous Oxymetry ($TcPO_2$) is currently the best tool available to evaluate tissue hypoxia and to select patients appropriate for HBO therapy. It can also be used to monitor progress during hyperbaric oxygen therapy. $TcPO_2$ measurements should be taken with the patient breathing room air. A value of greater than 50 mmHg around the wound site indicates that the wound has adequate oxygenation and hyperbaric oxygen is not likely to improve healing. Values below 40 at the wound site should be considered for HBO therapy. Patients with marginal $TcPO_2$ should be further tested while breathing 100% oxygen. $TcPO_2$ values of greater than 100 while breathing 100% oxygen is an indicator that they are likely to respond to HBO therapy. If this challenge $TcPO_2$ is less than 100, they still may benefit if the tested $TcPO_2$ at the wound site is greater than 200 mmHg while they are breathing 100% oxygen at 2.0 ATA in the hyperbaric chamber (22). A $TcPO_2$ value of less than 30 around a wound that does not exhibit this response, which indicates vascular compromise and the patient should be considered for revascularization if possible. Of note, 96% of limbs with $TcPO_2$ values below 30 mmHg had abnormal arteriograms. It is also important to follow $TcPO_2$ values weekly, and diabetic patients may have normal or falsely elevated noninvasive Doppler studies and a low $TcPO_2$, implying satisfactory perfusion and inadequate oxygenation of the wound and, as such, may pose a diagnostic dilemma. The diabetic patient with normal noninvasive Doppler and low $TcPO_2$ will respond best to HBO. HBO therapy should be reserved for those diabetic wounds not responding to traditional management of debridement, antibiotics, and general wound care, including vascular reconstruction. The use of HBO therapy is necessary in only 15–20% of these patients. HBO therapy increases wound oxygen tension, enhancing host antibacterial mechanisms and promoting wound healing and is reserved for wounds in which the primary etiologies are tissue hypoxia or infection (13). Treatments are delivered at 2.0–2.4 atmospheres for 90–120 min once or twice daily. When serious infections are present, patients are typically hospitalized and given IV antibiotics and hyperbaric treatments twice daily five days a week. The $TcPO_2$ values should be checked weekly because hyperbaric oxygen facilitates angiogenesis by a nitric oxide and vascular endothelial growth factor Beta (VEGF-B). When the room air $TcPO_2$ is greater than 40 mmHg, the hyperbaric oxygen therapy can safely be discontinued. HBO is an adjunctive treatment; therefore, diabetic control, debridement, and aggressive wound treatment are given first priority.

When the wound bed has adequate granulation tissue, application of grafts can shorten morbidity, hospital stay, and health-care costs. The underlying problem in failure of a wound to heal is usually hypoxia and infection. Hyperbaric oxygen treatments in selected patients can facilitate healing by increasing tissue oxygen tension, thus providing the wound with a more favorable environment for healing. Therefore, hyperbaric oxygen therapy can be an important component to any comprehensive wound care program.

COMPROMISED FLAPS AND GRAFTS

Skin grafts and flaps with adequate blood supply do not require HBO. Hyperbaric oxygen therapy is extremely useful in situations where the skin grafts or flaps suffer from compromised microcirculation or hypoxia.

Flaps

The benefits of HBO on flaps develop from a systemic elevation in oxygen tension (23–25). In addition, HBO therapy prevents neutrophil adherence and subsequent vasoconstriction following ischemia. Too often, a compromised flap is allowed to progress over the days following surgery until visible signs of necrosis obviate the use of HBO, because delayed treatment with HBO cannot revive dead tissue. The resulting disappointment, as well as the associated patient dissatisfaction, can be avoided by rapid diagnosis of the flap problem and early involvement of the hyperbaric physician. The keys to successful treatment of compromised flaps with HBO are accurate diagnosis of the specific flap problem and appropriate and expedient initiation of hyperbaric oxygen treatment. Awareness of the different etiologies of flap compromise is necessary to plan for effective HBO treatment. A random flap with distal necrosis is completely different from a free flap with total venous occlusion. Proper classification of flaps, different etiologies of flap compromise, and understanding of how HBO is thought to effect ischemia reperfusion injury defines which patients will benefit from HBO. Flap classification is based on an assessment of blood supply, tissue composition, and method of movement. Each of these elements must be evaluated, but it is blood supply that is most important. The blood supply to the flap is either axial, based on a named vessel, or random, based on the subdermal plexus. Commonly, flap compromise occurs when the surgeon tries to mobilize tissue outside the defined arterial supply, when there is a pedicle problem exists, or when free flaps are exposed to prolonged ischemia. The tissue composition of a flap may include skin, subcutaneous tissue, fascia, muscle, bone, other tissues, or a combination of these. Flap composition is very important because different tissue types have different tolerances to ischemia. For instance, a myocutaneous flap will be more susceptible to ischemia than a fasciocutaneous flap, because muscle is much more sensitive to ischemic injury than fascia and skin (26). In those circumstances where a prolonged primary ischemia or any secondary ischemia resulting from vessel thrombosis and revision anastomosis exists, the flaps will undergo ischemia reperfusion injury.

When treating compromised flaps, a multimodality approach should be initiated. This approach should include the use of vasodilators if arterial vasospasm is suspected, removal of sutures if tension or compression are suspected, dextran and pentoxifylline for rheological purposes, medicinal and chemical leeching for venous congestion, and the early use of hyperbaric oxygen if blood flow can be documented. The use of HBO therapy is appropriate only when the flap problem has been defined, documented perfusion of the flap exists, appropriate surgical salvage measures have been first considered, and HBO therapy can be performed in an expedient manner. Specifically with respect to free flaps, extended primary ischemia time greater than 2 h or any secondary ischemia time may result in partial or total flap necrosis. This injury is usually reversible if recognized early and treated expeditiously. Essentially, it is ischemia reperfusion injury. Numerous research studies support the use of HBO in the salvage of compromised free tissue transfers (27,28). A rat free-flap model showed similar improvement in flap survival (27). A clinical study evaluated free-flap salvage in the face of prolonged primary or any secondary ischemia (28). Salvage was significantly better in the HBO treatment group vs. controls, but only if initiated within 24 h. Free flaps compromised by prolonged primary or secondary ischemia have responded favorably to HBO treatment with complete salvage, in most cases, if HBO is started early. The treatment regimen is 2.0–2.4 ATA, 90 min q 8 h x 24 h, then q 8–12 h x 48 h (29). Treatment duration is based on clinical evaluation.

Grafts

Skin grafts are anatomically different from flaps in that skin grafts lack an inherent blood supply. Skin grafts are composed of avascular tissue that depends entirely on the recipient bed for oxygenation. HBO is useful in preparing the recipient bed and in promoting healthy granulation tissue to support split-thickness skin grafts. One controlled study showed a significant improvement in skin graft survival from 17% to 64% with the addition of HBO treatment. Although literature exists to support the use of HBO for composite grafts, a study by the University of Mississippi Medical Center found no significant effect of HBO on rat-ear composite grafts larger than 1 cm (30,31). Further research is needed to better understand the effects of HBO on composite graft survival. The rationale for use of HBO in crush injury, compartment syndrome, frostbite, and other traumatic ischemias is similar to those for compromised flaps as they are all cases of ischemia and ischemia reperfusion injury.

CRUSH INJURY, COMPARTMENT SYNDROME, AND OTHER ACUTE TRAUMATIC ISCHEMIAS

These conditions are trauma-related situations in which the underlying pathophysiology is that of ischemia reperfusion (IR) injury. Ischemia times of greater than 4 h will result in some degree of permanent necrosis. The physiologic basis of IR injury has become better under-

stood in recent years. Most of the animal research centers around the production of oxygen-free radicals. Although the endothelial xanthine oxidase pathway has received much attention in the literature (32), more recent evidence supports the fact that neutrophils are a more important source of oxygen-free radicals via membrane NADPH oxidase and degranulation. Also, neutrophil adhesion is felt to cause ischemia reperfusion IR-associated vasoconstriction.

A perceived paradox exists related to HBO for IR injury. The less-informed observer often does not understand why HBO improves reperfusion injury and might think HBO instead increases free radical formation. (An oxygen-free radical is an oxygen molecule with an unpaired electron in its outer shell.) During ischemia, ATP is ultimately degraded to hypoxanthine and xanthine, which are anaerobic metabolites. With reperfusion, oxygenated blood is reintroduced into the ischemic tissue, and the hypoxanthine and xanthine plus oxygen creates oxygen-free radicals. Superoxide and hydroxyl oxygen-free radicals are formed, which can cause extensive tissue damage. The authors believe that the major mediator of damage is, in fact, neutrophil adherence to postcapillary venules significant and progressive vasoconstriction occurs in arterioles adjacent to leukocyte-damaged venules. Neutrophil adherence and vasoconstriction lead to a low flow state in the microcirculation and then vessel thrombosis, which is the endpoint of IR injury. The leukocyte-damaged venule is thought to be responsible for the arterial vasoactive response. HBO inhibits neutrophil adherence to the endothelial cells and thereby inhibits the ultimate thrombosis of microvessels, but the complete mechanism is still poorly understood, but is thought to involve the elevation in nitric oxide mediated by an increase in nitric oxide synthase (33). Free radical formation is not felt to be worsened with HBO as fewer adherent neutrophils actually exist to contribute to the neutrophil oxygen-free radical-generating system.

Treatment with hyperbaric oxygen in the face of IR injury carried the concern that that providing extra oxygen would increase free radical production and tissue damage. This query has been resolved by studies that have shown that HBO actually antagonizes the ill effects of IR injury in a variety of tissues (33–35). One of the first studies evaluating HBO and IR injury showed that HBO, immediately upon reperfusion, significantly improved skin flap survival following 8 h of global ischemia in a rat axial skin flap model with increased microvascular blood flow during reperfusion. Free-flap survival improves with HBO treatment during reperfusion even following ischemia times of up to 24 h (36). Hyperbaric oxygen administered during and up to 1 h following 4 h global ischemia significantly reduced neutrophil endothelial adherence in venules and also blocked the progressive arteriolar vasoconstriction associated with reperfusion injury (37). HBO inhibited *in vitro* beta-2-integrin (CD18)-induced neutrophil adherence function, but did not alter other important neutrophil functions such as oxidative burst or stimulus-induced chemotaxis and migration. This latter finding is very important, because HBO, through its action on the CD18 adhesion molecule,

blocks the neutrophil adherence associated with IR injury without interfering with other neutrophil functions that would increase the risk of infectious complications. Initially, the focus in acute ischemia caused by trauma should be restoration of blood supply. The authors, therefore, recommend HBO therapy for all patients with muscle ischemia time greater than 4 h and skin ischemia time greater than 8 h. The major effects of IR injury are felt to occur within the first 4–7 h of reperfusion. 2 ATA hyperbaric oxygen increases the tissue oxygen tension 1000%. Treatment protocol is 2.0–2.5 ATA for 60 min, q 8 h x 24 h, then q 8–12 h x 48 h with clinical re-evaluation. If progressive signs of ischemic injury are still present, the treatment is continued at 2.0 ATA, q 12 h for 2–3 more days. Usually, 72 h of treatment is adequate as long as the first treatment is initiated within 4 h of surgery.

RADIATION TISSUE DAMAGE AND OSTeorADIONECROSIS

1.2 million cases of invasive cancer are diagnosed yearly, half of which will receive radiation therapy and 5% of which will have serious radiation complications, which represents 30,000 cases per year of serious radiation sequelae (38). HBO is also well studied for its use in treating osteoradionecrosis in conjunction with adequate debridement of necrotic bone. Carl et al. also reported success is applying HBO to 32 women with radiation injury following lumpectomy and radiation compared with controls (39). Feldmeier and his colleagues reviewed the literature and found no evidence to support the potentiation of malignant cells or the engancement of cancer growth (40). The treatment protocol is 2.5 ATA for 90 min daily for 20–50 treatments. HBO can also be used as a radiosensitizer and are as much as three times more sensitive to radiation kisses than are hypoxic cells (41).

REFRACTORY OSTEOMYELITIS

Chronic refractory osteomyelitis (CROM) is infection of the medullary and cortical portions of the bone that persists or recurs following treatment with debridement and antibiotics. The principles of treatment are fairly simple. First, the dead bone is debrided and bone cultures should be taken along with administration of appropriate antibiotics. Next, the interface or cicatrix, which separates the compromised bone from adequate blood supply, is removed. Finally, hypoxia in the wound must be corrected, which may be accomplished by HBO. The treatment protocol is 2.0 ATA for 90 min daily for 20–60 treatments. Note that CROM and refractory osteomyelitis require the longest treatment protocols. HBO is believed to oxygenate hypoxic/ischemic tissues, augment host antimicrobial responses, augment osteoclastic activity, and induce osteogenesis in normal and infected bone and antibiotic synergism.

ACUTE THERMAL BURNS

HBO is approved by the USMS but it is not covered by Medicare. Gruber demonstrated in 1970 that the area around and under a third-degree burn was hypoxic and could only be raised by oxygen at increased pressure (42). HBO has been found to prevent extension, reduce edema, increase healing rates, and decrease total cost in several randomized studies (43,44). HBO is also thought to decrease the rate of burn sepsis based on several early studies. The controversy, in part, surrounds current guidelines for early debridement and grafting of burns. Once excised, a burn no longer exists and HBO will not be helpful. In case burns are not easily amenable to excision such as flash burns to the face or groin, HBO may be helpful to prevent extension of the burn and to aid healing. Treatment must be started within 24 h. The recommended regimen is 2.0 ATA for 90 min every 8 h on the first day, then every 12 hours for 5 or 6 days.

ACUTE EXCEPTIONAL BLOOD LOSS ANEMIA

Hyperbaric oxygen for treatment of acute blood loss anemia is reserved for those patients whose anemia is not immediately treatable for practical, disease process, or religious reasons, which may include warm antibody hemolytic disease, Jehova's Witnesses, those with rare blood types, and those who refuse transfusion for other personal reasons. As explained in the physiology section, HBO dramatically increases the amount of solubilized oxygen the blood can carry. In fact, Boerema showed, in 1955, that pigs could be exsanguinated to four-tenths of one gram of hemoglobin per deciliter and be maintained in a hyperbaric environment of 3 ATA without hypoxia. The goal in HBO therapy for these conditions is to improve the oxygen depth with the daily or twice daily HBO treatments until the anemia can be improved. In between the treatments, the patients should be maintained a lower FIO_2 of inspired oxygen if possible to help reduce oxygen toxicity.

CARBON MONOXIDE POISONING

In 1966, Wada first used HBO to treat survivors of coal mine disasters with carbon monoxide poisoning and burns. The modern-day sources of carbon monoxide include automobile exhaust, home heaters, portable generators, propane engines, charcoal burners and camp stoves, and methylene chloride paint strippers. The initial treatment for carbon monoxide poisoning is 100% oxygen. The administration of 100% oxygen via a nonrebreather mask facilitates the dissociation of CO from hemoglobin to approximately 1.5 h. Hyperbaric oxygen delivered at 2.8–3.0 ATA reduced the half-life of CO-bound hemoglobin further to 23 min. In addition, patients who had one hyperbaric treatment for CO poisoning had 46% neuropsychiatric sequelae at discharge and 50% at one month versus two HBO treatments at 2.8–3.0 ATA having 13% at discharge and 18% at one month. The current recommendation is 3.0 ATA for 90 min with air breaks delivered every 8 h for a total of 3 treatments (called the Weaver protocol). Some authors still feel one treatment may be adequate (45).

CYANIDE POISONING

Hydrocyanide gas or HCN is formed when any number of substances burns, including furniture, asphalt, paper, carpeting (nylon), lighting baths (acrylic), plastic (polystyrene), and insulation (melamine resins). The antidote for cyanide poisoning begins with breathing 100% oxygen, ATLS protocols, and administration of IV sodium thiosulphate and is continued with a slow infusion of sodium nitrate and simultaneous HBO therapy if it is available. The sodium nitrate creates methemoglobin, which can impair the oxygen-carrying capacity of hemoglobin. HBO increases the amount of oxygen dissolved in plasma and may offer a direct benefit. The treatment regimen is 3.0 ATA with 30/10 airbreaks.

HYPERBARIC CHAMBER FACILITY DESIGN AND SAFETY

Over 500 hyperbaric facilities exist in the United States, and the number of hyperbaric chambers is steadily increasing worldwide. Hyperbaric chambers are classified as either monoplace or multiplace. They differ functionally in that the monoplace chamber instills oxygen into the entire chamber environment, whereas in a multiplace chamber, patients breathe 100% oxygen via a breathing mask or oxygen hood and exhaled gases are vented outside the chamber. Monoplace chambers are constructed either as an acrylic cylinder with metal ends or are primarily constructed of metal. Most commonly, the monoplace chambers are formed from an acrylic cylinder from 20 to 40 inches in diameter with tie rods connecting it to end caps. The opening is a rotating lock or a cam action lever closure. Separate oxygen and air sources provide the oxygen sources and air for air breaks during therapy. An oxygen vent must be exhausted outside the building. The through ports on the HBO chamber door allow passage of specially made intravenous monitoring devices and ventilators. The larger diameter monoplace chambers are more comfortable; however, they require more oxygen and can be heavier and more expensive to install. The acrylic chambers can provide a maximum of 3 ATA pressure. Alternatively, some monoplace chambers are constructed mostly of steel with acrylic view ports, which can accommodate pressures of up to 6 ATA and are often used in special situations such as offshore rigs where a compact chamber is needed to treat decompression illness required in U.S. Navy Table 5. Multiplace chambers are much larger and are designed to provide treatment to multiple people or to manage complex conditions. Some can even house operating rooms with special precautions. They are typically made of steel with acrylic view ports and are designed for operation up to 6 ATA or 165 feet of sea water. The gauges are reported in feet of sea water on these multiplace chambers to facilitate the use of dive tables for staff or patients. These multiplace chambers are, therefore, best-suited to treat deep water decompression illness. These chambers can accommodate from 2 to 20 people and have variable configurations including horizontal cylinders, spherical shapes, and rectangular chambers.

The primary professional hyperbaric medicine societies in the United States are the Undersea and Hyperbaric Medical Society (UHMS) and the American College of Hyperbaric Medicine. The UHMS has developed a clinical hyperbaric medicine facility accreditation program. This program can be accessed via the UHMS website at <http://www.uhms.org>, and it was designed to assure that clinical facilities are:

1. Staffed with well-trained specialists;
2. Using high quality equipment that is properly installed, maintained, and operated to the highest possible safety standards;
3. Providing high quality care;
4. Maintaining proper documentation of informed consent, treatment protocols, physician participation, training, and so on (46).

Safety Elements for Equipment and Facilities

The American Society of Mechanical Engineers (ASME) and the Pressure Vessel for Human Occupancy Committee (PVHO) define the design and fabrication guidelines for hyperbaric chambers. Although not required in all states or worldwide, it is accepted as the international standard (46). Next, the National Fire Protection Association (NFPA) has established a safety standard for hyperbaric facilities. The publication, NFPA 99, Safety Standard for Health Care Facilities, Hyperbaric Facilities, Chapter 20 explains the details of and criteria for equipment associated with a hyperbaric chamber facility. The requirements include fire abatement systems, air quality, and electrical requirements. These requirements apply to any hyperbaric chamber placed within a health-care facility. Each site must have a safety director. It is important to have only cotton clothing and to avoid any sources of sparks or static electricity given the 100% oxygen (Fig. 2). In addition to these guidelines, hyperbaric chambers are pressure vessels and, as such, are subject to boiler and pressure vessel laws. They are also medical devices and, in the United States, are also subject to FDA rules for class II medical devices. A chamber is required to have a clearance from the FDA before the device can be legally marketed or distributed, which is often called a 510 k clearance, denoting the form on which the clearance must be submitted. To check on whether a device has received clearance in the United States, one must contact the manufacturer or the Food and Drug Administration (FDA) most easily via their website, <http://www.fda.gov/scripts/cdrh/cfdocds/cfpmn/dsearch.cfm>.

Facilities must develop defined safety protocols and emergency plans that are available through both the Undersea and Hyperbaric Medicine Society (UHMS) and the American College of Hyperbaric Medicine (ACHM).

FRONTIERS AND INVESTIGATIONAL USES

The use of hyperbaric oxygen therapy has, at times, been surrounded with controversy and spurious claims from improving athletic performance to slowing the aging process. It is essential that the hyperbaric medicine

physician, staff, and potential patients understand and follow the principles of evidence-based practice, which means prescribing HBO therapy for the conditions proven to benefit from such treatment. The UHMS website, at www.UHMS.org, and AHCM are good resources for additional information as are numerous publications on hyperbaric medicine such as the hyperbaric medicine textbook available through the UHMS website. Investigational uses for hyperbaric oxygen therapy include carbon tetrachloride poisoning, hydrogen sulfide poisoning, sickle cell crisis, spinal cord injury, closed head injury, cerebral palsy, purpura fulminans, intraabdominal and intracranial abscess, mesenteric thrombosis, retinal artery occlusion, cystoid macular edema, bell's palsy, leprosy, Lyme disease, stroke and traumatic brain injury, and brown recluse spider bite. Some of the many investigational uses for HBO therapy may have merit, but these must be rigorously studied using well-designed trials. As the field of hyperbaric medicine continues to advance, so will our understanding of the complex physiologic effects of delivering oxygen under pressure.

ACKNOWLEDGMENT

Special thanks to Bob Bartlet, MD, for his help in preparing this chapter.

INTRODUCTION

Hyperbaric oxygen (HBO) is simply the delivery of molecular oxygen in very high dosage. Even though experience

has shown HBO to be very useful in a number of conditions, the exact mechanism of action at the molecular level is not fully understood. Studies done by Thom et al. (1) demonstrated that elevated oxygen tensions stimulated neuronal nitric oxide synthase (NOS1) and increased steady-state nitric oxide concentration in their microelectrode-implanted rodents. Buras et al. (2) in their studies with human umbilical vein endothelial cells (HUVEC) and bovine aortic endothelial cells (BAEC) showed that hyperbaric oxygen (HBO) down-regulated intracellular adhesion molecule 1 (ICAM 1) expression via the induction of endothelial nitric oxide synthase (NOS3), which proved beneficial in treating ischemia reperfusion injuries. Other studies talk about interactions between nitric oxide and oxygen species and their role in various disease states. Clearly, interest in HBO is growing.

Boerema (3) introduced hospital use of the hyperbaric chamber in the late 1950s in Holland, simply to maintain a semblance of normoxia in patients undergoing cardiac surgery. Heart–lung machines had not yet been invented, and the use of the chamber made certain kinds of cardiac surgery possible for the first time. Boerema felt that if enough oxygen could be driven physically into solution in the tissues, which he termed “drenching”, the circulation to the brain could be interrupted longer than 3–4 min. It also rendered surgery on many pediatric patients less risky. For example, if the normal arterial pO_2 in a patient with Tetralogy of Fallot was 38 mmHg, placing him in the chamber might raise it to 94 mmHg. Operating on the patient under hyperbaric conditions posed much less risk of ventricular fibrillation when the heart or great vessels were manipulated.

This idea caught on quickly, and soon large surgical hyperbaric chambers were built in Glasgow, New York, Los Angeles, Chicago, Minneapolis, and at Boston Children's Hospital. By the early 1960s, however, heart–lung machines became more common, and the need to do surgery in the hyperbaric chamber diminished substantially. Many large surgical chambers were left to gather dust or were dismantled, as hospital floor space is always at a premium. During this time the surgeons, who had been doing most of the research, left the field. Of the nondiving conditions, only carbon monoxide poisoning and gas gangrene seemed to be likely candidates for hyperbaric oxygen treatment based on credible research.

In 1969, however, a double-blind controlled study on the use of hyperbaric oxygen in senility was published in *The New England Journal of Medicine*. Results seemed promising, and this initiated the propagation of hyperbaric quackery. The original investigators made no sweeping claims for the research, but simply felt that the area merited further investigation. Eventually, further research showed that the results of the study reported in the *New England Journal* article were a statistical anomaly and could not be reproduced. However, hyperbaric enthusiasts seized upon the earlier report, and senility began to be treated in hyperbaric chambers, along with a host of other diseases. Most of these were not in medical centers. Fly-by-night “clinics” suddenly appeared claiming to cure anything and everything. Patients were treated for skin wrinkles, loss of sexual vigor, and a host of other

maladies. As there were few investigators doing good research in the area at that time, the field fell into disrepute.

Fortunately, a few legitimate investigators persisted in their work, looking at the effects of hyperbaric oxygen in greater detail. Soon it became clear that under hyperbaric conditions oxygen had some unusual effects. The Undersea and Hyperbaric Medical Society created a committee to investigate the field. After careful study, the committee laid down guidelines for what should be reimbursed by third-party payers and what conditions should be considered investigational. Their report appeared in 1977 and was adopted as a source document for Blue Cross/Blue Shield (4). About the same time, Jefferson C. Davis of the United States Air Force School of Aerospace Medicine edited the first textbook in hyperbaric medicine (5). It was only then that a firm scientific basis was reestablished for the field, leading to increased acceptance by the medical community. The number of chambers operating in hospitals has risen dramatically from only 37 in 1977 to > 500 today. The Undersea and Hyperbaric Medical Society (www.UHMS.org) and the American College of Hyperbaric Medicine (www.ACHM.org) have taken responsibility for setting standards in this field and for encouraging additional research. At this time, ~ 13 clinical disorders have been approved for hyperbaric treatment. They include air or gas embolism, carbon monoxide poisoning, clostridial myonecrosis, crush injury or compartment syndrome, decompression sickness, problem wounds, severe blood loss anemia, necrotizing soft tissue infections, osteomyelitis, radiation tissue damage, skin grafts or flaps, thermal burns and brain abscess.

Remember that hyperbaric oxygen was introduced initially into hospitals in order to simply maintain normoxia or near-normoxia in patients undergoing surgery. It was only later, and quite serendipitously that researchers discovered that oxygen under increased atmospheric pressure gained some of the attributes of a pharmacologic agent. Oxygen begins to act like a drug when given at pressures of 2 atm or greater. For example, oxygen under pressure can terminate lipid peroxidation *in vivo* (6), it can enhance the bacteriocidal capabilities of the normal leukocyte (7,8), and it can stimulate the growth of new capillaries in chronically ischemic tissue, such as in the diabetic foot, or in tissue that has undergone heavy radiation. It can reduce intracranial pressure on the order of 50% within seconds of its initiation, and this effect is additive to that of hypocapnia (9–11). HBOT can increase the flexibility of red cells, augmenting the effects of pentoxifylline (12). It can decrease edema formation by a factor of 50% in postischemic muscle and prevent second-degree burn from advancing to full-thickness injury (13–15). Hyperbaric oxygen has also been shown to hasten functional recovery of traumatized peripheral nerves by almost 30% following repair. Many of these discoveries have been made only in the last decade.

In a number of these areas, we are beginning to understand the basic mechanisms of action, but overall very little is understood at the molecular level. It is anticipated that studies involving nitric oxide synthase will provide insight regarding the elusive molecular mechanistic

explanation. Also, many contributions to our understanding have come from advances made in the biochemistry of normal wound healing. We understand that normal oxygen pressures are 80–90-mmHg arterially, that oxygen enters our tissues from the capillaries, and that at this interface carbon dioxide (CO₂) is removed. Under hyperbaric conditions, all of this changes. At a chamber pressure of 2.4 atm (ATA), the arterial oxygen pressure (pO_2) reaches ~ 1500 mmHg, immediately saturating the red blood cells (RBCs). Upon reaching the tissues, these RBCs never unload their oxygen. At this high partial pressure of gas, oxygen diffuses into the tissues directly from the plasma. Returning to the heart, the RBCs are bathed in plasma with a pO_2 of 150–200 mmHg. Tissue oxygen requirements are completely derived from the plasma. In theory, one might think that this condition could prove fatal, as red cells no longer can carry CO₂ away from the tissues. However, we are fortunate that CO₂ is 50 times more soluble in plasma than are oxygen and nitrogen, and the body has a very capable buffering system which overcomes the loss of the Haldane effect, which is the increase in CO₂ carrying capacity of deoxygenated red cells (16).

Another factor to be considered is the actual part of the circulatory system that overcomes the loss of the Haldane effect. Traditionally, we think of this exchange occurring in the capillaries. Under very high pressures, however, computer modeling has shown that nitrogen exchange under pressure (as in deep sea divers) is probably complete by the time the blood reaches the arteriolar level. Whether this is true when hyperbaric oxygen is breathed has not yet been determined. The rate of metabolism under hyperbaric conditions appears to be unchanged, and the amount of CO₂ produced appears to be about the same as when breathing air. It would be interesting to know just at what level oxygen exchange is accomplished in the tissues, as this might have practical implications when treating people with severe capillary disease.

Oxygen can be toxic under pressure. Pulmonary toxicity and lung damage can be seen at oxygen pressures > 0.6 atm during chronic exposure. Central nervous system (CNS) toxicity can manifest as generalized seizure activity when oxygen is breathed at pressures of 3 atm or greater. The CNS toxicity was first observed by Paul Bert in 1878, and is termed the “Paul Bert Effect” (17). Despite years of research into this phenomenon, the exact underlying or molecular cause of the seizure has not yet been discovered. There is a generalized vasoconstriction that occurs when oxygen is breathed at high pressure, reducing blood flow to muscle, heart, and brain by a factor of ~ 20%, as a defense against toxic quantities of oxygen. The exact mechanism responsible for this phenomenon is not fully understood.

Central nervous system oxygen toxicity was evaluated by the Royal Navy. The purpose of this research was to determine the time until convulsion so that combat swimmers would know their endurance limits under various conditions. Volunteer research subjects swam in a test tank using closed-circuit oxygen rigs until convulsion occurred and thus established safe oxygen tolerance boundaries.

Also related to the effect of oxygen, the "off" phenomenon (18) was first described by Donald in 1942. He observed that seizures sometimes occurred when the chamber pressure was reduced or when a diver surfaced and oxygen breathing under pressure was suddenly terminated. Lambertsen (19) provided a description of this type of seizure activity:

The convulsion is usually but not always preceded by the occurrence of localized muscular twitching, especially about the eyes, mouth and forehead. Small muscles of the hands may also be involved, and incoordination of diaphragm activity in respiration may occur. After they begin, these phenomena increase in severity over a period which may vary from a few minutes to nearly an hour, with essentially clear consciousness being retained. Eventually an abrupt spread of excitation occurs and the rigid tonic phase of the convulsion begins. Respiration ceases at this point and does not begin again until the intermittent muscular contractions return. The tonic phase lasts for about 30 seconds and is accompanied by an abrupt loss of consciousness. It is followed by vigorous clonic contractions of the muscle groups of the head and neck, trunk and limbs. As the incoordinated motor activity stops, respiration can proceed normally.

Within the wound healing community, current doctrine holds that a tissue pO_2 of 30–40 mmHg is necessary for adequate wound healing (20,21). Below 30 mmHg, fibroblasts are unable to replicate or produce collagen. Additionally, when the pO_2 drops < 30 mmHg, leukocytes are unable to utilize oxidative mechanisms to kill bacteria. We have noted that the tissue pO_2 is critical, but that the actual quantity of oxygen consumed in wound healing is relatively small. The amount of oxygen used to heal a wound is only ~ 10% of that required for brain metabolism.

Production of new collagen is also a requirement for capillary ingrowth or proliferation (22). As capillaries advance, stimulated by angiogenic growth factor, they must be supported by an extracellular collagen matrix to facilitate ingrowth into tissue. In the absence of new collagen, capillary ingrowth cannot occur. This effect is crucial in treating radionecrosis (23–25), where the tissue is primarily hypovascular, and secondarily hypoxic and hypocellular. It has been discovered that when collagen production can be facilitated, new capillaries will invade the previously irradiated area, and healing will then occur. The tissue pO_2 rises to ~ 80% of normal and plateaus; however, this is sufficient for healing and will even support bone grafting. Historically, the only means of managing radionecrosis was to excise the radiated area and bring in fresh tissue with its own blood supply. New collagen formation and capillary ingrowth also account for the rise in tissue pO_2 , which can be achieved in patients with diabetic foot lesions.

It is now well understood that the stimulus for growth factor production by the macrophage is hypoxia and/or the presence of lactic acid (26,27). Wounds managed in hyperbaric units are typically ischemic and hypoxic. Periods of relative hypoxia, required for the stimulation

of growth factor production, exist between hyperbaric treatments.

Surprisingly, oxygen levels remain high in tissues for longer than one would expect following hyperbaric treatment. In a study by George Hart (28) at Long Beach Memorial Hospital, a mass spectrometer probe was inserted in the unanesthetized thigh tissues of normal volunteers. Muscle and subcutaneous tissue pO_2 values in study subjects remained significantly elevated for 2–3 h following hyperbaric oxygen treatment. Arterial pO_2 was also measured and found to rise immediately and significantly under hyperbaric conditions but returned to normal levels within a couple of minutes upon egress from the chamber (Fig. 1). Thus, multiple daily HBO treatments can maintain useful oxygen levels for up to 12 h/day.

Mention has been made of enhanced leukocyte killing of bacteria under hyperbaric conditions. Jon Mader of the University of Texas-Galveston (29) carried out a rather simple, but elegant, experiment to demonstrate this. The fascinating part of this study is that in the evolution of the human body, a leukocyte has never been exposed to a partial pressure of 150 mmHg while in tissues. This level is impossible to attain breathing air. Nevertheless, when one artificially raises the pO_2 far beyond the leukocyte's normal functional parameters, it becomes even more lethal to bacteria. This is an anomaly, as one rarely can improve on Mother Nature. Of some interest in this regard is that if one bites one's tongue, one is never concerned about possible infection, even though it is a human bite. Similarly, hemorrhoidectomies rarely, if ever, become infected. The reason is that the pO_2 of the tissues in and around the oral cavity are very high, and the pO_2 in hemorrhoidal veins is nearly arterial. Tom Hunt has shown it is impossible to infect tissue that is injected with raw staphylococci if the pO_2 in the same tissue is > 50 mmHg. Both he and David Knighton have described oxygen as an antibiotic (30,31).

The reduction of intracranial pressure is facilitated by vasoconstriction. Experimentally, Rockswold has shown that mortality can be halved in victims of closed head injury with Glasgow Coma Scales in the range of 4–6. One of the major mechanisms here is a reduction of intracranial pressure while continuing to oxygenate hypoxic brain (32–36). Sukoff et al. (37) administered 100% O_2 , 1.5 ATA \times 60 min every 24 h (maximum of 7 h) to severely brain injured patients. This resulted in a 50% reduction in mortality.

A paper published by Mathieu (38) has shown that the flexibility index of red cells can be changed from 23.2 to 11.3 within 15 hyperbaric treatments. This increase in flexibility can prove quite useful in people with narrowed capillaries. However, whether this phenomenon plateaus at 15 treatments, its duration and underlying mechanism are still unknown.

Nylander et al. (39) demonstrated that following complete occlusion of the blood flow to rat leg for 3 h, post-ischemic edema could be reduced by 50% if the animals are promptly treated with hyperbaric oxygen. He also demonstrated that the mechanism for this was preservation of adenosine triphosphate (ATP) in the cells, which provides the energy for the cells to maintain their osmolarity. Cianci

Figure 1. Arterial, muscle and subcutaneous pO_2 after HBO treatment.

(40,41). Yamaguchi, and others have underscored the importance of ATP in preventing edema in burn. Treatment twice daily has shown to be more efficacious than treatment once a day.

Zamboni (42) and Gingrass, working at the University of Southern Illinois, have shown the effects of hyperbaric oxygen on speeding functional return in peripheral nerve repair and grafting. At 6 weeks, there is a 28% improvement of function in the affected leg of these rats.

Niezgoda (43) performed a randomized and double-blinded study in human volunteers investigating the effect of hyperbaric oxygen in a controlled burn wound model. He demonstrated statistically significant decreases in edema formation and wound exudate in the hyperbaric oxygen treated group.

Finally, the mechanism for the effects of hyperbaric oxygen in carbon monoxide poisoning (44,45) is now better understood. Traditionally, it was felt that the mere presence of carboxyhemoglobin blocked transport of oxygen to the tissues. However, studies by Goldbaum et al. (46) at the Armed Forces Institute of Pathology in 1975 lead us to different conclusions. Impairment of cytochrome A3 oxidase and lipid peroxidation occurring following a reperfusion injury are now suggested as the primary pathways in the pathophysiology causing fatality. Stephen Thom (47–50) at the University of Pennsylvania pioneered research in this area. It appears that as carbon monoxide levels fall, the products of lipid peroxidation rise, indicating that brain damage is occurring only during the resuscitative phase, thus becoming reperfusion injury. Thom demonstrated that a period of hypotension (even though it may only be a matter of seconds) is enough to initiate lipid peroxidation. Oxygen at 1 atm has no effect on halting the process. However, oxygen at 3 atm terminates lipid peroxidation. Patients who have been treated acutely with hyperbaric oxygen rarely exhibit signs of delayed deterioration, reported in 30–40% of severe cases treated only with normobaric oxygen. The probable mechanism for this

is the ability of hyperbaric oxygen at three ATA to terminate lipid peroxidation.

Finally, in many ways it seems paradoxical that oxygen at high pressure, which intuitively would seem to provide more substrate for free-radical formation, still benefits tissues from crush injury and postischemic states. But ironically, it is precisely this hyperbaric environment that promotes certain so-called reactive oxygen species with inherent protective qualities (51). More studies are certainly needed to investigate the underlying pharmacologic benefits afforded by hyperbaric oxygen. We have only just begun to explore and utilize a treatment modality whose time has come.

INTRODUCTION

Interstitial hyperthermia or thermal therapy is a minimally invasive method for the treatment of cancer. Radio frequency (RF), microwave, laser light, or ultrasound energy is delivered through one or more thin needle devices inserted directly into the tumor.

Interstitial devices have the significant advantage over external devices of being able to deliver thermal energy directly into the target region, thereby avoiding depositing energy into intervening nontarget tissue. Their main disadvantage is that the needle devices employed often deposit energy over only a small volume. This can make it challenging to deliver an adequate thermal dose to large target regions. This problem was highlighted in an early radiation therapy oncology group (RTOG) phase III trial in which only 1 out of 86 patients was deemed to have received an adequate thermal treatment (1).

These early challenges in interstitial hyperthermia have been addressed, to some extent, through the development of improved heating devices and more detailed monitoring of applicator placement and dose delivery. Quality assurance guidelines have been developed by the RTOG to raise the quality of heating (2). The guidelines recommend pretreatment planning and equipment checks, the implantation of considerations and documentation, the use of thermometry, and the development of safety procedures. Treatment procedures have also been improved through the use of more detailed thermometry, especially using magnetic resonance imaging approaches (3,4).

THERMAL DOSE AND HEAT TRANSFER

The goal of interstitial thermal therapy is to deliver a prescribed dose to a target volume. Thermal dose is defined as equivalent minutes at 43 °C, or TD. The units of TD are minutes, which represents the time tissue would need to be maintained at a constant temperature of 43 °C to have the same effect as the particular time–temperature history that the tissue was exposed to. The thermal dose after \square minutes of heating can be calculated if the time–

temperature history is known (5),

$$\text{TD}(t) = \int_0^t R^{43-T(\tau)} d\tau \quad \text{where}$$

$$R = \begin{cases} 0.25 & \text{for } T \leq 43^\circ\text{C} \\ 0.5 & \text{for } T > 43^\circ\text{C} \end{cases} \quad (1)$$

$$(2)$$

The dose prescribed for treatment depends on whether the heating is being used as an adjuvant to radiation or systemic therapy, or whether it is being used as a stand-alone treatment to coagulate tissue. For the former use, the dose prescribed is typically 10–60 min (Eq. 1) and for the latter it is usually prescribed to be > 240 min (Eq. 2). This is because temperatures employed for adjuvant treatment (usually referred to as hyperthermia) are in the 40–45 °C range. For stand-alone coagulation (usually referred to as thermal therapy or thermal ablation), temperatures in the range of 55–90 °C are used.

The temperature (T) produced in tissue depends on the heat deposition by the applicator, heat conduction, and blood flow according to

$$\rho c \frac{\partial T}{\partial t} - \nabla \cdot (k \nabla T) + \mathbf{v} \cdot \nabla T = Q$$

where ρ is the tissue mass density, ∇ is the heat capacity of the tissue, k is the thermal conductivity of the tissue, \mathbf{v} is the blood velocity profile, and Q is the heat absorbed per unit volume. Detailed knowledge of the blood velocity profile at the capillary level is generally unknown, and even if it were known the calculations would require impractically large computational resources. While several models have been proposed to calculate heat transfer due to perfusion, the Pennes bioheat transfer equation is most often employed (6)

$$\rho c \frac{\partial T}{\partial t} - \nabla \cdot (k \nabla T) + w c_b (T - T_b) = Q$$

where w is blood mass perfusion rate, c_b is the blood heat capacity, and T_b is the temperature of the blood entering the treatment field, and \mathbf{v} is the velocity field of any convective flow (e.g., as the blood in large vessels). This equation can be used to predict the temperature in tissue, and therefore plan thermal therapy or hyperthermia treatments if the perfusion rate is known. Pennes's equation does not accurately predict for the effect of large blood vessels that must be modeled individually.

ELECTROMAGNETIC HEATING

The heat absorbed (or deposited) in tissue is often described in terms of the power per unit mass. It is called the specific absorption rate or SAR. For electromagnetic devices heat is deposited by the motion of charges or ions. The movement of charge depends on the electric field produced by the applicator in tissue. In microwave and RF hyperthermia, the applicators are driven by sinusoidally time-varying signals. In this case, the electric field can be written in phasor form \mathbf{E} such that the electric field is given by, $E(t) = \Re(\mathbf{E}e^{j\omega t})$, where $\Re(\mathbf{x})$ is the real part of the complex vector \mathbf{x} , and ω is the angular frequency of the driving

signal. The SAR is then

$$\text{SAR} = \frac{Q}{\rho} = \frac{\sigma}{2\rho} (\mathbf{E} \cdot \mathbf{E}^*)$$

where σ is the electrical conductivity of the tissue.

The calculation of the electric field \mathbf{E} is based on Maxwell's equations. For microwave devices, these equations are combined to produce the Helmholtz vector wave equation

$$\nabla \times \nabla \times \mathbf{E} - k^2 \mathbf{E} = 0$$

where k is the complex-valued wavenumber given by $k^2 = \omega^2 \mu \epsilon - j \omega \mu \sigma$ and μ is the magnetic permeability of the medium, which for tissue is the same as the free-space value, and ϵ is the electrical permittivity of the medium. The divergence free condition, $\nabla \cdot \mathbf{E} = 0$, may have to also be explicitly imposed if the solution technique does not inherently do this.

For RF devices, the frequency is sufficiently low that the displacement currents can be ignored. In this case, it is usually simpler to determine the scalar electric potential V and from this derive the electric field, $\mathbf{E} = -\nabla V$. The electric potential obeys a Poisson-type equation

$$-\nabla \cdot (k \nabla V) = 0$$

For models of both microwave and RF devices, the governing Helmholtz or Poisson equation is imposed in a domain with a known electric field or electric potential specified as a boundary condition to represent the power source. Another condition that is often imposed on the surface of metals is that the tangential component of the electric field is zero, $\hat{n} \times \mathbf{E} = 0$.

The solution of the governing equations with appropriate boundary conditions is impossible for all but the simplest geometries. For most practical cases, numerical methods and computational tools are required. The finite difference time domain (FDTD) method (7), the finite element (FE) method (8,9), and the volume surface integral equation (VSIE) method (10) are the most commonly utilized methods for solving the governing equations in electromagnetic hyperthermia and thermal therapy. In the FDTD method, the domain is discretized into rectangular elements. The accuracy of a FDTD solution depends on the size of the mesh spacing. Smaller elements produce more accurate solutions, but also require more memory to store the system of equations. Since the grids are rectangular, their nonconformation to curved tissue boundaries produces a stair-casing effect. Therefore, a large number of elements are required to model such geometries accurately. Unlike the FDTD method, the FE method uses tetrahedral meshes in the domain and the VSIE method uses triangular meshes on domain surfaces. Tetrahedral and triangular meshes are more suitable than regular finite difference grids for three-dimensional (3D) modeling since they do not have the stair casing effect at tissue boundaries.

RADIO FREQUENCY DEVICES

In RF, thermal therapy tissue is heated by electrical resistive (or J) heating. The heating devices, or applicators, are

Figure 1. The heating in RF devices is caused by current flow. Since the current flows from the heating electrode to the ground pad, there is a high current density near the electrode due to its small size compared to the ground pad. This results in heating that is localized to the heating electrode.

inserted interstitially to produce currents in the tissue. The currents typically oscillate sinusoidally in the kilohertz or low megahertz frequency range. As a result, this modality is often referred to as radio frequency or RF heating. These devices have an advantage over other interstitial devices in their simplicity and low cost. They can operate at low frequency, and therefore do not require complex power generators. The RF probes, due their simplicity, tend to have the smallest diameter of all the types of interstitial heating probes. The RF heating technique has been extensively reviewed by others (11–15).

There are several designs of RF interstitial devices, which may be categorized into three groups. The simplest design consists of a single electrode at a probe tip (often referred to as a needle electrode) (9,16–20). The current flows between a single electrode at the end of an applicator and a large ground plate placed at a distal site. Since the current flows between a small electrode and a large plate, the currents are concentrated near the electrodes resulting in SAR patterns that are localized to the electrodes as illustrated in Fig. 1.

With these single electrode probes the coagulation diameter is usually limited to ~ 1.6 cm. Therefore several probes are needed to cover a larger area (21), or a single probe can be inserted into several locations, sequentially, during a treatment.

Since it is desirable to avoid the insertion of multiple interstitial probes, single probes that release multiple electrodes outward from the probe tip have been designed to produce large coagulation volumes. Two examples of these are the Boston Scientific (Watertown, MA; formerly Radio Therapeutics Corporation, Mountain View, CA) RF 3000 system in which 10–12 tines are deployed from a cannula to form an umbrella shape (Fig. 2) and the RITA Medical Systems (Mountain View, CA) Starburst probes with up to 9 tines. In some configurations, some of the tines in the Starburst probes are replaced with dedicated thermocouples while others are hollow electrodes through which saline can be infused into the target region to enhance heating. These multielectrode probes are able to produce coagulation regions with diameters up to 7 cm, although complete coverage of a large region can be difficult in high blood flow organs, such as the kidney (22).

The negative RTOG phase III trial, in which only 1 out of 86 patients was deemed to have received an adequate thermal dose (1) illustrated the need to not only increase the target volume coverage, but also to control the heating.

Figure 2. A Boston Scientific (Watertown, MA; formerly Radio Therapeutics Corporation, Mountain View, CA) interstitial RF probe with 10 tines that are deployed from the cannulus after insertion into a target region. The deployed tines produce a coagulation zone that is larger than the zone that can be produced by a single electrode probe. The top probe is shown with the tines undeployed (ready for insertion) and the bottom probe shows the probe with the tines deployed (as they would be after insertion).

Control is needed to enable the conformation of the heating to irregularly shaped target volumes while avoiding nearby organs at risk and to compensate for heterogeneous cooling by the vasculature (23). Partial control can be achieved by appropriate positioning of the probes and the adjustment their power. Further control along the direction of the probe is also needed (24,25) and multielectrode current source (MECS) applicators have been developed to provide this capability (26). The MECS applicators contain several electrodes placed along their length with the amplitude and phase of each electrode independently controlled. In the most common configuration, the electrodes are capacitively coupled (insulated) with the tissue. The electric fields induced by the electrodes produce currents in the tissue that cause heating. Since the electrodes are capacitively coupled, the probes can be inserted into brachytherapy catheters, for example, making it feasible to add interstitial heating as a simultaneous adjuvant to brachytherapy (interstitial radiation therapy). The electric field (and hence current) may be induced between electrodes on the same probe or on separate probes, or it may be induced between the probe electrodes and a grounding plane.

MICROWAVE DEVICES

Microwave applicators can produce larger coagulation regions than RF applicators due to their radiative nature. However, the construction of the power generator and matching circuitry makes these devices more complex, and therefore more expensive. Due to this, microwave interstitial hyperthermia has been used less often in the clinic than RF interstitial hyperthermia.

Ryan et al. reviewed and compared several types of microwave interstitial applicators (27) and several excellent reviews of microwave interstitial thermal therapy exist (28–32). The two most commonly used devices are the dipole antenna and the helical antenna. The dipole antenna is the simplest form of microwave interstitial antenna (7,8,33). It is usually constructed from a coaxial cable with the outer conductor removed from an end section (typically 1 or 2 cm in length) to expose the inner conductor (Fig. 3). A power generator feeds a sinusoidally oscillating signal into the cable at one of the ISM frequency bands between 400 MHz and 3 GHz. The inner- and

outer-conductor electrodes at the tip of the coaxial cable act as an antenna that produces microwaves that radiate out into the tissue. Tissue is an attenuating medium that absorbs microwaves, and this absorbed energy is converted into heat in the tissue.

The radiative or active length of a typical dipole interstitial device is 1–3 cm. The devices produce a coagulation region that is ellipsoidal shaped with a large axis of up to 3 cm along the length of the antenna and a small axis of up to 2 cm diameter. The drawback of the dipole applicator is that the region of highest SAR, or hot spot, is located at the point at which the outer conductor is cut away. Therefore, the tips of these antennas have to be inserted past the center of the target region, and this can be a problem if the target region is located adjacent to a critical structure.

A further problem with dipole antennas is that the SAR patterns are sensitive to the depth to which the antenna is inserted into tissue (8). A second common microwave applicator design, referred to as a helical antenna (34–36), has been designed to make the applicator insensitive to its insertion depth. In this applicator, one electrode is wrapped in a helix pattern around an exposed coaxial cable (Fig. 4). The antennas are also designed to extend the heating pattern along the applicator and toward the tip of the antenna compared to the dipole antenna. The SAR pattern from a BSD Medical (Salt Lake City, UT) helical antenna is shown in (Fig. 5). The antenna was operating at 915 MHz. The measurement was performed using the thermographic imaging technique (37) and demonstrates

Figure 3. A schematic representation of a microwave interstitial dipole antenna applicator. The outer conductor of a coaxial cable is stripped away to produce a radiating section.

Figure 4. Shown here is a BSD Medical (Salt Lake City, UT) helical microwave applicator. The inner conductor of a coaxial cable is extended backward in a helical pattern around the dielectric insulator. There is no connection between the helical section and the outer conductor.

that the heating extends along the length of the helix and that the hot spot is close to the tip of the applicator.

Interstitial microwave applicators have the advantage over RF applicators in the ability to use arrays of applicators to dynamically steer the SAR pattern (33). For large target volumes, several applicators can be inserted. The heating pattern can then be adjusted by not only adjusting the power to each applicator, but also by adjusting the relative phase of the signal to each applicator. The phase can be adjusted such that the microwaves produced by the applicators interfere constructively in regions that require heating and interfere destructively in regions that should be spared. The predetermination of the phase required for each applicator can be calculated during treatment planning. This is a challenging calculation for applications in which tissue is electrically heterogeneous or the placement of the applicators cannot be accurately predicted. In these cases real-time monitoring of the treatment is required and a manual or computer run feedback control is used to set the phase of the applicators to produce the desired heating profile.

The size of the coagulation volume is limited by the maximum temperature in the treatment field. Since the maximum temperature is usually located at the applicator, it is possible to increase the coagulation volume by cooling adjacent to the applicator. Using this technique, the cross-

Figure 5. The normalized SAR pattern along the coronal plane of a BSD Medical (Salt Lake City, UT) helical applicator operating at 915 MHz. The image was provided courtesy of Claire McCann.

section area of a coagulation volume has been noted to increase by a factor of 2.5 in one study (38) and the coagulation volume diameter was found to increase from 1.2 to 2.4 cm (39). In microwave heating, the cooling is usually done by passing water or air through the catheter containing the antenna (29,38,40). In RF heating, cooling water is passed inside the electrode to cool the tissue near the electrode (41,42).

In RF heating, it is also possible to increase the coagulation volume by saline injection from the lumen of the electrode (43). Since saline is electrically conductive, injecting it into the tumor increases the electrical conductivity of the tumor, and hence the SAR in the tumor. This technique has not gained popularity due to the inability of control the flow of saline in the tumor, resulting in irregular and unpredictable coagulation regions being produced.

CLINICAL STUDIES WITH MICROWAVE AND RF DEVICES

Interstitial microwave and RF heating systems have been widely used to clinically treat a variety of tumors in phase I (34,44–47), phase II (18,32,44–49) and phase III trials (1,50). The RF systems have been used to treat a large range of sites, including brain (45), head and neck (1), breast (1), myocardium (51), lung (14), liver (11,52), pancreas (18), prostate (48), and kidney (44,53). Microwave systems have also been used to treat a large range of sites, including liver (4), prostate (both carcinoma and benign hyperplasia) (29,36), head and neck (1,32,49), brain (34,50), breast (1), and other pelvic areas (1). The heat treatments are used alone (29,36), or combined with external beam radiation (54), interstitial radiotherapy (brachytherapy) (1,32,46), and/or chemotherapy (17). The heat treatments are used alone (29,36), or combined with external beam radiation (29,36,48,54,55), combined with external beam radiation (54) or interstitial radiotherapy (brachytherapy) (1,32,46,48,55), and with chemotherapy (17).

The interstitial hyperthermia treatments are usually administered under ultrasound, CT or MR guidance. During the treatment the hyperechogenicity of microbubbles that can be produced at sufficiently high temperatures can provide some real-time ultrasound feedback of the treatment. Posttreatment evaluation can be performed using contrast enhanced ultrasound, CT or MR. The vasculature in the coagulated volume is destroyed and the destroyed volume can be identified as an unenhanced region in the image (41,56,57).

LASER DEVICES

First described in 1983 by Bown (58), Interstitial Laser Photocoagulation (ILP) [sometimes referred to as Laser Induced Thermal Therapy (LITT)] involves the use visible or near infra-red (IR) light delivered through fibre optic cables to heat tissue for therapeutic purposes. The ILP has been investigated as an experimental treatment for a variety of solid tumors including liver, breast, stomach, pancreas, kidney, lung, and bone (59). The tissue temperature is raised causing coagulation of the target volume. Similar to the microwave and RF cases, the production of

heat in a local volume of tissue results from the amount of absorbed laser energy, $S(r)$. In biomedical treatments, such as LITT, it is the total absorbed laser energy that typically determines the therapeutic outcome. It is equal to the product of the local fluence rate, $\phi(r)$ which is the total photon power over all directions that pass through a point area of space, and the absorbing characteristics, $\mu_a(r)$ of the tissue (60):

$$S(r) = \mu_a(r)\phi(r)$$

The absorbed optical energy deposition pattern is governed by the absorption and scattering characteristics of the tissue. An absorption event causes the interacting molecule to enter a vibrational-rotational state that results in a transfer of energy to surrounding molecules that manifests as a local increase in temperature (61). Absorption occurs due to interactions with native molecules called chromophores with examples including melanin, hemoglobin, and water. In a given tissue, the concentration weighted sum of the absorption of different chromophores leads to its bulk macroscopic absorption. Scattering refers to a directional change in light propagation and likely results from differences in the index of refraction in the various cellular components, such as the between cell membranes and the extracellular space. Here the scattering is assumed to be elastic with no change in energy occurring during the interaction. The statistical quantities that govern light interactions are the scattering coefficient, $\mu_s(\text{cm}^{-1})$ and absorption coefficient, $\mu_a(\text{cm}^{-1})$ and are defined, respectively, as the probability of scattering or absorption per average distance traveled (also known as the mean free path). In the case of scattering, consideration is given to the probability of scatter in a particular direction. An additional parameter known as the anisotropy factor, g , quantifies this directionality by integrating the average cosine of the scattering probability over all directions. When $g = 0$, scattering is isotropic. However, in the case of biological tissues g typically lies within the range of 0.7 and 0.99 meaning that scattering typically occurs in the forward direction. The reduced scattering coefficient, $\mu'_s = \mu_s(1 - g)$, allows light scattering to be approximated as isotropic although scattering events are actually in the forward direction. The inverse of the reduced scattering coefficient is, therefore, the average distance that light travels before it changes direction from its original direction of propagation (62).

In theory, Maxwell's equations could be used to calculate the scattering and absorption of the EM vector fields due to the underlying tissue components (63). In this case, the tissue microstructure could be modeled as random perturbations, $\varepsilon_1(r)$ in the dielectric constant around a mean value, $\varepsilon_0(r)$, with the total dielectric constant, $\varepsilon(r)$, given by the sum of these quantities. However, in practice, due to the complex and random composition of tissue, a complete and accurate description of $\varepsilon(r)$ has yet to be realized. Instead a more commonly used solution is to consider light as a stream of neutral particles or photons with individual quanta of energy that propagate elastically throughout the medium. This formalism is governed by radiative transport theory (64), and assumes light to be

monochromatic while ignoring its conventional wave characteristics, such as polarization, diffraction, interference, and fluorescence. Although incomplete, the photon model has been shown to be consistent with experimental measurements in turbid media (65).

A commonly employed model of photon propagation is the Monte Carlo (MC) method (66), which utilizes probability distributions to simulate the propagation of thousands to millions of individual photon packets based on the optical properties of tissue to arrive at a statistical representation of the overall light distribution. The MC is amenable to heterogeneous and arbitrary geometries and does not suffer from the limiting assumptions of analytical solutions. However, its primary disadvantage is the requirement of long computational times, on the order of hours to days, to achieve reasonable statistics. Regardless, with the increasing speed of modern computers, the Monte Carlo method remains a viable option for photon simulations. The reader is referred to an excellent review by Roggan and Muller (67) for the implementation of the MC model for treatment planning of LITT.

Alternatively, one may employ formal solutions to the governing equations for photon transport. The energy flow of photons in a scattering and absorbing medium is described by the radiative transfer equation (RTE) (64). The RTE is an integro differential equation that describes the energy conservation of photons within an infinitesimally small volume that result from losses due to absorption and scattering as well as gains arising from photons scattered from other directions and from the laser source. Analytical solutions to the RTE are difficult to obtain. Hence, various approximations have been proposed to convert the RTE to a more mathematically tractable and practical form. A standard technique, called the P_n approximation, expands the radiance and source as a finite series of spherical harmonics to n th order. The P_1 approximation is the simplest of these expansions and in the steady state is also known as the diffusion approximation (63,64):

$$\nabla^2\phi(\vec{r}) - \frac{\mu_a}{D}(\vec{r})\phi(\vec{r}) = -\frac{1}{D}S(\vec{r})$$

Here $\phi(\vec{r})$ is the photon fluence rate, while D is the photon diffusion coefficient given by

$$D = \frac{1}{3[\mu'_s + \mu_a]}$$

The primary assumption of the diffusion equation, that is linear flux anisotropy, is only accurate when the scattering properties of the medium are much larger than the absorption properties and at locations $> 1/\mu'_s$ from the source. A number of analytical solutions to the diffusion equation exist for simple but practical geometries. The solution for a point source in an infinite homogeneous medium is given by (63)

$$\phi(\vec{r}) = \frac{P_0 e^{(-\mu_{\text{eff}}r)}}{4\pi r}$$

This solution is particularly useful as, assuming an infinite medium, it may be integrated numerically to provide the light distribution of cylindrical or extended source

of arbitrary geometries. However, it is well known that tissue optical properties often change from their native state after undergoing thermal coagulation. This results in heterogeneities in optical properties that effect the overall light distribution (68). In such cases, analytical solutions are available only for the simplest geometries and numerical methods such as the finite element (69), finite difference (70), and boundary element method (71) must be employed. A thorough discussion of these methods was given in the preceding section for microwaves and their implementation in the case of photon propagation is the same.

Initially, bare tipped optical fibers were used to deliver laser light to the tumor. High temperatures immediately adjacent to the fiber tip cause the tissue to char and form a zone of carbonization. The charred fiber then acts as a point heat source and the temperature of the fiber increases significantly leading to vacuolization of the surrounding tissue. The volume of coagulation around the fiber grows until thermal equilibrium is reached at the edges of the lesion. Here, the conduction of heat from the fiber is balanced by the tissue's ability to remove energy through blood flow and thermal conduction.

The size of the lesion depends on the thermal conduction properties of the tissue, but would normally be limited to ~ 2 cm in diameter. Larger tumors require multiple optical fiber implants to enable complete coverage of the tumor volume. For example, a 4 cm diameter tumor would require at least eight fibers to fully coagulate the tumor.

The limitations of the bare tipped fibers have been addressed in two ways. The first was to employ a line source geometry instead of a point source. This can be achieved by using a diffusing tip fiber where light gradually leaks out of the fiber over an extended distance of a few centimeters. The second approach is to restrict the temperature of the fiber to lower than the charring threshold by controlling the power delivered to the fiber. If charring is avoided, light can propagate into the tissue resulting in heating at a distance from the fiber and a broader SAR pattern. These two approaches can be combined to achieve greater lesion volumes from single fibers. Heisterkamp et al. (72) demonstrated an almost doubling of the coagulated volume from 4.32 cm³ (bare tipped) to 8.16 cm³ (temperature restricted diffusing tip) using such an approach.

The other major factor that affects the lesion size is the wavelength of the light used. Somewhat counterintuitively, light that is less absorbed by tissue, results in greater lesion sizes. This is because the light can penetrate further into the tissue, and therefore directly heat at greater distances from the fiber. The availability of high power sources at two specific wavelengths (810 nm as produced by diode lasers and 1064 nm as produced by Nd:YAG lasers) has dominated the development of interstitial laser thermal therapy. Wyman et al. (73) have shown that 1064 nm light can enable the creation of greater lesion sizes due to its greater penetration. However, Nd:YAG lasers are large, generally immobile and inconvenient and so many have adopted 810 nm as the wavelength of choice due to the availability of compact and inexpensive sources. More recently 980 nm lasers have been employed to combine mobility with greater light penetration (74,75).

Differences between Nd:YAG and Diode lasers are only realized if charring is avoided. Once charring and carbonization has occurred the fiber acts as a point or line heat source. There is no further light propagation into the tissue and subsequent heating has no wavelength dependency. In order to exploit the penetration of light into the tissue, the fiber tip temperature must be controlled to avoid charring. Achieving such control is somewhat challenging as the temperature of the tip can rise very quickly in a positive feedback loop. As charring begins, the rate of temperature rise increases that causes an increasing rate of charring. Robust, automatic feedback control mechanisms are necessary to ensure controlled heating and lesion formation.

INTERSTITIAL ULTRASOUND

The possibility of developing interstitial ultrasound devices for hyperthermia applications was proposed by Hynynen in 1992 (76). The initial studies examined various design parameters including the choice of ultrasound frequency, electric and acoustic power, and catheter cooling. As Hynynen showed (76), thin interstitial ultrasound applicators were likely capable of heating perfused tissue to therapeutic temperatures.

Ultrasound is a high frequency longitudinal pressure wave that can pass relatively easily through soft tissue. Consequently, it has been useful as an energy source for diagnostic imaging where focussed ultrasound radiators are used to produce high resolution images of soft tissue abnormalities. During transmission through tissue energy is lost due to absorption and to a much lesser extent to scattering. The absorption is caused by friction as the pressure wave causes relative motion of the tissue components. These frictional forces cause heating that can be significant if the incident ultrasound power is high enough. The absorption, α is frequency dependent where

$$\alpha = a f^m$$

and a and m are coefficients that are variable between tissues although m is ~ 1.5 for most soft tissues. Rapidly increasing absorption with frequency is the main reason that the penetration of diagnostic imaging is limited at very high ultrasound frequencies. Higher penetration is also the reason that relatively low ultrasound frequencies are used for ultrasound heating. Typically, frequencies in the range 0.5–2 MHz have been used in external focused ultrasound heating applications. However, this becomes problematic for interstitial devices that are small and resonate at high ultrasound frequencies.

Interstitial ultrasound applicators have since been developed and are usually designed as thin tubular radiators. The radiator consists of a piezoelectric material that will resonate acoustically at a frequency f determined by the wall diameter d :

$$f = \frac{v}{2d}$$

where v is the speed of sound in the piezoelectric material (e. g., 4000 m·s⁻¹ in the piezoelectric material PZT 4A). For interstitial applicators, thin radiators are required. A wall

thickness of 0.2 mm, for example, would translate into an operating frequency of ~ 10 MHz (76). The SAR for a cylindrical applicator is dependent on its dimensions and the frequency of operation as given by

$$\text{SAR} = 2\alpha f I_0 \left(\frac{r}{r_0}\right) e^{-2\mu f(r-r_0)}$$

where α is the ultrasound absorption coefficient in tissue, I_0 is the intensity of ultrasound at the applicator surface, r_0 is the radius of the applicator, r is the distance from the centre of the applicator to the point of interest and μ is the attenuation coefficient of ultrasound that includes absorption and scattering. Skinner et al. (77) have calculated and compared the SAR of ultrasound, laser, and microwave applicators assuming a simple cylindrical radiation pattern for each. The SAR of all these applicators is dominated by the thin cylindrical geometry so that despite the larger penetration depth of ultrasound, only slightly larger diameter lesions can be produced. In order to overcome the limiting geometry, new interstitial ultrasound applicators have been developed that take advantage of the focusing ability of ultrasound (78) or that employs acoustic matching that can result in efficient transmission at multiple frequencies (79).

The development of interstitial ultrasound applicators is still at the preclinical stage (80,81) although larger, intracavitary applicators are being applied in the treatment of prostate cancer using a transrectal technique (82).

INTRODUCTION

Systemic hyperthermia is deliberate heating of the whole body to achieve an elevated core temperature for therapeutic purposes. Other terms used are whole-body hyperthermia, systemic or whole body thermal therapy, and hyperpyrexia. The goal of systemic hyperthermia is to reproduce the beneficial effects of fever. Typically, core body temperatures of 41–42 °C are induced for 1–2 h, or alternatively 39–40 °C for 4–8 h. Systemic hyperthermia, by virtue of application to the whole body, aims to alleviate systemic disease conditions, in contrast to local or regional hyperthermia that treats only a specific tissue, limb, or body region.

HISTORICAL BACKGROUND

The use of heat to treat disease goes back to ancient times. Application of fire to cure a breast tumor is recorded in an ancient Egyptian papyrus, and the therapeutic value of elevated body temperature in the form of fever was appreciated by ancient Greek physicians. Hippocrates wrote, “What medicines do not heal, the lance will; what the lance does not heal, fire will,” while Parmenides stated,

“Give me a chance to create a fever and I will cure any disease.” In the first century AD, Rufus (also written as Refus or Ruphos) of Ephesus advocated fever therapy for a variety of diseases. Hot baths were considered therapeutic in ancient Egypt, Greece, Rome, China, and India as they still are in many aboriginal cultures today, along with burying diseased individuals in hot sand or mud. Hot baths and saunas are an integral part of health traditions throughout the Orient, in Indian Ayurvedic medicine, as well as in Eastern European and Scandinavian countries. Following several earlier anecdotal reports, several nineteenth century German physicians observed regression or cure of sarcoma in patients who suffered prolonged, high fevers due to infectious diseases. This led to efforts to induce infectious fevers in cancer patients, for example, by applying soiled bandages or the blood of malaria patients to wounds. The late nineteenth century New York physician, William Coley, achieved cancer cures by administration of erysipelas and other bacterial endotoxins, now known as Coley’s toxins, and attempted to create standardized preparations of these pyrogens (1). At around the same time, treatment of syphilis by placing the patient in a stove-heated room, or a heat box, became commonplace. Successful hyperthermic treatment of other sexually transmitted diseases, such as gonorrhea, and neurological conditions, such as chorea minor, dementia paralytica, and multiple sclerosis along with arthritis, and asthma were widely reported. Interestingly, it was noted by Italian physicians that upon completion of the draining of the Pontine Swamps near Rome by Mussolini in the 1930s, not only was malaria eradicated, but the prevalence of cancer in the area was the same as in the rest of Italy, whereas earlier the whole malaria-infected region was noted for its absence of cancer. It was concluded that the frequent fever attacks common in malaria stimulated the immune system to prevent the development of cancers.

The science of hyperthermia became grounded in the first few decades of the twentieth century when some of the biological effects of elevated body temperature were elucidated and attempts were made to understand and control the therapeutic application of heat. Numerous devices were developed to produce elevated temperatures of the body, by a variety of physical means. After a shift in focus to local and regional hyperthermia, there is now a resurgence of interest in systemic hyperthermia for treatment of cancer, as well as other systemic diseases. Whole-body hyperthermia treatment is now carried out at several university centers in the United States, and Europe (Table 1), where controlled clinical trials are being carried out. Numerous private clinics, principally in North America, Germany, Austria, Eastern Europe, Japan, and China also perform systemic hyperthermia, mostly as part of holistic, alternative, treatment regimens.

PHYSICS OF SYSTEMIC HYPERTHERMIA

As shown schematically in Fig. 1, in order to achieve body temperature elevation, there must be greater deposition of heat energy in the body than heat energy lost from

^bStarting in 2006.

Figure 1. Schematic of heat balance mechanisms in the human body. Body temperature is determined by the balance of metabolic heat production plus heating from external sources, and heat losses by radiation, evaporation, convection, and conduction.

conduction, convection, radiation and evaporation, that is,

$$Q'_{\text{dep}} \Delta t > Q'_{\text{loss}} \Delta t \quad (1)$$

where $Q' = \Delta Q / \Delta t$ represents the change in heat energy, Q (measured in Joules or calories), over a time period Δt . Net heat energy deposition in a volume element ΔV of tissue of density ρ_{tis} results in an increase in temperature ΔT dependent on the specific heat of the tissue, c_{tis} ,

$$\left(\frac{Q'_{\text{dep}}}{\Delta V} - \frac{Q'_{\text{loss}}}{\Delta V} \right) \Delta t = (\rho_{\text{tis}} \Delta V) c_{\text{tis}} \Delta T$$

$$\Delta T = (Q'_{\text{dep}} - Q'_{\text{loss}}) \cdot \frac{\Delta t}{\rho_{\text{tis}} c_{\text{tis}}} \quad (2)$$

Heat deposition is the sum of the absorbed power density, P_{abs} , from external sources and heat generated by metabolism, Q_{met} ,

$$\frac{\Delta Q'_{\text{dep}}}{\Delta V} = P_{\text{abs}}(x, y, z, t) + \frac{\Delta Q'_{\text{met}}}{\Delta V}(x, y, z, t) \quad (3)$$

If the air temperature is higher than the body surface temperature, heat is absorbed from air surrounding the body by the skin, as well as during respiration. Power deposition in tissue from external electromagnetic fields depends on the coupling of the radiation field (microwave, RF, ultrasound, visible or IR light) with tissue. The body's metabolic rate depends on the amount of muscular activity, the temperature, pressure and humidity of the environment, and the size of the body. Metabolic rate increases nonlinearly with core body temperature, in part due to the exponential increase of the rate of chemical reactions with temperature (Arrhenius equation). An empirical relationship between

basal metabolic rate and core temperature has been determined as

$$\text{Basal MR} = \frac{85 \times 1.07^{(T_{\text{core}})}}{0.5} \quad (4)$$

which can be exploited to maintain elevated body temperatures (2). At room temperature a human body produces ~ 84 W, which increases to ~ 162 W at a core temperature of 41.8 °C.

Heat losses from the body are often termed sensible (convective, conductive, radiative) and insensible (evaporative, latent). The primary mode of heat loss from the body is by radiation, as described by the Stefan–Boltzmann law,

$$\frac{Q'_{\text{rad}}}{\Delta V} = e_{\text{skin}} \sigma A_{\text{skin}} (T_{\text{skin}} - T_s)^4 \quad (5)$$

where $Q'_{\text{rad}} / \Delta V$ is the power radiated, e_{skin} is the emissivity of the skin (radiating material), σ is Stefan's constant $= 5.6703 \times 10^{-8} \text{ W} \cdot \text{m}^{-2} / \text{K}$, A_{skin} is the skin surface area, T_{skin} is the temperature of the skin (radiator), and T_s is the temperature of the surroundings (e.g., air, water, wax). Human skin is a near perfect radiator in the IR, with an emissivity of 0.97. At room temperature, $>50\%$ of the heat generated by metabolism is lost by radiation; a clothed adult loses some 50 W at room temperature. This increases to $\sim 66\%$ at a core temperature of 41.8 °C, as is targeted in a number of systemic hyperthermia protocols, when the skin temperature rises to 39 – 40 °C (3).

Direct transfer of body heat to the molecules around the body (typically air) occurs by conduction, or molecular agitation within a material without any motion of the material as a whole, which is described by Fourier's law,

$$\frac{\Delta Q'_{\text{cond}}}{\Delta V} = \kappa A_{\text{skin}} \frac{\Delta T}{\Delta x} \quad (6)$$

where ΔQ_{cond} is the heat energy transferred per unit volume in time Δt , κ is the thermal conductivity ($\text{W} \cdot \text{mK}^{-1}$) of the material surrounding the body (air, water), and ΔT is the temperature difference across thickness Δx of the material. Air is a poor thermal conductor, therefore heat loss by conduction is relatively low. On the other hand, water has a thermal conductivity 20 times that of air at 0 °C, increasing further with temperature, therefore during hyperthermia it is important that any water in contact with the skin is not at a lower temperature. The relative thermal conductivity of body tissues is important in determining thermal conduction within the body from external sources of heat. For example, fat is a relative thermal insulator with a thermal conductivity one third of that of most other tissues, therefore fat bodies are slower to heat.

Convective heat transfer involves material movement and occurs principally via blood moving heat to, or from, the skin and other tissues, and air currents (respiratory and environmental) moving warm air to or from the body. Equation 7 is written for the blood,

$$\frac{\Delta Q'_{\text{conv}}}{\Delta V} = \rho_b c_b [w_b(x, y, z, T) \cdot (T - T_b) + U_b(x, y, z, T) \cdot \nabla T] \quad (7)$$

where w_b is the specific capillary blood flow rate, U_b is the specific blood flow through other vessels. In the context of

systemic hyperthermia, where a patient is in a closed chamber, environmental air currents can be minimized. Heat loss by respiration, however, can amount to almost 10% of metabolic heat generation.

Another route of heat loss from the body is evaporation of perspiration from the skin. Because of the very large heat of vaporization of water, cooling of the blood in skin capillaries occurs due to evaporation of sweat. Evaporation from exhaled moisture also results in cooling of the surrounding air.

$$\frac{\Delta Q'_{\text{evap}}}{\Delta V} = m_w \frac{L_v}{\Delta t} \quad (8)$$

where m_w is the mass of the water and L_v is the latent heat of vaporization ($2.4 \times 10^6 \text{ J}\cdot\text{kg}^{-1}$ at 34°C). In hot conditions with maximal rates of evaporation, heat loss through evaporation of sweat can be as much as 1100 W. Heat loss in the lungs is $\sim 10 \text{ W}$.

Combining the heat generation and heat loss terms leads to a general heat transfer equation, an extension of the classic Pennes bioheat transfer equation.

$$\left[\left(\frac{\Delta Q'_{\text{met}}}{\Delta V} + P_{\text{abs}} \right) - \left(\frac{\Delta Q'_{\text{rad}}}{\Delta V} + \frac{\Delta Q'_{\text{cond}}}{\Delta V} + \frac{\Delta Q'_{\text{conv}}}{\Delta V} + \frac{\Delta Q'_{\text{resp}}}{\Delta V} + \frac{\Delta Q'_{\text{evap}}}{\Delta V} \right) \right] = \rho_{\text{tis}} c_{\text{tis}} \Delta T \quad (9)$$

into which the expressions given in Eqs. 2–8 may be substituted. Precise solution of this equation for temperature distribution is complex and requires a number of simplifying assumptions which have generated significant controversy in bioheat transfer circles. Modeling of temperature distributions within a body subjected to hyperthermia is also complex because of the heterogeneity of thermal characteristics between and within tissue, the directionality of power application, and the dynamic nature of thermoregulation by human body. Nonetheless, the factors governing systemic heating of the body can be appreciated.

INDUCTION OF SYSTEMIC HYPERTHERMIA

Apart from the induction of biological fever by pathogens or toxins, all methods of hyperthermia involve transfer of heat into the body from an external energy source. The required net power to raise the temperature of a 70 kg human from 37 to 41.8°C (2) is 400 W (5.7 mW). While the heat absorption from these sources is highly nonuniform, distribution of thermal energy by the vascular system quickly results in a uniform distribution of temperature. Indeed, systemic hyperthermia is the only way to achieve uniform heating of tissues. Because physiological thermoregulation mechanisms such as vasodilation and perspiration counteract attempts to increase core body temperature, careful attention must be paid to optimizing the physical conditions for heating such that there is efficient deposition of heat energy in the body and, even more importantly, minimization of heat losses. Wrapping the body in reflective blankets, foil, or plastic film to reduce radiative and evaporative losses, or keeping the surrounding air moist to

minimize losses by perspiration are key techniques for achieving a sustained increase in body temperature.

Noninvasive methods of heating include immersing the body in hot water or wax, wrapping the body in a blanket or suit through which heated water is pumped, placing the patient on a heated water mattress, surrounding the body with hot air, irradiating with IR energy, and applying RF or microwave electromagnetic energy. These techniques may be applied singly or in combination. For example, the Pomp–Siemens cabinet used until recently throughout Europe, as well as in the United States, a modification of a device originally developed by Siemens in the 1930s, has the patient lying on a heated water mattress under which an inductive loop generates an RF field, all inside a chamber through which hot air is circulated. The Russian Yakhta-5 system applies a high frequency (13.56 MHz) electromagnetic field through a water-filled mattress to permit whole body heating up to 43.5°C and simultaneous deep local hyperthermia through additional applicators providing 40.6 MHz electromagnetic radiation. The majority of whole-body hyperthermia systems currently in clinical use employ IR radiation to achieve systemic heating. Invasive approaches to systemic hyperthermia are extracorporeal heating of blood, removed from the body via an arteriovenous shunt, prior to returning it to the circulation, as well as peritoneal irrigation with heated fluid (4). A useful schematic summary of whole-body hyperthermia induction techniques along with references is provided by van der Zee (5).

All of these approaches involve a period of steady temperature increase, followed by a plateau or equilibrium phase where the target temperature is maintained for anywhere from 30 min to several hours, and finally a cool-down phase. Depending on the method of hyperthermia induction, the patient may be anesthetized, consciously sedated, administered analgesia, or not given any kind of medication at all. An epidural block is sometimes given to induce or increase vasodilation. During radiant heat induction, the temperature of the skin and superficial tissues (including tumors) is higher than the core (rectal) temperature whereas during the plateau (maintenance) phase, the skin–superficial tissue temperature drops below the core temperature. As already described, heat losses due to physiological mechanisms limit the rate of heating that can be achieved. When insulation of the patient with plastic foil was added to hot air heating, the heating time to 41.8°C was decreased from 230 to 150 min (65%), and further to 110 min (48%) by addition of a warm water perfused mattress (5). The homogeneity of the temperature distribution was also significantly increased by the addition of insulation and the water mattress. Noninvasive systemic hyperthermia methodologies typically produce heating rates of $1\text{--}10^\circ\text{C}\cdot\text{h}^{-1}$ with $2\text{--}3^\circ\text{C}\cdot\text{h}^{-1}$ being most common. More rapid heating can be achieved by the invasive techniques, at the expense of greater risk of infection and morbidity.

COMMERCIALLY AVAILABLE WHOLE-BODY HYPERTHERMIA SYSTEMS

A number of commercially available devices have resulted from the development of these initially experimental

systems. The Siemens–Pomp system has already been mentioned, but is no longer commercially available. Similarly, neither the radiant heat chamber developed by Robins (3), and marketed as the Aquatherm system, nor the similar Enthermics Medical Systems RHS-7500 radiant heat device, both producing far IR radiation (IR C) in a moist air chamber, are currently being sold, though they are still in use in several centers. A close relative is the Iratherm2000 radiant heat chamber originally developed by von Ardenne and co-workers (6). In this device, water-filtered infrared radiators at 2400 °C emit their energy from above and below the patient bed, producing near-IR (IR A) radiation that penetrates deeper into tissue than far IR radiation, causing direct heating of the subcutaneous capillary bed. Thermal isolation is ensured by reflective foils placed around the patient. However, note that significant evaporative heat loss through perspiration can be a problem with this system. Also with a significant market share is the Heckel HT 2000 radiant heat device in which patients lie on a bed enclosed within a soft-sided rectangular tent whose inner walls are coated with reflective aluminum foil that ensures that the short wavelength infrared A and B radiation emitted by four radiators within the chamber uniformly bathes the body surface. Once the target temperature is reached, the chamber walls are collapsed to wrap around the body, thereby preventing radiative and evaporative heat loss, and permitting maintenance of the elevated temperature, as shown in Fig. 2.

Another radiant heat device, used mainly in Germany, is the HOT-OncoTherm WBH-2000 whole-body hyperthermia unit which is a chamber that encloses all but the patient's head. Special light-emitting diode (LED) radiators deliver computer-generated, alloy-filtered IR A wavelengths that penetrate the skin to deliver heat to the capillary bed. The manufacturer claims that these wavelengths also preferentially stimulate the immune system. Recently, Energy Technology, Inc. of China has released the ET-SPACE whole-body hyperthermia system, which

Figure 2. Heckel HT-2000 radiant heat whole body hyperthermia system. Unit at the University of Texas Medical School at Houston. Patient is in the heat maintenance phase of treatment, wrapped in the thermal blankets which form the sides of the chamber during active heating.

produces IR A radiation in a small patient chamber into which warm liquid is infused to help increase the air humidity and thereby reduce perspiration losses. A number of low cost, far infrared, or dry, saunas are being sold to private clinics, health clubs, and even individuals for treatment of arthritis, fibromyalgia, detoxification, and weight loss. Examples are the Smarty Hyperthermic Chamber, the TheraSauna, the Physiotherm, and the Biotherm Sauna Dome. Table 2 summarizes features of these commercially available whole-body hyperthermia devices.

BIOLOGICAL EFFECTS OF SYSTEMIC HYPERTHERMIA

An understanding of the biological effects of systemic hyperthermia is critical to both its successful induction and to its therapeutic efficacy. Systemic responses to body heating, if not counteracted, undermine efforts to raise body temperature, while cellular effects underlie both the rationale for the use of hyperthermia to treat specific diseases, and the toxicities resulting from treatment. Although improved technology has allowed easier and more effective induction of systemic hyperthermia, most of the recent clinical advances are due to better understanding and exploitation of specific biological phenomena.

Physiological Effects of Elevated Body Temperature

The sympathetic nervous system attempts to keep all parts of the body at a constant temperature, tightly controlled by a central temperature ‘set point’ in the preoptic–anterior hypothalamus and a variety of feedback mechanisms. The thermostat has a circadian rhythm and is occasionally reset, for example, during fever induced by infectious agents and endotoxins, but not in endogenously induced hyperthermia. Occasionally, it breaks down completely as in malignant hyperthermia or some neurological disorders affecting the hypothalamus. Ordinarily, when core body temperature rises, the blood vessels initially dilate, heart rate rises, and blood flow increases in an effort to transport heat to the body surface where it is lost by radiation, conduction, and convection. Heart rate increases on average by $11.7 \text{ beats} \cdot \text{min}^{-1} \cdot ^\circ\text{C}^{-1}$ and typically remains elevated for several hours after normal body temperature is regained. Systolic blood pressure increases to drive the blood flow, but diastolic pressure decreases due to the decreased resistance of dilated vessels, thus there is an increase in cardiac output. Heart rate and blood pressure must therefore be monitored during systemic hyperthermia, and whole-body hyperthermia is contraindicated in most patients with cardiac conditions. Interestingly, hyperthermia increases cardiac tolerance to ischemia/reperfusion injury probably due to activation of manganese superoxide dismutase (Mn-SOD) and involvement of cytokines.

Respiration rate also increases and breathing becomes shallower. Perspiration results in evaporation of sweat from the skin and consequent cooling, while the respiration rate increases in order to increase cooling by evaporation of moisture from expired air. Weight loss occurs despite fluid intake. There is a decrease in urinary output and the urine has a high specific gravity, concentrating urates and

phosphates. In endogenously induced hyperthermia, but not in fever, glomerular filtration, as evidenced by the creatinine clearance, decreases with increasing temperature. As already mentioned, metabolic rate increases non-linearly with temperature, which leads to an increase in blood sugar, decreased serum potassium levels, and increased lactic acid production. All the above normal physiological effects may be enhanced or counteracted by anesthesia or sedation, as well as by disease states such as cancer because of drugs used in treatment or intrinsic pathophysiological consequences of the disease.

At $\sim 42.5^\circ\text{C}$, the normal thermocompensatory mechanisms break down and the body displays the symptoms of advanced heat stroke, namely, lack of sweating, rapid heart beat, Cheyne–Stokes breathing, central nervous system dysfunction, and loss of consciousness. Ultimately, breathing ceases despite the continuation of a heart beat.

Cellular Thermal Damage

When temperature is increased by a few degrees Celsius, there is increased efficiency of enzyme reactions (Arrhenius equation), leading to increased metabolic rates, but at temperatures $> 40^\circ\text{C}$ molecular conformation changes occur that lead to destabilization of macromolecules and multimolecular structures, for example, to the side chains of amino acids in proteins, which in turn inhibit enzyme action. Small heat shock proteins (HSP) interact with the unfolding proteins to stabilize them and prevent their aggregation and precipitation. Eventually, however, at $\sim 42^\circ\text{C}$, complete denaturation of proteins begins that totally disrupts many molecular processes, including deoxyribonucleic acid (DNA) repair. Thus systemic hyperthermia can have significant effects when paired with drugs that cause DNA damage (e.g., for chemotherapy of cancer).

Membranes are known to be extremely sensitive to heat stress because of their complex molecular composition of lipids and proteins. At a certain temperature, lipids change from the tightly packed gel phase to the less tightly packed liquid crystalline phase, and permeability of the cell membrane (membrane fluidity) increases. As temperature increases further, the conformation of proteins also becomes affected, eventually resulting in disorderly rearrangement of the lipid bilayer structure and receptor inactivation or loss. Temperature changes of $\sim 5^\circ\text{C}$ are necessary to cause measurable changes in normal cell membrane permeability. Heat-induced cell membrane permeability can be exploited to increase drug delivery, for example, transdermally, or into tumor cells. Increased vascular permeability due to thermal increase of endothelial gap size also aids drug delivery into tumors. At higher temperatures, heat damage to membranes can cause cell death, but it will also interfere with therapeutic approaches that depend on membrane integrity (e.g., receptor targeted drug delivery, antibodies, etc.). Irreversible disruption of cytoplasmic microtubule organization and eventual disorganization, as well as disruption of actin stress fibers and vimentin filaments, occur at high temperatures ($43\text{--}45^\circ\text{C}$) above those used in whole-body hyperthermia, but these cytoskeletal effects are of concern with loco-regional hyperthermia.

A variety of effects in the cell nucleus also occur at high temperatures ($>41^\circ\text{C}$) including damage to the nuclear membrane, increases in nuclear protein content, changes in the structure of nucleoli, inhibition of DNA synthesis and chromosomal damage in S-phase. These changes in nuclear structure compromise nuclear function and may cause cell death, though they are unlikely to be significant at the temperatures achieved in systemic hyperthermia. Disaggregation of the spindle apparatus of mitotic cells may be responsible for the high thermal sensitivity of cells in mitosis, as well as in S phase. Hyperthermic inactivation of polymerase β , an enzyme primarily involved in DNA repair, is sensitized by anesthetics and may have a role to play in the enhancement of the effects of ionizing radiation by systemic hyperthermia, as well as in augmenting the cytotoxic effect of drugs that cause DNA damage.

Metabolic Effects

Moderate increases in temperature lead to increased cellular reaction rates, which may be seen as increased oxygen consumption and glucose turnover. In consequence, cells may become deprived of nutrients, the intracellular ATP concentration falls, accumulation of acid metabolites increases pH, and thermal sensitivity increases. Such conditions are found in tumors and may contribute to their sensitivity to heat. Further acidifying tumor cells during hyperthermic treatment seems a promising approach as is discussed further below. At high temperatures, the citric acid cycle may be damaged leading to other acidic metabolites. Increased plasma acetate has been measured following clinical whole-body hyperthermia treatments, which reduces both release of fatty acids from adipose tissue into plasma and subsequent lipid oxidation.

Endocrine Function

Increases in plasma levels of an array of hormones have been noted after whole-body hyperthermia. Increased ACTH levels appear to be accompanied by increased levels of circulating endorphins. This may explain the sense of well-being felt by many patients after systemic hyperthermia treatment, and the palliative effect of hyperthermia treatments for cancer. Increased secretion of somatotrophic hormone after systemic hyperthermia has also been measured (7).

Thermal Tolerance

Thermal tolerance is a temporary state of thermal resistance, common to virtually all mammalian cells, which develops after a prolonged exposure to moderate temperatures ($40\text{--}42^\circ\text{C}$), or a brief heat shock followed by incubation at 37°C , and also certain chemicals. The decay of thermotolerance occurs exponentially and depends on the treatment time, the temperature, and the proliferative status of the cells. Several days are usually required for baseline levels of heat sensitivity to be regained, which has important implications for fractionated therapy. When pH is lowered, less thermal tolerance develops, and its decay is slower. Thus the long periods at moderate temperature achieved by clinical systemic hyperthermia systems should

Figure 3. Increase in tumor uptake of large liposomes after 1 h of 41.5 °C whole-body hyperthermia. Systemic heat treatment increased the effective pore size from ~210 to 240 nm. Because of the large pore size in MTLn3 tumors, 100 nm (average diameter) liposomes were able to pass into the tumor equally well at normal and elevated temperatures. The increased effective pore size due to hyperthermia allowed larger 200 nm liposomes, which were partially blocked at normal temperatures, to pass more effectively into the tumor.

induce thermal resistance in normal cells, while the acidic parts of tumors should be relatively unaffected. This has not, however, been studied clinically. The mechanisms involved in the induction of thermotolerance are not well understood, but there is mounting evidence that heat shock proteins are involved.

Step-Down Sensitization

Another distinct phenomenon is step-down sensitization in which an exposure of cells to temperatures >43 °C results in increased sensitivity to subsequent temperatures of 42 °C or lower. This can be important clinically for local and regional hyperthermia if there are marked variations in temperature during the course of treatment, the magnitude of the effect depending on the magnitude of the temperature change. It has been suggested that this phenomenon could be exploited clinically by administering a short, high temperature treatment prior to a prolonged treatment at a lower temperature, thereby reducing pain and discomfort. Since temperatures >43 °C cannot be tolerated systemically, a local heat boost would be required to take advantage of this effect for whole body hyperthermia. So far, there is no evidence that tumor cells are differently sensitized by step-down heating than normal cells.

Effect of Hyperthermia on Tumors

It was initially thought that tumor cells have intrinsically higher heat sensitivity than normal cells, but this is not universally true. Although some neoplastic cells are more sensitive to heat than their normal counterparts, this appears to be the case at temperatures higher than those used in systemic hyperthermia. Tumors *in vivo*, on the other hand, often do have a higher thermal sensitivity than normal tissues because of abnormal vasculature (reduced blood flow), anaerobic metabolism (acidosis), and nutrient depletion. Due to their tortuous and poorly constructed vasculature, tumors have poor perfusion, thus heat dissipation by convection is reduced. At high temperatures (43 °C and up) this means that tumors become a heat reservoir with a consequent rise in temperature, which if maintained for too long damages the microcirculation and further impairs convective heat loss. Also increased fibrinogen deposition at damaged sites in the vascular wall leads to clusion of tumor microvessels. Significant heating of the tumor cells results, which may be directly cytotoxic. Additionally, the impaired blood flow brings about acidosis, increased hypoxia and energy depletion all of which increase the heat sensitivity of tumor cells (8). At lower temperatures, typical of those achieved in whole-body hyperthermia, blood flow increases (9) though the mechanism is not well understood. For these reasons, along with the historical evidence for antitumor effects of fever and the metastatic nature of malignant disease, cancer has become the main focus of systemic hyperthermia.

Systemic hyperthermia results in increased delivery of drugs to tumor sites because of increased systemic blood flow. It can also increase blood vessel permeability by increasing the effective pore size between the loosely bound endothelial cells forming tumor microvessels, permitting larger molecules, such as nanoparticles and gene therapy vectors, to pass into the interstitium (10). Figure 3 shows increased uptake of 210 nm liposomes in rat breast tumors after 1 h of 41.5 °C whole-body hyperthermia. Heat may also be toxic to endothelial cells, resulting in a transient normalization of vascular architecture and improvement in blood flow (11). Another barrier to drug delivery is the high interstitial pressure of many tumors. Since whole-body hyperthermia, even at fever-range temperatures, causes cell death (apoptosis and necrosis) within tumors it reduces the oncotic pressure allowing greater penetration of large molecules. Table 3 summarizes the interactions of systemic hyperthermia which facilitate nanoparticle delivery to tumors.

Table 3. Whole-Body Hyperthermia Facilitates Nanoparticle Therapy

Heat Interaction	Therapeutic Effect
↑ Blood flow	↑ Nanoparticle delivery to tumor
↑ In endothelial gap size	↑ Nanoparticles in interstitium
↑ Endothelial cell apoptosis/necrosis → transient normalization of vasculature	↑ Nanoparticles in interstitium
↑ Tumor cell apoptosis/necrosis ↓ oncotic pressure	↑ Nanoparticles in interstitium
Temperature-dependent ↑ in permeability of liposome bilayer	↑ And synchronization of drug release
Cellular and molecular effects in tumor	↑ Drug in tumor cell ↑ drug efficacy
Direct interactions with drug	↑ Drug efficacy

Whole-Body Hyperthermia and the Immune System

An increase in ambient temperature can serve as a natural trigger to the immune system and it appears that the thermal microenvironment plays a critical role in regulating events in the immune response. The early work of Coley on cancer therapy with infectious pyrogens implicated fever-induced immune stimulation as the mediator of tumor responses (1). While there have been numerous *in vitro* studies of the effect of temperature on components of the immune system, indicating that the thermal milieu regulates T lymphocytes, natural killer (NK) cells, and dendritic cells (DC), *in vivo* examinations of the immune effects of systemic hyperthermia are relatively few. Initial animal model studies concluded that whole-body hyperthermia resulted in immunosuppression, but high temperatures were used, tumors were mostly immunogenic, and immune response was merely inferred from the incidence of metastatic spread rather than from measurement of specific markers of immune system activation. The majority of *in vivo* studies in animals provide evidence of a nonspecific host reaction in response to hyperthermia in which both T and B lymphocytes, as well as macrophages, are involved (12). Although NK cells are intrinsically more sensitive *in vitro* to heat than B and T cells, their activation by systemic hyperthermia has been observed. Microwave induced whole-body hyperthermia of unrestrained, unanesthetized mice at 39.5–40 °C for 30 min, three or six times weekly, resulted in increased NK cell activity and reduced pulmonary metastasis in tumor-bearing mice, but none in normal mice (13). Evidence for hyperthermia-induced human tumor lysis by IL-2 stimulated NK cells activated by HSP72 expression also exists (14). Increased numbers of lymphocyte-like cells, macrophages, and granulocytes are observed in the tumor vasculature and in the tumor stroma of xenografts and syngeneic tumors in mice immediately following a mild hyperthermia exposure for 6–8 h. In the SCID mouse/human tumor system tumor cell apoptosis seen following treatment was due largely to the activity of NK cells. The investigators hypothesize heat dilatation of blood vessels and increased vessel permeability may also give immune effector cells greater access to the interior of tumors (15). In balb/C mice, fever-range whole-body hyperthermia increased lymphocyte trafficking, resulting in early responsiveness to antigen challenge (16). Thus systemic hyperthermia may be an effective, nontoxic adjuvant to immunotherapy.

A recent clinical study examined the effect of whole-body hyperthermia combined with chemotherapy on the expression up to 48 h later of a broad range of activation markers on peripheral blood lymphocytes, as well as serum cytokines and intracellular cytokine levels in T cells, and the capacity of these cells to proliferate. Immediately after treatment with 60 min of 41.8 °C WBH as an adjunct to chemotherapy, a drastic but transient, increase in peripheral NK cells and CD56+ cytotoxic T lymphocytes was observed in the patients' peripheral blood. The number of T cells then briefly dropped below baseline levels, a phenomenon that has also been observed by others (17). A marked, but short-lived, increase in the patients' serum levels of interleukin-6 (IL-6) was also noted. Significantly

increased serum levels of tumor necrosis factor-alpha (TNF-alpha) were found at 0, 3, 5 and 24 h posttreatment. Further immunological consequences of the treatment consisted of an increase in the percentage of peripheral cytotoxic T lymphocytes expressing CD56, reaching a maximum at 48 h post-WBH. Furthermore, the percentage of CD4+ T cells expressing the T cell activation marker CD69 increased nearly twofold over time, reaching its maximum at 48 h. Since similar changes were not observed in patients receiving chemotherapy alone, this study provided strong evidence for prolonged activation of human T cells induced by whole-body hyperthermia combined with chemotherapy (18).

Activation of monocytes has been observed following hot water bath immersion such that response to endotoxin stimulation is enhanced with concomitant release of TNF- α . Macrophage activation and subsequent lysosomal exocytosis were observed in the case of a patient treated for liver metastases by hyperthermia. Lysosomal exocytosis induced by heat may be an important basic reaction of the body against bacteria, viruses, and tumor growth and was proposed as a new mechanism of thermally induced tumor cell death mediated by an immune reaction (19).

Several investigators have suggested that the immune changes seen during *in vivo* whole-body hyperthermia are mediated by elevations in the plasma concentrations of either catecholamines, growth hormone, or beta-endorphins. In volunteers immersed in a heated water bath, neither recruitment of NK cells to the blood, nor the percentages or concentrations of any other subpopulations of blood mononuclear cells were altered by hormone blockade. However, somatostatin partly abolished the hyperthermia induced increase in neutrophil number. Based on these data and previous results showing that growth hormone infusion increases the concentration of neutrophils in the blood, it was suggested that growth hormone is at least partly responsible for hyperthermia induced neutrophil increase. A similar study suggested that hyperthermic induction of T lymphocytes and NK cells is due to increased secretion of somatotrophic hormone (7).

The peripheral blood level of prostaglandin E₂ (PGE₂), which may act as an angiogenic switch, transforming a localized tumor into an invasive one by stimulating new blood vessel growth, and which also has an immunosuppressive effect, is elevated in patients with tumors compared to healthy control subjects. In a clinical study of cancer patients receiving 1–2 h of 41.8–42.5 °C whole-body hyperthermia, or extracorporeal hyperthermia, blood levels of PGE₂ decreased markedly after treatment and correlated with tumor response (20).

In addition to their role as protectors of unfolding proteins, extracellular heat shock proteins (HSP) can act simultaneously as a source of antigen due to their ability to chaperone peptides and as a maturation signal for dendritic cells, thereby inducing dendritic cells to cross-present antigens to CD8+ T cells (21). Heat shock proteins can also act independently from associated peptides, stimulating the innate immune system by eliciting potent proinflammatory responses in innate immune cells. The heat shock response also inhibits cyclooxygenase-2 gene expression at the transcriptional level by preventing the activation of

nuclear factor-kappaB (NF κ B) (22). Thermal upregulation of HSPs (HSP70 and HSP110) is strongest in lymphoid tissues and may relate to the enhanced immune responses that are observed during febrile temperatures. It has been proposed that local necrosis induced by hyperthermic treatment induces the release of HSPs, followed by uptake, processing and presentation of associated peptides by dendritic cells. By acting as chaperones and as a signal for dendritic cell maturation, HSP70 might efficiently prime circulating T cells. Therefore, upregulating HSP70 and causing local necrosis in tumor tissue by hyperthermia offers great potential as a new approach to directly activate the immune system, as well as to enhance other immunotherapies (23,24).

CLINICAL TOXICITIES OF WHOLE-BODY HYPERTHERMIA TREATMENT

At fever-range temperatures, adverse effects of systemic hyperthermia treatment are minimal however, at higher temperatures they can be significant, even fatal. On the other hand, the teratogenic effects (birth defects, still births, spontaneous abortions) and ocular damage (cataract induction) resulting from electromagnetic fields used in local hyperthermia are not seen in systemic hyperthermia. The transient cardiorespiratory effects of elevated temperature can, however, lead to severe toxicity. Elevated heart rate, especially at high temperatures may result in arrhythmias or ischemic heart failure, consequently patients have to be very carefully screened with regard to their cardiac status. Beta blockade has generally been found to be deleterious although infusion of esmolol has been safely carried out (25). Pulmonary hypertension and edema due to capillary leak may also be seen, but like the cardiac effects, these return to baseline a few hours after treatment. Increased serum hepatic enzymes have been noted, but these may be cancer related. All these toxicities are less prevalent or less severe with radiant heat systems, particularly at lower temperatures, and when light conscious sedation is used rather than general anesthesia. For example, decreased platelet count, decreased plasma fibrinogen, and other factors leading to increased blood clotting have been noted, particularly in extra-corporeal hyperthermia, but also with other methods of heating carried out under inhalation-administered anesthesia drugs. On the other hand, with whole-body hyperthermia under conscious sedation there is no evidence of platelet drops (26) and animal studies even show platelet stimulation providing protection against radiation induced thrombocytopenia.

Since systemic hyperthermia is almost never used as a single treatment modality, it is important to recognize that whole-body hyperthermia combined with radiation and chemotherapy can enhance some of the toxicities associated with these modalities. For example, the cardiotoxicity of doxorubicin and both the renal toxicity and hematological toxicity of platinum agents may increase under hyperthermia (27), while the muscle and peripheral nervous system effects of radiation and some drugs can also be enhanced (28). Bone marrow suppression is the limiting

toxicity of many chemotherapy drugs but there is little data to suggest that whole body hyperthermia exacerbates this effect. On the contrary, the synergy of hyperthermia with several chemotherapy agents may mean that lower doses can be used, resulting in less toxicity. For example, systemic hyperthermia combined with carboplatin achieves therapeutic results without elevation of myelosuppression and responses have occurred at lower than normal doses (29). Pressure sores can easily develop at elevated temperatures thus care must be taken not only in patient placement and support, but also with application of monitoring devices. If heat dissipation is locally impaired, for example, at pressure points, hot spots occur that can lead to burns. This is rarely a problem with fever-range whole-body hyperthermia, but in anesthetized patients undergoing high heat regimens burns are not uncommon.

Following systemic hyperthermia treatments, malaise and lethargy are almost universally experienced although these may be counteracted by pain relief and a sense of well-being due to released endorphins. However, the faster the target temperature is reached, the less the exhaustion (6), thus attention to minimizing heat dissipation during the heat-up phase and using efficient heating devices, such as those that generate heat by several mechanisms (e.g., radiant heat and EM fields), add a regional heat boost, or produce near-IR radiation that is preferentially absorbed, is advantageous to patient well being. Fever after treatment in the absence of infectious disease is not uncommon and may be associated with an inflammatory response to tumor regression. Nausea and vomiting during the first couple of days after treatment are also common. Outbreaks of herpes simplex (cold sores) in susceptible individuals have also been noted, but are easily resolved with acyclovir.

THERMAL DOSE

The definition of dose for systemic hyperthermia is problematic. An applied dose would be the amount of heat energy generated or delivered to the body but even if it can be measured, this quantity does not predict biological effects. By analogy with ionizing radiation, the absorbed dose would be amount of thermal energy absorbed per unit mass of tissue ($\text{J}\cdot\text{kg}^{-1}$), however, this is not a quantity that can be readily measured, or controlled, neither would it necessarily predict biological effects. As indicated in the previous sections, the effects of systemic hyperthermia depend on (1) the temperature, and (2) the duration of heating, but not on the energy required to produce the temperature rise. This leads to the concept of time at a given temperature as a practical measure of dose. In reality, however, temperature is seldom constant throughout a treatment, even in the plateau phase of systemic hyperthermia, so time at temperature is at best a crude measure. Nonetheless, it is the one that is used most often clinically for whole-body hyperthermia because of its simplicity. Ideally, the dose parameter should allow for comparison of treatments at different temperatures. Based on the Arrhenius relationship and measured cell growth inhibition curves, the heating time at a given temperature relative to the heating time at a standard temperature or

thermal dose equivalent (TDE), was defined empirically as,

$$T_1 = t_2 \cdot R^{(T_1 - T_2)} \quad (10)$$

A discontinuity occurs in the temperature-time curves between 42 and 43 °C for both cells in culture and heated tissues, thus the value of R changes for temperatures above the transition: $R \sim 2 < 42.5$ °C and $R \sim 5 > 42.5$ °C *in vitro* while for *in vivo* heating studies, $R = 2.1$ below the transition temperature and 6.4 above 42.5 °C. In practice, a finite time is required for the body or tissue of interest to reach the target temperature, temperature fluctuates even after the target temperature is reached, and there is a cooling period after heating ceases. If the temperature is measured frequently throughout treatment, the temperature-time curves can be integrated to provide the accumulated thermal dose that produces an equivalent effect to that resulting from holding the cells-tissue at a constant reference temperature for a given a period of time:

$$t_{43} = \int_{t_i}^{t_f} R^{43-T(t)} dt \quad (11)$$

where t_i and t_f are the initial and final times of the heating procedure (30). This thermal isoeffect dose (TID) is usually expressed in minutes is sometimes known as the tdm43 or the cumulative equivalent minutes (CEM 43 °C). While a biological factor has now been built in to the dose measure, and the integrated TID allows for temperature variations during heat-up and cool-down phases, it does not take into account thermal tolerance and step-down sensitization. Nor is it particularly relevant to clinical whole-body hyperthermia where multiple physical and biological effects combine in a complex manner although for a given patient, time-temperature profiles are generally reproducible from one treatment to another. A further modification attempts to take into account temperature inhomogeneity through the measurement of temperature at multiple sites and defining T90, namely, that temperature exceeded by 90% of the measurements (or correspondingly 20%: T20; or 50%: T50). The TID is then expressed as cumulative equivalent minutes that T90 is equal to 43 °C (CEM 43 °C T90) (31).

The efficiency of adjuvant hyperthermia in enhancing the biological effectiveness of other treatments is often reported in terms of the thermal enhancement factor (TEF) or thermal enhancement ratio (TER). This quantity is defined in terms of the isoeffect dose as,

$$\text{TER} = \frac{\text{dose of treatment to achieve a given endpoint}}{\text{dose of treatment with heat to achieve the same endpoint}} \quad (12)$$

In clinical and laboratory studies, the TER is often computed on the basis of isodose rather than isoeffect, for example, in the case of hyperthermia plus drug induced arrest of tumor growth, $\text{TER} = \text{TGD}_{\text{HT}}/\text{TGT}_{\text{RT}}$, where TGD_{HT} is the tumor growth delay due to hyperthermia plus chemotherapy, and TGT_{RT} is the tumor growth delay resulting from chemotherapy at room temperature. Similarly, the enhancing effect of hyperther-

mia on radiation treatment may be expressed through $\text{TER} = \text{D0}_{\text{HT}}/\text{D0}_{\text{RT}}$ or $\text{TER} = \text{LD50}_{\text{HT}}/\text{LD50}_{\text{RT}}$, where D0 is the time required to reduce survival to 1/e of its initial value, and LD50 is the lethal dose to 50% of cells.

TEMPERATURE MEASUREMENT

Since systemic hyperthermia achieves a uniform temperature distribution, except for possible partial sanctuary sites, thermometry for systemic hyperthermia is much less challenging than for regional or intracavitary hyperthermia, but it is still important to prevent adverse effects, especially burns. Also, convection can induce steep thermal gradients, especially around major blood vessels, so that careful placement of temperature probes is required. Most practitioners of whole-body hyperthermia measure temperature in several locations, typically the rectum, the esophagus, and at several skin sites. During heat-up, the esophageal temperature is usually 1–2 °C higher than the rectal temperature, but during plateau phase it drops to 0.5–1.5 °C below the rectal temperature. Continuous and accurate temperature measurement is particularly important when temperatures >41°C are to be achieved, as critical, life-threatening changes can occur in minutes or even seconds and over changes in temperature of as little as 0.1–0.2 °C because of the nonlinear response to temperature. For moderate temperature systemic hyperthermia, temperature measurement to within 0.1 °C is usually adequate, but a precision of 0.01 °C is desirable when heating to >41 °C and also allows determination of the specific absorption rate from the slope of the temperature versus time curve. The temperature measuring device must be insensitive to all other influences, such as ambient temperature, moisture, nearby electromagnetic fields, and so on and satisfying this criterion can be difficult. Frequent calibration of thermometers in the working range of temperatures is important since some thermometers appear fine at 30 °C, but drift substantially at 40 °C and above. Stringent quality control of any thermometry system is required to monitor accuracy, precision, stability, and response time.

Table 4 summarizes the different types of thermometer probes available for internal and external body temperature measurements, and their relative merits and disadvantages for systemic hyperthermia. Thermistors are most often used for standard temperature monitoring sites while thermocouples are used for tumor or other intra-tissue measurements. Recently, noninvasive methods of temperature measurement have been developed that are beginning to see application in hyperthermia. Thermography provides a two-dimensional (2D) map of surface temperature by measurement of infrared emission from the body, though deep-seated hot structures may be visualized because of heat carried by blood flow from the interior heat source to the skin. It is useful to detect skin hotspots and therefore in burn prevention. Since temperature-induced changes in the mechanical properties of tissue lead to altered ultrasound propagation velocity, mapping of ultrasound velocity can also provide a visual map of temperature. Tomographic reconstruction of 2D or 3D temperature is theoretically possible, but it is difficult in practice because of the heterogeneity of tissue characteristics. A

Table 4. Temperatures Probes for Systemic Hyperthermia

Probe Type	Measurement Principle	Accuracy	Sensitivity	Stability	Advantages or Disadvantages
Clinical	Expansion of mercury or alcohol in glass	Moderate ≤ 0.1 °C	Low	High	Large size, inflexible. Slow response.
Platinum resistance thermometer	Linear resistance change with temperature	High ~ 0.02 °C		Used as standard for calibration of other types of thermometers.	Expensive. Difficult to calibrate. Large size. Sensitive to shock.
Thermocouple	Seebeck effect: temperature dependent voltage difference between two conductors made of different metals	Moderate ≤ 0.1 °C	Moderate to high	Moderate	<i>Small sensor</i> . Nonlinear voltage change with temp. Sensitive to EM fields. Can't handle steep temp. gradients.
Thermistor (e.g., Bowman Loop Larsen probe)	Inverse relationship between temperature and semiconductor resistance	High < 0.05 °C	High	Poor recalibration	<i>Short time constant</i> . Not interchangeable. Sensitive to EM fields.
GaAs	Temperature specific absorption	Moderate	Low		<i>Small size</i>
Optical (fiber optic probe):	Change w/temp.:		Low		<i>Not sensitive to EM fields</i> . <i>Small size</i> .
LCD birefringent crystal	Color reflectance		Low	Low	Unstable
fluorescent phosphor	Refraction of polarized light Decay of fluorescence	Very high	Low		

Table 5. Summary of Clinical Trials of Whole-Body Hyperthermia^a

First Author	Public Year	Study Type	Number of Patients	Disease	Protocol	Result of WBH	Reference, PMID
WBH Alone							
Kraybill, W.G.	2002	Phase I		Advanced solid tumors	3–6 h at 39.5–40.0 °C	Well tolerated No significant adverse events ↓ in circulating lymphocytes	16, 12028640
Steinhausen, D.	1994	Phase I	103	Advanced refractory or recurrent cancers	1 h at 41.8 °C + hyperglycemia + hyperoxemia	Minimal side effects 52 responses (50%)	8023241
WBH + Chemotherapy							
Bakshandeh, A.	2003	Phase II	25	Nonmetastatic malignant pleural mesothelioma	1 h at 41.8 °C + ifosfamide + carboplatin + etoposide	Grade III/IV neutropenia and thrombocytopenia 5 partial remissions (20%)	12609573
Bull, J.M.	1992	Phase II	17	Advanced metastatic sarcoma	2 h at 41.8–42.0 °C + BCNU	Limiting toxicity = thrombocytopenia 7 responses/SD (41%) ↑ survival	33, 1607734
Bull, J.M.	2002	Phase I	13	Various chemotherapy resistant cancers	6 h at 40.0 °C + doxil + 5-FU + metronomic interferon-α	Grade III toxicities 9 responses/SD (69%)	60
Bull, J.M.	2004	Phase I	33	Advanced metastatic cancers (GI, breast, head and neck, sarcoma, neuroendocrine)	6 h at 40.0 °C + cisplatin + gemcitabine + interferon-α	20 responses/SD (66%) ↑ survival ↑ quality of life	35
Douwes, F.	2004	Pilot	21	Ovarian cancer	1-2 h at 41.5–42.0 °C + cisplatin or carboplatin + hyperglycemia	18 responses/SD (86%) ↑ quality of life	15108039
Engelhardt, R.	1990	Pilot	23	Advance metastatic melanoma	1 h at 41.0 °C + cisplatin + doxorubicin	Slight ↑ in myelotoxicity 10 responses/SD Response rate = that in literature for chemo alone	52, 2198312
Guan, J.	2005	Phase II	32	Advanced cancers		94% responses/SD Pain reduction in all pts. Increased KPS	65
Hegewisch-Becker, S.	2002	Phase II	41	Pretreated advanced metastatic colorectal cancer	1 h at 41.8 + oxaliplatin + leucovorin + 5FU	Decreased tumor markers No excess toxicity 31 responses/SD (76%)	55, 12181242
Hildebrandt, B.	2004	Phase I/II	28	Metastatic colorectal cancer	1 h at 41.8–42.1 °C + hyperglycemia + hyperoxemia + folinic acid + 5-FU + mitomycin C	Grade III/IV toxicities 11 responses/SD (39%)	44, 15204528

Hou, K.	2004	Phase II	54	Advanced cancers	1–2 h at 41.8–42.5 °C, extracorporeal + chemotherapy vs. chemotherapy alone	75.3% responses/SD 72.6% ↓ tumor markers 70% pain relief improved sleep ↑ weight, appetite, KPS All signify > control Reversible toxicities	68
Ismael-Zade, R.S.	2005	Pilot	5	Pediatric renal cell carcinoma	3 h at 41.8–42.5 °C + doxorubicin + interferon-α	No complications 5 responses (100%)	15700247
Kurpeshev, O.K.	2005	Phase II	42	Various disseminated cancers	1–2 h at 41.0–42.3 °C + poly-chemotherapy	Regression of metastases. Pain reduction	66
Richel, O.	2004	Phase II	21	Metastatic and recurrent cervical cancer	1 h at 41.8 °C + carboplatin	Grade III/IV leucopenia, thrombopenia, anemia, renal toxicity 16 responses/SD (76%)	57, 15581981
Robins, H.I.	1993	Phase I	30	Various refractory cancers	1 h at 41.8 °C + carboplatin	Myelotoxicity 9 responses (30%)	53, 8355046
Robins, H.I.	1997	Phase I	16	Various refractory cancers	1 h at 41.8 °C + L-PAM	Lower platelet nadir myelosuppression 8 responses/SD (50%)	48, 8996137
Strobl, B.	2004	Phase II	7	Metastatic cervical cancer	1 h at 41.5–41.8 °C + paclitaxel + carboplatin	Grade II alopecia Grade III/IV thrombopenia, neutropenia ↑ survival	58
Westermann A.M.	2001	Phase II	14	Platinum resistant ovarian cancer	1 h at 41.8 °C + carboplatin	Grade IV thrombocytopenia, grade III neutropenia 9 responses/SD (64%)	11378341
Westermann A.M.	2003	Phase II	95	Metastatic sarcoma	1 h at 41.8 °C + ifosfamide + carboplatin + etoposide	Neutropenia, thrombocytopenia, infection 58 responses/SD (61%)	50, 12759526
WBH + Radiation	1995	Randomized multicenter	70	Metastatic melanoma	1 h at 43 °C + fractionated RT vs. FRT alone	Improved local tumor control, ↑ survival	41, 7776772
Robins, H.I.	1990	Pilot	8	Nodular lymphoma, chronic lymphocytic leukemia	41.8 °C + TBI vs. LON + TBI	8 responses/SD ↑ survival	24, 2182581

number of magnetic resonance (MR) techniques have been used for thermal mapping and BSD Medical and SIEMENS Medical Systems have collaborated to develop a hybrid hyperthermia/MRI system, although it is not a whole-body hyperthermia machine. Currently, the most widely accepted MR technique is the proton resonance frequency (PRF) method that exploits the temperature dependence of the chemical shift of water. Unlike the value of the water spin-lattice relaxation time or the molecular diffusion coefficient, both of which have been used for MRI temperature measurements, the thermal coefficient relating temperature to the water chemical shift has been shown to be essentially independent of tissue type and physiological changes induced by temperature (32). Recently an interleaved gradient echo–echo planar imaging (iGE-EPI) method for rapid, multiplanar temperature imaging was introduced that provided increased temperature contrast-to-noise and lipid suppression without compromising spatio-temporal resolution (33).

CLINICAL EXPERIENCE

Cancer

Systemic hyperthermia has been used mostly for treatment of cancer because of its potential to treat metastatic disease. Initial treatments aimed to produce direct killing of tumor cells based on the premise, now understood not to be universally true, that cancer cells are more susceptible to elevated temperatures than normal cells, and the higher the temperature the greater the tumor cell kill. Maximally tolerated temperatures of 41.5–42 °C were therefore maintained for 1–2 h as the sole treatment. Response rates were, however, disappointing. Tumor regressions were observed in less than half the cases, no tumor cures were achieved, and remissions were of short duration. It became apparent that the heterogeneity of cell populations within tumors, along with micro-environmental factors, such as blood/nutrient supply, pH, and oxygen tension prevent the thermotoxic results achieved in the laboratory. Consequently, the focus of research on systemic hyperthermia shifted to using hyperthermia as an adjunct to other cancer therapies, principally chemotherapy and radiotherapy. It is important to note that because of the experimental status of systemic hyperthermia treatment for cancer, almost all clinical trials, summarized in Table 5, have been performed on patients with advanced disease for whom whole-body hyperthermia, either as a sole therapy, or as an adjunct, is a treatment of last resort. In these cases, any response whatsoever is often remarkable. Nonetheless, a number of hyperthermia centers in Europe have discontinued systemic hyperthermia because the high temperature protocols required intensive patient care and led to unacceptable toxicities, especially in light of the efficacy and reduced toxicities of newer generation chemotherapies. Large, randomized, multicenter, Phase III trials are, however, needed to firmly establish the benefits of systemic hyperthermia in conjunction with chemotherapy and radiation. Also, validation and optimization of fever-range temperature protocols are much needed.

Systemic Hyperthermia and Chemotherapy. The beneficial interaction of hyperthermia with several classes of chemotherapy agents, acting via several mechanisms as summarized in Table 6, has spurred a variety of thermo-chemotherapy regimens and several clinical trials of systemic hyperthermia and chemotherapy are ongoing. While the results have been mixed, elevated response rates were recorded in the treatment of sarcoma when systemic hyperthermia was combined with doxorubicin and cyclophosphamide (54) or BCNU (34). Systemic hyperthermia is the only way to heat the lung uniformly, and impressive response rates and increased durations of response have been achieved in both small cell and nonsmall cell lung cancer treated with the combination of whole body hyperthermia at 41 °C for 1 h with adriamycin, cyclophosphamide, and vincristine (ACO protocol) (34). Neuroendocrine tumors also appear to have increased sensitivity to systemic hyperthermia and multidrug chemotherapy (51).

Optimal combination of whole-body hyperthermia with chemotherapy requires an understanding of the mechanisms of interaction of heat with individual drugs or drugs in combination. Preclinical data is consistent with the concept that the timing of chemotherapy during whole-body hyperthermia should affect therapeutic index. For example, Fig. 4 shows the effect on tumor cures in mammary carcinoma bearing rats of 6 h of 40 °C whole-body hyperthermia administered with, or 24 or 48 h after gemcitabine. A synergistic response was obtained when hyperthermia was begun with gemcitabine administration or 48 h later. The effect of gemcitabine was completely negated, however, when hyperthermia was administered 24 h after the start of heating, perhaps due to cell cycle effects. With cisplatin, the greatest therapeutic index is achieved if the drug is given 24 h before the start of whole-body hyperthermia, thereby preventing thermal augmentation of cisplatin induced nephrotoxicity (55). In a clinical investigation of multiple cycles of radiant heat whole-body hyperthermia combined with carboplatin, Ifosfamide, etoposide, and granulocyte colony stimulating factor, it was found that toxicity was minimized when carboplatin was

Figure 4. Schedule dependence of fever range whole-body hyperthermia enhanced gemcitabine tumor cures. A supraadditive cure rate occurred when whole-body hyperthermia (WBH) was given at the same time as gemcitabine administration or 48 h later. When hyperthermia followed gemcitabine by 24 h the number of cures dropped to almost zero, well below the number achieved with gemcitabine alone.

given during the plateau phase of WBH, 10 min after target temperature was reached (56).

A major rationale for whole-body hyperthermia in cancer treatment is the ability to treat metastases, but this is actually a controversial issue. There have been no clinical studies specifically designed to study the effect of systemic hyperthermia on either the efficacy against metastatic disease or prevention of development of metastases. Increased survival in advanced malignancies is often interpreted to mean a reduction in metastatic disease, but direct measurement of the incidence and response of metastases is rare. Based on some animal studies, it has been suggested that systemic hyperthermia could actually promote the metastatic spread of tumor cells, but this has not been confirmed. One clinical study found an increase of tumor cells in blood 24 h after 41.8 °C WBH, but there was no

evidence that this caused metastatic spread of disease (57). Several animal experiments do support the efficacy of whole-body hyperthermia against metastases. In mouse models of lung cancer and melanoma, the number of lung metastases was scored after repeated systemic microwave heating. It was found that the number of lung metastases was significantly reduced, and NK-cell activity was higher, in treated animals. The authors hypothesized that WBH interferes with the spread of organ metastases, possibly through a mechanism involving NK cells (13). Another study of mouse Lewis lung carcinoma in which the animals were treated with 60 min of systemic hyperthermia at 42 °C, demonstrated a reduction in the number and percentage of large metastases (>3 mm) on day 20 post-tumor implantation. Addition of radiation led to a reduction to 50% of control of the number of lung metastases as

well as the percent of large metastases on day 20 (58). In a breast cancer occult metastasis model in rats, 6 h of 40 °C whole-body hyperthermia combined with daily, low dose, metronomic irinotecan resulted in delayed onset, and reduced incidence, of axillary lymph node metastases compared to control in rats, as did treatment with 40 °C WBH alone. The combination therapy also reduced axillary metastasis volume. Interestingly, none of the therapies significantly affected inguinal lymph node metastases, but lung metastases were decreased in both the combination therapy and WBH alone groups. Rats treated with fever-range whole-body hyperthermia and metronomic irinotecan also survived significantly longer (36%) than control animals (59).

Systemic Hyperthermia and Radiotherapy. The augmentation of ionizing radiation induced tumor kill by hyperthermia is well documented for local hyperthermia and has led to numerous protocols combining whole-body hyperthermia with radiation therapy (60,61). Hyperthermia is complementary to radiation in several regards: ionizing radiation acts predominantly in the M and G₁ phases of the cell cycle while hyperthermia acts largely in S phase; radiation is most effective in alkaline tissues whereas hyperthermic cytotoxicity is enhanced under acidic conditions; radiation is not effective in hypoxic regions yet hyperthermia is most toxic to hypoxic cells. Thus when hyperthermia is combined with radiotherapy, both the hypoxic, low pH core of the tumor is treated as well as the relatively well perfused outer layers of the tumor. Furthermore, because of its vascular effects, hyperthermia enhances tumor oxygenation thus potentiating radiation cell kill. Hyperthermia also increases the production of oxygen radicals by radiation, and reduces the repair of DNA damage caused by ionizing radiation. Thus hyperthermia and radiotherapy together often have a synergistic effect, and this combination is now well accepted for treatment of a number of tumors.

Fever-Range WBH. Like systemic hyperthermia alone, combined modality treatments were initially aimed to achieve maximally tolerated temperatures. Such regimens, however, carry significant risk to the patient, require general anesthesia, and necessitate experienced, specialist personnel to provide careful monitoring of vital signs and patient care during the treatment. More recently, it has been appreciated that lower core body temperatures (39–40 °C) maintained for a longer time (4–8 h), much like fever, can indirectly result in tumor regression through effects on tumor vasculature, the immune response, and waste removal (detoxification). The optimum duration and frequency of mild hyperthermia treatment has, however, not yet been determined. Protocols range from single treatments of 4–6 h, or similar long duration treatments given once during each cycle of chemotherapy, to daily treatments of only 1 h. Several studies of mild, fever-range, whole-body hyperthermia with chemotherapy have demonstrated efficacy against a broad range of cancers (34,17) and clinical trials are currently being conducted at the University of Texas Health Science Center at Houston, Roswell Park Cancer Institute,

New York, and by the German Interdisciplinary Working Group on Hyperthermia (62).

Systemic Hyperthermia and Metabolic Therapy. Increased rates of metabolic reactions lead to rapid turnover of metabolites, causing cellular energy depletion, acidosis, and consequent metabolic dysregulation. Tumors, which have increased metabolic rates [glucose, adenosine triphosphate (ATP)] compared to normal cells, may be particularly sensitive to thermally induced energy depletion and this has been exploited in the Cancer Multistep Therapy developed by von Ardenne, which is a combined hyperthermia–chemotherapy–metabolic therapy approach to cancer (63). The core of this approach is systemic hyperthermia at 40–42 °C, sometimes with added local hyperthermia to achieve high temperatures within the tumor. A 10% solution of glucose is infused into the patient to achieve a high accumulation of lactic acid within the tumor that cannot be cleared because of sluggish blood flow and confers an increased sensitivity to heat to the tumor cells. Administration of oxygen increases the arterial oxygen pressure and stimulates lysosomal cytolysis. Finally low dose chemotherapy is added.

Palliation. Pain relief is reported by many patients receiving systemic hyperthermia treatment, whether with chemotherapy or radiation. Indeed, almost all patients undergoing thermoradiotherapy report pain relief. Immediate pain relief following treatment is likely to stem from an increased level of circulating β -endorphins, while longer term pain relief may be due to increased blood flow, direct neurological action, and disease resolution, for example, tumor regression in cancer patients, or detoxification. Meaningful improvements in quality of life typically result from such pain relief. Localized infrared therapy using lamps radiating at 2–25 μ m is used for the treatment and relief of pain in numerous medical institutes in China and Japan.

Diseases Other than Cancer. Therapeutic use of heat lamps emitting IR radiation is commonplace throughout the Orient for rheumatic, neurological and musculoskeletal conditions, as well as skin diseases, wound healing, and burns. The improvements reported appear to be largely due to increased blood flow bringing nutrients to areas of ischemia or blood vessel damage, and removing waste products. Scientific reports of these treatments are, however, difficult to find. Application of heat via hot baths or ultrasound has long been standard in physical therapy for arthritis and musculoskeletal conditions, though ice packs are also used to counter inflammatory responses. Heat decreases stiffness in tendons and ligaments, relaxes the muscles, decreases muscle spasm, and lessens pain. Unfortunately, few clinical trials of efficacy have been performed, and methodological differences or lack of rigor in the studies hinder comparisons (64). A clinical trial in Japan reported a supposedly successful solution for seven out of seven cases of rheumatoid arthritis treated with whole-body IR therapy, and it is reported that the King of Belgium was cured of his rheumatoid arthritis in three months due IR treatments. Systemic hyperthermia with

whole-body radiant heat units is being carried out in clinical centers as well as many private clinics in Germany for the purpose of alleviating rheumatoid arthritis. It has been proposed that the induction of TNF receptors by WBH may induce a remission in patients with active rheumatoid arthritis. The use of heat packs has long been standard to relieve the pain of fibromyalgia. Again, the therapeutic effect is believed to be due to increased circulation flushing out toxins and speeding the healing process. Whole-body hyperthermia treatment for fibromyalgia and chronic fatigue syndrome (CFS) is to be found in a number of private clinics. Hyperthermia increases the number and activity of white blood cells, stimulating the depressed immune system of the CFS patient.

Because of its immune stimulating effects, whole-body hyperthermia is a strong candidate for treatment of chronic progressive viral infections, such as HIV and hepatitis C. A clinical trial at the University Medical Center Utrecht, The Netherlands has evaluated extracorporeal heating to induce systemic hyperthermia of 41.8 °C for 120 min under propofol anesthesia for treatment of hepatitis C (65). Human immunodeficiency virus (HIV)-infected T cells are more sensitive to heat than healthy lymphocytes, and susceptibility increases when the cells are presensitized by exposure to tumor necrosis factor. Thus, induction of whole-body hyperthermia or hyperthermia specifically limited to tissues having a high viral load is a potential antiviral therapy for acquired immunodeficiency syndrome (AIDS). An Italian study has found treatment of AIDS with beta-carotene and hyperthermia to be synergistic, preventing progression of early disease and also increasing the survival time in patients with severe AIDS. A single treatment of low flow extracorporeal hyperthermia was found effective against AIDS associated Kaposi's sarcoma, though there was significant toxicity. Core temperature was raised to 42 °C and held for 1 h with extracorporeal perfusion and *ex vivo* blood heating to 49 °C. Complete or partial regressions were seen in 20/29 of those treated at 30 days post-treatment, with regressions persisting in 14/29 of those treated at 120 days post-treatment. At 360 days, 4/29 maintained tumor regressions with 1 patient being in complete remission still at 26 months (66).

THE FUTURE OF SYSTEMIC HYPERTHERMIA

While there is a resurgence of interest in systemic hyperthermia, this modality has not yet been adopted as a mainstream therapy, and optimal clinical trials have not yet been carried out. Well-designed, well-controlled, multicenter clinical trials need to be conducted. In order to unequivocally demonstrate the utility of whole-body hyperthermia in the treatment of cancer as well as other diseases, it will be important to accrue a sufficiently large number of patients who do not have end-stage disease. Thanks to the commercial availability of systemic hyperthermia systems, the variability between induction techniques at different institutions can be removed. Newer instrumentation, particularly near-IR radiant heat devices, along with treatment at lower temperatures (fever-range thermal therapy) should lead to significantly reduced toxicity. Better exploitation of

Figure 5. Fever range whole-body hyperthermia increases therapeutic gene (grp78-HSVtk) delivery in tumor.

the narrow window of effective temperatures within which the cellular effects of heat can be exploited yet damage remains minimal, and improved understanding of the biological interactions *in vivo* of systemic heat with chemotherapy and radiation will be essential to optimize therapy.

The effects of systemic hyperthermia on tumor blood flow and vascular permeability have the potential to increase delivery of various small molecules, nanoparticles, and gene therapy vectors to tumors. Ferromagnetic nanoparticles can be heated by external magnetic fields and offer the potential for internal hyperthermia, both locally and systemically. Thermally sensitive liposomes that release their contents at designated temperatures are also of interest. The ability of systemic hyperthermia to aid in systemic delivery of gene therapy vectors (the holy grail of gene therapy) and enhance transfection of cells with therapeutic gene plasmids is under investigation in several laboratories (67,68), and shows potential along with targeted gene therapy via the heat shock response. For example, Fig. 5 shows a fourfold hyperthermic increase of therapeutic gene delivery to tumor when plasmid DNA was injected intravenously into mammary carcinoma bearing rats immediately after 6 h of whole-body hyperthermia at 40 °C. Thus systemic hyperthermia is likely to see increasing application as an enhancer of drug delivery.

There is a great deal of interest in the immunological consequences of whole-body hyperthermia, and as they become better understood, the combination of systemic hyperthermia with specific immunotherapies will undoubtedly be pioneered, not just for cancer but also, by analogy with fever, in a broad range of diseases.

SUMMARY

Systemic hyperthermia is founded on solid physical and biological principles and shows promise in the treatment of a number of diseases. Modern whole-body hyperthermia devices use IR-A radiation sources together with effective heat loss techniques to achieve a controlled, uniform temperature distribution throughout the body with minimal patient toxicity. A shift in paradigm has occurred away from achieving direct cell killing with short

bouts of maximally tolerated temperatures, to inducing indirect curative effects through longer duration treatments at lower temperatures, and synergy with other modalities, such as radiotherapy. Better understanding of the interactions of elevated temperature with metabolic and genetic pathways will allow thermally driven targeted therapies. Of particular promise is the use of systemic hyperthermia as an immune system stimulator and adjunct to immunotherapy. Application of systemic hyperthermia to nanoparticle delivery and gene therapy is emerging. Whole-body hyperthermia is moving from being dubbed an alternative therapy to becoming a standard treatment and clinical hyperthermia centers are to be found all over the world.

INTRODUCTION

The use of elevated temperature as a form of medical treatment has been fairly ubiquitous across cultures throughout the course of time. The earliest record of heat for therapeutic use was found in an Egyptian surgical papyrus dated to 3000 BC (1). Hippocrates, considered by many to be the father of medicine, used heat to treat breast cancer. He based his practice of medicine on an ancient Greek ideology that advises using heat after trials of surgery and medications have failed (2). German physicians in the 1800s noted cases where cancer patients had developed high fevers secondary to infections that resulted in a miraculous disappearance of their tumors (3). These observations provided inspiration for the development of several techniques that attempted to induce hyperthermia. One such popular method entailed wrapping a patient's body in plastic and then dipping him in hot wax. Another popular technique involved removing a portion of the patient's blood, heating it, and then transfusing the warmed blood back to the patient's body, thereby creating systemic hyperthermia (4). These treatments had varied success rates, often culminating in fatality, and were subsequently discarded. Thus, the interest in hyperthermia lessened in the face of more conventional cancer treatments (e.g., chemotherapy and radiation). The current revival of interest in hyperthermia has resulted from a combination of clinicians searching for a therapeutic mode other than chemotherapy and radiation, in tandem with several preliminary randomized clinical trials in a small selected group of patients that have shown marked improvement in disease states with the use of either hyperthermia alone or particularly as an adjuvant to other more traditional modalities.

Traditionally, conventional hyperthermia has been defined as a therapeutic elevation of whole body temperature or target tissue while maintaining low enough temperatures to avoid tissue coagulation (3). This definition of hyperthermia can be broadened to include the therapeutic elevation of temperature to cause tissue destruction and coagulation, such as that implemented in HIFU (high intensity focus ultrasound) procedures. Classically, microwaves, radio frequency (RF), electromagnetic radiations, or ultrasounds have been used to heat tissue to 40–44 °C (5). This article compares and contrasts electromagnetic waves to ultrasonic waves as a heating modality, explain the physics behind ultrasound

generation, and explores the thermal and mechanical biophysics involved with ultrasound delivery to tissue. Then, the medical fields that are currently benefitting from conventional ultrasound hyperthermia and HIFU are considered, and finally some of the many applicators involved with thermal ultrasound delivery are evaluated.

ULTRASONID VERSUS ELECTROMAGNETIC RADIATION

Electromagnetic waves were often used in various applications of conventional hyperthermia treatments. However, ultrasound has emerged as a better option because of its shorter wavelength and lower energy absorption rate, which make it easier to control and to localize the area that is being heated. For example, for a half-power penetration depth of 4 cm, the ultrasound wavelength in tissues (e.g., muscle) is 1 mm; however, electromagnetic wavelength required for the same transmission is 500 mm. Focusing energy into a volume smaller than a wavelength is generally not possible. Using 500 mm (~ 40 MHz) of electromagnetic waves to heat a tumor that is situated 4 cm below the skin with proportions of 6 cm in diameter in the upper abdomen results in a temperature elevation of the entire abdomen including the spleen, liver, and all major vessels. More than one-half of the body's cardiac output circulates through the abdominal area, and this widespread heating results in a systemic elevation of temperature, thereby limiting the use of electromagnetic radiation for tumors in the body cavity (3). Electromagnetic waves are currently limited to regional hyperthermia and treating very superficial tumors (6). Conversely, ultrasound that has a wavelength of 1 mm can be focused within the area of the tumor, thus allowing less energy to be radiated to other areas of the body, resulting in less damage to surrounding healthy tissue. The current fabrication technology allows for practical applicator dimensions and multiple transducer configurations that makes it possible to control and shape a wide variety of ultrasound beams. The use of focused transducers or electronically phased arrays allow for better localization and temperature control of the target tissue (7). In contrast to these positive attributes, high acoustic absorption at bone-soft tissue interface and reflection from gas surfaces may make certain therapeutic scenarios difficult.

GENERATION AND PROPAGATION OF ULTRASONID

Ultrasonic Transducers

In order to generate ultrasonic waves for tissue warming, a transducer containing piezoelectric crystals is required. Piezoelectric crystals are found in Nature or can be artificially grown. Quartz and synthetic ferroelectric ceramics (e.g., lead metaniobate, lead zirconate, and titanates of barium) all have strong piezoelectric properties (8). The ceramic most commonly used in the fabrication of ultrasound transducers is synthetic plumbium zirconium titanate (PZT). Transducers are manufactured by applying an external voltage to these ferroelectric materials to orient their internal dipole structure. They are then cooled to permanently maintain their dipole orientation. Finally,

they are cut into any desired shape, such as spherical bowls for focused ultrasonic fields (3,8). Ultrasound transducers have electrodes attached to the front and back for application and detection of electrical fields. With the application of an alternating electrical field parallel to the surface of piezoelectric material, the crystals will contract and vibrate for a short time with their resonant frequency. The frequency at which the transducer is able to vibrate is indirectly proportional to its thickness; higher frequencies are a result of thinner transducers, lower frequencies a result of thicker transducers (8).

Piezoelectric crystals are able to contract or expand when an electrical field is applied to them because dipoles within the crystal lattice will realign themselves as a result of attractive and repulsive forces causing a change in physical dimension of the material in the order of nanometers (electrostriction or reverse piezoelectric effect). When echos are received, the ultrasound waves will compress and expand the crystals (8). This mechanical stress causes the dipoles to realign on the crystal surface creating a net charge (piezoelectric effect) (Fig. 1).

Transducers function optimally when there is broad bandwidth in the frequency domain and short impulse response in the time domain. Also, when there is little electroacoustical conversion inefficiency, and little mismatch between the electrical impedances of the generator and the transducer (3,9). A transducer's ability to transmit energy is dependent on the characteristics of acoustic impedances and its contact medium. Both the density of the material and propagation velocity of ultrasound waves will determine its impedance. When both impedances match, then less energy is lost through reflection back into the transducer. For example, at the interface between air and the transducer, most of the energy will be reflected back to the transducer and will travel to the opposite direction because air has ~ 16 times less impedance than the transducer. If the transducer is a half wavelength in thickness, the reflected wave arrives at the opposite surface in phase with the direction of its motion and can then be transmitted into the medium. Since the efficiency at which a transducer transmits energy has a direct relationship to the degree of impedance match, efficiency can be increased significantly by adding an impedance matching layer of a quarter wavelength thickness, subsequently making the characteristic impedance equal to the geometric average of those of the transducer and the loading medium (3,8).

RADIATION FIELD OF ULTRASONIC TRANSDUCERS

The radiation field of an ultrasonic transducer depends on its physical properties and the transmission characteristics of the medium through which it will pass. Conventional planar transducers create a nonfocused field, whereas some modifications to the same transducer can create a focused field.

NONFOCUSED FIELDS

Planar Transducers

Ultrasonic waves that are radiated from the transducer surface can be described as a tightly packed array of

Figure 1. A piezoelectric compound consists of aligned molecular dipoles. (a) At equilibrium, the dipoles are arranged in a configuration that results in a neutral net charge. When the piezoelectric compound is mechanically stressed (e.g., an ultrasound wave) the element changes its physical dimensions. At peak pressure amplitudes, the element will contract. When no stress is placed upon the element it is in equilibrium. At peak rarefaction, the element will expand. This realignment of dipoles results in the production of a net positive or negative surface charge. (b) When an electrical field is applied to the piezoelectric element the dipoles can be realigned in response to attractive or repulsion forces. This rearrangement results in either expansion or contraction of the element. In the absence of an applied electrical field the element is in equilibrium and has a neutral net charge. (Published with the permission from Ref. 8).

separate point sources of sound energy (Fig. 2a). Each of these points emits a spherical wavelet (Fig. 3). These waves interact both constructively and destructively creating a diffraction pattern. Any point in the medium is a compilation of all the sources that reach that target at that period of time. This diffraction pattern can be calculated using Huygen's principle. Two separate transducers whose emission fields interact in the same media are subject to the same laws of construction and destruction. Planar transducers operating in continuous wave mode are shown in (Fig. 2). In the Fresnel zone or the near field, the beam energy distribution is collimated, which is a result of the many destructive and constructive interactions of the spherical wavelets (Figs. 2c and 3). The

Figure 2. A planar transducer operating in a continuous wave mode. (a) The envelope containing almost all of the ultrasonic energy. (b) The relative intensity of the ultrasonic beam along a central axis. The intensity across the field fluctuates greatly at small distances from the surface of the transducer. At greater distances along the central axis the intensity distribution across the field stabilizes and deteriorates with beam divergence. (c) Ring diagrams illustrating the energy distribution at positions indicated in (b). In the near field, the ring pattern is collimated, but at greater distances from the transducer surface the beam diverges. (Published with permission from Ref. 3).

beam path is a function of the dimension of the active part of the transducer surface, thus the beam diameter that is converging at the end of the near field is approximately one-half of the size of transducer diameter. The intensity and pressure amplitudes fluctuate greatly at small distances from the surface transducer (Fig. 2b). As the distance from the transducer surface increases, the beam path diverges (Fig. 2c and 3). In large diameter, high frequency transducers, there is less beam divergence in the far field. After a certain distance from the transducer surface, the intensity stabilizes; however, intensity along the axis deteriorates along with beam divergence (Fig. 2b). Circular, square, and rectangular transducers have similar fields; albeit, circular transducers have more pronounced fluctuations of intensity in the near field (3,8).

Figure 3. Ultrasonic waves that are radiated from the transducer surface are described as a tightly packed array of separate point sources. Each of these points radiates a spherical wavelet (Huygen's principle). These spherical wavelets will interact constructively and destructively. In the near field, these interactions result in a convergent beam pattern. In the far field, the beam pattern diverges. (Published with permission from Ref. 8).

FOCUSED FIELDS

Single-Element Transducers

When an ultrasonic wave travels through different media, the laws of geometric optics can be applied. Ultrasonic waves can be reflected, refracted, and scattered. When there is a high degree of impedance mismatch between the generator and transducer, ultrasonic waves will be reflected back into the transducer. The angle of reflection is equal to the angle of incidence, much like that of a mirror. Single element transducers can be focused by using a curved acoustic lens or a curved piezoelectric element (8). When an ultrasonic wave goes through two media with different propagation velocities there is a certain degree of refraction. Ultrasonic propagation through water is $1500 \text{ m}\cdot\text{s}^{-1}$. In order to focus the ultrasound field, a lens of plastic (e.g., polystyrene), which has a higher propagation velocity, is placed between the transducer and the water media; these converging lenses are then concave to the water media and at plane with the transducer interface. In an unfocused transducer, the focal length is directly proportional to the transducer frequency and diameter. In a focused single element transducer, the focal distance is brought closer to the transducer surface. The focal distance is defined as the distance between the transducer surface and the portion of the beam that is narrowest. The focal zone, which is the area of best lateral resolution, is defined as the area at which the width of the beam is less than two times the width at the focal distance (3,8) (Fig. 4). The focal zone is dependent on the aperture and the wavelength of the ultrasound. The focal area through which 84% of the ultrasound passes is two to four wavelengths in hyperthermia systems. With ultrasonic transducers, the intensity distribution dimensions are a function of frequency and aperture. Therefore, the larger the aperture, the shorter the focal region, the higher the frequency and the smaller the diameter of the beam (Fig. 5). Ceramic curved bowl-shaped transducers, while more efficient than a lens, do not have the versatility of a lens. Once a ceramic bowl is fabricated, the focal length is set. Lenses can be interchanged creating a variety of focal lengths with one transducer (8).

Figure 4. The focal zone is the area of optimal lateral resolution. The use of a curved element or an acoustic lens allows the focal distance to be brought closer to the transducer surface. The use of a curved element decreases the beam diameter at the focal distance and increases the angle of beam divergence far field. The focal zone, which is the area of best lateral resolution, is defined as the area at which the width of the beam is less than two times the width at the focal distance. (Published with permission from Ref. 8).

Figure 5. The intensity distribution in the focus of an ultrasound transducer. The diameter and the length are a function of frequency. The lower the frequency, the larger the diameter, and the smaller the aperture, the longer the focal region. (Published with permission from Ref. 3).

Multielement Transducers

Linear array transducers contain 256–512 narrow piezoelectric elements. They produce a beam by firing a portion of the total number of elements as a group. If a single element were fired the beam pattern would be divergent in the near field. By firing a group of elements, it is possible to focus and converge the beam. All the individual beams interact both constructively and destructively to produce a collimated beam. A phase array transducer is composed of 64–128 elements. The ultrasound beam can be steered and focused without moving the transducer by electrically activating the separate elements on the transducer surface at slightly different times (8).

PROPAGATION OF ULTRASOUND IN BIOLOGICAL TISSUES

The journey of an ultrasound wave through human tissue is sometimes arduous. As the waves propagate through different biological media, they are subject to reflection, refraction, scattering, and absorption (8). When there is a difference in acoustic impedance between the boundaries of two tissues, reflection occurs (Table 1). There is 100% reflection at the air–skin interface. However, if a coupling medium (e.g., gel) is used, reflection is reduced to 0.1%. When the beam is not perpendicular to tissue boundary, the transmitted ultrasound energy undergoes a change in direction at the boundary; this directional change is termed refraction. As waves propagate through tissue they must overcome internal friction resulting in a loss of energy. The mechanical energy that is lost is converted to heat, which is termed absorption. At higher frequencies, ultrasonic waves move quicker, thus forcing the molecules to move against each other creating friction. The more these molecules move, the more energy is consumed or absorbed, and subsequently will be converted to heat. The speed at which the ultrasonic wave travels is dependent on the arrangement of the molecules. If they are densely arranged, they will collide sooner when they are exposed to a stimulus, and will lose energy quickly and at shorter distances. Ultrasonic waves can travel through the skin without much absorption until they reach tissues with high collagen content, (e.g., bone, periosteum, ligaments, capsules, fascia, and tendons). Ultrasonic waves travel through most solid tissues at a speed of 1500–1600 $\text{m}\cdot\text{s}^{-1}$. Its velocity in fat and postmenopausal breast tissue may be as low as 1450 $\text{m}\cdot\text{s}^{-1}$ and the lens of the eye $\sim 1600 \text{ m}\cdot\text{s}^{-1}$. As a general rule, ultrasonic waves move through soft tissue with relatively little reflection or refraction (3,8) (Table 2).

Ultrasonic speed through bone is $\sim 4080 \text{ m}\cdot\text{s}^{-1}$. Bone easily absorbs ultrasonic energy and reflects it to tissues that are located at the bone–tissue interface. Since bone absorbs ultrasonic energy so readily, it heats up very quickly, consequently making it harder to control temperature. Thus, bone and its immediate surrounding tissue were once considered problematic for therapeutic use of ultrasonic hyperthermia (3,8). Nevertheless, in a recent study, Moros et al. noted that the presence of underlying

bone in superficial unfocused ultrasound hyperthermia could actually be exploited to induce more uniform and enhanced temperature distributions in superficial target volumes. In particular, they have shown that the presence of bone in superficial target volumes enhances temperature elevation not only by additional direct power deposition from acoustic reflection, but also from thermal diffusion from the underlying bone (10).

The intensity at which an ultrasonic beam is transmitted has an effect on target tissue temperature. Intensity is defined as the amount of power per unit area. Doubling the amount of power used will result in quadrupling the intensity. Ultrasonic waves will lose intensity as they propagate further into the tissue. The attenuation coefficient is the relative intensity loss per centimeter of travel in a given medium (Table 3). Beam divergence, absorption, and scattering will also cause a loss in intensity of the propagating beam. The absorption coefficient of the tissue being exposed to us determines the target temperature that tissue will reach. The absorption coefficient is dependent on the density of the tissue and will linearly increase at higher frequencies. The absorption coefficient in soft tissue is 4–10 times lower than that of bone, and therefore bone heats more quickly (3). At short exposure times (e.g., $< 0.1 \text{ s}$), temperature and intensity are directly propor-

tional. However, as the time intervals increase, other factors in addition to intensity, (e.g., blood perfusion), must be considered. An approximate estimate of the ultrasonic energy requirements for heating a target volume to therapeutic temperature depends on assessing thermophysical properties of that tissue, intensity of the ultrasound beam, ultrasonic absorption coefficient, and additional factors (e.g., blood circulation to target tissue) (3,8,11). The thermal index is defined as the ratio of acoustic power created by the transducer to raise the target area by 1 °C. This is calculated by using an algorithm that takes into account the ultrasonic frequency, beam area, and the acoustic power output of the transducer (8).

Ultrasonic waves act on tissues thermally and mechanically. Mechanical effects on tissues via ultrasound include acoustic torque, acoustic streaming, radiation force, stable cavitation, and unstable cavitation (11). Any object situated within an acoustic field will be subject to acoustic pressure and acoustic force. Acoustic pressure in a standing wave field is inversely proportional to velocity. Acoustic torque results from variations in the acoustic field, which can be described as a time-independent twisting action. Acoustic torque causes a rotational movement of cells and intracellular organelles in the medium. Acoustic streaming describes the movement of fluid in an ultrasonic field. The compression phase of an ultrasonic wave deforms tissue molecules. Radiation force affects gas bubbles that are in the tissue fluids. Negative pressure induces the bubbles originally dissolved in the medium to fall out of solution. With positive and negative pressure wave fluctuations, these bubbles expand and contract without reaching critical size (stable cavitation). Unstable cavitation occurs when bubbles collapse violently under pressure after growing to critical size due to excessive energy accumulation. This implosion produces large, brief local pressure and temperature release, as well as causing the release of free radicals. Organs that are air-filled, (e.g., the lungs or intestines), are subject to greater chance of unstable cavitation. Unstable cavitation is somewhat random, and as such it may lead to uncontrollable tissue destruction (8,11). Bubble growth can be limited by low intensity, high frequency, and pulsed ultrasound. Higher frequency means shorter cycle duration so time for bubble growth is regulated. Pulsed ultrasound restricts the number of successive growth cycles and allows the bubble to regain its initial size during the off period. The mechanical index estimates the possibility of cavitation occurrence. The mechanical index is directly proportional to peak rarefaction pressure, and inversely proportional to the square root of the ultrasound frequency (8).

MEDICAL APPLICATIONS OF CONVENTIONAL HYPERTHERMIA

Ultrasound as a heating modality has been used in several different medical fields. It is used in treating sprains, bursitis, joint inflammation, cardiac ablations, and in gynecology. However, the main area conventional hyperthermia is currently used is in oncology. The use of conventional hyperthermia as an oncologic treatment is

supported by a plethora of studies that demonstrate that heat on cell lines and on animal tumor transplant models can result in tumor regression; however, it is rarely used alone because its efficacy is greatly potentiated in combination with radiation or chemotherapy. Conventional hyperthermia treatments elevate target tissue temperatures to 42–46 °C (12). Treatment times are usually between 30 and 60 min. Treatment applications are administered once or twice a week and are applied in conjunction with or not long after radiation. In all of the recent phase III trials, a sequential delivery scheme was used. This means that radiation and hyperthermia were administered separately, with radiation preceding hyperthermia treatments (13). Tumoricidal effects *in vivo* are achieved at temperatures between 40 and 44 °C (5). Large tumors often have an inadequate blood supply and resultantly, have difficulty meeting their requirements for oxygen and nutrients. This situation creates a hypoxic environment that is low in pH (2–3) (3,5,14). When tumor cells are heated to therapeutic temperatures, their cellular metabolic processes are accelerated, thereby further increasing the demands for oxygen and nutrients in an already depleted environment. Most tumor cells are unable to reproduce in this hostile environment, resulting in termination of tumor growth and shrinkage of the tumor (5,15). In temperatures > 40 °C, protein denaturation has been observed as the main mechanism of cellular death. Widespread protein denaturation results in structural changes in the cytoskeleton and the cell membrane, and in enzymes that are necessary for deoxyribonucleic acid (DNA) synthesis, cellular division, and cellular repair (5). Hyperthermic efficacy is a function of temperature and exposure time. To quantify, at temperatures > 42.5–43 °C, the exposure time can be halved with each 1 ° temperature increase to give an equivalent cell kill (5,16). Healthy tissues remain undamaged at temperatures of 44 °C for a 1 h duration (5,17). The exceptions are central nervous tissues, which suffer irreversible damage after being exposed to heat at temperatures ranging from 42 to 42.5 °C for >40–60 min (5,18). Peripheral nervous tissue that has been treated for > 30 min at 44 °C or an equivalent dose results in temporary functional loss that is reversed in 4 weeks (5,19). Therefore, since a small difference in temperature produces a large difference in the amount of cells killed, it is important to be able to have good control on the site and duration of heat delivery to reduce the damage to surrounding healthy tissue.

RADIATION COUPLED WITH CONVENTIONAL HYPERTHERMIA

While hyperthermia independently has been found to have antitumor effects, its efficacy is greatly potentiated when coupled with radiation. Cells that are in a low pH hypoxic environments, those that are in the S or M phases of cell division, and those that are malnourished are relatively resistant to radiation (5,7). Hyperthermia increases radiation damage and prevents cellular repair of damaged DNA (5,16). Hyperthermia increases blood perfusion via

vasodilation which results in increased oxygenation, thus allowing increased radiosensitivity (5,7,16). Response rates with hyperthermia alone are ~15%, with radiotherapy ~35%, with combined radiotherapy, and hyperthermia ~70% (20). There have been many U.S. and European clinical trials that support substantial improvement in patients who have been treated with a combination of radiation and hyperthermia. Examples of some recent trials include randomized multiinstitutional phase III trials for treating melanoma (20,21), glioblastoma multiforme (20,22), chest wall recurrence of breast cancer (20,23), head and neck cancer (20,24,25), head and neck in superficial measurable tumors (20,26,27), in various recurrent persistent tumors (20,28), cervical cancer (29), uterine cancer (30) and in locally advanced pelvic tumors (20,31) (Table 4). Trial success rates were very dependent on the uniformity of temperature delivery. In the past, trials had often provided mediocre results because temperatures were ~1–1.5 °C too low and consequently not able to achieve adequate tumoricidal levels (7). It is often difficult to uniformly heat larger tumor (3,7). When radiation and hyperthermia are used simultaneously excellent radiation delivery is achieved, often resulting in tumor regression; however, its delivery is equally as toxic to healthy cells that necessitate the need for a very precise delivery system.

CHEMOTHERAPY IN CONJUNCTION WITH CONVENTIONAL HYPERTHERMIA

Chemotherapeutic efficacy is enhanced by hyperthermia (5,20,34,35) (Table 5). As areas are heated, perfusion is increased, thus allowing an increase in drug concentrations in areas of the tumor that are poorly vascularized, increased intracellular drug uptake, and enhanced DNA damage. Drugs (e.g., mitomycin C, nitrosureas, cisplatin, doxorubicin, and mitoxantrone) are subject to less drug resistance when used with heat. The synergistic effect of chemotherapy and hyperthermia was demonstrated in virtually all cell lines treated at temperatures >40 °C for alkylating drugs, nitrosureas, and platin analogs dependent on exposure time and temperature. Chemotherapeutic agents can be revved up 1.2–10 times with the addition of heat (5). *In vivo*, experiments showed improvement when doxorubicin and mitoxantrone were combined with hyperthermia. However, antimetabolites vinblastine, vincristine, and etoposide did not show improvement with the addition of hyperthermia. In animal studies, increased toxicities were seen in skin (cyclophosphamide, bleomycin), heart (doxorubicin), kidney (cisplatin, with a core temperature >41 °C), urinary tract (carmustine, with core temperatures >41 °C), and bone marrow (alkylating agents and nitrosureas) (5,34). Lethal toxicity was enhanced when systemic hyperthermia was applied in combination with cyclophosphamide, methyl-CCNU, and carmustine (5). The success of hyperthermia and chemotherapy combinations depends on the temperature increase in the organs for which the drug is used and its subsequent toxicity, all of which can be influenced by the accuracy of the heating device and the operator.

MODES OF CONVENTIONAL HYPERTHERMIA APPLICATION

Externally Applied Techniques

In the past, single planar transducers were used to apply local heat. A disk shaped piezoelectric transducer (range from 0.3–6.0 MHz in frequency and up to 16 cm in diameter) is mounted above a chamber of cooled degassed water. This device has a coupling chamber which allows water to circulate (3) (Fig. 6). It is coupled to the body via a plastic or latex membrane. Unfortunately, these types of devices are unable to achieve homogenous therapeutic thermal levels. The reason is that this system uses an unfocused energy source. When an unfocused energy source is applied to the skin, the intensity and the temperature will be the highest at the contact point and will subsequently lose intensity as it travels deeper into the tissue. However, by cooling the skin, the “hot spot” is shifted to the subcutaneous fatty tissue that is poorly vascularized. Fat is an insulator and as a result much energy is conserved rather than lost. Furthermore, cooling the skin will produce vasoconstriction which conserves even more heat and facilitates the heating of deeper tissues (3) (Figs. 7, 8a and b). However, even with this strategy adequate temperatures could not be reached. The reason for this is that large tumors often consist of three zones, a central necrotic core, an intermediate zone that is normally perfused, and a marginal zone that has a greater number of vessels due to proliferation induced angiogenesis. Due to the abundance of vasculature on the marginal surface, much heat is dissipated to the surrounding tissue. The relatively avascular center will heat to a higher temperature than the marginal or intermediate zone because there is little dissipation of heat, creating hot spots (Fig. 9) (7,54). Thus, it is not possible to therapeutically heat a tumor with a single planar source. This theory is substantiated by a significant number of clinical trials (7,55–61). Most trials reported that patients had some difficulty with dose-limiting pain, extensive central tumor necrosis, blistering, and ulceration (7). Conversely, a focused ultrasound source localizes energy within the tumor volume while sparing the surrounding tissue (Fig. 10). The use of a focused beam allows for homogenous heating and higher intensity which allows the generation of greater temperatures within the target area. Attenuation and beam divergence cause rapid deterioration of intensity beyond the focal zone (3) (Fig. 11 a and b). Focused ultrasound sources overcome some of the limitations of planar heating. Focusing allows for controlling the amount of heat that is delivered to the poorly perfused areas thus limiting hot spots and some of the side effects. For a heating system to be successful clinically on a large scale, it must account for geometric and dimensional variations of target tissue, possess the ability to heat the sites that need it, and avoid side effects and complications as much as possible (3).

Technological advances in hyperthermia devices have paved the way for better therapeutic options. The use of mosaics or separately controlled transducers allowed better spatial and temperature control to target bulky irregularly shaped tumors. The multielement planar

ultrasound applicators met these demands and are capable of treating tumors at depths up to 8 cm. The multisector applicator allows for heating to the edge of the aperture and the acoustic beams are nondiverging in the near field,

thus allowing large tumor heating with lateral measurements of 15 × 15 cm. Each of these 16 sectors can be varied from 0 to 100% power to uniformly heat across the tumor. If an area of the tumor is too difficult to treat, more energy

Figure 6. A cross-sectional diagram of a single planar element hyperthermia applicator. The chamber between the latex membrane and the piezoelectric element contains cooled degassed water. During local hyperthermia treatment an ultrasonic conducting gel is applied to the target site that is then coupled to the latex membrane. (Published with permission from Ref. 3).

can be directed to just that target segment. The temperatures can be adjusted in relation to variations in temperature distribution due to blood flow, variations in target tissue morphology, and based on the patient's comfort level. These devices have the ability to contour the energy field to match the tumor outline. These systems generally have two frequencies: 1 MHz (used to heat 3–6 cm) and 3.4 MHz (used for more superficial 2–3 cm) (7,62). Examples of heating temperatures for different ultrasound hyperthermia devices are shown (Table 6). These planar array systems have been adapted to allow for thermoradiation in conjunction with an external beam radiation (7). An extended bolus configuration with an internal reflecting system was created to direct the ultrasound energy into desired tissue. This configuration allows the ultrasound transducer to be outside the radiation beam thus preventing potential interference of the two (7,70).

Another approach to achieving greater spatial control is to use a larger variety of small transducers in a nonplanar geometric configuration. This approach has been used in

Figure 7. The pattern of ultrasound delivery via plane wave radiation targeting a tumor that is located deep within the tissue. (Published with permission from Ref. 3).

Figure 8. (a) Ultrasound intensity is greatest at the surface. Intensity will deteriorate exponentially due to attenuation as the depth from the surface increases. Published with the permission of (3). (b) Since temperature and intensity are directly proportional, temperature will decrease exponentially as depth increases. Cooling the skin will cause the “hot spot” to shift to the poorly perfused fatty tissue. (Published with permission from Ref. 3).

treating intact breast with cancer (7,71). The patient lies prone while the breast is immersed within the water filled cylindrical applicator (Fig. 12). The cylindrical applicator is composed of eight rings (each ring is 25 cm in diameter by 1.6 cm in height), with up to 48 transducers (1.5 × 1.5 cm plane transducers), which are interspersed around the

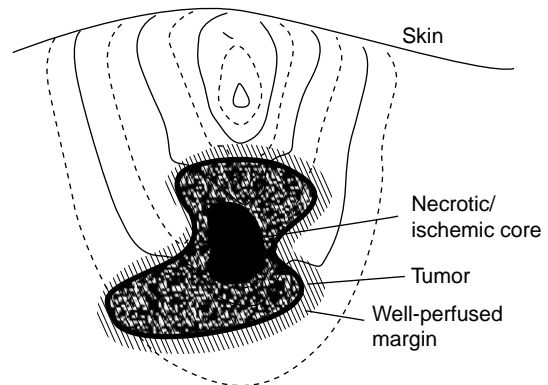

Figure 9. Temperature distribution in a subcutaneous tumor by plane wave transducer. The temperature at the necrotic zone is higher than in the surrounding tissues. (Published with permission from Ref. 3).

ring. The frequency ranges from 1.8 to 2.3 and 4.3–4.8 MHz. The driving frequency and the power can be individually selected within each ring, which allows for better spatial and temperature control. This technique has not yet reached widespread clinical use (7).

The Scanning Ultrasound Reflector Linear Array System (SURLAS), which may soon be implemented in clinical practice allows for 3D power distribution while applying simultaneous external hyperthermia in conjunction with radiation to superficial areas (7,13,72–77). (Fig. 13). The SURLAS applicator consists of two parallel opposed ultrasound linear arrays that aim their sound waves to a V-shaped ultrasound reflector that further organizes and spreads the energy over the scanned target site (7,13). The two arrays operate at different frequencies (1.9 and 4.9). This allows for control of penetration depth through the exploitation of intensity modulation of the two beams (13). The applicator housing this transducer and the temperature regulated water bolus are placed on the patient. This system allows both the radiation and the ultrasonic waves to enter the patient's body concurrently. During the scanning interval, power levels and frequencies in each transducer can be individually regulated, thus allowing for good control over depth penetration and lateral heating (7). This system can treat superficial tumors that are 15 × 15 cm in area and with distal margins up to 3 cm deep (13). However, scan times must be limited to <20 s to avoid transient temperature variations >1 °C (7,73).

Large superficial tumors ranging from 3 to 4 cm deep 20 × 20 cm in surface area have been successfully treated with mechanically scanned planar transducers with 2D

Figure 11. (a) With the use of a focused field, higher intensities can be achieved in target tissue at a greater depth. (Published with permission from Ref. (3)). (b) Since temperature and intensity are directly proportional greater temperatures can also be attained in target tissue at greater depths. (Published with permission from Ref. 3).

motion (7,63) (Fig. 14). This approach can be used in treating tumors in the chest region, which often have a heterogenous thickness and are situated close to bone. Once an ultrasound is launched into tissue, it cannot leave the body; consequently, it will just “bounce” around until it is completely absorbed. If the ultrasound is absorbed by bone or nerves, neuropathies and bone necrosis can occur. Mechanically scanned planar transducer frequencies can range from 1 to 6 MHz. Accurate spatial control has been achieved by controlling the operating frequency and

applied power levels, as a function of location, to account for variations of tumor thickness. Separate transducers, which are driven at different frequencies or by time multiplexing the driving frequency of a given transducer between its fundamental and odd harmonic frequencies, are able to create a situation that allows control over penetration depth (7). The penetration depth, as well as the temperature distribution resulting as a function of depth, can be controlled online during the scanning by regulating the frequency amplitude. In the clinical setting, all these biophysical properties must be coupled with the patient's ability to tolerate the treatment to create a functional algorithm (7,63).

Scanned focus ultrasound systems (SFUs) provide the most flexibility for clinical applications (7,64–67,78,79). These systems provide the greatest possibility of overcoming the challenges of tissue heating. The SFUs systems generally use four to six 1 MHz spherically focused transducers each overlapped so that a common focal zone of 3 mm o.d. to treat deep tissue. This focal zone is mechanically scanned in circular or octagonal patterns within the tumor at rates of 20–100 mm·s⁻¹. In order to guarantee that there is a consistency in temperature, scan cycles must be shorter than 10 s. During scanned focused ultrasound hyperthermia treatments, temperature distributions can be controlled by utilizing the measured temperatures to vary the power output as a function of the location. The resolution is determined by a variety of thermometry

points, scanning, and computer control speed (7). The regulation of temperature can be controlled by the clinician or the computer (7,80).

External applicator systems for hyperthermia have now been developed that use electrically phased focused transducer arrays. The advantages of using an electrically phased focused transducer array is that it allows for better synthesis of complex beam patterns and the ability to electronically focus and steer. The 3D complex beam-forming techniques result in higher scanning speeds, smaller applicators, and better reliability due to more static parts (7). Examples of electrically phased focused transducer arrays include concentric ring arrays (7,81), sector-vortex phased arrays (7,82), spherical and cylindrical arrays (7,83,84), and tapered phased arrays (7,85).

Intracavitary Techniques

Conventional ultrasonic hyperthermia can be used for intracavitary applications. This modality can be used to treat tumors that are situated deep within the body or with those that situated close to a body cavity. Clinically, prostate cancer and benign prostate hyperplasia are the best suited for this treatment (7). The transrectal applicator consists of one-half cylindrical transducer segments 10–20 mm o.d. × 10 mm long. It is sectored for better angular control with frequency range of 1.0–1.6 MHz. The transducers are housed in a plastic head; also, a temperature regulated degassed water within an extendable bolus is attached (7,86–88) (Fig. 15). The heating energy is emitted radially from the length of each transducer segment, and the power is applied along the length of the applicator. This technique is able to heat tissues that are 3–4 cm deep from the cavity wall. The temperature controlled water bolus maintains a safe temperature for

Figure 15. A nonfocused multielement applicator with longitudinal and angular power deposition abilities. This device is used in the treatment of the prostate cancer or BPH. (Published with permission from Ref. 7).

the rectal mucosa. Improved versions of this applicator have added four sectors on each tubular section for 16 channels total. These devices are being fabricated to be compatible with MRI guide protocols (7,89).

Interstitial Techniques

Interstitial techniques are used for treating deep-seated and/or large tumors that are not amenable for surgical resection. Heating sources are implanted into the tumor, thus focusing the energy directly to the site. Interstitial radiation is a standard practice in the treatment of tumors, therefore incorporating adjuvant heat is a logical progression to maximizing treatment. There are three basic designs of interstitial ultrasonic applicators: catheter cooled and direct coupled that consists of tubular piezoceramic transducers, and acoustic waveguide antennas (7) (Figs.16a-c).

Multielement ultrasound applicators with catheter cooling use piezoceramic tubular transducers (1.0-1.5 mm o.d. x 10-20 mm long, with frequency ranging from 7 to 10 MHz) have circulating coolant channels incorporated within the support structures to allow the applicator to be sealed in place within closed end implant catheters (13-14 gauge) (7) (Fig. 16a). These catheters are able to improve control of radial penetration of heat. In addition, it has the ability to control longitudinal power deposition along the length of the applicator (7,90-94). The power to each tubular transducer can be adjusted to control tissue temperature along the length of the catheter. The length and the number of transducers can be selected depending on the desired temperature and longitudinal resolution. This feature is very valuable in that it allows adjustability to

tumor geometry variations, blood perfusion variations, and the variation within the tumor tissue. Another advantage of this device is that, unlike microwaves and RF hyperthermia, the power deposition pattern is not limited by the length of insertion or whether other catheters are within the implant. These catheters are more challenging than others for the operator to use skillfully because it is complicated to control both the electronics and the water cooling. Also, small transducers are less reliable. However, it is this complexity that allows for great plasticity in therapeutic temperature distributions (7).

Direct coupled applicators are used to deliver thermo-brachy therapy via remote after-loading radiation sources (Fig. 16b). Larger applicator size limits these catheters to few clinical treatments. The implant catheter consists of the transducer and an acoustically compatible housing, which is biologically and electrically insulated. The implant catheter usually ranges from 2.2 to 2.5 mm in diameter. The inner lumen is formed from a catheter that is compatible with standard brachytherapy and commercial after loaders. The transducers have sensors that are able to monitor tissue temperature. In order to conserve size, a water cooling mechanism was not included as part of the catheter. This device is less efficient because transducer self-heating increases the wall temperature and thus reduces radial heating. Therefore, the thermal penetration is sensitive to acoustic frequency (7,95,96). Some studies have shown that integrating an air cooling system to this catheter will allow for better heating penetration (7,95).

The acoustic wave-guide antenna has a minimally invasive 16-24 gauge stainless steel needle that is coupled by a conical tapered velocity transformer to a piezoceramic disk transducer (1.3 cm o.d. operating at 1 MHz) (7,99) (Fig. 16c). The length of the radiating tip can be changed by adjusting the length of the plastic sleeve by 1-1.5 cm. The needle diameter size minutely fluctuates due to Raleigh surface waves propagating from the wave-guide generating flexural vibrations of the needle portion. Acoustic patterns that have been measured demonstrate peaks and nodes in adjacent tissue along the radiating aperture. The temperature of the tissue that is radiated matches the temperature of the radiating antennae. The disadvantages of this system are that the power output is potentially limited for larger or more perfused tumors, and it is difficult to control the longitudinal power deposition (7).

Figure 17. Schematic of HIFU. (a) Illustrates a formation of a single lesion. (b) Illustrates a confluent array of lesions required for a therapeutic effect. (Published with permission from Ref. 98).

Figure 18. Image of coagulation and liquefied necrosis created with HIFU in an *ex vivo* porcine kidney. (Published with permission from Ref. 108).

A Brief History of HIFU

Using HIFU as an extracorporeal technique of creating coagulative necrosis was first conceptualized in 1942 by Drs. Lynn and Putnam (12,98,99) (Fig. 17a). In 1954, Dr. William Fry was the first to use HIFU to destroy central nervous tissue in the brains of cats and monkeys (12,98,100,101). Later, Frank Fry treated patients with Parkinson's disease and neuromata (12,98,102). Throughout the 1950s and 1960s, HIFU research continued, although it was often plagued with limited success due to lack of technology (103–106). In 1956, Dr. Burov suggested that HIFU can be implemented in the treatment of cancer (12,98,107). Since then, the popularity of HIFU has gradually increased with the advent of better devices and with the success of its use *in vitro* and *in vivo* experimental trials. In current literature, HIFU is categorized as a high temperature hyperthermia because higher temperatures than those used in conventional hyperthermia are required to achieve therapeutic goals.

BASIC PRINCIPLES OF HIFU

The concept of HIFU is similar to that of using a magnifying glass to focus the sun's beams to set fire to some dry leaves. Only the leaves that are in focus will be set on fire, the surrounding ones will be spared (12,98). Likewise, if an ultrasonic beam with sufficient energy is tightly focused, it can be used to elevate temperatures within a target tissue resulting in cell death and coagulative necrosis while sparing the skin and surrounding tissues (98,108) (Fig. 18). Histologically, there is a sharp demarcation between the necrotic tissue that was radiated with HIFU and the healthy surrounding tissue. In the liver, 2 h after exposure, the cells look normal, however, approximately a 10 cell wide rim of glycogen poor cells can be found. After 48 h, the entire area that was radiated will be dead (109).

During HIFU procedures, tissue temperature $>56^{\circ}\text{C}$ are used because at that temperature irreversible cell

death through coagulative necrosis occurs. The main mechanism used is coagulative necrosis via thermal adsorption (110). The other mechanism is cavitation induced damage that is caused by both thermal and mechanical properties of the ultrasound wave (110,111). However, recent studies have been investigating the use of cavitation to enhance the level of ablation and to reduce exposure times. It has been proposed that a focused ultrasound protocol that induces gas bubbles at the focus will enhance the ultrasound absorption and ultimately create larger lesions (110,112). Individual HIFU exposure times can be as little as 1–3 s, while larger volumes may require up to 30–60 s. Individual lesions can be linearly complied to create a clinically relevant lesion (Fig. 17 b). Since individual exposure time is quick, issues (e.g., the cooling effects of blood perfusion) can be considered negligible (7,98,113,114). Therefore, energy transfer and temperature elevation in tissue is considered proportional to acoustic field energy (100). The lesions are cigar-shaped or ellipsoid with the long axis parallel to the ultrasonic beam (12,98). In order to ablate tissue transducer frequency must be between 0.5 and 10 MHz. The higher the frequency, the narrower and shallower the lesion will be. The wavelength ranges from 3 to 0.25 mm. The size of the focal point is determined by the wavelength. Thus, the transverse diameter of the focus is limited to one wavelength and the axial diameter is eight times that wavelength. As a result of this, all generators create a focal size that is 10×1 mm. The shape of the lesion is determined by the acoustic properties of the tissue, ultrasound intensity in conjunction with exposure time, and transducer geometry (12). Lesion size is determined by power density at the focus, pulse duration, and the number of pulses. In order to create a well-demarcated lesion the intensity must be $>100 \text{ W}\cdot\text{cm}^{-2}$, thus being able to reach temperatures that are $>65^{\circ}\text{C}$ in <5 s (11). Focal peak intensities generally range between 300 and $2000 \text{ W}\cdot\text{cm}^{-2}$ (7). The ultrasonic waves used in HIFU are generated by piezoelectric elements. In order to achieve high intensity focus ultrasound that is able to ablate tissues three techniques have been found to focus the ultrasound beam: (1). spherical arrangement of piezoelements (Fig. 19), (2) combination of a plane transducer with an acoustic lens (Fig. 20), (3). cylindrical piezoelements together with a parabolic reflector (11) (Fig. 21).

CURRENT EXTRACORPOREAL DEVICES, INTRACAVITARY DEVICES, AND IMAGING

While there are many devices that are used in experimental trials, few of those are currently used in widespread clinical practice. The two main categories of HIFU devices are extracorporeal and transrectal. Extracorporeal devices have been implemented in experimental trials in many medical fields. Extracorporeal devices use larger transducers, lower frequencies, and longer focal lengths than intracavitary devices (97).

An important factor in clinical application of these devices is the ability to monitor treatment accurately. In current practice, this is accomplished either by using real-time ultrasound (116–118) or MRI (119–122). When

Figure 19. A single spherically curved focused transducer. (Published with permission from Ref. 110).

MR is used to guide HIFU treatments, sublesioning ultrasound exposures are used to identify the target region, local rise in temperatures are used to confirm the position of the ultrasound focus and then higher intensity therapeutic exposures are used for treatment. Currently, several groups are using ultrasound surgery systems that utilize MRI to map temperature elevations online during HIFU procedures (110,120–122). This technique has been used to treat breast tumors and uterine fibroids, and these treatments are in the process of being used clinically in several countries (110,123–125). The MR can effectively use temperature data to determine the parameter of thermal tissue damage (110) and is limited in that it is costly, has lower spin resolution, and because of its technology for producing MR compatible ultrasound equipment required for HIFU is lagging.

When ultrasound is used as a guide, the diagnostic transducer is arranged confocally with the therapeutic transducer and their relationship is fixed. The position

Figure 21. A cylindrical transducer with parabolic reflector. (Published with permission from Ref. 108).

of the therapeutic focus can be reliably identified on the diagnostic image. The extent of treatment can be monitored by recording post-treatment gray scale changes on the diagnostic image (98). Ultrasound as a guide is advantageous in that it is less expensive and is more readily accessible, it has faster treatment times, compact sized equipment, and provides a good correlation between observed ultrasound changes and the region of necrosis in the tissue. The disadvantage of using ultrasound as a guide is that image quality is not optimal (98,110,126). Furthermore, ultrasound waves are obstructed by bone and air-filled viscera.

MEDICAL APPLICATIONS OF HIFU

Liver Cancer

While hepatocellular carcinoma is frequently encountered in clinical practice, hepatic metastasis from other primary sources is much more common. Currently, the only definite treatment choice for hepatic metastases is surgery, however, 5 year survival rates are only 25–30%. Arterial embolization is another emerging technique. Therefore, the desire to find a noninvasive technique is preminent (98). The Chongqing HAIFU device has been used for a couple of years in China to treat a variety of tumors, however, adequate data has not yet been collected (98,127,128) (Fig. 22). The JC-HIFU system (HAIFU Technology Company, Chongqing, PR China) uses an extracorporeal transducer that operates at 0.8–1.6 MHz, the aperture 12–15 cm, focal length 9–15 cm. It operates at Isp of 5–15 kW·cm⁻². A diagnostic ultrasound probe (3.5 MHz) is aligned along the same axis as the therapeutic transducer. Both the treatment and diagnostic transducers are placed in a reservoir of degassed water in the center of the

Figure 22. A Hifu System that is used both clinically and experimentally in the treatment of liver metastases. (Published with permission from Ref. 128).

treatment table. The degassed water provides acoustic coupling between the patient and the transducer. Horizontal movement of the transducer is possible along three orthogonal axes of the bed because it is facilitated by the cylindrical gantry at one end of the table. All movement is controlled by the adjacent computer terminals (128). In a recent clinical trial carried out in Churchill Hospital in Oxford, England in conjunction with Chongqing University of Medical Sciences in Chongqing China, 11 patients with liver metastases were treated with the JC-HIFU device. While it is not possible to have a good statistical analysis with such a small subject pool, some general observations were made about the safety of this device. Of the 11 patients treated, 7 out of 11 patients complained of transient pain and 3 out of 11 complained of superficial burns. Out of the 7 patients that experienced pain, oral analgesia brought relief to 6. Burn sites were treated with ice-packs and aloe gel. Two of the three burn sites were only millimeters across. One of the burns was 2×3 cm and had healed by the 2 week follow-up period. It appears that from a safety standpoint the JC-HIFU is a feasible treatment option for hepatic metastases, however, larger trials will be needed to determine the true efficacy of the treatment (128).

Another study by Wu et al looked at 55 patients with hepatocellular carcinoma with cirrhosis. Tumor size ranged 4–14 cm in size with an average size of 8.14 cm. Patients were classified according to progression of disease: 15 patients had stage II, 16 had stage IIIA, and 24 had stage IIIC. All patients were treated with an extracorporeal HIFU device similar to the one previously mentioned for the treatment of liver metastases. The average number of treatment applications was 1.69. There were no serious side effects. Imaging following HIFU treatment evaluated for the absence of tumor vascular supply and shrinkage of treated lesions. Serum alpha-fetoprotein returned to normal in 34% of patients. At 6 months, 86.1% of the patients were still alive, at 12 months 61.5% of the patients were still alive, and at 18 months 35.3% of the patients were still alive. The survival rates were the highest in patients who were stage

II. Therefore, this study demonstrated that HIFU is a safe option in the treatment of hepatocellular carcinoma (129).

Prostate Cancer

Prostate cancer is one of the common types of cancer in males, and it is frequently the cause of cancer-related death (130). Since physicians are able to detect prostate cancer early, there has been an increase in the number of patients needing treatment. Radical prostatectomy is the treatment of choice in patients who have organ-confined disease and a life expectancy of >10 years. Radical prostatectomy offers excellent results 5 and 10 years after the operation, although there is still risk of morbidity associated with the operation, thus precipitating the need for a noninvasive procedure. Currently, brachytherapy, cryosurgery, 3D conformal radiotherapy, and laparoscopic radical prostatectomy have been implemented with good results (130,131). However, if a cure is not achieved, these treatments cannot be repeated and there is high risk of morbidity associated with salvage radical prostatectomy, thus necessitating the need for another treatment option. In 1995, Madersbacher reported that they were able to destroy the entire tumor within the prostate (98,132). Early reports showed success rates of controlling local tumors at 50% at 8 months and then approaching 90% in later studies (98,133,134). In the later years, as clinicians gained more experience and as technology has improved, treatment of the entire gland was performed (98,135,136).

A recent report was published that looked at 5 year results with transrectal high intensity focused ultrasound in the treatment of localized prostate cancer. One hundred and forty six patients were treated with Ablatherm device (EDAP, Lyon, France). The tablespoon-shaped intracavitary applicator contains both a 7.5 MHz retractable ultrasound scanner for diagnosis and a piezoelectric therapeutic transducer that can be driven at frequencies of 2.25–3.0 MHz. The computer-controlled treatment head is able

to move three dimensionally. The applicator can be rotated 45° in the rectal ampulla. A cooling device that consists of a balloon containing degassed coupling fluid surrounds the treatment head. Energy can be released from the balloon rectal interface thereby maintaining rectal temperatures $<15^\circ\text{C}$. Out of 137 patients 6 reported symptomatic UTI, 2 reported chronic pelvic pain, 16 reported infravesicular obstruction, 8 reported grade I stress incontinence, and 1 reported rectourethral fistula. The success rate of the Ablatherm system is between 56 and 73% (131).

Another study that was published by Uchida et al. performed 28 HIFU treatments on 20 patients to treat localized prostate carcinoma (T1b-2NOMO). A modified Sonoblate 200 HIFU device (Focus Surgery, Indianapolis Ind.) was used in this study. Sonoblate 200 uses a 4 MHz PZT transducer for both imaging and treatment. Each pulse delivery ablates a volume of $2 \times 2 \times 10 \text{ mm}^3$ in a single beam with 2.5 and 4.5 cm focal length probes. Probes with focal lengths of 3.0, 3.5, 4.0 cm can be used in a split-beam conformation to create lesion sizes of $3 \times 3 \times 10 \text{ mm}^3$. A cooling device maintains rectal temperatures at $<22^\circ\text{C}$. In this study, there was a 100% success rate. The UTI-like symptoms were common in the first 2 weeks post-HIFU, but were easily remedied with alpha-blockers and painkillers. One patient had a rectourethral fistula after a second HIFU treatment. Of 10 patients who were still able to attain tumescence prior to the procedure, 3 reported postoperative impotence. It is hypothesized that the reason the Sonoblate 200 is getting superior results to the Ablatherm system is that the treatable focal length is longer in the Sonoblate system. This allows the Sonoblate 200 to treat prostates $<50 \text{ mL}$, whereas the Ablatherm can only treat prostates that are $<30 \text{ mL}$. However, a controlled prospective study is needed to evaluate the potential reasons for this difference in efficacy (130).

Gynecology

The most common pelvic tumor in women of reproductive age is fibroids. The current surgical options available to manage fibroids are either hysterectomy or myomectomy. Hysterectomy is often not a viable option for women who wish to have children. Myomectomies often result in 50% tumor recurrence in 5 years. Hormone therapy results in temporary reduction in tumor size by 35–65% (115). Therefore, there is a need for a permanent, noninvasive technique to manage fibroids. A device was developed for treating uterine fibroids. The prototypic device aligns a commercial abdominal diagnostic ultrasound transducer with a therapeutic ultrasound intracavitary probe (Fig. 23). This device was constructed to accommodate the specific constraints of the female pelvic anatomy. The transducer contains a 3.5 MHz PZT-8 crystal, 25.4 mm in diameter bonded by an aluminum lens to focus the ultrasound beam. A water-filled latex condom is used for acoustic coupling of the transducer and also has the potential for transducer and tissue cooling. Ergonomics testing in humans demonstrated clear visualization of the HIFU transducer in relation to the uterus, thereby demonstrating a potential for HIFU to treat fibroids from the cervix to the fundus through the width of the uterus. However, this device

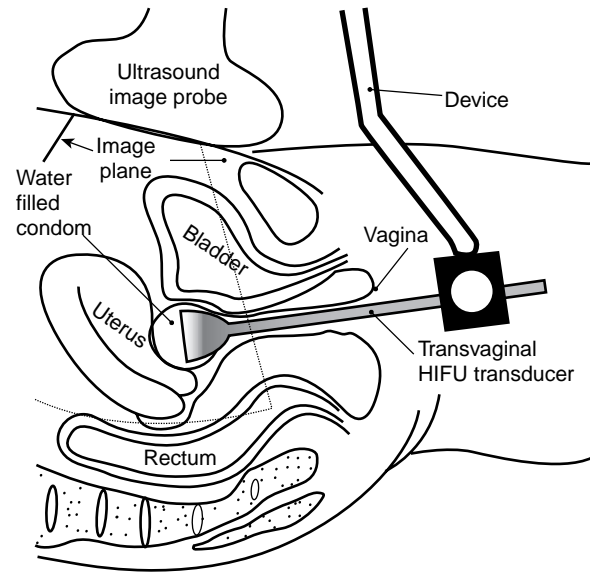

Figure 23. Conceptual diagram of the transvaginal device HIFU in use. The dotted line represents the image plane. Three factors determine what area can be treated by the HIFU transducer: focal length, the range of water stand-off, and the range of mobility once inside the vagina. (Published with permission from Ref. 115).

needs to be tested in treating the uterus in large animal models prior to beginning human trials (115). Extracorporeal devices have been used in a small clinical phase I trials, but the results are still pending (98,137).

Breast Cancer

Every year >1 million new cases of breast cancer are diagnosed. Breast cancer is the most common malignancy in women (138,139). In the past, the only options available to women were radical and modified radical mastectomy that included dissection of the axillary lymph nodes. More recently, breast conservation surgery in conjunction with radiotherapy, chemotherapy, and hormone therapy has gained popularity in early stages of breast cancer. However, the change in approach toward a less radical surgery, while being better for a woman's body image, has not really increased long-term survival rates in breast cancer patients (138,140). Other options, such as cryoablation and laser frequency have been studied as minimally invasive approaches, however, these techniques are limited in that they require percutaneous access and that they are only able to treat small masses. In a recent study by Wu et al., (65) women with breast cancer (T1-2, N0-2, M0) verified with biopsy were studied. Patients were divided into a control group that had a modified radical mastectomy, and a group that had extracorporeal HIFU followed by a radical mastectomy. The HIFU system used is the same one described earlier in the treatment of liver malignancies, the JC-HIFU therapeutic system. The therapeutic U.S. beam was produced by a 12 cm in diameter PZT-4 ceramic transducer with a focal length of 90 mm that was driven at a frequency of 1.6 MHz. The ellipsoid focal region dimensions were 3.3 mm along the beam axis, and 1.1 mm

along the transverse axis. A real-time imaging U.S. device, the AU3 (Esaote, Genoa, Italy) was used at frequencies of 3.5–5.0 MHz. The diagnostic transducer is placed in the center of the therapeutic transducer. Real-time imaging can accomplish three separate tasks. It can locate the tumor that needs to be treated, it can guide the deposition of U.S. energy into the tumor, and it can provide real-time assessment of the coagulation necrosis during therapy. The results demonstrated that there were no severe side effects. Those that were reported included mild local pain, warmth, and a sensation of heaviness in the affected breast. However, only 4 of the 23 HIFU patients had significant pain to require a 3–5 day course of oral analgesics. Only one patient had a minor skin burn. Pathologic examination of the breast tissue revealed complete coagulative necrosis, and the tumor vasculature was damaged. The immunohistological staining revealed that no expression PCNA, MMP-9, and CD44v6 was found, indicating that the tumor cells had lost their ability to proliferate, invade, and metastasize. Therefore, this study demonstrated the safety and efficacy of HIFU in the treatment of breast cancer (138).

Neurology

Recently, there have been some published studies that propose using large array ultrasound transducers to overcome distortions caused by the skull (110). The goal has been to be able to create an array that can focus to destroy target tissue while preserving surrounding tissue. A 320 element array has been used to focus ultrasound through 10 human skulls. This approach is completely noninvasive. This technique is modeled after a layered wave vector-frequency domain-model and uses a hemisphere-shaped transducer to propagate ultrasound through the skull using CT scans as a guide (110,141,142). The ability to focus energy has implications that are not limited to just tumor treatment. It has been shown that focused ultrasound can selectively and consistently open the blood brain barrier (BBB) (110).

Another neurological area that may benefit from HIFU is in the treatment of nerve spasticity and pain. Spasticity, which is signified by uncontrollable muscle contractions, is difficult to treat. In a recent study, HIFU was used to treat and suppress the sciatic nerve complex of rabbits *in vivo*. An image-guided HIFU device including a 3.2 MHz spherically curved therapeutic transducer and an ultrasound diagnostic device were used. A focal intensity of 1480–1850 W/cm² was used to create a complete conduction block in the 22 nerve complexes. Treatment times averaged 36 s. Gross histological examination revealed blanched nerve complex with lesion dimensions of 2.8 cm³. Further histological examination revealed the probable cause of nerve block as axonal demyelination and necrosis of Schwann cells. This study illustrates the potential that HIFU may have in the treatment of nerve spasticity (143).

Cardiovascular System

The role of ultrasound in cardiology has been instrumental to the increasing knowledge of the cardiovascular system.

Diagnostic ultrasound technology has led to a greater understanding of the anatomy and physiology of the human heart and vascular systems. Over the years, in addition to diagnostic use, the role of ultrasound has been expanded to the therapeutic realm. Both conventional ultrasound and HIFU modalities have been used with varied success in many cardiovascular therapeutic applications. These applications range from harvesting the internal mammary artery for coronary artery bypass surgery to ablation of cardiac arrhythmias. An ultrasonically activated (vibrating up to 55,000 Hz) harmonic scalpel (Ethicon Endosurgery, Cincinnati, OH) produces low heat (<100 °C) thereby effectively coagulating and dividing the tissue and has a wide range of applications in cardiothoracic surgery (144). By using a 1 MHz phased array transducer with an acoustic intensity of 1630 W·cm⁻² or 22547 W·cm⁻² one can successfully create precise defects ranging from 3 to 4 mm in diameter *ex vivo* in porcine valve leaflet, canine pericardium, human newborn atrial septum, and right atrial appendage (145). Cardiac arrhythmia is one area where significant work has been done using ultrasonic hyperthermia for therapeutic purposes. Strickberger et al. demonstrated an extracorporeal HIFU ablation of the atrioventricular junction of beating canine heart after thoracotomy (146). Their experimental system consisted of a polyvinyl membrane covering the heart and lungs. The thoracic cavity was filled with degassed water serving as a coupling medium. A 7.0 MHz diagnostic 2D ultrasound (Diasonics VST Master Series, Diasonics/Vingmed Ultrasound Inc) attached to a spherically focused single piezoelectric element therapeutic ultrasound transducer (1.4 MHz frequency; 1.1 × 8.3 mm focal length and 63.5 cm focal zone) with the maximum intensity of 2.8 kW·cm⁻² was applied during the diastole for 30 s to achieve complete AV nodal junctional block (Fig. 24a–c). Experience with HIFU application is very preliminary and has not been tried for AV nodal ablation in humans yet.

Ultrasound had also been used clinically in the treatment of atrial fibrillation (AF), which is the most common arrhythmia affecting 0.5–2.5% of the population globally. Over the last decade, ablation procedures by isolating the pulmonary veins and eliminating electrical triggers from the atria has become a popular and effective mode of therapy for AF. Traditionally, RF energy has been used as an energy source for ablation. Radio frequency catheter ablation of AF requires good tissue contact, multiple lesions, significant experience and manual skills with long procedure time. Complications related to RF application in AF ablation include pulmonary vein stenosis, atrioesophageal fistula, left atrial rupture due catheter perforation or inappropriate amount of power. The limitations of the existing RF technology could be overcome with the use of HIFU balloon systems (147).

Our group performed the initial work on pulmonary vein isolation in humans using a through-the-balloon circumferential ultrasound (conventional-unfocused) ablation system for treatment of recurrent atrial fibrillation (148). Fifteen patients with drug refractory atrial fibrillation underwent a PVI using a novel transballoon ultrasound ablation catheter (Atronix, Inc) (Fig. 25a–c). The ablation system was composed of a 0.035 in. diameter

Figure 24. (a) Schematic of the experimental HIFU apparatus. The therapeutic ultrasound transducer is mounted 63.5 mm from the target (X). A polyvinyl chloride membrane covers the heart and the lungs. Degassed water flows in and out of the thoracic cavity at a rate of $600 \text{ mL}\cdot\text{min}^{-1}$. Combined diagnostic/ablation transducers are placed into degassed water. (Published with permission from Ref. 146). (b) ECG and Echocardiogram of a canine heart. Prior to ablation of the AV node. (c) After ablation of the AV node using HIFU, the ECG shows complete AV block and the echo image depicts an increased density of the ablated tissue. (Published with permission from Ref. 146).

Figure 25. Anatomical pulmonary vein variations and technical limitations. (Published with permission from Refs. 148 and 149).

luminal catheter with a distal balloon (2.2 cm at maximum diameter) housing a centrally located ultrasound transducer (8 MHz). The ultrasound ablation system was advanced over a guide wire (0.035 in., 0.088 cm) to the intended pulmonary vein. The ablation performance and tissue temperature are monitored by thermocouples on the balloon and the therapeutic transducer. The ablation time was 2 min with an additional minute to deflate the balloon. The energy was delivered perpendicularly to the surface of the balloon and ablation at the funnel portion of the pulmonary vein (antrum) could not be achieved with the original design. Additionally, other anatomical characteristics of the target sites like ostial diameter larger than the balloon size, inability to reach the right inferior or other pulmonary vein ostia, ostial instability, early branching of the vein, and eccentric position of the ultrasound transducer in the vein made it difficult to deliver energy effectively (Fig. 26). These technical limitations have been addressed in some of the newer balloon systems where the energy delivery could be accomplished in a divergent angle enabling ablation around the antrum with the tip of the balloon sitting at the pulmonary vein ostium. Early animal studies on HIFU mediated AF ablation have shown promising results with an experimental device that focuses ultrasonic energy via a parabolic balloon, using gas or fluid as a reflector (ProRhythm INC.) (Fig. 25c–e). (149,150).

Since 2003 ~60 patients were treated using this system. With improved catheter design the success rate of AF ablation has increased from ~50 up to 80% without evidence of pulmonary vein stenosis. These preliminary human study results need to be confirmed in larger series. Since there are no large clinical trials on AF ablation with this technology, it is still somewhat premature to predict if HIFU is the complete answer. This device is expected to be released in Europe in 2005 (149,150).

Attempts have been made to harness HIFU for transmyocardial revascularization (TMR) to improve blood supply to damaged myocardium caused by advanced heart disease. Using a 10 cm diameter transducer operating a frequency of 2.52 MHz, intensity of $2300 \text{ W} \cdot \text{cm}^{-2}$ and pulse repetition period of 40 ms at 50% duty cycle, small chan-

nels were successfully created in canine myocardium (151). This shows the potential for future application for HIFU in TMR in a noninvasive fashion.

Other Applications of HIFU

Several branches of medicine have already begun to benefit from the use of HIFU with the prospect of many more applications in the future. Thus far the greatest influence of HIFU has been in oncology, with other fields now exploring and experimenting with HIFU to determine its potential utility. The HIFU has been proposed as a tool for synovectomy in the treatment of rheumatoid arthritis (RA) (98,152) and has been used to control opiate refractory pain in pancreatic cancer patients (98,127) and internal bleeding in organs and vessels (98,153). A hand-held HIFU device has been successfully used to perform vasectomies in dogs as a 1–2 min procedure (98,154).

Future Perspectives in Conventional Hyperthermia and HIFU Use

Heat as therapeutic entity has had a rich history punctuated with many successes and failures. The evolution and integration of therapeutic hyperthermia in the clinical setting have been the product of clinical trials, development of new devices, and education of the medical personnel. Conventional hyperthermia has been used for a long time with many energy sources such as electromagnetic, ultrasound, and microwaves. Similarly, it has been >50 years since HIFU was first conceptualized and actualized. Many subspecialties of medicine have benefitted from the use of hyperthermia. Some of the limitations that were miring conventional hyperthermia and HIFU have only recently begun to be overcome and now these therapies can reach a wider patient population. Both of these techniques share similar obstacles due to the limitations that are inherent to ultrasound. Indeed, ultrasound hyperthermia procedures are limited in that ultrasound cannot propagate through air-filled cavities (e.g., lung or bowel). Consequently, lung tumors other than those that are at the periphery are not likely to be amenable to treatment with HIFU or conventional hyperthermia. Also, tumors that are in close proximity to the bowel or within the bowel wall pose an increased chance of visceral perforation with HIFU use. In addition, other side effects such as pain, soft tissue and bone damage, and skin burns have been reported. Often these side effects can be minimized by varying scan paths, altering frequency, power deposition, or the applicator position (7). The success of both hyperthermia techniques is determined by whether ultrasound energy can be properly directed to the site of interest, or if therapeutic temperatures are achieved, and if other factors can be compensated for, such as hemodynamic changes. Other challenges facing ultrasound hyperthermia systems include the ability to gain control over spatial distribution of heat, tissue temperature monitoring, and improved diagnostic visualizations in order to better treat the tumor site. The HIFU treatment times also need to be shortened. Despite this, treatment times of 1 h for a 2 cm superficial tumor using HIFU is preferable to surgical resection; conversely, at present the same tumor can be treated much

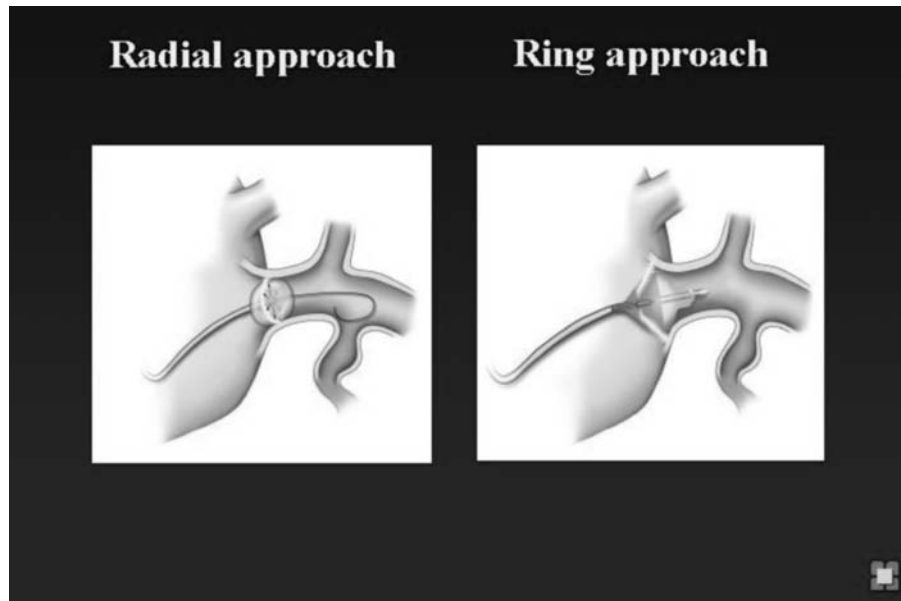

Figure 26. (a) A schematic of the first ultrasound balloon system illustrating the radial delivery of ultrasound energy that is transferred perpendicularly to the tissue. (b) 8F transballoon ultrasound ablation catheter with a central lumen that can accommodate a 0.035 in. guidewire. The distal end of the catheter lodges a cylindrical transducer axially with a saline-filled balloon inflated over it. (c) The balloon is advanced over a guidewire at the ostium of the left upper pulmonary vein. An occlusive pulmonary venogram is done to confirm that the transducer is located at the proximal portion of the vein. Published with permission from Refs. 148 and 149. (d) A schematic of the HIFU device illustrating a ring pattern of ultrasound transmission. The parabolic balloon focuses the ultrasound beam forward. The HIFU catheter is able to create lesions in the antrum away from the lumen of the pulmonary veins thus reducing the likelihood of pulmonary vein stenosis. (e) The HIFU catheter at the ostium of the pulmonary vein.

more quickly with radiofrequency ablation. However, in large tumors longer treatment times are justified because there are very low mortality and morbidity rates associated with the use of HIFU (98).

The benefits of both conventional hyperthermia and HIFU are limitless, but both need more testing in larger patient populations to fully delineate their clinical role. At present, the scarcity of available equipment, the required technical expertise and the lack of thoroughly trained providers, the increased complexity and difficulty involved in using conventional hyperthermia and HIFU when compared to other systems (e.g., electromagnetic) have limited the widespread use of this treatment modality (7). Issues, such as accurate delivery of focused ultrasound to the target tissue, the ability to monitor and control temperatures, and reasonable treatment times, have all been improved upon and will continue to be refined with further testing and research. Imaging modalities like MRI and high resolution CT scan will enhance the precision of HIFU in various system applications. In the future, HIFU could emerge as a good alternative to traditional surgery, and conventional hyperthermia may become a mainstay as an adjunct to chemotherapy and radiation to ultimately improve the arsenal of methodologies available to better treat patients.

IMAGE INTENSIFIERS AND FLUOROSCOPY

MELVIN P. SIEDBAND
University of Wisconsin
Fitchburg, Wisconsin

INTRODUCTION

Early fluoroscopic systems used a phosphor-coated sheet or screen to convert incident X-ray photons to light. The radiologist observed the image through a lead glass protective screen. A film camera was often used to record the image. There are two serious disadvantages to this method: the radiologist had to be dark adapted so that image details were hard to see and the collection solid angle of the eye or camera lens was small. The small collection angle meant that the X-ray exposure had to be increased by almost 100 times to have the same diagnostic quality as a conventional radiograph. Photographing the fluoroscopic screen, photography, is no longer used because of the high exposure to the patients. All X-ray images are noise limited by the finite number of X-ray quanta detected and seen. A 50 keV X-ray photon can, at best, produce ~ 1000 visible light photons, if absorbed by the old-type phosphor. About 5–10% of the incident X-ray photons are stopped and converted to light by the fluorescent screen. The quantum detection efficiency, (QDE) of the screen is the product of the ability to absorb the incident X-ray photon and the probability of emitting light. A thicker screen would absorb more photons, but would also cause more lateral spreading of the light and reduce the resolution of the image. The 5–10% QDE figure is a practical compromise between resolution and sensitivity. If it is assumed that the visible light photons are emitted isotropically, then the lens of the eye or camera subtends only a very small fraction of this light radiation hemisphere. A sheet of film in a radiographic cassette has a phosphor-coated sheet on either side and can collect light photons far more efficiently.

The invention of the image intensifier overcame these objections. The concept of the early image intensifiers was to use a thin, curved, glass meniscus, ~ 15 cm diameter, coated on the convex side with a scintillator, originally of the same composition as the zinc:cadmium sulfide fluoroscopic phosphor plates, and a photoemitter on the concave surface. Light produced by the scintillator did not have far to travel to excite the photoemitter. This assembly was placed in a vacuum tube and the photoelectrons were accelerated toward an output viewing screen where a small and very bright image was produced. Because the photoemitter was in close optical contact with the scintillator, the collection angle was very large so that a higher radiation exposure was not needed and the image at the viewing screen was bright enough so that dark adaptation was

obviated and fine details could be seen. An optical viewer comprising an objective lens and relay lens, similar in design to a submarine periscope, was used to observe the image.

Modern image intensifiers use an epitaxially grown scintillator of CsI with the photoemitter deposited directly on the surface of that layer. Because the epitaxial layer can be made much thicker than the powdery deposit of the older type scintillator for the same resolution, the new image intensifiers require less exposure-image than conventional radiographs. The thicker layer has a higher QDE than the fluoroscopic screens (Fig. 1).

Many modern image intensifiers use a thin curved steel window on which the scintillator and photoemitter are deposited. This geometry eliminates the X-ray scatter produced by the glass window of the older tubes and improves image contrast. Larger tubes up to 35 cm sensor diameter have been made with variable magnification or zoom capability. The window of thin steel is the flash with a coating of aluminum or other metal and etched to create a domain structure, similar to the domains seen in the zinc coating of galvanized steel. The domains here are very small, $\sim 100 \mu\text{m}$ diameter. Cesium iodide is then vapor deposited on this surface and forms epitaxially (i.e., crystal growth follows the orientation of the metallic substrate), and grows as a collection of optically isolated fibers. This scintillator can be made quite thick with little light spreading. The greater thickness means higher quantum efficiency (i.e., a measure of the fraction of incident X-ray photons converted to light photons), when compared to conventional phosphor plate scintillators. A thin layer of silver and antimony is vapor deposited on top of the scintillator and the final sensitization is accomplished by depositing cesium from heated tubes or reservoirs after assembly in the vacuum tube. The AgCs:Sb photoemitter on the surface of the scintillator is similar to the photocathode of a photomultiplier (PMT), tube.

Figure 1. In the image intensifier, X rays strike the input phosphor screen, thus generating light. Light stimulates the photocathode to emit electrons, which are accelerated through 25 kV to strike the output phosphor screen. Brightness gain is due to both geometric gain and electronic gain.

The vacuum tube uses a series of metal cylinders between the photoemitter and the output phosphor. The photoemitter, cylinders, and output phosphor are connected to voltage sources to create shaped electric fields. The field potential at any point affects an electron beam in the same way that the index of refraction of a glass lens affects a beam of light. These cylinders and their potentials form electrostatic lenses to focus the photoelectrons to produce the small and bright image on the output phosphor. Like optical lens elements, the metal cylinders can make compound electrostatic lenses so that focal length can be varied to change the size of the output image: variable zoom.

The brightness gain of an image intensifier is a measure that compares the brightness of the image at the small output screen to that of the older fluoroscopic screens. This gain is a result of the added energy imparted to the photoelectrons, the higher probability of stopping an incident X-ray photon, and the effect of compressing the large input area signal to the small area of the output screen. The older term, brightness gain, has been replaced by conversion efficiency. This term is defined as the output luminance in $\text{candela}\cdot\text{m}^{-2}$ for an input exposure rate of $1 \text{ mR}\cdot\text{s}^{-1}$ or $10 \mu\text{Gy}\cdot\text{s}^{-1}$. If assumed it is that a single 50 keV input X-ray photon has a 50% probability of interacting with the input scintillator and producing light (i.e., QDE is 50%) and produces 2000 visible light photons, of which ~ 1000 reach the photoemitter. About 100 of these will produce electrons that will be accelerated by the electric field across the tube and strike the output phosphor as 25 keV electrons. Each 25 keV photoelectron has about a 10% probability of converting its energy into 2.2 eV visible light photons. The QDE, quantum detection efficiency, of the image intensifier is assumed to be 50% because of the thicker CsI scintillator.

An input exposure rate in the diagnostic range produces $\sim 200,000$ X-ray photons $\cdot\text{mm}^{-2}\cdot\text{s}^{-1}$, converts to 100,000 light photons/X-ray photon. In the visible range, $\sim 10^{10}$ photons $\cdot\text{mm}^{-2}$ have a light intensity of 1 candela $\cdot\text{m}^{-2}$. Substituting in the above, a 1 mR (10 μGy) input would produce $\sim 1 \text{ candela}\cdot\text{m}^{-2}$ for an output screen the same size as the input scintillator. This is >200 times brighter than the older fluoroscopic screens. Because the output screen area of an image intensifier is 25 mm diameter for an input screen of diameter of 220 mm, the same number of output light photons are emitted from a smaller area resulting in an additional gain factor of ~ 75 . This yields a total brightness gain of $>15,000$ over the old fluoroscopic screen!

A fluoroscopic television system is used for dynamic studies, to enable the viewer to see how a contrast agent is swallowed, how blood flows, to locate objects for a surgical procedure, and so on. During the study, an image record (formerly a film record) could be made for later examination using a video recorder or computer. A rapid succession of images could be recorded and then viewed to find the few images revealing the particular problem, for example, how a heart valve functioned or to diagnose an eroded region in the esophagus as the contrast medium sped by. Or a single image could be made to show the problem for later correction.

A fast optical lens optically collimates the small output image of the image intensifier. Collimation, in this case,

means that the optical object is at the focal plane of the collimating lens and its image is focused on an infinite distance away. Any optical device with its own objective lens, such as a TV or film camera, could be aimed through the collimating lens and its image size would be the original intensified image size times the ratio of (objective focal length)/(collimator focal length). The lenses could be separated by several centimeters before image vignetting occurs. A beam splitting mirror can be interposed on the collimator and the objective lenses so that image light is simultaneously apportioned between a TV and film camera. A small mirror or prism and lens could sample the light and form an image over a small hole in the cover of a PMT tube. The hole would permit only light from the center of the image to reach the PMT. The output of the PMT is used to control the X-ray tube current to maintain constant image brightness for continuous viewing or for automatic exposure control of one or a sequence of recorded images. This automatic brightness stabilizer scheme is similar in concept to automatic exposure control of most digital cameras.

The quality of an X-ray image is a compromise between exposure to the patient and the noise or "graininess" of the image. Most images are made using the ALARA principal (As Low As Reasonably Achievable). For any given X-ray exposure, there are a finite number of X-ray photons incident on the patient and then, through the patient, incident on the image sensor. The statistics of photons-area follow the Poisson distribution, so that the variance (noise) is the square root of the average number of photons in a pixel (picture element). To produce a second image having twice the linear resolution (detail) as the first requires four times the exposure. Because the eye averages exposure time >0.2 s, to record an equivalent image in 0.02 s requires an exposure rate 10 times greater. X-ray exposure requirements are determined by the by the X-ray absorption of the patient, diagnostic needs and are different for continuous viewing (real-time fluoroscopy), a sequence of images (video or motion pictures), or single images for later diagnoses.

Before the rapid growth and improvement of digital cameras and computer technologies, still and motion picture film cameras were the only practical means to record images. Because of differences of integrating capability of the eye and detail required of the recorded film images, the X-ray beam current, pulse width (exposure time/image), and so on, the ratio of transmission/reflection of the beam splitting mirror, and other operating parameters, must, be adjusted to obtain the required image quality for each image application requirement while minimizing total exposure to the patient.

Most modern systems use charge-coupled image sensors with a high dynamic range and pulse the X-ray beam current to the required level while digitally recording video images. Computer display of selected images or a dynamic sequence of images has largely displaced motion picture film techniques. Video tape recorders are used in simple systems. The automatic brightness control-automatic exposure control of the digital system uses signals from selected image areas derived from the computer image to optimize image quality in the region of interest.

INTRODUCTION

Historically, external radiation treatment of deep-seated malignancies was performed using ortho-voltage equipment. The radiological characteristics of these beams caused maximum dose deposition to occur on the skin of the patient. At that time, skin damage was the limiting factor for dose delivery to the tumor. When the skin turned red due to radiation damage (erythema), the physician had to find another area or portal through which to deliver radiation. The portal was then defined by its orientation and the surface of skin it irradiated.

Nowadays, the treatment is performed with higher photon energies that permit a skin-sparing effect (i.e., the dose at the skin is lower than that deposited a few centimeters deeper) due to the absence of electronic equilibrium. The historic name "portal" still denotes a radiotherapy treatment beam oriented for entry within a patient. Physicians verify whether the treatment is correct using megavoltage treatment beams (4–20 MV photons) as an imaging tool. A transmission image, obtained much like a diagnostic transmission image, provides information describing the patient anatomy and gives clues on the beam orientation and positioning, but also on the extent and shape of the treated area (or portal field). As such, portal imaging is the most direct manner to confirm accuracy of treatment delivery.

Traditional portal verification is done using radiographic films, much like the classical diagnostic films. Films are positioned at the beam exit side of the irradiated patient. Portal image analysis involves comparison with a simulation image that is typically obtained using diagnos-

tic quality X rays (60–120 kV photons). The simulation image serves as the reference image, showing anatomical information clearly and delineating the intended treatment field. Comparison of the simulation image with the portal image is complicated due to the inherent poor quality obtained when imaging using high energy photons (1). The whole procedure of patient positioning, artifact removing, imaging processing, and evaluation using film represents a significant fraction of the total treatment time. This procedure increases the workload per patient, and as a result, the number of images taken is minimized due to economic concerns rather than concerns for efficiency or treatment quality. Indeed, studies have demonstrated that weekly portal image verification, which is the current clinical standard, does not guarantee accurate treatment setup for a population of patients (2).

Portal imaging differs considerably from diagnostic transmission imaging. The main difference is the photon energies used to generate the images. In diagnostic imaging, photons having energies ranging from 50 to 120 kV interact in patients primarily via the photoelectric effect. The cross-section for these interactions is highly dependent on the atomic number of the medium in which they traverse: A higher atomic number increases the probability of interaction. The average atomic number of bony anatomy is higher than that of soft-tissue, yielding good contrast for the bony anatomy. At treatment energies (1–10 MeV) the predominant photon interaction is Compton scattering. The cross-section for this interaction is largely dependent on the media density, and the resulting image will show the largest contrast when large differences in density are present. In practice, this means that differences in soft tissues will contribute most to the visible signal.

These considerations imply that the dynamic range of an electronic portal imaging detector (EPID) is used to obtain information on soft-tissue variations (3), divergence effects (4), scatter contributions (5), field-edge information, and in the case of fluoroscopic imagers: vignetting and glare. With the exception of field-edge information, all of these factors are nonlocalized and tend to change gradually within an image. Not only are these features slowly varying, but they also have a large contrast-to-noise ratio (CNR) compared to the clinically important bone–soft-tissue contrast.

The EPIDs permit the same tasks as film-based imaging, but increase the efficiency and provide added value by using digital imaging techniques. The EPIDs are devices that electronically capture the photon energy fluence transmitted through a patient irradiated during treatment, and allow direct digitization of the image. This image is then immediately available for visualization on a computer screen and electronic storage. When the treatment verification process uses EPIDs, departmental efficiency is increased and quality is improved at the same cost as when using film-based imaging.

Proposals to generate electronic images started in the beginning of the 1980s mainly through the work of Bailey et al. (6), who used systems based on video techniques. This seminal work was then further developed toward more clinically applicable systems by Shalev and co-workers (7), Leong (8), Munro et al. (9), and Visser et al. (10). All

of these systems were the basis for the first generation of commercially available EPIDs. They all combined an analog camera with a fluorescent screen generating the optical coupling using a mirror system. Wong et al. (11) replaced the mirror system with optical fibers (one for each pixel). The technology developed further, and is described below in greater detail.

PHYSICAL ASPECTS OF ELECTRONIC PORTAL IMAGING TECHNOLOGY

Camera-Based Detectors

The initial experience using EPIDs was obtained using camera-based systems. Again similar to film-based portal imaging, the camera-based systems measured the photon energy fluence exiting the patient. However, phosphorescent and fluorescent screens replaced the film, and a mirror was oriented at an angle of 45° to reflect the screen toward a video camera. Subsequently, the image was digitized. Because of the intrinsically low-detector efficiency, bulky detector size, and poor image quality, this technology has now become outdated in comparison with more sophisticated technologies.

The low-detector efficiency was due to many limitations in the signal path from screen to computer. Screen conversion efficiency was not ideal when using Gd₂O₂S. In addition, <0.1% of the light emitted reached the video camera, due to the poor light collection efficiency of the video camera lens. This low rate of signal collection was subsequently impacted by competing electronic noise from the camera in close proximity to the operating linear accelerator (linac). Also, image acquisition typically required a full treatment fraction as compared to the technique using partial fraction irradiating that is commonly used for radiographic portal imaging. Due to the camera-based system detector orientation, rigid positioning of the large mirror was crucial. Changes in linac gantry rotation could cause apparent changes in patient positioning due to physical sag of the camera and mirror mounting system. Furthermore, image quality was suboptimal due to

the large lenses required to focus the light signal to the video camera. Degradation of spatial resolution, field uniformity, signal-to-noise (SNR), and field flatness all contributed to minimizing the utility of this detector type.

LIQUID IONIZATION CHAMBERS

The liquid ionization chamber (LIC) is based on a design proposed by Wickman (12), who proposed to use liquid as an ionization medium to increase the efficiency of ionization chambers. Indeed, the introduction of iso-octane increased the signal level by over a factor of 10, but also deleteriously increased the recombination of the electrons due to their low mobility. A first prototype was built by Meertens et al. (13) using two printed circuit boards with perpendicular electrode strips. This resulted in a 30 × 30 matrix of ionization chambers, and was further refined by van Herk et al. (14) to include 128 × 128 and finally 256 × 256 matrices.

To obtain an image, the matrix is scanned row by row, by successively switching high voltage to different row electrodes and measuring all column electrodes. The ionization chamber polarizing voltage is typically 300 V, which is comparable to the voltage applied over a regular megavoltage ionization chamber. The typical current produced by the chamber is of the order of 100 pA. Due to the high voltage switching there is a limit on the speed with which the image may be obtained.

In most of the commercially available imagers, ~1 s is required to readout the complete matrix. Figure 1 shows a schematic diagram of a EPID. The LIC is efficient in that it is able to obtain information constantly in between readouts. The low recombination rate ($\alpha \approx 4.510^{-16} \text{ m}^3/\text{s}$) of the ions in the liquid makes that the signal accumulates during radiation and provides an averaging effect.

Multiple Detector Combinations

An alternative way to obtain two-dimensional (2D) transmission images is to use a line detector much like the ones found in computer-tomography devices. They consist of a

Figure 1. Implanted gold seeds, imaged using a flat-panel portal imager.

line of point detectors, which usually contain a phosphorescent material and an optical light detector (15). Alternatively, Lam et al. (16) constructed a device containing 256 silicon diodes. The line of detectors is scanned through the field in a mechanical fashion. However, this approach is time intensive and not appropriate for clinical techniques such as respiratory gated radiotherapy for treatment of lung cancer where the exiting photon energy fluence is of a dynamic nature.

Flat Panel Technology

The advance of flat-panel displays, where the use of amorphous silicon created surfaces that locally behaved as a crystalline material, allowed for lithography of integrated circuits. The same thin-film technology (TFT) was used to generate photodiode circuits detecting optical light. The TFT is deposited on a glass substrate of ~ 1 mm thick as is shown in Fig. 2. One of the major advan-

tages of these circuits is that they are highly radiation resistant and can be placed directly in a radiation beam. As with computer integrated circuit chip technology, the TFT EPID can be etched with a resolution of a few micrometers, permitting construction of a large detector matrix. As the photodiodes only detect visible light, a phosphorescent screen is used to perform the conversion much as for camera-based EPIDs. The TFT EPID is non-conducting during the radiation. To read out the TFT, a voltage bias is applied to allow collected charge to flow between the photodiode and an external amplifier. An amplifier records this charge, which is proportional to the light intensity. The TFT EPID array has a maximum readout rate of 25 Hz. In comparison to the camera-based EPID system, the large TFT detectors are designed to be in direct contact with the conversion screen, thus eliminating the poor optical coupling and efficiency intrinsic to the camera-based systems.

Figure 2. Schematic cross-section (not to scale) of a single a-Si:H imaging pixel.

Figure 3. Illustration of EPID conversion screens used to trap optical light. Fig. 3a shows a regular $\text{Gd}_2\text{O}_2\text{S}$ -screen with optical spread, while Fig. 3b shows a CsI screen which limits optical spread and increases detector resolution.

The resolution and efficiency of flat-panel imagers are theoretically superior to those from camera-based and LIC EPIDs. Research performed by Munro et al. (17) indicates that the amorphous silicon imager is X-ray quantum limited, and that the resolution is limited by the spread of the optical photons in the imager. The increase in quality and the compact size of TFT EPIDs means that they may be easily installed onto a linac using a robotic arm. Consequently, TFT EPIDs are now the only type of detectors commercially available. Efforts are underway to replace the current conversion screens, which usually are $\text{Gd}_2\text{O}_2\text{S}$ phosphors, with CsI, which can be grown as single crystals the size of a pixel. The optical light is then trapped in a manner similar to an optical fiber, and therefore optical spread is eliminated, as shown in Fig. 3.

Figure 4 shows pelvic images taken with a camera-based detector, LIC, and flat-panel imager.

EPID APPLICATIONS

Replacement of Radiographic Film

Just as is common in radiology departments, electronic acquisition and management of imaging data is quickly becoming standard practice. Because of the fast pace of detector evolution in the past decade, EPID technology is facilitating hospital-wide imaging digitization. However, to understand why widespread implementation of EPID systems has not yet occurred, it is important to perform a brief cost analysis.

Compared to radiographic film-based portal imaging, up-front capital expenditures for EPID systems are about a factor of 5 larger (e.g., \$25,000 vs. 125,000). However, on-going costs associated with an EPID system as compared to a radiographic film-based portal imaging program are much less. For example, regular purchasing of film and maintenance of a film processor (including silver harvesting) is not required with an EPID program. This cost-analysis makes EPID highly competitive given the digital direction facing modern health care.

With direct image digitization comes the ability to transmit data as required for telemedicine. Furthermore, imaging data storage and retrieval, as required for radi-

ology picture archiving and communication systems (PACS), has additional advantages over conventional radiographic film storage. In radiation oncology departments, it is now commonplace for record-and-verify systems to be coupled to an electronic patient charting system. By storing the EPID images in this domain, many of the concerns for patient record keeping, retrieval, and preservation of treatment confidentiality are overcome.

Improvement of Patient Positioning

The original purpose of portal imaging is to reduce the incidence and extent of errors made during radiation treatment. The type of errors can be categorized as gross errors and stochastic errors. Examples of such errors are shown in Fig. 5. The gross errors occur only once and when detected can be removed from the treatment after one fraction. Stochastic errors contain a random component, which implies that the error changes from day to day. Errors and QA-problems can also introduce a systematic component hidden by the random component, which can only be corrected for if its extent is known.

To reduce stochastic errors, there are two general methodologies, on- or off-line corrections. The most straightforward methodology uses on-line correction where an image is obtained in “localization mode” where minimal dose to the patient is applied. If a discrepancy is observed in the patient setup, and if this discrepancy is larger than a predetermined threshold or action level, efforts are taken to eliminate the error by changing the patient position or changing the treatment configuration. The aforementioned threshold is based on the precision to which position can be determined *and* with which the patient setup correction can be applied. Given the digital nature of EPID images, it is possible to increase the accuracy using computerized algorithms to objectively measure patient positioning with respect to the treatment field (18–21). This approach has not been widely adopted, mainly due to the perceived labor intensity and some medico-legal aspects. However, this may change with the advent of other on-line repositioning techniques (cf. ultrasound-based repositioning) and increased process automation.

Weekly port-filming is the standard procedure in the QA of external beam radiation therapy, which generally

(a)

(b)

(c)

implies that a sample of 4 positions is taken out of a 20 fraction treatment. Errors are corrected after the first image. An interesting study by Valicente et al. (2), showed that this practice is suboptimal. The use of EPIDs allows us to obtain images in a more economical way. Most off-line correction strategies assume that the distribution formed by all consecutive errors is a normal distribution characterized by the mean error and the standard deviation calculated as in

Mean:

$$\langle x \rangle = \frac{1}{N} \sum_{i=1}^N x_i \quad (1)$$

Standard Deviation:

$$\sigma = \sqrt{\frac{1}{(N-1)} \sum_{i=1}^N (\langle x \rangle - x_i)^2}$$

(c)

(d)

Figure 5. (Continued)

By repeated sampling of the distribution (e.g., taking port films), the strategy estimates the value of $\langle x \rangle$ as close as possible and corrects for the error, which will reduce the systematic error in the treatment. Several groups have studied the implications of this strategy and its variations. The most successful approach seems to be the following strategy: The set-up variations are recorded and averaged. This is compared to an action level that depends on how many samples have been taken already (the level shrinks as the amount of information on the systematic error increases). These studies showed that systematic errors could be reduced to ~ 2 mm (22).

Organ Motion

One of the major reasons for use of EPIDs is the fact that the patients anatomy and position vary from those used for treatment planning purposes. The factors involving this variation are

- Patient movement.
- Patient positioning inaccuracies.
- Organ motion.

Any of these factors will influence the actual dose distribution to be different from that obtained using treatment planning. It is straightforward to correct for the first two problems using portal imaging as the patients position is typically well-characterized using bony anatomy. An excellent compilation on the incidence, extent, and repercussions of organ movement was performed by Langen and Jones (23). Efforts to incorporate organ movement during radiotherapy treatment planning involves enlarging the target to be treated. Sophisticated algorithms that calculate the extent of these enlargements were developed independently by Stroom et al. (24) and by van Herk et al. (25). The general framework for this enlargement is given in ICRU 50 and ICRU 60 (26,27). In these reports the gross target volume (GTV) is defined as the volume containing demonstrated tumor. A margin is added to the GTV to account for suspected microscopic tumor involvement, and is defined as the clinical target volume (CTV). Finally, the planning target volume (PTV) is defined by the CTV and an additional margin to allow for geometrical variations such as patient movement, positioning errors, and organ motion. The margins added to GTV and CTV can substantially increase the PTV since the margins are applied in three dimensions. Because of volume effects of radiation therapy, there is a tendency to minimize the PTV by increasing the precision of the treatment. As explained above, EPIDs are able to minimize uncertainties caused by patient motion and positioning errors using off- or on-line correction strategies.

Except in a few cases like in lung or where air pockets are present (24,28), the target is virtually indiscernible using X rays. To solve this problem, other modalities, like CT (29) and ultrasound (30,31), have been used to determine the position of the organ. The EPIDs can also be used to image the position of organs if radioopaque markers are implanted. The markers need to be of high density and migration needs to be limited. The efficacy

and feasibility of using markers with EPIDs was studied by Balter et al. (32), application of the use of markers have been extensively studied by Pouliot and co-workers (33). The use of markers is becoming more popular and EPID systems are being augmented with software to detect markers as well as perform the requisite positional calculations.

Quality Assurance and *In Vivo* Dosimetry

In 2001, Task Group No. 58 of the American Association of Physicists in Medicine Radiation Therapy Committee issued a protocol to define the standard-of-care for performing EPID QA on a daily, monthly, and annual basis (34). In this protocol, a quality assurance program is proposed where daily checks of EPID system performance, image quality, and safety interlocks are performed by a radiation therapy technologist. In addition to reviewing results and independently performing checks conducted by the technologist, a medical physicist should conduct the following checks on a monthly basis: perform constancy check of SNR, resolution, and localization; inspect images for artifacts; do a mechanical inspection of all EPID components; and maintain the computer system. The annual QA tasks are also performed by the medical physicist, and include all of the above tasks plus a full check of the EPID geometric localization accuracy. By performing these QA tasks, the radiotherapy department may be reasonably assured of a reliable EPID system for clinical use.

The QA tests typically utilize a vendor-supplied phantom designed to facilitate evaluation of the aforementioned tasks. Since clinical linacs are typically dual energy (e.g., 6 and 15 MV) in design, tests are applied to both photon energies. As expected, the lower photon energy will demonstrate improved image quality (e.g., SNR and spatial resolution). Since many EPID systems utilize sophisticated computer software utilities, testing of this software in a realistic setting is an integral component of the EPID quality management program. As can be expected with tests that are subjective in nature, it is recommended that multiple users be employed to evaluate the subjective criteria so as to minimize user bias.

In addition to the aforementioned advantages, an EPID system permits unique opportunities of radiotherapy treatment QA. Treatment fields are typically blocked with beam modifiers to account for irregularities in patient shape. These beam modifiers include compensating materials when minor changes are required, or beam wedges when gross changes are required. Because modern linacs have features like dynamic wedges and dynamic multileaf collimators, the nonintegral approach that EPIDs offer over radiographic film (i.e., the ability to obtain several images at different stages during a dynamic process) permits continued high-quality QA. Due to the electronic nature of EPID measurement of the photon energy fluence exiting a patient, one can perform exit dosimetry and quantitative comparisons with treatment planning intentions (35). However, these efforts are currently research driven, and widespread clinical implementation may not be expected for a few years.

INTRODUCTION

Diagnostics as a whole represent a large, well-established, and continually expanding market. Methods for the selective determination of analytes in biological fluids, such as blood and urine, are important. When a foreign substance (antigen) invades the human body, the immune system produces antibodies that interact with the antigen. Such a recognizing process involves the formation of an immunocomplex based on interactions between the immunospecies. The recognition is specific for the antibody-antigen system and, thus, for the measurement of antigen concentration (1,2). This determination is of importance for diagnosis because the antigens can be viruses, bacteria that are involved in many human illnesses, such as cancer and AIDS. The analytes detected and measured have also included many other medical diagnostic molecules such as hormones, clinical disease biomarkers, drugs, and environment pollutants such as pesticides. Antibody diversity is so great that virtually any biomolecule can be recognized (3). The range of analyte concentrations encountered is extremely large, from greater than 10^{-3} M for species such as glucose and cholesterol and to less than 10^{-12} M for certain drugs and hormones (4). It is for the detection of these low level analytes that the application of immunological techniques is essential.

An immunoassay is a multistep diagnostic test based on the recognition and binding of the analyte by the antibody. Most immunoassay techniques are based on the separation of free and bound immunospecies (5). In these techniques, one of the immunoagents (antibody or antigen) is immobilized on a solid phase. The solid phase facilitates the separation and washing steps required to differentiate bound and free fractions of the label. Quantification of a bound immunoagent is conducted by using labels covalently bound to the immunoagent with specific properties suitable for detection. The most common labels are radioactive markers, enzymes, and fluorescent labels. For many of the nonisotopic labels, the reagents have been designed such that binding of labeled antigen to antibody in some way modulates the activity of the label, resulting in a homogenous immunoassay without the need for a separation step. The most familiar type of enzyme immunoassay in clinical analysis is known as enzyme-linked immunosorbent assay (ELISA) (6). Different schemes of enzyme immunoassay exist, and, in clinical laboratory practice, the most popular are the "Sandwich" method for large analytes, and compe-

titive binding immunoassay methods for the determination "haptens" (low molecular weight analytes).

The advent of biosensor technology, with the possibility of direct monitoring of immunoreactions, provides opportunity to gain new insight into antigen-antibody reaction kinetics and create rapid assay devices with wider applications. A biosensor is composed of (1) a biochemical receptor, which uses biosubstances such as enzymes, antibodies, or microbes to detect an analyte, (2) a transducer, which transforms changes in physical or chemical value accompanying the reaction into a measurable response, most often in the form of electrical signal (7-9). The term immunosensor is used when antibodies are immobilized to recognize their appropriate antigens (or vice versa) (10). Immunosensors possess several unique features, such as compact size, simplicity of use, one-step reagentless analysis, and absence of radioactivity, which make them attractive alternatives to conventional immunoassay techniques. Immunosensors can be divided, in principle, into two categories: nonlabeled and labeled (11). Nonlabeled or direct-acting immunosensors are designed in a way that the immunocomplex (i.e., the antibody-antigen complex) is directly determined by measuring physical changes induced by the formation of the complex. In contrast, labeled or indirect-sensing immunosensors have incorporated a sensitively detectable label. The immunocomplex is thus entirely determined through measurement of the label. In order to determine an antigen, the corresponding antibody is immobilized on the membrane matrix, which is held on an amperometric-or potentiometric-sensing transducer used to measure the rate of the enzymatic reaction (12-14).

Of the electrochemical technologies for biosensors, the Ion-Sensitive Field Effect Transistor (ISFET) has been the center of special attention as a transducer. ISFETs were introduced by Bergveld in 1970 (15), and were the first type of this class of sensor in which a chemically sensitive layer was integrated with solid-state electronics. A field effect transistor (FET) can be considered as a charge-sensitive device (i.e., any change in the excess interfacial charge at the outer insulator surface will be mirrored by an equal and opposite charge change in the inversion layer of the FET). By excluding the gate metal in a FET and using a pH-sensitive gate insulator, a pH-sensitive FET was constructed (16,17). After the invention of the ISFET, many different types of FET-based sensors have been presented. The application of enzymes as the selecting agent in ISFET-based sensing systems leads to the development of highly sensitive sensors. Such enzyme-modified ISFETs (EnFETs) can, in principle, be constructed with any enzyme that produces a change in pH on conversion of the concerning substrate (18). By combining the ISFET with a membrane that contains a biological substance, like an antibody, the sensor can detect a specific antigen (19). The ISFET immunosensors or Immunologically sensitive FETs (IMFETs) have several advantages over the conventional enzyme immunoassay. The ISFET could be mass-produced by an integrated circuits (IC) process, which makes it very small and economical. An electric circuit can be integrated on the same chip. The biosensor platform finds many applications in various

fields, such as medical diagnostics, fermentation process control, and environmental monitoring.

THEORY

In order to understand the operation of the IMFET, one must trace its origins back to the ISFET or ChemFET (Fig. 1). The latter devices have been described in depth elsewhere (20–22). A packaged ISFET is shown in Fig. 2 (23). ISFETs and ChemFETs have, in turn, evolved from the Metal Oxide Semiconductor Field Effect Transistor (MOSFET), currently the most popular active device in the entire semiconductor industry. It is a unipolar device, where the current is given by the flow of majority carriers, either holes in PMOS type or electrons in NMOS type. The operation of the MOSFET can be considered as a resistor controlled by the status of a gate region, so-called MIS structure. It is a sandwich consisting of a stacked-gate

Figure 1. The hierarchy of field effect transistor. a. MOSFET. b. ISFET. c. IMFET.

Figure 2. Photomicrograph of an ISFET device packaged on PCB (23).

metal layer, an insulator (typically silicon oxide), and a semiconductor. Assume a low-level doped p-type (NMOS device). Three different states of charge distribution can occur, depending on the voltage V_g , applied between the metal and a semiconductor. A negative value of V_g causes positive holes to accumulate at the semiconductor-insulator interface. A positive value of V_g of a low magnitude leads to the “depletion” condition in which mobile holes are driven away from the interface, resulting in a negative charge of low density due to the presence of immobile acceptor atoms. Finally, if the V_g exceeds a certain threshold voltage (V_{th}), electrons accumulate at the semiconductor-insulator interface at a density greater than the hole density, a situation opposite to that normally found with p-type semiconductors. This depletion of mobile charge carriers followed by surface inversion is known as the “field effect.” It forms an electrically conductive channel between two other terminals, a source and a drain (see Figure 1a). The drain current I_d through the transistor is a function of drain and gate voltage. Without surface inversion (i.e., $V_g < V_{th}$) the drain current is negligible, because the drain-to-substrate PN junction is reverse biased.

The MOSFET and its descendants are charge-controlled devices. In analytical applications (e.g., ISFETs, ChemFETs, and IMFETs), the change in charge density is brought about by adsorption of one or more species present in the solution onto the FET structure. In the ISFET, the gate metal is replaced with a conventional reference electrode (Ag/AgCl or Hg/Hg₂Cl₂), a solution containing an ionic species of interest, and an electroactive material (membrane) capable of selective ion exchange with the analyte (Fig. 1b), which is an example of a nonpolarizable interface, that is, reversible charge transfer occurs between the solution and the membrane. The analyte generates a Nernst potential at the membrane-solution interface, which then modulates the drain current analogously to the manner in which changing the externally applied voltage does for the MOSFET.

Direct-Acting (Label-Free) IMFET

The structure of the direct-acting IMFET is similar to that of the ISFET, except that the solution-membrane interface is polarized rather than unpolarized. If the solution-membrane interface of the ISFET is ideally polarized (i.e., charge cannot cross the interface), then the ISFET can measure the adsorption of charged species at the interface as shown below. As antibodies, antigens, and proteins are generally electrically charged molecules, the polarized ISFET could be used to monitor their nonspecific adsorption at the solution-membrane interface. To render the polarized ISFET selective for a given antigen and thus create the so-called IMFET, the specific antibody for that antigen has to be immobilized on the surface of the ISFET (see Fig. 1c). The adsorption of this antigen would then be specifically enhanced over other molecules in the solution and the signal measured by the ISFET would be mostly due to the adsorption of that particular antigen. The ISFET interacts with the analyte through an ion-exchange mechanism, whereas the IMFET interaction is based on the antigen-antibody reaction.

This design for the measurement of the adsorption of charged molecules is practicable only if charge cannot cross the interface, which, thus, acts as an ideal capacitor. As will be seen, failure to achieve a perfectly polarizable interface has a detrimental effect on the specificity of the IMFET. Few reports exist on direct-acting IMFETs; a brief analysis on the work of Janata research group will be presented here (24–26). The capacitance of a polarized interface is described by electrical double-layer theory and is usually modeled as a series combination of two capacitors, C_G and C_H , where C_G is the capacitance of the diffuse Gouy–Chapman part of the double layer and C_H is the capacitance of the Helmholtz part of the double layer (27). The total capacitance, C_{dl} , is therefore

$$1/C_{dl} = 1/C_G + 1/C_H \quad (1)$$

The electrical circuit through the gate of an ISFET with an ideally polarized interface can be modeled, therefore, as a series combination of C_G , C_H , and C_0 , as drawn in Fig. 3, where C_0 is the capacitance of the insulator. A gate voltage V_G is applied through a reference electrode between the solution and the semiconductor. The process of adsorption of charged molecules can be modeled as the transfer of a

Figure 3. Electrical model for the measurement of charge adsorption with the CHEMFET.

quantity of charge from the solution to the surface of the transistor as would occur if the switch were closed for a short time period allowing the current source to transfer the charge. As adsorption occurs, the charge on each plate of the capacitors will change to accommodate the new charge balance. The charge change on capacitor C_0 is the quantity of interest as it represents the charge in the inversion layer of the FET, Q_i , and will affect the drain current of the transistor, which can be directly measured. If a quantity of charge, Q_{ads} , is transferred by the adsorption of charged molecules, then the charge change on C_0 , Q_i , can be represented by

$$Q_i = Q_{ads} \{C_0 / (C_0 + C_{dl})\} \quad (2)$$

Hence, only a fraction of the adsorbed charge will be mirrored in the transistor. When adsorption occurs, because electroneutrality must be observed in the system, an equal quantity of the opposite charge must either enter the inversion layer of the FET or enter the double layer from the solution. Equation 2 predicts that part of the image charge will come from the solution as ions entering the double layer with the adsorbing molecules. This fraction of charge, which is mirrored in the inversion layer of the FET, will be defined as β , and it is defined as

$$\beta = Q_i / Q_{ads} = C_0 / (C_0 + C_{dl}) \quad (3)$$

According to this model, only 0.3% of the charge on the adsorbing molecules will be mirrored in the inversion layer of the FET. The authors conservatively estimated β to be 10^{-4} . Considering the I_d current as a function of the potential at the solution-membrane interface, it is clear that a relationship between the adsorbed charge and interfacial potential, $\Phi_{Sol-mem}$, is necessary to describe the chemical response of the IMFET. This potential is merely the charge change induced in the inversion layer divided by the insulator capacitance:

$$\Phi_{Sol-mem} = Q_i / C_0 = \beta Q_{ads} / C_0 \quad (4)$$

Substitution of this expression in to Equations 5 and 6 yields the response equations for the polarized ISFET. The authors derived the following expressions for the polarized ChemFET relating to Q_i to the observed parameter, the drain current (I_d):

$$I_d = \frac{\mu_n W C_0}{L} \left(V_g - V_t - E_r - \Phi_{sol-mem} - \frac{V_d}{2} \right) V_d \quad (5)$$

$V_d < V_{dsat}$

and

$$I_d = \frac{\mu_n W C_0}{2L} (V_g - V_t - E_r - \Phi_{sol-mem})^2 \quad (6)$$

$V_d > V_{dsat}$

where W is the width of the source-drain conducting channel, μ_n is the effective electron mobility in the channel, C_0 is the capacitance per unit area of the gate insulator, L is the channel length, V_d is the drain-to-source voltage, V_g is the applied gate voltage, V_t is the threshold voltage (for surface inversion), and E_r is the potential of the reference electrode.

The antibody-antigen binding reaction in its simplest form can be expressed in terms of the following

biomolecular reaction:

where Ab is the antibody, Ag is the antigen, and AbAg is the complex. The reaction is characterized by the equilibrium constant K ,

$$K = [\text{AbAg}]/[\text{Ab}][\text{Ag}] \quad (7)$$

The total charge change at the interface due to the binding, Q_i , can be shown to be

$$Q_i = \beta Q_{\text{ads}} = \beta z F \frac{K[\text{Ag}][\text{S}]}{1 + [\text{Ag}]} \quad (8)$$

where z is the ionic charge of the antigen and $[\text{S}]$ is the surface concentration of binding sites (the surface concentration of immobilized antibodies before binding). Substitution of this expression into Equation 4 yields

$$\Phi_{\text{Sol-mem}} = \frac{\beta z F K [\text{Ag}][\text{S}]}{C_0(1 + [\text{Ag}])} \quad (9)$$

From Equation 9, the limit and range of the detection for the IMFET can be predicted. Assume that the equilibrium constant is in typical range from 10^5 to 10^9 (28), which gives a value of $\beta = 10^{-4}$. If the antibodies are immobilized with a surface concentration of 1 molecule per 10 nm^2 and the charge on an antigen is five electronic charges of an antibody, the IMFET's detection limit would be in the range of $10^{-7} - 10^{-11} \text{ M}$ of concentration antibody concentration. The antigen concentration that gives 90% surface coverage can similarly be calculated to be in the range of $10^{-4} - 10^{-8} \text{ M}$. Similar equations can be derived for the case where the antigen is immobilized at the interface rather than the antibody. However, it has been argued by many researchers that a static measurement concerning the presence of a protein layer on an electrode is difficult, because the charged groups are, of course, neutralized by surrounding counter ions (29). In order to avoid interference from other charged species present in the solution, the substrate for immobilization should preferably be inert and nonionic (24–30), which in aqueous solutions implies a hydrophobic surface (31). Ideal conditions that are required in this coherence are a truly capacitive interface at which the immunological binding sites can be immobilized, a nearly complete antibody coverage, highly charged antigens, and a low ionic strength.

Schasfoort et al. (32) extensively studied the requirements for the construction of IMFET, which would operate on the direct potentiometric sensing of protein charges. The charge redistribution around immobilized proteins at the insulator-solution interface can be described by the double-layer theory (33). On adsorption, the diffuse layer of counter ions around the protein charges may overlap with the diffuse layer of the electrolyte-insulator interface. The thickness of diffuse-charge layers is described by the Debye theory (34) and defined by the distance where the electrostatic field has dropped to $1/e$ of its initial value:

$$\kappa^{-1} = \left(\frac{\epsilon_0 \epsilon k T}{2 q^2 I} \right)^{1/2}$$

where κ^{-1} is the Debye length, q the elementary charge, k Boltzmann's constant, T absolute temperature, ϵ_0 the permittivity of vacuum, ϵ the dielectric constant, and $I = 1/2 \sum c_i z_i^2$ represents the ionic strength in which c_i is the concentration of ion i with valency z (for 1-1 salt, I can be replaced by c).

It can be seen from the equation that the Debye length is strongly dependent on the ionic strength of the solution; more precisely, the Debye length is inversely proportional to the square root of the ionic strength. Therefore, one can expect that the chance of overlapping of the double layers of the substrate-solution interface and the adsorbed proteins can be substantial only if low electrolyte concentrations are used, owing to the dimensions of the proteins (Fig. 4). In a physiological salt solution, the Debye length is limited to ca. 0.8 nm. It is obvious that only charge density changes that occur within the order of a Debye length of the ISFET surface can be detected. With the macromolecules, such as protein, the dimensions are much larger (about 10 nm) than those of the double layer of the electrolyte-insulator interface, which means that, in such a case, most of the protein charge will be at a distance greater than the Debye length from the surface. If, moreover, on top of a monolayer of antibody molecules a second layer on antigens is coupled, it is obvious that the chance of overlap of the diffuse layers of antigens with electrolyte-substrate interface will decrease even more. At high ionic strength, the additional charges of the antigen are nearly always located far outside the diffuse layer at the ISFET surface and pure electrostatic detection of these antigenic charges, therefore, is impossible. In addition, a theoretical approach is

Figure 4. Schematic representation of the potential distribution in a direct-acting IMFET. κ^{-1} is the Debye length; d_{Ab} , dimension of macromolecule (e.g., antibody).

given based on the Donnan equilibrium description, which provides an insight into the potential and ion distribution in the protein layer on the IMFET (32). It is shown that the Donnan potential and the internal pH shift, induced by the protein charges, compensate each other to a greater extent. If the ISFET shows Nernstian behavior, it can be concluded that a direct detection of protein charge is impossible. In order to construct an IMFET, a reference FET or ISFET with a low sensitivity would satisfy the detection of the partially compensated Donnan potential in the presence of an adsorbed protein layer. However, the application of such an IMFET is limited to samples with low ionic strength.

An alternative, indirect approach is proposed by Schasfoort et al. (35,36) for the detection of an immunological reaction taking place in a membrane, which covers the gate area of an ISFET (Figs. 5a and 5b). The protein layer on the gate is exposed to pulse-wise increases in electrolyte concentration. As a result, ions will diffuse into the protein layer and, because of a different mobility of anions and cations, transients in potential will occur at the protein-membrane solution interface. The ISFET, being a voltage-sensitive device, is suitable for the measurement of these transients. As the mobility of ions is a function of the charge density in the protein membrane, changes in the charge density will influence the size and direction of the transients. By exposing the ISFET to a pH gradient and a continuous series of ion concentration pulses, the isoelectric point of the protein layer can be detected and, thus, changes as the result of an immunological reaction. When a membrane separates two

Figure 5. An ion-step arrangement: an ISFET exposed to an increased electrolyte concentration. Transient potential can be measured, developing from transient transport of ions across the membrane, which is caused by stepwise changes in electrolyte concentration. The ISFET response ϕ as a result of the stepwise changes in electrolyte concentration (C_1 – C_2).

compartments with different electrolyte concentrations, a potential gradient can be measured. The different diffusion rates of anions and cations through the membrane set up a static membrane potential, which can be expressed by the Nernst–Planck equation (33):

$$\phi_m = \frac{RT}{F} \cdot U \cdot \ln \frac{a_2}{a_1} \quad U = \frac{D_+ - D_-}{D_+ + D_-}$$

where ϕ_m = the membrane potential, RT and F have their common meaning, U = the ratio of the diffusion coefficients (D_+ and D_-) of cations and anions, and a_1 and a_2 are the electrolyte activities in the respective compartments. The ion-step method is further developed by Schasfoort and Eijmsma (37), and a detailed theoretical understanding of the ion-step response has been presented by Eijiki et al. (38). Recently, an impedance spectroscopy method was used to characterize immobilized protein layers on the gate of an ISFET and to detect an antigen-antibody recognition event (39).

Indirect-Sensing IMFET

Although the ion-step method is an indirect way of measuring antigen-antibody reaction that occurs on the gate region of an ISFET, it does not involve any reagents that enhance or amplify the signal intensity. Many approaches to transduction of the antibody-antigen combining event are indirect. They are based on the ability of an enzyme label to produce electroactive substances within a short span of time. Antibody or antigen is immobilized on the gate area of pH-FET. In the competitive binding assay, the sample antigen competes with enzyme-labeled antigen for the antibody-binding sites on the membrane. The membrane is then washed, and the probe is placed in a solution containing the substrate for the enzyme. IMFETs based on the sandwich assay are applicable for measuring large antigens that are capable of binding two different antibodies. Such sensors use an antibody that binds analyte-antigen, which then binds an enzyme-labeled second antibody. After removal of the nonspecifically adsorbed label, the probe is placed into the substrate-containing solution, and the extent of the enzymatic reaction is monitored electrochemically. Gate voltage is supplied by reference electrode, such as Ag/AgCl or a Hg/Hg₂Cl₂ electrode, that is immersed in a sample solution. It is, however, difficult to make a small conventional electrode, which prevented the IMFET from being miniaturized as a whole. When a noble metal, such as platinum or gold, is used as a reference electrode, the potential between the metal electrode and sample solution fluctuates. The fluctuation makes stable measurement impossible. A method to cancel the fluctuation using a reference ISFET (REFET) is reported. A combination of two kinds of ISFET is used, one of which detects a specific substance whereas the other (REFET) does not detect it (Fig. 6). Thus, measuring the differential output between the two ISFETs can cancel the potential fluctuation in the sample solution and drift due ISFET (40–42).

Most of the indirect-sensing IMFET studies are carried out using urease-conjugated antibodies. Urea is used as a substrate. The immunosensor uses a reaction wherein urea is hydrolyzed by the urease-labeled second antibody. The

reaction is

According to the reaction, the pH value in the membrane becomes high. On the other hand, on the ISFET surface with inactive antibody membrane, the above reaction does not occur and pH remains constant. Hence, by measuring the differential output between two ISFETs, only pH changes due to urea hydrolysis are detected. In some cases, the authors used antibodies conjugated with the glucose oxidase. These sensors use oxidation of glucose by glucose oxidase. In the reaction, gluconic acid is produced and the pH value in the glucose oxidase immobilized membrane becomes low. To achieve a high sensitivity of horseradish peroxidase (HRP) detection, various substrates, either alone or in combination, are tested and the result is shown in Fig. 7.

PRACTICE

Direct-Acting IMFET

The rationale for attempting to combine the fields of immunology and electrochemistry in the design of analytical devices is that such a system should be sensitive due to the characteristics of the electrochemical detector while exhibiting the specificity inherent in the antigen-antibody reaction. The ideal situation would be to detect the binding of immunoreagents directly at an electrode, for example, by changes in surface potential, which could be truly described as an immunosensor (43,44). Much more effort has been committed to develop transducers, which rely on direct detection of antigen by the antibody immobilized on its surfaces (or vice versa). In 1975, Janata immobilized a sugar-binding protein Concanavalin A on a PVC-coated platinum electrode and studied its responses in the presence of sugar (30). The potential of the electrode with respect to an Ag/AgCl electrode changed owing to adsorption of the charged macromolecule. Although the system reported was not based on an immunochemical reaction, the finding of a potentiometric response stimulated further investigations in this field. Direct potentiometric sensing of antigen human choriogonadotropin (hCG) with an anti-hCG antibody sensitized titanium wire resulted in 5 mV shifts with respect to a saturated calomel electrode (45). The change in potential was explained by a simple charge transfer model.

In 1978, Schenck first proposed a concept of direct immunosensing by an ISFET (46,47). He suggested using FET with, on the gate region, a layer of antibody specific to a particular antigen. Replacement of electrolyte solution with another electrolyte solution-containing antigen should alter the charge of the protein surface layer due to the antigen-antibody reaction, thus affecting the charge concentration in the inversion layer of the transistor. The corresponding change in the drain current would then provide a measure of the antigenic protein concentration in the replacement solution. Many research groups have tried to realize the proposed concept of Schenck, but the results obtained are meager (48,49). Collins and Janata immobilized a PVC membrane containing cardiolipin antigen onto the gate of a previously encapsulated ChemFET (50). They demonstrated that the solution-membrane interface was somewhere between a polarized and a non-polarized interface, based on the measured membrane exchange current density. The measured potential was therefore a mixed potential deriving out of the permeation of Na^+ and Cl^- ions into and out of the membrane. The change in potential following specific binding of antibody to the membrane was due primarily to a perturbation of the mixed potential, rather than to the adsorbed charge from the antibody itself. Therefore, the device could not be considered selective for the immunoreactive species of interest. Besides, Janata reported that it is impossible to construct an IMFET without having an ideal polarized solution-insulator interface. He proclaimed all of his earlier results as artifacts (51). In spite of these practical difficulties, Gotoh et al. (52) published results obtained with an IMFET sensitive to Human serum albumin (HSA).

Figure 8. Outline of an Ion-step flow through system.

A 2 mV shift was detected with HSA containing polyvinylbutyral membrane deposited on an ISFET after reaction with its antibody. It appears that experimental results obtained with direct detection of protein on solid-state electrode or similar devices are, so far, limited to second-order effects. Nevertheless, a real theoretical explanation is absent. Therefore, until more experimental evidence is available, the true value of direct-acting IMFET concept remains to be established.

Schasfoort et al. (36) proposed an alternative approach to overcome the above-described difficulties of a direct detection of immunological reaction with ISFET. By stepwise changing the electrolyte concentration of the sample solution, a transient diffusion of ions through the membrane-protein layer occurs, resulting in a transient membrane potential, which can be measured by the ISFET. A flow-through system was used to carry out the experiments as schematically drawn in Fig. 8. The pH of the electrolyte can be changed by using a gradient vessel. When the solution flows under hydrodynamic pressure out of vessel 1, the pH will change through mixing with a solution of different pH from vessel 2. By opening the valve for a few seconds, the ISFET can be exposed to a higher salt concentration. The step change in ion concentration was completed within 50 ms. After 2 s the valve was closed and the membrane can gain equilibrium with the buffer flowing out of vessel 1. In order to exchange the electrolyte concentration rapidly, the volume between the valve and the ISFET was kept small. ISFETs with a polystyrene-agarose membrane were incubated with 10^{-5} M HSA for 3 h. The ISFET response was measured as a function of the pH, and the inversion point was determined to be $pI = 3.72 \pm 0.05$. Subsequently,
