Another method is the phase-inversion nanoencapsulation (PIN), which has been used to encapsulate insulin for oral administration (351). A limitation of these two techniques is the use of toxic and fluorinated solvents, which may cause drug degradation. For these reasons, other techniques, that do not compromise drug stability have been developed.

One of these is the emulsification–diffusion method. In this case, the polymer and the active compound are dissolved in a partially water-soluble solvent. This organic solution is added, and then emulsified in an aqueous phase containing a surfactant. To favor the precipitation of nanoparticles, additional water is added to the emulsion under stirring. At the end of the process, the solvent can be removed by centrifugation or dialysis.

The nanoprecipitation method involves the dissolution of the polymer and the drug in a freely water-miscible organic solvent (e.g., acetone) and then the addition of this organic solution into a water phase containing a nonionic surfactant (e.g., Pluronic F68). The organic solvent is then removed under reduced pressure by a rotavapor (352). This procedure leads to the formation of nanospheres, but if a biocompatible oily component is added in the organic solution nanocapsules are formed (353).

The formation of nanospheres or nanocapsules also can be achieved by an *in situ* polymerization process. The emulsion or micellar polymerization is the most used approach to achieve nanocapsules and nanospheres by starting from the polymeric monomer, respectively. In the case of micellar polymerization, reactions take place in the solvent phase. The following polymers can be prepared as nanosphere colloidal suspensions following this preparation procedure: PMMA, poly(alkyl cyanoacrylate), and acrylic copolymer. When the polymerization is carried out at the interface (interfacial polymerization) between an oil phase and an aqueous solution, nanocapsules are formed (354).

The determination of the loading capacity of nanoparticle colloidal suspensions can be carried out by separation of the untrapped material with ultracentrifugation followed by the drug analysis after dissolution of the pelleted polymeric matrix. Other reliable separation methods are ultrafiltration and gel permeation chromatography (345,346). The drug loading capacity also can be calculated by determining the drug content in the supernatant or in the filtrate. In fact, the amount of drug entrapped in nanoparticle colloidal systems can be obtained by subtraction of the untrapped drug amount from the total amount of drug present in the suspension.

The mechanisms of drug release from nanoparticle colloidal suspensions depends on the characteristics of the colloidal suspension, as well as on physicochemical

properties of the drug. In particular, the release of a drug may occur by one of the following mechanisms or a cooperation of more than one of them: (1) drug desorption from the colloidal surface (both for nanospheres and nanocapsules); (2) drug diffusion through the polymeric network of the nanospheres; (3) drug diffusion through the polymeric shell of nanocapsules; (4) polymeric matrix erosion of nanoparticles. The drug release rate is dependent on the release mechanism, the diffusion coefficient, and polymer biodegradation rate. The nanoparticle drug release is also greatly influenced by the type of interaction with the biological substrate (345).

Besides the previous mentioned drug release mechanisms, it should be considered that the drug delivery function of nanoparticles also can be accomplished by a direct contact with the biological membranes, thus leading to an enhanced drug delivery through membranes with respect to a simple drug solution (355). As a consequence of this behavior, it may happen that the *in vitro* drug release profiles are poorly related to the *in vivo* drug delivery and release situation (356).

Size and zeta potential are important physicochemical parameters to be determined to achieve a suitable colloidal carrier. Nanoparticle size is influenced by the preparation technique and by the polymer used, that is, low molecular weight polymers form small-sized nanoparticles, but this fact reduces the amount of encapsulated drug. An increase of polymer concentration usually elicits an increase of both nanoparticle size and encapsulation efficiency (357,358).

The zeta potential is a measure of the surface electrical charge of the particles. As the zeta potential increases, the repulsion phenomenon between particles will be greater, thus leading to a more stable colloidal dispersion. The minimum zeta potential value to prevent particle aggregation and to have a stable nanosuspension was defined to be ± 30 mV (359).

Therapeutic Applications of Nanoparticles. The oral administration is one of the promising application of nanoparticles that have been administered either for achieving a systemic uptake or for having a local residence within the GI tract. The polymers used for peroral application are nondegradable polymers (cellulose, acrylate derivatives, etc.) and are designed not to be adsorbed (359).

Polymer nanoparticles for oral treatment may be formulated as an aqueous suspension or incorporated into traditional dosage forms. A lot of different nanoparticle formulations have been incorporated into tablets or capsules, and then compared with traditional dosage forms. In all cases, nanoparticles maintained the advantages of a colloidal carrier, such as an enhanced dissolution of lipophilic drugs and a prolonged and sustained release (360).

An innovative nanoparticle application in this field is oral chemotherapy, which can be a valid alternative, because it allows a continuous exposure of the cancer cells to anticancer drugs at a lower concentration, thus reducing or avoiding side effects. In addition, it is more convenient and better tolerated by the patients, especially for those with advanced metastatic cancers. Unfortunately, most anticancer drugs cannot be administered orally because of their poor solubility, stability, and permeability. It has

been found that anticancer drug encapsulation into an oral formulation of nanoparticles has been able to play a key role in drug adhesion and interaction with cancer cells. For example, PEG-coated nanoparticles are able to adhere to intestinal cells and subsequently to escape from the multidrug resistance pump proteins (361).

Chitosan-coated nanoparticles are used for colon targeted drug delivery of diclofenac. Chitosan nanoparticles are microencapsulated in Eudragit L-100 or S-100 to form a gastroresistant reservoir system in which the drug release is triggered only in the basic (pH 8) environment of colon (362).

For parenteral delivery, nanoparticles can be formulated as aqueous dispersions or they are converted in lyophilized powders to be resuspended just before their administrations (345,359).

Cancer therapy is one of the most important applications of polymeric nanoparticles. Nowadays, the aim of any anticancer research is to improve patient survival after chemo- or radiotherapy. Unfortunately, traditional anticancer therapy is affected by a lot of side effects that involve healthy cells leading to an unsuitable quality of life for cancer patients. So the effectiveness of a treatment is related to the ability to target the cancer cells while affecting as few healthy cells as possible. Nanoparticles can provide an alternative solution for the site-specific delivery of anticancer drugs due to their small size and the possibility to escape RES recognition and uptake, thus leading to a prolonged blood circulation time.

Biodegradable nanoparticles made of PLGA have been used to incorporate paclitaxel, a microtubule-stabilizing agent that causes cell death by promoting the polymerization of tubulin during cell division. Paclitaxel was encapsulated to a very large extent (~100% encapsulation efficiency) and this paclitaxel-loaded colloidal system showed a 70% loss of viability of human small-cell lung cancer cells at a drug concentration as low as 0.025 $\mu\text{g} \cdot \text{mL}$. Paclitaxel also has been incorporated in poly(ethylene oxide) modified poly(β -amino ester) nanoparticles to obtain a sustained release into most solid tumors (363). Also, Tamoxifen (364) and verteporfin (365) have been encapsulated into PLGA or poly(ϵ -caprolactone) particles for *in vivo* studies against breast cancer. Doxorubicin, a widely used anticancer drug, has been encapsulated into PLGA nanoparticles (366) that presented the ability to release the drug up to 1 month. In addition, this carrier system avoids a lot of the undesirable effects of doxorubicin (e.g., cardiotoxicity).

If a sustained release of the drug in the tumor site is required, then the nanoparticle surface must be modified in order to avoid RES macrophages, which recognize hydrophobic particles as foreign. To escape RES, the surface of nanoparticles is modified with hydrophilic molecules that form a steric barrier on the particle surface. Polyoxypropylene-polyoxyethylene (POP/POE) surfactants are suitable macromolecules to prevent nanoparticles from sticking to the blood vessel endothelium and to inhibit RES recognition. Indeed, among the various copolymer members, poloxamine and poloxamer have the best prolonged circulation time of nanoparticles (367). Unfortunately, poloxamer and poloxamine do not exhibit prolonged circulation times

when nanoparticles are made up of PLGA (368). Recently, the most common moiety used for nanoparticle surface coating to obtain the so-called Stealth nanoparticles is PEG and its derivatives (369,370). Attachment of PEG on the nanoparticle surface can be performed in different ways: (1) by adsorption, (2) by incorporation during the preparation process, (3) by covalent linkage with the nanoparticle polymeric matrix.

In the passive targeting, as with stealth liposomes, long circulating nanoparticles escape from the blood circulation through the fenestrations of capillaries perturbed by inflammatory processes or by tumors (235). Inflamed vessels present fenestration sized up to 700 nm, so improved colloidal nanoparticles (<200 nm) are able to pass across, thus accumulating and releasing the drug just in the site of action. These particular characteristic of nanoparticles leads to an increased therapeutic index of the incorporated drug. Nowadays, chitosan-based particulate systems are attracting the most attention as potential long-term drug delivery systems because of mucoadhesive and long circulating properties of chitosan. Doxorubicin-dextran conjugates were encapsulated into chitosan nanoparticles to minimize the cardiotoxicity of the drug. This system reduced not only the drug side effects, but also improved the therapeutic efficacy of doxorubicin in the case of solid tumors (371).

The strategy of nanoparticle passive targeting is widely used for cancer therapy, but it presents a limitation due to a high resistance factor of some solid tumors that cannot be circumvented by PEG-coated nanoparticles. Therefore, an alternative approach is the use of temperature-sensitive nanoparticles, which are able to release its drug content only in hyperthermic zones (235). Other approaches may involve the use of biochemical triggers, such as the pH-sensitive lipid-anchored copolymers, to generate fusogenic particles (249).

The strategy of active targeting increases the probability of having a selective direction of nanoparticles to a designed site. In this case, ligands that specifically bind to surface receptors of target sites are coupled to long-circulating particulates. Among polymers suitable for coupling to specific ligands, poloxamers and PEG have received the most attention. A derivatization is achieved between the end group of the poloxamer chains with pyridyl disulfide. After a disulfide exchange with a thiol-containing moiety on the peptide or antibody to be attached on the surface of the nanoparticle, long-circulating actively targeted particles are obtained (372).

The use of nanoparticles as drug delivery systems can overcome the barriers to the penetration of anti-infective drugs into cells, that is, strong protein binding, an unfavorable lipid-water distribution coefficient, an unfavorable pH gradient between different cellular compartments, and the existence of active transport pump mechanisms that prevent the accumulation of sufficient antibiotic concentrations in the interior of the infected cells (278). In particular, a suitable nanoparticle coating can promote the permeation of hydrophilic drugs through membranes (Fig. 54). In fact, the free drug, able to freely diffuse in the aqueous medium and to interact with the outer-hydrophilic zone of the membrane model, has to pass

Figure 54. A model of the interaction between the aqueous phase containing a free hydrophilic antibiotic, or the drug-loaded PECA nanospheres and the biological membrane model. The permeation driving force is the different drug concentration between phases I and II (355).

through the lyophobic layer of the same membrane. This process could represent the limiting step in the diffusion through the membrane model of a hydrophilic molecule. In the case of nanoparticles, the outer hydrophilic shell of the particles (coated with nonionic surfactant) could ensure an interaction with the hydrophilic layer of the membrane, while the internal lyophobic core of the particle can ensure a close interaction with the hydrophobic layer of the membrane, providing a high permeation of the drug (354). The nanosphere-mediated increase of drug membrane permeation leads to an improvement of the antibacterial activity (373) and to an intrabacterial drug accumulation. The entrapment of antibiotics in nanospheres may prevent the bacterial resistance to drugs due to pleiotropic drug resistance and changes in the bacterial outer membrane leading to a decrease in OmpF porin, which probably causes decreased drug permeation.

Nanoparticles can be used for the treatment of various viral infection diseases localized at the level of the RES. For example, RES cells can be infected by both strains of the HIV, namely, HIV-1 and HIV-2. Monocytes and macrophages seem to have a fundamental role in the immunopathogenesis of the HIV infection, by behaving as virus reservoirs from which HIV can disseminate throughout the body and brain. Because nanoparticles can be easily phagocytosed by macrophages, they may represent a suitable and promising drug delivery system for the treatment of HIV infection persisting in these cells.

In vitro studies showed that human macrophages are able to phagocytose different types of polyacrylic and albumin nanoparticles (374). Interestingly, HIV-infected macrophages seem to have a higher phagocytotic activity concerning nanoparticle uptake than noninfected macrophages

Figure 55. Influence of HIV infection on phagocytosis of poly(butylcyanoacrylate) nanoparticles by human macrophages. Cell cultures were infected with HIV-1 at day 1 after start of the culture. At day 7 or 21, the nanoparticles (200 nm diameter) were added at a final concentration of $0.5 \text{ mg} \cdot \text{ml}^{-1}$ to the infected cultures and incubated for 6 h. Data from Ref. 374.

(Fig. 55). This phenomenon can be due to an activated state of these infected cells, leading potentially to a preferential phagocytosis of drug-loaded nanoparticles, and hence to a targeted delivery of antiviral drugs to these cells.

The RES tropism of conventional nanoparticles also can be efficiently used for the treatment of protozoa infection (i.e., leishmaniasis) (348). Contrary to liposomes, empty poly(isobutylcyanoacrylate) nanospheres exhibit a certain *in vitro* and *in vivo* antiparasitic activity against (375). Probably, this action could be attributed to peroxide production following nanosphere phagocytosis, which led to a respiratory burst, more pronounced in infected than uninfected macrophages.

One of the major problems connected with ophthalmic therapy is drug loss after instillation of eyedrops. To improve ocular bioavailability, mainly nanoparticles have been used. Colloidal systems have the convenience of a drop and are able to maintain drug concentration and activity at its site of action, probably due to an improved ocular mucoadhesion. In fact, poly(butylcyanoacrylate) nanospheres were able to improve the amikacin ocular delivery (376) by increasing the corneal and aqueous humor concentration of amikacin with respect to the free drug and to other formulations. The surface coating of nanospheres can also be used for ophthalmic application and can be a crucial factor to achieve a well-tailored and efficient drug delivery. In spite of the nanoparticle polymer and the method of coating, the presence of PEG on the surface of nanoparticles improves the ocular drug permanence time and increases the drug level in various ocular structures compared with both conventional ocular formulations and uncoated nanoparticles (352,377). Ocular gene therapy is also possible with polymeric nanoparticles (378).

In recent years, mucosal surfaces (nasal, pulmonary, buccal, and ocular) have received much attention as alternative routes of systemic administration (379). Chitosan-coated nanoparticles present mucoadhesive properties that can be useful to enhance mucosal drug adsorption. An example is the enhanced nasal absorption of insulin-loaded chitosan nanoparticles that do not damage the biological system.

The buccal adsorption of vaccine encapsulated into nanoparticles is an alternative to the parenteral route of administration of vaccines. The oral or nasal delivery of ovalbumine from chitosan microparticles enhances the systemic and local immune response against diphtheria toxoid vaccine (380).

Lipid-Based Nanoparticles. Lipids instead of polymers can be used to obtain colloidal drug carriers. Solid lipid nanoparticles (SLN), nanostructured lipid carriers (NLC), and lipid drug conjugates (LDC) are nanoparticles with a solid lipid matrix and present an average diameter in the nanometer range. These innovative colloidal carriers have attracted increasing attention in recent years. They are regarded as an alternative carrier system to traditional colloidal systems (e.g., polymeric micro- and nanoparticles). General ingredients include solid lipids, emulsifiers, and water. Lipids include triglycerides, partial glycerides, fatty acids, steroids, and waxes. All excipients are generally recognized as safe (GRAS) substances, so a wide variety of compounds can be used for formulation purposes.

Solid Lipid Nanoparticles. These nanoparticles are colloidal systems made up of solid lipids and are stabilized by surfactants. During the 1950s, lipid nanoemulsions were introduced for the parenteral nutrition and later they were used as carriers for lipophilic drugs. The major problem with nanoemulsions was the loss of drugs related to their liquid form. The SLN were developed to overcome this problem. In fact, the use of solid lipids instead of liquid oils is a very attractive idea to achieve controlled drug release, because drug mobility is much slower into a solid lipid than in a liquid oil.

The SLN can be prepared using different procedures. The main preparation process is the high pressure homogenization (HPH) method, in which a dispersion of the drug in the melted lipid is constricted through a narrow gap (in the range of few microns) under very high pressure, thus disrupting lipid particles down to the submicron range. Other methods are the solvent emulsification–evaporation method and the microemulsion-based preparation (381). The first is a method to prepare nanoparticles by precipitation in o/w emulsions. The second production method is based on the preparation and the subsequent dilution in cold water (2–3 °C) of a microemulsion made up of a low melting lipid, an emulsifier, a coemulsifiers, and water. Following preparation, as for other colloidal carriers, the determination of the mean size, size distribution, and zeta potential of SLN is necessary to define their physicochemical properties.

Formulative Aspects of SLN. Evaluations on the degree of crystallinity and lipid modifications are very important for

SLN. In fact, the organization of lipids into a crystalline reticulate is fundamental for the determination of the drug encapsulation and release rates. In general, if the lipid matrix is made-up of pure molecules (i.e., tristearin or tripalmitin), a perfect crystal with few imperfections, is formed. As incorporated drugs are located between fatty acid chains, in crystal imperfections, and between the lipid layers, a highly ordered crystal form cannot accommodate large amounts of drug (382). Also, the lipid modification influences the encapsulation and release degree of a drug. In fact, glycerides exist in three different polymorphic forms: α , β' , and β . The degree of reticulate imperfection of the lipid decreases in this sequence: $\alpha < \beta' < \beta$. Lipid nanoparticles recrystallize at least partially in the α -form, but with increasing formation of the more stable β'/β modifications, the lattice is becoming perfected, the number of imperfections decreases, and drug is expelled from nanoparticles.

The coexistence of additional colloidal structures, such as micelles, liposomes, and supercooled melts, has to be taken into account after the preparation of SLN; the quantification of these additional structures is a serious challenge because of their size similarities with those of the SLN. Therefore, it would be desirable to use methods that are sensitive to the simultaneous presence of different colloidal species. Both NMR and ESR techniques meet these requirements.

Physical stability of SLN dispersions is generally >1 year (383), up to 3 years in the case of SLN made of glyceryl palmitate. The storage stability of SLN depends on two factors: (1) the physical modification of lipid structure ($\alpha \rightarrow \beta'/\beta$); (2) the presence of additional colloidal structures (liposomes, micelles, drug nanoparticles).

Gelation phenomena, that is, increase of particle sizes and drug expulsion from the lipid carrier, are the major problems of storage stability. Gelation is the transformation of a low viscosity SLN colloidal dispersion into a viscous gel. It occurs when SLN is put in contact with other surfaces and shear forces, and it is connected with crystallization processes. This destabilizing phenomenon can be retarded or prevented by the addition of coemulsifying surfactants with high dynamic mobility, such as glycocholate (381).

The increase of particle sizes is a consequence of particle aggregation and it is less significant when SLN have a zeta potential value of -25 mV, while it becomes an important phenomenon when the zeta potential is -15 mV or less (381).

Drug expulsion is related to crystallization of lipids and their modification to the β'/β form, in which the lipid lattice is packed in a more ordered way with a reduction of imperfections.

To have an optimal storage conditions, SLN can be lyophilized or spray-dried. During lyophilization, a colloidal lipid dispersion is deprived of its solvent to guarantee a better chemical and physical stability. However, two transformations in the formulation occur during and after this process, which might be the source of additional stability problems: (1) passage of SLN from an aqueous dispersion to a powder with possible changes of osmolarity and pH; (2) resolubilization that favors particle aggregation. To overcome these problems, a cryoprotector (e.g., trehalose,

sorbitol, mannose, and glucose) is added to the SLN dispersion before lyophilizing. These protective agents are used in a 10–15% (w/v) concentration and act to decrease the osmotic activity of water and favour a glassy state of the frozen sample (384).

Spray drying is an alternative method to transform an aqueous SLN dispersion into a dry product. It is cheaper and simpler than lyophilization, but has the disadvantage of needing high temperatures, which can cause particle aggregation. Therefore, it is recommended to use lipids with melting points $>70^{\circ}\text{C}$ for spray drying. Also, in this case the addition of cryoprotective agents may be useful to prevent particle aggregation.

Drug incorporation into SLN is related to crystalline modification of the lipids and is inversely proportional to the β'/β modification of lipids. Depending on the drug/lipid ratio and solubility, the drug is located in the core of the particles, in the shell, or dispersed throughout the matrix, so that drug loading capacity of conventional SLNs is generally from 25 up to 50% (381). The drug-loading capacity is higher for lipid mixtures with different acyl chain lengths than for lipids that form a perfect crystal with few imperfections and cannot accommodate large amount of drug.

The release profiles could be modulated showing a burst release followed by a prolonged release, or generating systems without any burst release at all. The release kinetic can be controlled by modification of the preparation procedures and the type of surfactant and lipid material.

Therapeutic Applications of SLN. Due to their small sizes, SLN may be administered through every route: oral, transdermal, and IV administration can be possible.

The SLN for oral administration may include aqueous dispersions or conventional dosage forms (e.g., tablets, capsules, and pellets). Camptothecin-loaded particles are an example of orally administered SLN. This is a stearic acid/Ploxamer 188 formulation of SLN that present a zeta potential value of -69 mV and an encapsulation efficiency of 99.6%. The incorporation of camptothecin into SLN provided drug protection from hydrolysis (381). A better bioavailability, prolonged plasma levels, and lack of nephrotoxicity are observed for orally administered SLN encapsulating drugs, thus leading to the conclusion that SLN are a promising sustained release system for the oral administration of lipophilic drugs (381,385).

The SLN are formulated into creams, hydrogels, or ointments before their application onto the skin and form an adhesive film upon the skin, which is able to restore the protective action of the naturally occurring hydrolipidic skin film when it is damaged. Many different cosmetic ingredients have been encapsulated into SLN (i.e., coenzyme Q_{10} , vitamin E, and retinal) (386). A modern approach to an intelligent release of the drug from SLN to the skin is related to lipid modification from the α to the β form. An intelligent drug-loaded SLN is a colloidal system that maintains itself into the more energetic α -form during storage, while transforming into the β -form after application onto the skin, thus releasing its incorporated drug by expulsion from the lipid crystalline reticule. The SLN per se also have a sun protective effect (387) that is due to their particulate nature and their ability to scatter UV light. In

this case, SLN show a synergistic effect if formulated with a molecular sunscreen, also showing better skin protection and a reduction in side effects.

It is possible to use SLN for pulmonary drug delivery since they maintain their particle size and polydispersion index after nebulization. Only very little aggregation could be detected, which is of no significance for pulmonary administration (388). In addition, SLN may be used as a powder for inhalation. The use of SLN instead of polymeric nanoparticles has many advantages, such as high tolerability, faster degradation, and passive targeting toward lung macrophages.

The SLN can be injected intravenously and used to target drugs to particular organs. They also can be administered intramuscularly or subcutaneously. When administered subcutaneously, SLN act as a depot of the drug, while they are cleared from the circulation by RES (liver and spleen) when administered intravenously. The incorporated drug is released upon erosion by diffusion from the particles or by enzyme degradation. Obviously, in the case of IV administration, the SLN size must be $<5\ \mu\text{m}$ to avoid the possibility of embolism into the fine capillaries. Similar to any colloidal drug with a small mean size ($\leq 200\text{ nm}$), SLN have been coated by polyoxyethylene in order to achieve long circulating colloidal lipid particles (389). Stealth SLN can be prepared by using Pluronic F188, a block poly(oxyethylene/polyoxypropylene) copolymer that anchors its hydrophobic portion in the SLN lipid matrix, while the hydrophilic portion forms the hydrophilic coating of SLN. Stealth SLN can be used in tumor and antibacterial therapy. Paclitaxel-loaded SLN provided a higher and prolonged plasma level of the drug with respect to the cremophor EL-based commercial formulation with a consistent reduction of side effects (381). In all the investigated cases, SLN containing an anticancer drug showed higher blood levels with respect to the relative commercial drug formulations after IV injection.

The therapy at the level of the brain is always difficult due to the presence of the blood–brain barrier, and hence the possibility of having a suitable drug delivery system that is able to reach the brain can be extremely useful. Stealth SLN allow brain delivery of drugs that are not capable of passing through the blood–brain barrier (390).

The potential SLN toxicity has to be considered as a function of the administration route. Topical and oral administration are absolutely nonproblematic because all excipients used in SLN formulations are those currently employed for the formulation of traditional dosage forms or cosmetic products. The situation is slightly different for parenteral administration. In this case, only surfactants accepted for parenteral administration can be used (e.g., lecithin, Tween 80, PVP, Poloxamer 188). Up to now, there is no SLN product for parenteral use on the market. However, SLN show a very good tolerability both *in vitro* and *in vivo* (381).

Nanostructured Lipid Carrier. The NLC were introduced at the end of the 1990s in order to overcome some limitations of SLN: (1) too low payload for a number of drugs, (2) drug expulsion during storage, (3) high water content of SLN dispersions.

Figure 56. Schematization of the three types of NLCs.

The NLC are made up of very different lipid molecules mixed together, that is, a blend of solid with liquid lipids (oils). The resulting matrix of the lipid particles shows a melting point depression compared to the original solid lipid, but the matrix is still solid at body temperature. There are three different models of NLC, depending on the way of production and the composition of the lipid blend (Fig. 56). In the first model, called the imperfect type, spatially different lipids lead to larger distances between the fatty acid chains of the glycerides and to general imperfections in the crystal structure, thus allowing a greater extent of drug entrapment. The second type of NLC, the so-called amorphous type, contains liquid oil nanocompartments within the lipid particle matrix. In this way, crystallization can be avoided and the solid character of NLC can be maintained as shown by NMR and DSC measurements (391). The third type of NLC, the so-called multiple type, are produced by mixing a solid lipid with a high amount of oil. In this way, a phase separation occurs between solid lipids and oil molecules thus forming nanocompartments. This phenomenon occurs during the cooling process after the hot homogenisation method.

The NLC are produced successfully by the high pressure homogenization method and it is possible to obtain particle dispersions with a solid content of 50 or 60% (392). The particle dispersions thus produced have a high consistency with a cream-like or almost solid appearance.

Because of their high particle concentrations, NCL can be used for granulation or as wetting agents in pellet production. In addition, NLC can easier be processed to traditional oral dosage forms, such as tablets or capsules (393).

These carriers have been used for dermal delivery. Similarly to SLN, they can be incorporated in to existing products or formulated in a final product containing only NLC. When incorporated into an o/w emulsion saturated with the drug, the NLC disordered structure is preserved and the drug remains inside the particles. Following skin application, and then increased temperature, water loss and NLC lipid transition to a more stable polymorphic form triggers drug expulsion. The drug expelled from NLC is supersaturated with the drug already present in the emulsion. The supersaturation phenomenon can be used to increase the skin drug permeation as observed for cyclosporine (394).

In the future, an area of particular interest can be the prolonged release of drugs after subcutaneous or intramuscular injection (e.g. erythropoietin). Also, NLC dispersions for IV injection appear feasible (395).

To overcome the important limitation of SLN and NLC to incorporate only lipophilic drugs or very low concentrations of highly potent hydrophilic drugs, lipid drug

conjugates were recently developed with drug loading capacities of up to 33% (396). In this type of lipid nanoparticle, an insoluble drug–lipid conjugate bulk is prepared using two different methods: (1) salt formation with a hydrophobic moiety (e.g., with a fatty acid) and (2) covalent linking (e.g., to ethers or ester).

FUTURE PERSPECTIVES

Drug delivery technology has had considerable advances, bringing many clinical products to the market. However, the major needs for drug delivery devices are still unmet and important classes of drugs have yet to benefit from these technological successes. The central focus of any controlled delivery devices is “control.” This can be achieved if: (1) the size of the device can be modulated as accurately as possible; (2) the device can be produced with a certain reproducibility; (3) the device is stable enough for administration purpose; (4) the device is biocompatible; (5) the rate of drug delivery should be independent of the surrounding environment. To date, it is possible to have recourse to a lot of innovative approaches characterized by different features as a function of the physicochemical properties of the delivered drug, the administration route, and therapeutic aims.

Many aspects of these drug delivery devices require an improvement to be applied to clinical use, but considering the *in vitro* and *in vivo* results, they seem to be very interesting.

From the appearance of the first drug delivery device to date, a constant improvement has been made, that is, from microtechnology we have passed to nanotechnology, and from an aspecific drug delivery, we have passed to a selective drug delivery. New challenges for the future are the feasibility of scaling-up processes to bring to the market quickly innovative therapeutic entities and the possibility of obtaining multifunctional devices that will be able to fulfill the different biological and therapeutic requirements.

DRUG INFUSION SYSTEMS

SELAHATTIN OZCELIK
Texas A&M University
Kingsville, Texas

INTRODUCTION

An infusion system can be described as the process of delivering fluids and medications in solution to patients by way of an infusion device. Intravenous route is generally

used for drug delivery; however, subcutaneous, epidural, and enteral routes are also used for special drug administration (1). Administration of medication into the patient by way of some kind of drug infusion device provides the desired level of medication in the patient and allows direct control over pharmacological variables, such as onset of drug effects and peak serum drug concentrations (1). This type of drug administration has been the choice especially for specific conditions, including the use of antibiotics for severe infection, chemotherapy for malignant conditions, cardiac medication in critical cases, and analgesics for relief of severe pain.

When curing all common medical disorders that justify therapeutic intervention, pharmacological therapy is the preferred and effective method of treatment. Device-based drug delivery systems for the administration of effective pharmacological therapy can be grouped as injection–infusion, transdermal patch-based, and inhalation systems (2). Among the established methods of injection and infusion systems are the needle and jet injection, intravascular, intraspinal, intraoperative site, and intraperitoneal–transperitoneal infusion systems. Major applications of drug infusion are anesthesia delivery, antibiotic–antiviral therapy, nutritional support, pain management, cardiovascular disease therapy, chemotherapy, diabetes management, hydration therapy, bone marrow and organ transplant support therapy, and transfusion therapy (2).

The use of powered infusion devices has grown enormously in the last two decades. Infusion pumps together with an appropriate administration set provide an accurate flow of fluids over a prescribed time period. The simplest devices are the gravity controllers, in which the flow of liquid under the force of gravity is regulated by clamping action. More complex infusion systems include a positive pumping action for infusion (3). Volumetric pumps possess a linear peristaltic pumping mechanism. Syringe pumps work by pushing the plunger of a disposable syringe along at a predetermined rate. The type of pump used depends on the required volume and speed of infusion (3).

Medication errors are a major concern of healthcare professionals and medical institutions and have been reported to contribute to between 7000 and 140,000 deaths only in the United States each year (4–9). The impact of medication errors was found to be more severe in pediatric patients (4). There are a wide variety of reasons for medication errors. Reports suggest that the most significant factor is the user errors; however, the contribution of device-related problems to medical errors cannot be underestimated. Many reports of incidents have also been received involving infusion pumps. These incidents are primarily due to over infusions and may result in patient harm or death (3). In practice, some of the common problems in drug infusion systems originate from syringe pumps. Most of the patient morbidity and mortality, being the most significant among all the problems, has happened when using syringe pumps. Another common problem with drug delivery is venous air embolisms, which can be caused by air ingress due to improper drug delivery technique, damaged equipment and tubing, leaking or loose tubing connectors, or failure to stop delivery prior to complete evacuation of IV bags. Venous air embolisms have been

observed in central venous cannulation and pressurized intravenous infusion systems (3).

Today it has been proved that technology is essential in reducing risk in medication delivery. Computerized physician order entry (CPOE) and bar code applications for drug administration are such technologies that are capable of reducing medication errors. Unfortunately, most hospitals have not yet implemented these systems; therefore, many errors that otherwise might be eliminated continue to put patients at risk (10). Computerized intravenous (IV) infusion devices, so-called smart pumps include software that incorporates dosage limits established by the medical institution, warnings when dosage limits are exceeded, configurable settings by patient type, and access to transaction data for quality improvement efforts. Such systems make it possible to provide an additional verification at the point of care to help prevent IV medication errors (11). The Institute for Safe Medication Practices and the Emergency Care Research Institute recognize safety systems for IV medication as vital to reducing medication-related errors (10,12). A couple of examples utilizing a new technology is MEDLEY from Alaris Medical Systems and COLLEAGUE CX by Baxter Healthcare Corporation. These infusion systems allow hospitals to enter various drug infusion protocols into a drug library with predefined dose limits. For example, if a dose is outside the programmed range or clinical parameters, the pump halts or informs the physician by providing an alarm. Some pumps are even capable of integrating patient monitoring and other parameters, such as patient's age or clinical condition. More and more manufacturers are bringing similar devices to market (10).

The aim of this section is to provide a review on drug infusion systems, basic operational principles of pumps used in such systems, new infusion devices that are being developed, and recent developments for the control of infusion devices. With this goal in mind, this section is organized as follows: The section Common Infusion Systems presents most commonly used infusion systems and their operational principles. In the section, New Developments in Drug Infusion Systems, smarter, smaller, reliable, and cost effective new infusion devices, which are currently under development, are reviewed. Since the performance of any automated system highly depends on its controller structure, most recent research work on the control of drug infusion devices is reviewed in the section

Recent Advancements in Controller Design for Drug Infusion Systems.

COMMON INFUSION SYSTEMS

Any drug infusion system requires some kind of control unit in which necessary parameters are monitored continuously so that the drug is delivered to the patient in a desired manner. Infusion devices range from very simple mechanical devices based on elastic containers, springs, and flow restrictors to sophisticated microprocessor controlled pumps. The choice of an infusion device depends on both the type of therapy to be applied and patient characteristics. Some IV infusions can safely and effectively be delivered via gravity drip systems, while others require sophisticated microprocessor controlled pumps for more precise control, positive pressure, and greater flow rate range. Traditionally, these devices are used in hospitals for the controlled delivery of drugs and fluids. However, as these devices become smarter with the use of new technology, more and more patients are using them for home therapy.

Therefore, the use of infusion pumps is increasing in the community. To ensure that a patient receives the correct dose, the appropriate infusion device should be chosen for the drug. Syringe pumps are commonly used at low rates of infusion, but may not be suitable for drugs that require constant blood levels (13). It is required that any infusion system be able to reliably deliver the prescribed drug dose-volume to the patient, at pressures that overcome all baseline and intermittent resistance, while causing no harm to the patient. Additive resistances, such as the small bore and kinking potential of connecting tubing, cannula, needles, and patient vessels, make infusion flow difficult. Filters, viscous solutions, and syringe stiction can also adversely affect the infusion flow. Therefore, infusion pumps are required to overcome these resistances and accurately deliver prescribed drugs to patients. These pumps must be capable of delivering infusions at pressures of between 100 and 500 mmHg (2–10 psi or 13.79–68.95 kPa) (13). Ideally, pumps should also reliably detect the infusion pressure and the presence of air in the line close to the patient vessel being infused. Table 1 provides pressure ranges for IV pump pressure settings. Infusion devices can be classified according to their power source as gravity controllers and infusion pumps.

Table 1. Pressure Ranges for IV Pump Pressure Setting^{a,b}

Pressure, mmHg	Example	Pressure, psi
2–20	Central venous pressure range	0–0.4
10–30	Peripheral venous pressure range	0.2–0.6
100	Extravasation risk	2
100–150	Systolic arterial pressure range	2–3
75	Gravity pressure of fluid 100 cm above cannulation site	1.5
500	Highest probable pressure required by an infusion pump	10
1000	Maximum modern–Ambulatory pump occlusion pressure setting	20
3000	Common max. pressures form older peristaltic pumps	60

^aSee Ref. 14.

^b1 mmHg = 1 psi = 6.89 kPa.

Figure 1. Common gravity drip infusion device.

Gravity Drip Systems

The simplest infusion device is the gravity drip system in which a bag or bottle is hung on a hook of a pole sufficiently high from the level of the patient. Figure 1 shows a typical gravity drip infusion system. The fluid flows by gravitational force down the line and into the catheter. They are quite suitable for lower risk applications, including fluid replacement therapy, provided that the required flow rate is achieved by the delivery pressure of the device (4). Gravity controllers are based on gravity to provide the infusion pressure. Therefore, in order to achieve the desired flow rate, the fluid container is placed sufficiently high above the patient's heart. A drop sensor monitoring the drip rate is attached to the drip chamber of the administration set. The rate of flow in a simple gravity drip system is controlled by a special clamp or valve on the line that can be manually adjusted to permit the prescribed amount of fluid to flow through (usually described in drops per minute).

These devices range in complexity and ease of operation from roller and slide clamps to more sophisticated rotating valves. Compared with slide and roller clamps, rotating valves are less awkward to manipulate and provide a more consistent flow rate. However, even the most sophisticated manual drip valve cannot offer precise flow control, due to the viscosity of the solution being infused. Another factor to be taken into account is the second flow control caused by the size of the needle at the end of the line through which the fluid flows into the catheter. The smaller the needle is the slower the maximum rate of flow into the body (15). These types of devices are quite effective in controlling overinfusion; however, control of underinfusion would not be satisfactory due to increased resistance to flow. One way to avoid this problem is to use a drip rate controller with a visible flow status system (14). The pressure available from a bag of saline is equal to the height that the bag is above the patient's heart. Drip rate controller is a type of gravity controller, in which the desired flow rate is set in drops per minute and controlled by occlusion valves powered by electricity. All models of drip controllers have a drop sensor. More advanced models incorporate a flow status system, which gives a visual indication of resistance to flow (4). The required number of drops delivered by gravity controllers is controlled by the drop counting mechanism that is quite accurate. However, the actual amount of volume delivered to patients may vary because of error involved when converting the number of drops to milliliters (mL). Conversion chart values for drops \cdot mL⁻¹ are approximate and a small error made for each drop may result in a large difference in the entire volume of drug delivered.

The volume of fluid in a drop depends on several factors, some of which are the fluid's composition, temperature and

surface tension, the drip rate set, the size, shape, and condition of the drop-forming orifice (3). Expected nominal volume for a drop is 20 drops \cdot mL⁻¹. This nominal rate can easily be achieved for most simple aqueous solutions of electrolytes, lactates, or dilute sugars. However, due to the viscosity characteristics of parenteral nutrition mixtures, fat soluble vitamins and solutions containing alcohol, the drop volume will be lower than nominal resulting in longer infusion time (3). Naturally, with all fluids, the drop volume decreases as the delivery rate increases. These variations are acceptable for the majority of infusions. However, if the volumetric accuracy is critical, then an infusion pump must be used (3).

There is a standard formula for calculating the flow rate on any type of IV tubing as follows:

$$(V \times df)/t = \text{drops min}^{-1}$$

t = time to be infused (in min); V = volume of solution to be infused; df = drop factor of solution set (drops mL⁻¹); (mL \times drop factor)(min⁻¹) = drops min⁻¹.

If the result of the calculation includes a decimal point, round-off to the nearest.

Electronic controllers provide better accuracy for the regulation of flow by controlling uneven or runaway flow of fluid in a gravity drip system. These electronic devices are equipped with a drop sensor to monitor flow rate and can detect infiltrations and mal-positioning of the catheter or IV tubing by measuring backflow. An alarm sounds when flow rate is altered or when backflow is detected.

The gravity drip is conceptually simple, inexpensive, and requires less equipment than most other infusion systems. In the home setting, however, it has some limitations. First, it is difficult to maintain a constant infusion rate in a gravity drip system due to factors, such as the decreasing volume of fluid in the bag (i.e., the infusion rate will decrease as the bag empties) and changes in the shape of the tubing around the clamp. Consequently, a gravity system may provide insufficient flow control for drugs that require a very slow, very precise, or very long infusion time. Second, errors in using the gravity drip that remain unnoticed can result in serious complications (15). In addition, a gravity drip system may be an inappropriate choice for certain patients due to functional limitations of the patients or their caregivers. Because the IV bag is suspended well above the catheter site in this system, patients with decreased mobility may have difficulty changing the bag. Ambulatory patients on continuous infusion may also find gravity drip frustrating because the system is not easily portable. Despite the drawbacks of this traditional method of IV administration, it does maintain some important functional advantages over more expensive electronic infusion devices discussed below. Because the drugs are

forced into the vein under the pressure of gravity alone, there may be less irritation at the catheter site, especially peripheral catheter sites. Gravity drip systems may also be preferred for patients who are confused by and resistant to learning how to use more complex, computerized drug delivery systems (15).

Infusion Pumps

An electronically controlled device that could deliver constant and precise amounts of fluid over a specified time period was a major technological advance in infusion therapy. Although many therapies can be delivered safely and effectively via gravity drip systems, others require the highly precise and constant flow rate offered by electronic infusion devices (15). For example, intraarterial infusions usually require positive pressure pumps because the back pressure is higher in arteries than in veins (15). Volumetric or syringe pumps are the most common. Other methods include elastomeric, pneumatic, implantable, clockwork, or spring (3). They are used to accurately administer intravascular drugs, fluids, whole blood, and blood products. These pumps can administer up to 2000 mL of fluid (normally from a bag or bottle) at flow rates of 0.1–2000 mL · h⁻¹.

Volumetric Pumps. Most volumetric pumps will perform satisfactorily at rates as low as 5 mL · h⁻¹. However, these pumps are generally not used for delivering drugs at rates <1 mL · h⁻¹, even though the device can be set to such low rates. The rate is in milliliters per hour (mL · h⁻¹) or micrograms per kilogram per hour (μg · kg⁻¹ · h⁻¹) (3).

Most volumetric pumps have the feature of automatic alarm and shut down in case air enters the system, an occlusion is detected, or the reservoir is empty. The device controls the total volume to be infused and provides digital read-out of volume infused. Some of the other features include automatic switching to keep the vein open (KVO) rate at the end of infusion; switch to internal battery operation automatically if the mains supply fails; micro and macro delivery modes; computer interface; operator call alarm; a drop sensor—used for monitoring and alarm purposes (e.g., as an empty container) rather than as a control of the delivery rate; primary and secondary infusion capability; technical memory log for incident analysis. Features, such as air-in-line detection or a mechanism that cannot pump air and comprehensive alarm systems, make IV infusion much safer (3).

Most infusion pumps work by peristaltic action, which is achieved by alternately squeezing and releasing the tube containing the fluid to force the fluid through at a predetermined rate. There are two types of volumetric pumps: peristaltic and dedicated cassette. Peristaltic mechanisms can be further classified as linear peristaltic and rotary peristaltic. Both mechanisms consist of fingers, cams, or rollers that pinch off a section of the set. In linear peristaltic mechanisms as seen in Fig. 2, cams are located on a camshaft. Required volume is delivered to the patient by pinching off each section as the shaft rotates. These mechanisms are commonly used. In rotary peristaltic mechanisms, as seen in Fig. 3, rollers are placed on a

Figure 2. Schematic of a linear peristaltic pump (3) © CROWN COPYRIGHT.

Figure 3. Schematic of a rotary peristaltic pump (3) © CROWN COPYRIGHT.

hub and as it rotates the volume in each pinched off section is delivered to the patient. The volume delivered varies according to the size of the cams, rollers, the tube, and the speed at which they rotate. These mechanisms are usually designed for a particular administration set (3).

Another mechanism used in infusion pumps is the dedicated cassette mechanism. Commonly, these types of pumps consist of a cassette body in which a valve and cylinder are placed, a piston, valve actuator, and a crank mechanism. This type of pump is depicted in Fig. 4. Drug is sucked to the cylinder from a bag or a container as the piston moves down and it is pumped to the patient through

Figure 4. Dedicated cassette set (3) © CROWN COPYRIGHT.

a valve as the piston moves up (3). Although volumetric pumps can develop high pressures, they generally have a preset default value. In determining what pressure level is to be set, one needs to determine the factors of pressure raisers and calculate the needed pressure. However, it is important that the occlusion pressure should be set to the lowest possible value in order to observe early warning of occlusions.

A specific type of infusion set is required when using volumetric infusion pumps in order to achieve satisfactory drug delivery and to detect occlusion pressure. If an infusion set other than the required one is considered to be used, then extra care must be given when configuring the pump for that infusion set. Although using incorrect sets might seem to operate satisfactorily, this may be misleading and the actual performance and accuracy of drug infusion would be far from the desired level. This would lead to severe consequences. Air-in-line detectors use ultrasonic or optics for detecting air bubbles in the line. Air-in-line and occlusion detectors are designed for use with a particular infusion set. Therefore, these detectors may not be working properly if an incorrect set is used. Some other unwanted results are underinfusion due to very small inner-diameter of tube; overinfusion due to tubing material that is not flexible enough; and wear or rupture of tube from pumping action due to tubing material that is not strong enough. It is therefore important to use recommended sets for infusion. Specifications for testing of pumps at maximum flow rates are currently not given by the international standard for infusion devices. Therefore

some fall-off in performance at high flow rates should be expected (3).

Most infusion pumps used today are modern, sophisticated versions of one of these two types of pumps. With the development of small, portable pumps with specialized uses for particular types of therapies and adaptations, these pumps are being used commonly by nonprofessionals as part of home therapy. Because computerized pumps can deliver medication at a wide range of dose frequencies and intensities, they broaden the scope of therapies that can be safely and effectively administered at home.

Pumps specifically for the infusion of narcotics to treat cancer-related pain, for example, may have adaptations that provide a low level of ongoing infusion, but also permit patients to dose themselves with bursts of medication when pain becomes intense, up to a preprogrammed number of such extra doses per day. Other pumps, designed for the volume of fluid typical of most antibiotic therapy, can be preprogrammed to deliver infusions at standard intervals (e.g., four times per day), thus enabling patients to sleep undisturbed while receiving therapy. Pumps used for long-term IV nutrition administration, on the other hand, may be designed to administer the large volume of fluid required for the overnight infusions typical of patients receiving this therapy. Infusion pumps currently available range from very simple, single-medication stationary infusion pumps to fully programmable, ambulatory pumps.

Sophisticated pumps can deliver multiple medications and are equipped with a variety of alarms, bells, and other warning mechanisms. While stationary pumps may be appropriate for patients who are bedridden or whose medications are delivered over shorter periods of time, ambulatory pumps provide greater independence for patients on continuous, frequent, or long-term therapy regimens. Many pumps also have automatic piggyback mechanisms that control secondary infusions at an independent rate, decreasing the nursing time required for multiple infusions (15). Besides these benefits and advancements, infusion pumps do have certain disadvantages. If patients, caregivers, or even health professionals find the level of sophistication of these pumps confusing, the patients' safety could be jeopardized through misuse of equipment. Many patients, and the nurses who instruct and care for them, might prefer simpler models that are easier to operate. Even many hospital nurses are unfamiliar with or unaware of sophisticated features of pumps they use on a regular basis. Highly sophisticated pumps cost more and often require considerably more training for both the health professional and the patient than simpler models. New types of electronic infusion pumps are constantly evolving, widening the menu from which providers must choose and from patients and health professionals must learn to operate.

Syringe Pumps. In this type of pump, drug is pumped forward in the tubing by a syringe-type pushing action. Schematic drawing of a syringe pump is depicted in Fig. 5. The syringe is placed in a housing of the pump, while syringe plunger is attached to a moving carriage. The carriage is attached to the lead screw through a nut,

Figure 5. Typical syringe pump (3) © CROWN COPYRIGHT.

and the lead screw is attached to the motor through a gearbox. As the motor rotates, lead screw forces the carriage to slide on the guide, resulting syringe plunger to move forward in the syringe. This forward action delivers the drug to patient and empties the syringe. Controlled rate for the delivery of a drug is ensured by controlling the motor speed and rotation. This controlled rate may be in steps or continuous.

Advanced syringe pumps permit the simultaneous administration of several different therapies at different intervals, with dosages and administration regimens pre-programmed on a microchip that fits in the back of the pump. Syringe pumps can deliver small volumes of drugs at low flow rates. Single-use syringes are inexpensive and mass manufactured items, and are not meant to be highly accurate. When used in a syringe pump at low plunger speeds, the friction between the syringe plunger and the barrel causes a jerking effect and the fluid is delivered as a series of small boluses. The fit between the plunger and the barrel may vary from batch to batch and, consequently, the jerking effect may also vary. This problem is commonly known as stiction. In general, the bigger the syringe and the lower the flow rate, the more pronounced the stiction. Stiction may not be a problem with drugs having a long half-life or that do not require steady blood levels in the short term, such as heparin or insulin. In contrast, the delivery of powerful drugs with short half-life, like catecholamines, at rates under $5 \text{ mL} \cdot \text{h}^{-1}$ from large syringes ($>30 \text{ mL}$) is not recommended.

Some currently available peristaltic pumps provide reasonably smooth flows at low delivery rates and should be considered as an alternative. Occasionally, the dimensions of a particular model of disposable syringe may be changed by the manufacturer. As a safe practice, only the syringe recommended by the manufacturer should be used with a syringe pump. These pumps are suitable for lower volume and low flow rate infusions. It is important to note that the actual drug delivered at the beginning of infusion process may be considerably less than the preset value. Due to the backlash, especially at low flow rates, it takes some time for the flow rate to reach steady-state regime.

Syringe pumps vary according to their functionality and so do their features. More advanced and expensive models have many features, including delivery pressure displays and in-line pressure monitoring. In most recent advanced

pumps, one can set occlusion alarm pressures to very low values. This feature helps patients to prevent hazards due to occlusions by the alarm signal from the system in shorter times. These advanced pumps may also prevent the delivery pressure rising to unwanted high values. Since these devices are powered externally, placing them approximately at the patient's level will suffice for the pump to work satisfactorily. In fact, if the pump is placed well above patient's level, some draining could result.

Implantable Pumps. Some therapies that require very small drug dosages can be administered by way of totally implantable pumps. Insulin delivery, continuous epidural morphine administration for chronic pain management, and continuous venous antineoplastic therapy infusion for liver cancer patients are some examples where implantable pumps are used. The only service directly related to infusion therapy for these devices is refilling of the pump's reservoir, which may be done weekly or even less frequently in a medical outpatient or home setting (15).

Patient Controlled Analgesia (PCA) Pumps. These pumps are designed specifically for use in PCA. Unlike a general-purpose infusion pump, these pumps allow the patients to deliver the drug on their own by operating a switch or pressure pad connected by a cord to the pump. It is important that free-flow is prevented. These pumps can be connected to a computer or printer and have a memory, where data in terms of usage is stored. This feature allows the clinician to review when, how often, and how much of drug infused by the patient. The PCA pumps are typically syringe pumps, since the required drug to be infused can usually be supplied in a single-use syringe. Some PCA pumps are based on volumetric designs, in which a battery powered volumetric pump has a disposable internal fluid reservoir. The PCA pumps can be disposable (pneumatic and elastomeric) or nondisposable (3). The PCA pumps can be programmed by clinical staff in different ways. Options include loading dose, continuous infusion (basal rate), continuous infusion with bolus on demand, bolus on demand only, with choice of units (mL or $\mu\text{g} \cdot \text{mL}^{-1}$, etc.) and variable lockout time, drug concentration. Once programmed, a key or software code is needed to access control of the pump. In some cases, patients are given limited access in order to change some parameters.

Elastomeric Infusers. Elastomeric infusers are devices that can be used as substitutes for infusion pumps. These infusers consist of disposable containers with inner-elastic bladders that can be filled with the medication. The devices are sold empty and are filled by the pharmacist through a port at the top of the bladder. The drug flows through an opening at the base of the bladder membrane and into the tube leading to the patient. The force of the flow, and thus the rate of infusion, is determined by the elasticity of the bladder and the concentration of the drug, regardless of whether the bladder is above, below, or on level with the IV site. Different drugs and dosages require devices of differing size and bladder membrane composition. Most devices currently on the market are designed for either antibiotic or antineoplastic therapy administration. They can be used

for IV, intraarterial, and subcutaneous administration of drugs.

A patient on a twice-a-day regimen of home IV antibiotics would use two infusers per day, while a patient on continuous antineoplastic therapy might use a single device for several days at a time. Some devices allow patient-controlled administration of bolus doses above and beyond the continuous infusion rate. A disadvantage to the use of these devices for patient-controlled analgesia is the lack of a memory function that can record the frequency of patient-requested bolus doses, like that found in some electronic infusion pumps. Bladder devices are also not appropriate for multiple drug regimens. According to one home infusion provider, the availability of disposable elastomeric infusion devices has increased the feasibility of home-based care for disabled elderly patients. Like sophisticated electronic infusion pumps, these devices can deliver a precise dose over a specific period of time. However, because they are self-contained and much simpler to operate, they may be less confusing for patients who are uncomfortable with high tech equipment. The patient or caregiver need only hook the device to the catheter at dosing time and disconnect and dispose of it when the dose has been completed.

Anesthesia Pumps. These are also syringe-type pumps designed particularly for anesthesia infusion. Operating of these pumps is limited to theaters and high dependency areas. It is possible that the rate and other functions can be adjusted during infusion. Their flow rates are normally much higher than the typical syringe pumps rate. It therefore allows quick delivery in a single operation. These pumps can be interfaced with a computer and have built-in drug libraries. They are embedded with a drug-specific smart card and can be programmed for drug concentration and patient's body weight. The pump is automatically configured for the drug being infused. If the pump is to be used for other applications, automatically built-in features for specific application must be disabled.

Ambulatory Pumps. These pumps are designed so that patients can continue their drug therapy away from the hospital. These pumps allow patients to continue their normal life while treatment is being given. For ease of use and carry they are light and small in size, and are powered by battery. Alarming features of these pumps are not fully provided due to limitation in their size; therefore, their use in therapies in which precise flow is required for critical drugs is not recommended. The main mechanism used in these pumps is the syringe or cassette type.

Therapies that can be administered by ambulatory pumps include analgesia, continuous and PCA, antibiotic or antiviral infusions, chemotherapy, and hormone delivery. Back pressure, temperature of the flow-limiting element, temperature, and viscosity of the fluid are such factors that determine the accuracy of ambulatory pumps. One type of ambulatory pump manufactured by Baxter is given in Fig. 6. Depending on the pumping mechanism used, flow rates can range between 0.01 and 1000 mL · h⁻¹. Different models have different features. Flow rates can be set in millimeters per hour or day, milliliters per hour or day. They can also be programmed for different delivery modes (3). Ambulatory pumps are generally powered by electricity. Accuracy and alarming features will be limited if the pump is not powered by electricity. The pumping mechanism is generally the same mechanism used in volumetric and syringe pumps.

Some ambulatory pumps are reusable. They consist of a syringe that is operated by pressurized gas, usually carbon dioxide or a precompressed spring. In the case of a pressurized-gas-operated system, the force generated by the pressurized gas pushes the syringe plunger. As the syringe plunger moves forward, it infuses the drug to the patient. The infusion rate is determined by the pressure of the gas as well as the rate at which pressurized gas is released. When the infusion is completed, syringe and gas cartridges are thrown away and the rest of the device is kept for future use. Infusers and bolus-only analgesia devices controlled by the patient are of disposable devices. They

consist of a calibrated bolus chamber that is filled from an elastomeric reservoir or syringe by a capillary tube (3).

There are a number of companies that manufacture a variety of drug infusion systems. Some of the state-of-the-art products are given in Fig. 7–11. Abbott Laboratories' hospital products business (now Hospira), introduced the Plum A+ IV drug delivery medication management

system. This system is an innovative infusion system for electronic control of intravenous medication administration. It is used for standard, piggyback, or concurrent delivery and are suitable for a wide range of medical-surgical and critical care applications

NEW DEVELOPMENTS IN DRUG INFUSION SYSTEMS

Advances in science and technology result in new materials and devices. These materials and in particular electronic devices allow engineers to develop smarter, better performed, smaller, reliable, and cost-effective products. Therefore, new drug infusion systems are being developed and increasingly used in hospitals as well as in home therapies. Some of these developments are summarized in the following list.

Automated Syringe-Filling System: Stanford Research Institute's (SRI) drug delivery system expertise is to develop a compact, home device for diabetics that would help them fill their insulin syringes accurately. The system needed to handle both long- and fast-acting insulin formulations and needed to be easy to use and reliable for elderly and vision-impaired patients. The SRI developed an automated system that stored both types of insulin, automatically resuspended the long-acting insulin, checked for adequate drug supply, dispensed the proper amount of medication, and kept a dosage record. The system is under test and evaluation (16).

Disposable Drug Infusion Pump: Medical devices and pharmaceutical companies working with SRI to reengineer a disposable drug infusion pump design that reduced the number of parts by 30%, and reduced cost (16).

Tiny Drug Infusion System: A tiny meter in a belt will someday monitor dosages of up to 12 drugs needed around the clock by patients with diabetes, cancer, or acquired immune deficiency syndrome (AIDS). The dime-sized device is being developed by Integrated Sensing Systems Inc. The device will make sure patients are receiving the correct drug in the right volume at the right flow rate. It will hook into a drug controller that attaches to a patient's belt. The controller, $\sim 2.5 \times 1$ in., (6.35×2.54 cm) will deliver drugs from an attached reservoir to the patient. The system, as envisioned, will

Figure 10. The Ipump Pain Management System by BAXTER can be programmed for epidural, IV, or subcutaneous delivery. The PCA doses can be set per hour. Control flow rates can be set in $0.1 \text{ mL} \cdot \text{h}^{-1}$ increments for maximum flexibility with continuous flow rates up to $90 \text{ mL} \cdot \text{h}^{-1}$.

Figure 11. This AITECS by EO Systems is a multipurpose syringe pump with flow rates from 1 to $1500 \text{ mL} \cdot \text{h}^{-1}$, can be used for any nuclear cardiology and nuclear medicine infusion.

simultaneously deliver up to 12 drugs in units as small as nanoliters, or billionths of a liter (17).

Bar-Coded Infusion System: B. Braun Medical has introduced the Horizon Outlook IV Safety Infusion System. Braun notes that the most common source of human error is inaccurate manual programming of intravenous pumps. The Braun infusion system uses bar code technology to ensure the right patient is receiving the right drug in the right dose from an “authorized” clinician. Its patented DoseScan bar code technology creates a primary level of safety, with automated checks and balances that augment the manual procedures in use today. Secondary protection is provided by its DoseGuard software, which notifies clinicians if institution defined dose limits are exceeded (18).

Coronary Micro-Syringe: EndoBionics has created the first micromedical device to inject safely through vessel walls. Using standard interventional procedures, physicians will position the EndoBionics μ Syringe (Micro-Syringe) in coronary or peripheral vessels. While the μ Syringe is closed, the microneedle is hidden and does

not injure vessel walls as it is maneuvered into place. When the μ Syringe is opened, the microneedle slides through the vessel wall to inject drugs directly to the surrounding tissue. The drugs are deposited around the outside of the vessel and diffuse inward through the vessel layers. The microscopic puncture is so small that it heals almost immediately, limiting trauma and bleeding (19).

Needleless Injection: PowderJect Technologies has developed a technology that could be considered a hybrid of transdermal and parenteral (injection): a needleless injection. The company’s device propels powder drugs with a supersonic jet of helium gas. A high pressure ampule of helium within the device is broken open, the gas flows through a cassette that is holding the powder between two membranes. The membranes rupture and the gas stream picks up the particles. The particles are propelled fast enough to penetrate the stratum corneum, the outer layer of the skin. The drug is targeted to the boundary between the epidermis and the dermis. Drugs then dissolve and either reach systemic circulation or exert a local effect. Vaccines can be picked up by antigen-presenting cells in the epidermis or by the lymph system (20).

Alza is another company that is developing technologies to deliver drugs through the skin. One of these technologies, called E-Trans, uses electrical current to deliver drugs across the skin, a process known as iontophoresis. The lead product is for the on-demand delivery of fentanyl, an opioid analgesic used for the treatment of acute pain. When a patient pushes a button on the device, current flows between two electrodes. As current flows, we get a predetermined amount of drug injected into the body. That gives a very reliable way of delivering a particular amount of drug into the body (20).

Alza is also developing what it calls Macroflux technology, which incorporates a thin titanium screen with microprojections to create mechanical pathways for drug transport. It expands the range of drugs amenable to transdermal delivery to include small hydrophilic molecules and macromolecules. It can be incorporated with the E-Trans technology or more traditional transdermal patches. One simple prototype in early exploration involves a Macroflux system where the projections have been coated with the therapeutic agent, such as a macromolecule. After application, the agent is rapidly absorbed into the skin (20).

Elan Pharmaceutical Technologies have a technology known as Medipad worn by the patient on the chest, back, or abdomen. The device is a small, plastic gas-driven pump with an adhesive backing. The adhesive is used to attach the device to the patient’s body, and a button is pressed. A needle is deployed, which enters the subcutaneous space and then delivers the drug at a constant rate until the entire content of the reservoir is expended. The first applications for this device will be in chronic pain management and in the delivery of macromolecules that have inherently short biological half-lives (20).

A Novel Device for Flow Monitoring: A novel device for blockage detection in catheters during drug delivery is designed. This device consists of a low cost disposable microfluidic chip and a nondisposable detection unit. The microfluidic chip consists of a microstructured silicon layer bonded between two glass covers using anodic bonding technology. The flow monitoring is performed by a robust light transmission method. The main component of the microfluidic chip is a movable element coupled with a spring to a base. Depending on the drug flow state the element is blocking or vacating an optical path through the chip (21).

A High Performance Silicon Micropump: A new, low cost, high performance silicon micropump has been developed for a disposable drug delivery system (22). It is reported that the pump demonstrated linear and accurate ($\pm 5\%$) pumping characteristics for flow rates up to $2 \text{ mL} \cdot \text{h}^{-1}$ with intrinsic insensitivity to external conditions. The stroke volume of 160 nL was maintained constant by the implementation of a double limiter acting on the pumping membrane. The chip is a stack of three layers, two Pyrex wafers anodically bonded to the central silicon wafer. The technology is based on the use of Silicon On Insulator (SOI) technology, silicon Deep Reactive Ion Etching (DRIE), and the sacrificial etch of the buried oxide in order to release the structures (22).

An Implantable Microfabricated Drug Delivery System: A fully implantable drug delivery system capable of delivering hundreds of individual doses has been developed by MicroCHIPS (23). This product is intended for the controlled release of potent therapeutic compounds that might otherwise require frequent injections. The device is capable of storing therapeutic drugs in solid, liquid, or gel form. It allows individual storage of discrete doses for multiple-drug regimens. Device monitoring and therapy modification can be achieved via wireless communication with an external controller. Currently, a fully implantable device contains 100 individual doses. A future device intended for human clinical trials will contain 400 doses, enough for a daily release of drug for >1 year (23).

A Water-Powered Microdrug Delivery System: A plastic microdrug delivery system has been designed by utilizing the principle of osmosis without any electrical power consumption. The system has an osmotic microactuator and a polydimethylsiloxane (PDMS) microfluidic cover compartment consisting of a reservoir, a microfluidic channel, and a delivery port. The typical dimension of the microfluidic channel is 1 cm in length with a cross-sectional area of $30\text{--}100 \mu\text{m}^2$ to minimize the diffusive drug flow while pressure drop remains moderate. Employing the net water flow induced by osmosis, the prototype drug delivery system has a measured constant delivery rate of $0.2 \mu\text{L} \cdot \text{h}^{-1}$ for 10 h, with an accumulated delivery volume of $2 \mu\text{L}$. Both the delivery rate and volume could be altered by changing the design and process parameters for specific drug delivery applications up to a few years (24).

Microflow Regulator for Drug Delivery Systems: A micro-machined flow regulator has been designed to provide a constant liquid flow rate of $1 \text{ mL} \cdot \text{h}^{-1}$ within a pressure difference of 100–600 mbar (0.01–0.06 kPa). At pressures >600 mbar (0.06 kPa) the device is designed to block the flow, preventing an overdosage of medicine. One application of this device is the replacement of the flow restrictor in an elastomeric infusion system, which will increase the accuracy and safety of the drug delivery system. This pressure compensating flow regulator is passive; hence it needs no external energy source. The device is small, lightweight, and relatively inexpensive; therefore, it could be used as a disposable unit in a microfluidic system (25).

Nanoengineered Device for Drug Delivery: A high precision device has been developed to yield long-term zero-order release of drugs for therapeutic applications. The device contains nanochannels that were fabricated in between two directly bonded silicon wafers, and therefore poses high mechanical strength. Diffusion through the nanochannels is the rate-limiting step for the release of drugs (26).

Smartdose by PRO-MED AG: This device is a safe, accurate, and simple infusion system. It is a disposable prefilled drug delivery system for enteral or parenteral controlled infusion. SmartDose is equipped with its own source of energy (chemical reaction) to dispense liquid over a specific time with a predetermined administration rate. The administration accuracy and safety is comparable with those of electronic pumps, yet the ease of use is similar to a simple infusion bag. The system is especially convenient for emergency, ambulatory, and homecare therapy, as well as for hospitalized patients (27).

Biodegradable Polymeric Drug Delivery Systems: These systems are increasingly being used for the design of temporary drug delivery systems. As these polymers hydrolyze in the body into low molecular degradation products, which are either metabolized or excreted, biodegradable delivery systems do not have to be removed after completion of release. Poly(DL-lactide-co-glycolide) (PLGA) is the most widely investigated biodegradable polyester and is widely used as a carrier polymer in parenteral sustained release formulations, either as microspheres, microparticulates or injectable gels (28).

RECENT ADVANCEMENTS IN CONTROLLER DESIGN FOR DRUG INFUSION SYSTEMS

Closed-loop system control is a technological concept that may be applicable to several aspects of critical care practice. This is a technology in the early stages of evolution and much more research and data are needed before its introduction into usual clinical practice. Furthermore, each specific application and each device for each application are sufficiently different in terms of hardware and computer algorithms (29). Studies have shown that closed-loop infusion systems may have a role in critical care

practice, improve clinical outcomes, eliminate errors due to poor performance of automated infusion devices, and provide precise, error-free drug administration. Some of the most recent works in advanced controller designs are reviewed below:

Huzmezan et al. (30) states that feedback control of drug administration is well suited to anesthetized surgical patients as well as the critically ill patients because of drugs with rapid onset times, short duration of action and small margins of safety are frequently used. The application of an adaptive predictive process control technology to drug administration will assist physicians in avoiding both overdosages and underdosages in their patients. An adaptive controller would avoid overdosing and underdosing by compensating for nonlinear drug responses as well as inter- and inpatient variation (30).

Linkens has proposed the design of a fuzzy control for patient muscle relaxation (31). With advancements in sensor and instrumentation technology, automated drug infusion systems are also evolving into hierarchical systems. Research in this area has led to a variety of control strategies ranging from simple linear controllers to complex adaptive and rule-based schemes to handle inter- and inpatient variability in drug responses (31).

For the assessment of depth of anesthesia, an intelligent system has been developed, which utilizes auditory evoked brain potentials, heart rate, and blood pressure measurements (32). Using wavelet analysis, the features within the auditory evoked signals are extracted and then fed to a learning neurofuzzy system, which in turn classifies the depth of anesthesia. In addition, the heart rate and blood pressure signals are used as a second measure based on a rule-based fuzzy logic system. The two measures are then fused to give a final indication of anesthetic depth. This is then fed back to a target controlled infusion (TCI) system for regulating the infusion of the drug Propofol for the maintenance phase of anaesthetic state (32).

A control strategy is developed by Bequette to regulate blood pressure and cardiac output during surgery (33). Adaptation is incorporated through a multiple model predictive control (MMPC) approach. A Bayesian-based estimator recursively updates weighting functions to find the best combination of models that describes the current input-output behavior; this weighted model is used for the output prediction (33).

A robust direct model reference adaptive controller (DMRAC) is developed by Palerm et al. (34) for plants with uncertainty in both the time delay elements and in the transfer function coefficients. The control of hemodynamic variables, particularly mean arterial pressure (MAP) and cardiac output (CO), is a challenging problem. A good controller is difficult to design, due to the complex, nonlinear behavior of the system. Adding to this are the significant changes in dynamics from one patient to another, and even variations in the patient's response to the drugs as his condition evolves (34).

A model predictive control strategy is developed and tested on a nonlinear canine circulatory model for the regulation of hemodynamic variables under critical care conditions (35). Different patient conditions, such as con-

gestive heart failure, postoperative hypertension, and sepsis shock are studied in closed loop simulations. The model predictive controller, which uses a different linear model depending on the patient condition allows constraints to be explicitly enforced. The controller is initially tuned based on a linear plant model, then tested on the nonlinear physiological model; the simulations demonstrate the ability to handle constraints, such as drug dosage specifications, commonly desired by critical care physicians (35).

To evaluate the use of intelligent systems in the improvement of patient care, an agent was developed to regulate ICU patient sedation by Moore et al. in (36). A temporal differencing form of reinforcement learning was used to train the agent in the administration of intravenous propofol in simulated ICU patients. The agent utilized the well-studied Marsh-Schnider pharmacokinetic model to estimate the distribution of drug within the patient. A pharmacodynamic model then estimated drug effect. The agent demonstrated satisfactory control of the simulated patient's consciousness level in static and dynamic set-point conditions. It also satisfactorily demonstrated superior stability and responsiveness when compared to a well-tuned PID controller, which is a method of choice in closed-loop sedation control literature (36).

Advanced model-based controllers that can take into account the model of the patient and constraints on the state of the patient and the drug infusion rates have been developed (32). Delivery of insulin to type 1 diabetics, control of anesthesia, and chemotherapy for cancer patients are typical examples of drug delivery systems. The main objective of a drug delivery system is to provide effective therapy while minimizing the side effects. These controllers are based upon the theory of multiparametric programming. This theory allows an optimal division of the multidimensional space of the state of the patient into a set of regions and each region is characterized by a unique drug infusion law that is an explicit function of the state in the corresponding region. These developments simplify controller implementation and result in tighter control of drug infusion rates and better lifestyle for patients (37).

Parker et al. in (38) discusses closed-loop blood glucose regulation algorithms that use the intravenous route for insulin delivery to insulin-dependent diabetic patients. Classical control methods and advanced algorithms using implicit knowledge or explicit models (empirical, fundamental, or gray-box) of the diabetic patient are examined in (38). Current research on characterizing patient variability is presented, in the context of a model predictive controller able to adjust to changes in patient glucose and insulin sensitivity (38).

Linkens in (39) presents the control of on-line drug infusions to patients in an operating theater for regulating their muscle relaxation according to necessary surgical procedures. It is stated that fuzzy logic control (FLC) offers the advantages of model-free controller design for systems that are dynamically nonlinear, uncertain, and possibly time varying (39).

Rao et al. discusses the design of two different control methodologies for automated regulation of hemodynamic variables in (40). These controllers are designed to regulate

MAP and CO in critical care subjects using inotropic and vasoactive drugs. Both controllers account for inter- and inpatient variability and handle drug infusion constraints. The first approach is a multiple model predictive controller (MMPC). The algorithm uses a multiple model adaptive approach in a model predictive control framework to account for variability and explicitly handle drug rate constraints. The second approach, a robust direct model reference adaptive controller (DMRAC) is developed for plants with uncertainty in both the time delay elements and in the transfer function coefficients, such as the drug infusion process. The controllers are experimentally evaluated on canines that are pharmacologically altered to exhibit symptoms of hypertension and depressed cardiac output (40).

Bequette (41) discusses the development of an artificial pancreas and current efforts in the control of complex systems. It is stated that advances in continuous glucose sensing, fast-acting insulin analogues, and a mature insulin pump market allow commercial realization of a closed-loop artificial pancreas. Model predictive control is discussed in-depth as an approach that is well suited for a closed-loop artificial pancreas (41).

Target controlled infusion (TCI) systems are discussed by Van Poucke et al. (42). In their work, a novel mathematical algorithm is proposed for controlling the effect site concentration using a TCI device. The algorithm limits the peak plasma concentration, thereby slowing the onset of anesthetic drug effect, but potentially ameliorating side effects. Simulations are used to examine the delay in time to peak effect for fentanyl, alfentanil, sufentanil, remifentanil, and propofol when the peak plasma concentration is limited by the algorithm. Results showed that the plasma overshoot can be reduced by 60% with only ~ 20% delay in the onset of drug effect (42).

McKinley et al. (43) compares the effectiveness of a new method of closed-loop control of blood pressure with usual manual control. In their work, closed-loop and manual drug administrations were studied. The target and observed MAP and drug infusion rate were recorded electronically. Time taken to achieve initial control; fidelity of control, and average drug dose administered were all measured. Results showed that closed-loop achieved faster initial control and greater fidelity as compared to manual control. There was no difference in average drug dose administered. It was concluded that the new closed-loop system is more effective than the usual manual control in managing acute blood pressure disturbances in the seriously ill patients (43).

The bispectral index (BIS) was used for automatic control of propofol anesthesia, using a proportional-integral-differential control algorithm (44). The performance of the controlled system was measured in patients undergoing minor surgery under propofol and remifentanil anesthesia. Anesthesia was manually induced with target-controlled infusions (TCI) of propofol and remifentanil. After the start of surgery, when anesthesia was clinically adequate, automatic control of the propofol TCI was commenced using the closed-loop system. The system provided adequate operating conditions and stable cardiovascular values in all patients during closed-loop control. The sys-

tem was able to provide clinically adequate anesthesia in all patients (44).

Brock et al. in (45) presents a study to determine the relative advantage of computer-controlled couch movement versus manual repositioning to correct patient setup error measured using an electronic portal imaging device (EPID). The speed of setup adjustment and accuracy of corrected setup were determined. Computer-controlled setup adjustment was determined to be faster and slightly more accurate than manual correction (45).

Another comparison study between computer and manual control is presented in (46) by Hoeksel et al. They investigated the effects of computer-controlled blood pressures on hemodynamic stability when compared to conventional manual control. Systemic artery blood pressures were managed either by computer or by a well-trained anesthesiologist. Hemodynamic stability was determined from the standard deviation of the MAP samples and from the percentages of time that arterial pressure was hypertensive or hypotensive. The average standard deviation of the MAP samples was smaller for the computer-controlled than for the manually controlled group. The systemic artery pressure was less hypertensive and less hypotensive in the computer-controlled than in the manually controlled group. It was concluded that, compared with manual control, computer control of systemic hypertension significantly improved hemodynamic stability during cardiac surgery (46).

The clinical applicability of administering sodium nitroprusside by a closed-loop titration system compared with a manually adjusted system was evaluated. The MAP was registered and the results were then analyzed. It was reported that the computer-assisted therapy provided better control of MAP, was safe to use, and helped to reduce nursing demands (47).

Chitwood et al. in (48) states that hypertension is common after a cardiac operation and has been treated using manually controlled doses of intravenous sodium nitroprusside. To evaluate the clinical impact of an automated closed-loop administration system on patients after cardiectomy, a prospective trial was conducted. Patients with hypertension were managed by either manual nitroprusside titration or a closed-loop automated titration system. The automated group showed a significant reduction in the number of hypertensive episodes per patient. At the same time, the number of hypotensive episodes per patient was reduced with automated closed-loop titration. Chest tube drainage, percentage of patients receiving transfusion, and total amount transfused were all reduced significantly by the use of an automated titration system (48).

A nonprogrammable and programmable insulin external pump using regular insulin on glycemic stability, the risk of severe hypoglycemia, and metabolic control in type 1 diabetic patients was compared (49). The results of the study suggest that programmable external insulin pumps, although more complex and more expensive than nonprogrammable insulin pumps, significantly reduce fasting glycemia during the day without increasing the risk of severe hypoglycemia and are safer during the night (49).

In Ref. 50, it was argued that continuous improvements in microelectronics, as well as in the development of bio-materials and stable insulin solutions, led to the availability of implantable pumps that are able to infuse insulin by the peritoneal route, in a continuous and programmable way, for several years. These systems represent the most efficient and physiological mode of insulin therapy at the present time. It was demonstrated during clinical trials that intravascular, implantable, glucose sensors using glucose oxidase were able to measure with good accuracy real-time blood glucose for several months. In their study, they performed the first trials of closed-loop insulin delivery according to sensor signal for periods of 48 h in type 1 diabetic patients. This mode of functioning appeared to be feasible and able to establish glucose control closer to physiology than the use of implantable pumps in open loop (50).

Tamborlane et al. (51) states that while treatment of Type 1 diabetes mellitus (T1DM) in children and adolescents is especially difficult, recent technological advances have provided new therapeutic options to clinicians and patients. The urgency to achieve strict diabetes control and the introduction of new and improved insulin pumps have been accompanied by a marked increase in use of continuous subcutaneous insulin infusion (CSII) therapy in youth with diabetes. Results of clinical outcome studies indicate that CSII provides a safe and effective alternative to MDI therapy, even when employed in a regular clinic setting in a large number of children (51).

PREFACE

This six-volume work is an alphabetically organized compilation of almost 300 articles that describe critical aspects of medical devices and instrumentation.

It is comprehensive. The articles emphasize the contributions of engineering, physics, and computers to each of the general areas of anesthesiology, biomaterials, burns, cardiology, clinical chemistry, clinical engineering, communicative disorders, computers in medicine, critical care medicine, dermatology, dentistry, ear, nose, and throat, emergency medicine, endocrinology, gastroenterology, genetics, geriatrics, gynecology, hematology, hepatology, internal medicine, medical physics, microbiology, nephrology, neurology, nutrition, obstetrics, oncology, ophthalmology, orthopedics, pain, pediatrics, peripheral vascular disease, pharmacology, physical therapy, psychiatry, pulmonary medicine, radiology, rehabilitation, surgery, tissue engineering, transducers, and urology.

The discipline is defined through the synthesis of the core knowledge from all the fields encompassed by the application of engineering, physics, and computers to problems in medicine. The articles focus not only on what is now useful but also on what is likely to be useful in future medical applications.

These volumes answer the question, "What are the branches of medicine and how does technology assist each of them?" rather than "What are the branches of technology and how could each be used in medicine?" To keep this work to a manageable length, the practice of medicine that is unassisted by devices, such as the use of drugs to treat disease, has been excluded.

The articles are accessible to the user; each benefits from brevity of condensation instead of what could easily have been a book-length work. The articles are designed not for peers, but rather for workers from related fields who wish to take a first look at what is important in the subject.

The articles are readable. They do not presume a detailed background in the subject, but are designed for any person with a scientific background and an interest in technology. Rather than attempting to teach the basics of physiology or Ohm's law, the articles build on such basic concepts to show how the worlds of life science and physical science meld to produce improved systems. While the ideal reader might be a person with a Master's degree in biomedical engineering or medical physics or an M.D. with a physical science undergraduate degree, much of the material will be of value to others with an interest in this growing field. High school students and hospital patients can skip over more technical areas and still gain much from the descriptive presentations.

The *Encyclopedia of Medical Devices and Instrumentation* is excellent for browsing and searching for those new divergent associations that may advance work in a peripheral field. While it can be used as a reference for facts, the articles are long enough that they can serve as an educational instrument and provide genuine understanding of a subject.

One can use this work just as one would use a dictionary, since the articles are arranged alphabetically by topic. Cross references assist the reader looking for subjects listed under slightly different names. The index at the end leads the reader to all articles containing pertinent information on any subject. Listed on pages xxi to xxx are all the abbreviations and acronyms used in the *Encyclopedia*. Because of the increasing use of SI units in all branches of science, these units are provided throughout the *Encyclopedia* articles as well as on pages xxxi to xxxv in the section on conversion factors and unit symbols.

I owe a great debt to the many people who have contributed to the creation of this work. At John Wiley & Sons, Encyclopedia Editor George Telecki provided the idea and guiding influence to launch the project. Sean Pidgeon was Editorial Director of the project. Assistant Editors Roseann Zappia, Sarah Harrington, and Surlan Murrell handled the myriad details of communication between publisher, editor, authors, and reviewers and stimulated authors and reviewers to meet necessary deadlines.

My own background has been in the electrical aspects of biomedical engineering. I was delighted to have the assistance of the editorial board to develop a comprehensive encyclopedia. David J. Beebe suggested cellular topics such as microfluidics. Jerry M. Calkins assisted in defining the chemically related subjects, such as anesthesiology. Michael R. Neuman suggested subjects related to sensors, such as in his own work—neonatology. Joon B. Park has written extensively on biomaterials and suggested related subjects. Edward S. Sternick provided many suggestions from medical physics. The Editorial Board was instrumental both in defining the list of subjects and in suggesting authors.

This second edition brings the field up to date. It is available on the web at <http://www.mrw.interscience.wiley.com/emdi>, where articles can be searched simultaneously to provide rapid and comprehensive information on all aspects of medical devices and instrumentation.

JOHN G. WEBSTER
University of Wisconsin, Madison

LIST OF ARTICLES

ALLOYS, SHAPE MEMORY
AMBULATORY MONITORING
ANALYTICAL METHODS, AUTOMATED
ANESTHESIA MACHINES
ANESTHESIA, COMPUTERS IN
ANGER CAMERA
ANORECTAL MANOMETRY
ARRHYTHMIA ANALYSIS, AUTOMATED
ARTERIES, ELASTIC PROPERTIES OF
AUDIOMETRY
BIOCOMPATIBILITY OF MATERIALS
BIOELECTRODES
BIOFEEDBACK
BIOHEAT TRANSFER
BIOIMPEDANCE IN CARDIOVASCULAR MEDICINE
BIOINFORMATICS
BIOMAGNETISM
BIOMATERIALS, ABSORBABLE
BIOMATERIALS: AN OVERVIEW
BIOMATERIALS: BIOCERAMICS
BIOMATERIALS: CARBON
BIOMATERIALS, CORROSION AND WEAR OF
BIOMATERIALS FOR DENTISTRY
BIOMATERIALS: POLYMERS
BIOMATERIALS, SURFACE PROPERTIES OF
BIOMATERIALS, TESTING AND STRUCTURAL

BJT	Bipolar junction transistor	CHO	Carbohydrate
BMDP	Biomedical Programs	CHO	Chinese hamster ovary
BME	Biomedical engineering	CI	Combination index
BMET	Biomedical equipment technician	CICU	Cardiac intensive care unit
BMO	Biomechanically optimized	CIF	Contrast improvement factor
BMR	Basal metabolic rate	CIN	Cervical intraepithelial neoplasia
BOL	Beginning of life	CK	Creatine kinase
BP	Bereitschafts potential; Break point	CLAV	Clavicle
BR	Polybutadiene	CLSA	Computerized language sample analysis
BRM	Biological response modifier	CM	Cardiomyopathy; Code modulation
BRS	Bibliographic retrieval services	CMAD	Computer managed articulation diagnosis
BSS	Balanced salt solution	CMI	Computer-managed instruction
BTG	Beta thromboglobulin	CMRR	Common mode rejection ratio
BTPS	Body temperature pressure saturated	CMV	Conventional mechanical ventilation; Cytomegalovirus
BUN	Blood urea nitrogen	CNS	Central nervous system
BW	Body weight	CNV	Contingent negative variation
CA	Conductive adhesives	CO	Carbon monoxide; Cardiac output
CABG	Coronary artery by-pass grafting	COBAS	Comprehensive Bio-Analysis System
CAD/CAM	Computer-aided design/computer-aided manufacturing	COPD	Chronic obstructive pulmonary disease
CAD/D	Computer-aided drafting and design	COR	Center of rotation
CADD	Central axis depth dose	CP	Cerebral palsy; Closing pressure; Creatine phosphate
CAI	Computer assisted instruction; Computer-aided instruction	CPB	Cardiopulmonary bypass
CAM	Computer-assisted management	CPET	Cardiac pacemaker electrode tips
cAMP	Cyclic AMP	CPM	Computerized probe measurements
CAPD	Continuous ambulatory peritoneal dialysis	CPP	Cerebral perfusion pressure; Cryoprecipitated plasma
CAPP	Child amputee prosthetic project	CPR	Cardiopulmonary resuscitation
CAT	Computerized axial tomography	cps	Cycles per second
CATS	Computer-assisted teaching system; Computerized aphasia treatment system	CPU	Central Processing unit
CAVH	Continuous arteriovenous hemofiltration	CR	Center of resistance; Conditioned response; Conductive rubber; Creatinine
CB	Conjugated bilirubin; Coulomb barrier	CRBB	Complete right bundle branch block
CBC	Complete blood count	CRD	Completely randomized design
CBF	Cerebral blood flow	CRL	Crown rump length
CBM	Computer-based management	CRT	Cathode ray tube
CBV	Cerebral blood volume	CS	Conditioned stimulus; Contrast scale; Crown seat
CC	Closing capacity	CSA	Compressed spectral array
CCC	Computer Curriculum Company	CSF	Cerebrospinal fluid
CCD	Charge-coupled device	CSI	Chemical shift imaging
CCE	Capacitance contact electrode	CSM	Chemically sensitive membrane
CCF	Cross-correlation function	CT	Computed tomography; Computerized tomography
CCL	Cardiac catheterization laboratory	CTI	Cumulative toxicity response index
CCM	Critical care medical services	CV	Closing volume
CCPD	Continuous cycling peritoneal dialysis		

C.V.	Coefficient of variation	EBS	Early burn scar
CVA	Cerebral vascular accident	EBV	Epstein–Barr Virus
CVP	Central venous pressure	EC	Ethyl cellulose
CVR	Cardiovascular resistance	ECC	Emergency cardiac care; Extracorporeal circulation
CW	Continuous wave	ECCE	Extracapsular cataract extinction
CWE	Coated wire electrodes	ECD	Electron capture detector
CWRU	Case Western Reserve University	ECG	Electrocardiogram
DAC	Digital-to-analog converter	ECM	Electrochemical machining
DAS	Data acquisition system	ECMO	Extracorporeal membrane oxygenation
dB	Decibel	ECOD	Extracranial cerebrovascular occlusive disease
DB	Direct body	ECRI	Emergency Care Research Institute
DBMS	Data base management system	ECS	Exner's Comprehensive System
DBS	Deep brain stimulation	ECT	Electroconvulsive shock therapy; Electroconvulsive therapy; Emission computed tomography
dc	Direct current	EDD	Estimated date of delivery
DCCT	Diabetes control and complications trial	EDP	Aortic end diastolic pressure
DCP	Distal cavity pressure	EDTA	Ethylenediaminetetraacetic acid
DCS	Dorsal column stimulation	EDX	Energy dispersive X-ray analysis
DDC	Deck decompression chamber	EEG	Electroencephalogram
DDS	Deep diving system	EEI	Electrode electrolyte interface
DE	Dispersive electrode	EELV	End-expiratory lung volume
DEN	Device experience network	EER	Electrically evoked response
DERS	Drug exception ordering system	EF	Ejection fraction
DES	Diffuse esophageal spasm	EF	Electric field; Evoked magnetic fields
d.f.	Distribution function	EFA	Estimated fetal age
DHCP	Distributed Hospital Computer Program	EGF	Epidermal growth factor
DHE	Dihematoporphyrin ether	EGG	Electrogastrogram
DHEW	Department of Health Education and Welfare	EIA	Enzyme immunoassay
DHHS	Department of Health and Human Services	EIU	Electrode impedance unbalance
DHT	Duration of hypothermia	ELF	Extra low frequency
DI	Deionized water	ELGON	Electrical goniometer
DIC	Displacement current	ELISA	Enzyme-linked immunosorbent assay
DIS	Diagnostic interview schedule	ELS	Energy loss spectroscopy
DL	Double layer	ELV	Equivalent lung volume
DLI	Difference lumen for intensity	EM	Electromagnetic
DM	Delta modulation	EMBS	Engineering in Medicine and Biology Society
DME	Dropping mercury electrode	emf	Electromotive force
DN	Donation number	EMG	Electromyogram
DNA	Deoxyribonucleic acid	EMGE	Integrated electromyogram
DOF	Degree of freedom	EMI	Electromagnetic interference
DOS	Drug ordering system	EMS	Emergency medical services
DOT-NHTSA	Department of Transportation Highway Traffic Safety Administration	EMT	Emergency medical technician
DPB	Differential pencil beam	ENT	Ear, nose, and throat
DPG	Diphosphoglycerate	EO	Elbow orthosis
DQE	Detection quantum efficiency	EOG	Electrooculography
DRESS	Depth-resolved surface coil spectroscopy	EOL	End of life
DRG	Diagnosis-related group	EOS	Eosinophil
DSA	Digital subtraction angiography	EP	Elastoplastic; Evoked potentiate
DSAR	Differential scatter-air ratio	EPA	Environmental protection agency
DSB	Double strand breaks	ER	Evoked response
DSC	Differential scanning calorimetry	ERCP	Endoscopic retrograde cholangiopancreatography
D-T	Deuterium-on-tritium	ERG	Electron radiography; Electroretinogram
DTA	Differential thermal analysis	ERMF	Event-related magnetic field
d.u.	Density unit	ERP	Event-related potential
DUR	Duration	ERV	Expiratory reserve volume
DVT	Deep venous thrombosis		
EA	Esophageal accelerometer		
EB	Electron beam		
EBCDIC	Extended binary code decimal interchange code		

ESCA	Electron spectroscopy for chemical analysis	GC	Gas chromatography; Guanine-cytosine
ESI	Electrode skin impedance	GDT	Gas discharge tube
ESRD	End-stage renal disease	GFR	Glomerular filtration rate
esu	Electrostatic unit	GHb	Glycosylated hemoglobin
ESU	Electrosurgical unit	GI	Gastrointestinal
ESWL	Extracorporeal shock wave lithotripsy	GLC	Gas-liquid chromatography
ETO, Eto	Ethylene oxide	GMV	General minimum variance
ETT	Exercise tolerance testing	GNP	Gross national product
EVA	Ethylene vinyl acetate	GPC	Giant papillary conjunctivitis
EVR	Endocardial viability ratio	GPH	Gas-permeable hard
EW	Extended wear	GPH-EW	Gas-permeable hard lens extended wear
FAD	Flavin adenine dinucleotide	GPO	Government Printing Office
FARA	Flexible automation random analysis	GSC	Gas-solid chromatography
FBD	Fetal biparietal diameter	GSR	Galvanic skin response
FBS	Fetal bovine serum	GSWD	Generalized spike-wave discharge
fcc	Face centered cubic	HA	Hydroxyapatite
FCC	Federal Communications Commission	HAM	Helical axis of motion
Fct	Fluorocrit	Hb	Hemoglobin
FDA	Food and Drug Administration	HBE	His bundle electrogram
FDCA	Food, Drug, and Cosmetic Act	HBO	Hyperbaric oxygenation
FE	Finite element	HC	Head circumference
FECG	Fetal electrocardiogram	HCA	Hypothermic circulatory arrest
FEF	Forced expiratory flow	HCFA	Health care financing administration
FEL	Free electron lasers	HCL	Harvard Cyclotron Laboratory
FEM	Finite element method	hcp	Hexagonal close-packed
FEP	Fluorinated ethylene propylene	HCP	Half cell potential
FES	Functional electrical stimulation	HDPE	High density polyethylene
FET	Field-effect transistor	HECS	Hospital Equipment Control System
FEV	Forced expiratory volume	HEMS	Hospital Engineering Management System
FFD	Focal spot to film distance	HEPA	High efficiency particulate air filter
FFT	Fast Fourier transform	HES	Hydroxyethylstarch
FGF	Fresh gas flow	HETP	Height equivalent to a theoretical plate
FHR	Fetal heart rate	HF	High-frequency; Heating factor
FIC	Forced inspiratory capacity	HFCWO	High-frequency chest wall oscillation
FID	Flame ionization detector; Free-induction decay	HFER	High-frequency electromagnetic radiation
FIFO	First-in-first-out	HFJV	High-frequency jet ventilation
FITC	Fluorescent indicator tagged polymer	HFO	High-frequency oscillator
FL	Femur length	HFOV	High-frequency oscillatory ventilation
FM	Frequency modulation	HFPPV	High-frequency positive pressure ventilation
FNS	Functional neuromuscular stimulation	HFV	High-frequency ventilation
FO	Foramen ovale	HHS	Department of Health and Human Services
FO-CRT	Fiber optics cathode ray tube	HIBC	Health industry bar code
FP	Fluorescence polarization	HIMA	Health Industry Manufacturers Association
FPA	Fibrinopeptide A	HIP	Hydrostatic indifference point
FR	Federal Register	HIS	Hospital information system
FRC	Federal Radiation Council; Functional residual capacity	HK	Hexokinase
FSD	Focus-to-surface distance	HL	Hearing level
FTD	Focal spot to tissue-plane distance	HMBA	Hexamethylene bisacetamide
FTIR	Fourier transform infrared	HMO	Health maintenance organization
FTMS	Fourier transform mass spectrometer	HMWPE	High-molecular-weight polyethylene
FU	Fluorouracil	HOL	Higher-order languages
FUDR	Floxuridine	HP	Heating factor; His-Purkinje
FVC	Forced vital capacity	HpD	Hematoporphyrin derivative
FWHM	Full width at half maximum	HPLC	High-performance liquid chromatography
FWTM	Full width at tenth maximum	HPNS	High-pressure neurological syndrome
GABA	Gamma amino buteric acid	HPS	His-Purkinje system
GAG	Glycosaminoglycan	HPX	High peroxidase activity
GBE	Gas-bearing electrodyamometer		

HR	Heart rate; High-resolution	IMIA	International Medical Informatics Association
HRNB	Halstead-Reitan Neuropsychological Battery	IMS	Information management system
H/S	Hard/soft	IMV	Intermittent mandatory ventilation
HSA	Human serum albumin	INF	Interferon
HSG	Hysterosalpingogram	IOL	Intraocular lens
HTCA	Human tumor cloning assay	IPC	Ion-pair chromatography
HTLV	Human T cell lymphotropic virus	IPD	Intermittent peritoneal dialysis
HU	Heat unit; Houndsfield units; Hydroxyurea	IPG	Impedance plethysmography
HVL	Half value layer	IPI	Interpulse interval
HVR	Hypoxic ventilatory response	IPPB	Intermittent positive pressure breathing
HVT	Half-value thickness	IPTS	International practical temperature scale
IA	Image intensifier assembly; Inominate artery	IR	Polyisoprene rubber
IABP	Intraaortic balloon pumping	IRB	Institutional Review Board
IAEA	International Atomic Energy Agency	IRBBB	Incomplete right bundle branch block
IAIMS	Integrated Academic Information Management System	IRPA	International Radiation Protection Association
IASP	International Association for the Study of Pain	IRRAS	Infrared reflection-absorption spectroscopy
IC	Inspiratory capacity; Integrated circuit	IRRS	Infrared reflection spectroscopy
ICCE	Intracapsular cataract extraction	IRS	Internal reflection spectroscopy
ICD	Intracervical device	IRV	Inspiratory reserve capacity
ICDA	International classification of diagnoses	IS	Image size; Ion-selective
ICL	Ms-clip lens	ISC	Infant skin servo control
ICP	Inductively coupled plasma; Intracranial pressure	ISDA	Instantaneous screw displacement axis
ICPA	Intracranial pressure amplitude	ISE	Ion-selective electrode
ICRP	International Commission on Radiological Protection	ISFET	Ion-sensitive field effect transistor
ICRU	International Commission on Radiological Units and Measurements	ISIT	Intensified silicon-intensified target tube
ICU	Intensive care unit	ISO	International Organization for Standardization
ID	Inside diameter	ISS	Ion scattering spectroscopy
IDDM	Insulin dependent diabetes mellitus	IT	Intrathecal
IDE	Investigational device exemption	ITEP	Institute of Theoretical and Experimental Physics
IDI	Index of inspired gas distribution	ITEPI	Instantaneous trailing edge pulse impedance
I:E	Inspiratory: expiratory	ITLC	Instant thin-layer chromatography
IEC	International Electrotechnical Commission; Ion-exchange chromatography	IUD	Intrauterine device
IEEE	Institute of Electrical and Electronics Engineers	IV	Intravenous
IEP	Individual educational program	IVC	Inferior vena cava
BETS	Inelastic electron tunneling spectroscopy	IVP	Intraventricular pressure
IF	Immunofluorescent	JCAH	Joint Commission on the Accreditation of Hospitals
IFIP	International Federation for Information Processing	JND	Just noticeable difference
IFMBE	International Federation for Medical and Biological Engineering	JRP	Joint replacement prosthesis
IGFET	Insulated-gate field-effect transistor	KB	Kent bundle
IgG	Immunoglobulin G	Kerma	Kinetic energy released in unit mass
IgM	Immunoglobulin M	KO	Knee orthosis
IHP	Inner Helmholtz plane	KPM	Kilopond meter
IHSS	Idiopathic hypertrophic subaortic stenosis	KRPB	Krebs-Ringer physiological buffer
II	Image intensifier	LA	Left arm; Left atrium
IIIES	Image intensifier input-exposure sensitivity	LAD	Left anterior descending; Left axis deviation
IM	Intramuscular	LAE	Left atrial enlargement
IMFET	Immunologically sensitive field-effect transistor	LAK	Lymphokine activated killer
		LAL	Limulus amoebocyte lysate
		LAN	Local area network
		LAP	Left atrial pressure
		LAT	Left anterior temporalis
		LBBB	Left bundle branch block
		LC	Left carotid; Liquid chromatography

LCC	Left coronary cusp	MDP	Mean diastolic aortic pressure
LCD	Liquid crystal display	MDR	Medical device reporting
LDA	Laser Doppler anemometry	MDS	Multidimensional scaling
LDF	Laser Doppler flowmetry	ME	Myoelectric
LDH	Lactate dehydrogenase	MED	Minimum erythema dose
LDPE	Low density polyethylene	MEDPAR	Medicare provider analysis and review
LEBS	Low-energy brief stimulus	MEFV	Maximal expiratory flow volume
LED	Light-emitting diode	MEG	Magnetoencephalography
LEED	Low energy electron diffraction	MeSH	Medline subject heading
LES	Lower esophageal sphincter	METS	Metabolic equivalents
LESP	Lower esophageal sphincter pressure	MF	Melamine-formaldehyde
LET	Linear energy transfer	MFP	Magnetic field potential
LF	Low frequency	MGH	Massachusetts General Hospital
LH	Luteinizing hormone	MHV	Magnetic heart vector
LHT	Local hyperthermia	MI	Myocardial infarction
LL	Left leg	MIC	Minimum inhibitory concentration
LLDPE	Linear low density polyethylene	MIFR	Maximum inspiratory flow rate
LLPC	Liquid-liquid partition chromatography	MINET	Medical Information Network
LLW	Low-level waste	MIR	Mercury-in-rubber
LM	Left masseter	MIS	Medical information system; Metal-insulator-semiconductor
LNNB	Luria-Nebraska Neuropsychological Battery	MIT	Massachusetts Institute of Technology
LOS	Length of stay	MIT/BIH	Massachusetts Institute of Technology/ Beth Israel Hospital
LP	Late potential; Lumboperitoneal	MMA	Manual metal arc welding
LPA	Left pulmonary artery	MMA	Methyl methacrylate
LPC	Linear predictive coding	MMECT	Multiple-monitored ECT
LPT	Left posterior temporalis	MMFR	Maximum midexpiratory flow rate
LPV	Left pulmonary veins	mm Hg	Millimeters of mercury
LRP	Late receptor potential	MMPI	Minnesota Multiphasic Personality Inventory
LS	Left subclavian	MMSE	Minimum mean square error
LSC	Liquid-solid adsorption chromatography	MO	Membrane oxygenation
LSI	Large scale integrated	MONO	Monocyte
LSV	Low-amplitude shear-wave viscoelastometry	MOSFET	Metal oxide silicon field-effect transistor
LTI	Low temperature isotropic	MP	Mercaptopurine; Metacarpal-phalangeal
LUC	Large unstained cells	MPD	Maximal permissible dose
LV	Left ventricle	MR	Magnetic resonance
LVAD	Left ventricular assist device	MRG	Magnetoretinogram
LVDT	Linear variable differential transformer	MRI	Magnetic resonance imaging
LVEP	Left ventricular ejection period	MRS	Magnetic resonance spectroscopy
LVET	Left ventricular ejection time	MRT	Mean residence time
LVH	Left ventricular hypertrophy	MS	Mild steel; Multiple sclerosis
LYMPH	Lymphocyte	MSR	Magnetically shielded room
MAA	Macroaggregated albumin	MTBF	Mean time between failure
MAC	Minimal auditory capabilities	MTF	Modulation transfer function
MAN	Manubrium	MTTR	Mean time to repair
MAP	Mean airway pressure; Mean arterial pressure	MTX	Methotroxate
MAST	Military assistance to safety and traffic	MUA	Motor unit activity
MBA	Monoclonal antibody	MUAP	Motor unit action potential
MBV	Maximum breathing ventilation	MUAPT	Motor unit action potential train
MBX	Monitoring branch exchange	MUMPI	Missouri University Multi-Plane Imager
MCA	Methyl cryanoacrylate	MUMPS	Massachusetts General Hospital utility multiuser programming system
MCG	Magnetocardiogram	MV	Mitral valve
MCI	Motion Control Incorporated	MVO ₂	Maximal oxygen uptake
MCM1	Millon Clinical Multiaxial Inventory	MVTR	Moisture vapor transmission rate
MCT	Microcatheter transducer	MVV	Maximum voluntary ventilation
MCV	Mean corpuscular volume	MW	Molecular weight
MDC	Medical diagnostic categories		
MDI	Diphenylmethane diisocyanate; Medical Database Informatics		

NAA	Neutron activation analysis	OPG	Ocular pneumoplethysmography
NAD	Nicotinamide adenine dinucleotide	OR	Operating room
NADH	Nicotinamide adenine dinucleotide, reduced form	OS	Object of known size; Operating system
NADP	Nicotinamide adenine dinucleotide phosphate	OTC	Over the counter
NAF	Neutrophil activating factor	OV	Offset voltage
NARM	Naturally occurring and accelerator- produced radioactive materials	PA	Posteroanterior; Pulmonary artery; Pulse amplitude
NBB	Normal buffer base	PACS	Picture archiving and communications systems
NBD	Neuromuscular blocking drugs	PAD	Primary afferent depolarization
N-BPC	Normal bonded phase chromatography	PAM	Pulse amplitude modulation
NBS	National Bureau of Standards	PAN	Polyacrylonitrile
NCC	Noncoronary cusp	PAP	Pulmonary artery pressure
NCCLS	National Committee for Clinical Laboratory Standards; National Committee on Clinical Laboratory Standards	PAR	Photoactivation ratio
NCRP	National Council on Radiation Protection	PARFR	Program for Applied Research on Fertility Regulation
NCT	Neutron capture theory	PARR	Poetanesesthesia recovery room
NEEP	Negative end-expiratory pressure	PAS	Photoacoustic spectroscopy
NEMA	National Electrical Manufacturers Association	PASG	Pneumatic antishock garment
NEMR	Nonionizing electromagnetic radiation	PBI	Penile brachial index
NEQ	Noise equivalent quanta	PBL	Positive beam limitation
NET	Norethisterone	PBT	Polybutylene terephthalate
NEUT	Neutrophil	PC	Paper chromatography; Personal computer; Polycarbonate
NFPA	National Fire Protection Association	PCA	Patient controlled analgesia; Principal components factor analysis
NH	Neonatal hepatitis	PCG	Phonocardiogram
NHE	Normal hydrogen electrode	PCI	Physiological cost index
NHLBI	National Heart, Lung, and Blood Institute	PCL	Polycaprolactone; Posterior chamber lens
NIR	Nonionizing radiation	PCR	Percent regurgitation
NIRS	National Institute for Radiologic Science	PCRC	Perinatal Clinical Research Center
NK	Natural killer	PCS	Patient care system
NMJ	Neuromuscular junction	PCT	Porphyria cutanea tarda
NMOS	N-type metal oxide silicon	PCWP	Pulmonary capillary wedge pressure
NMR	Nuclear magnetic resonance	PD	Peritoneal dialysis; Poly-p-dioxanone; Potential difference; Proportional and derivative
NMS	Neuromuscular stimulation	PDD	Percent depth dose; Perinatal Data Directory
NPH	Normal pressure hydrocephalus	PDE	Pregelged disposable electrodes
NPL	National Physical Laboratory	p.d.f.	Probability density function
NR	Natural rubber	PDL	Periodontal ligament
NRC	Nuclear Regulatory Commission	PDM	Pulse duration modulation
NRZ	Non-return-to-zero	PDMSX	Polydimethyl siloxane
NTC	Negative temperature coefficient	PDS	Polydioxanone
NTIS	National Technical Information Service	PE	Polyethylene
NVT	Neutrons versus time	PEEP	Positive end-expiratory pressure
NYHA	New York Heart Association	PEFR	Peak expiratory now rate
ob/gyn	Obstetrics and gynecology	PEN	Parenteral and enteral nutrition
OCR	Off-center ratio; Optical character recognition	PEP	Preejection period
OCV	Open circuit voltage	PEPPER	Programs examine phonetic find phonological evaluation records
OD	Optical density; Outside diameter	PET	Polyethylene terephthalate; Positron-emission tomography
ODC	Oxyhemoglobin dissociation curve	PEU	Polyetherurethane
ODT	Oxygen delivery truck	PF	Platelet factor
ODU	Optical density unit	PFA	Phosphonoformic add
OER	Oxygen enhancement ratio	PFC	Petrofluorochemical
OFD	Object to film distance; Occiputo-frontal diameter	PFT	Pulmonary function testing
OHL	Outer Helmholtz layer	PG	Polyglycolide; Propylene glycol
OHP	Outer Helmholtz plane		
OIH	Orthoiodohippurate		

PGA	Polyglycolic add	PURA	Prolonged ultraviolet-A radiation
PHA	Phytohemagglutinin; Pulse-height analyzer	PUVA	Psoralens and longwave ultraviolet light photochemotherapy
PHEMA	Poly-2-hydroxyethyl methacrylate	P/V	Pressure/volume
PI	Propidium iodide	PVC	Polyvinyl chloride; Premature ventricular contraction
PID	Pelvic inflammatory disease; Proportional/integral/derivative	PVI	Pressure-volume index
PIP	Peak inspiratory pressure	PW	Pulse wave; Pulse width
PL	Posterior leaflet	PWM	Pulse width modulation
PLA	Polylactic acid	PXE	Pseudo-xanthoma elasticum
PLATO	Program Logic for Automated Teaching Operations	QA	Quality assurance
PLD	Potentially lethal damage	QC	Quality control
PLED	Periodic lateralized epileptiform discharge	R-BPC	Reverse bonded phase chromatography
PLT	Platelet	R/S	Radiopaque-spherical
PM	Papillary muscles; Preventive maintenance	RA	Respiratory amplitude; Right arm
PMA	Polymethyl acrylate	RAD	Right axis deviation
p.m.f.	Probability mass function	RAE	Right atrial enlargement
PMMA	Polymethyl methacrylate	RAM	Random access memory
PMOS	P-type metal oxide silicon	RAP	Right atrial pressure
PMP	Patient management problem; Poly(4-methylpentane)	RAT	Right anterior temporalis
PMT	Photomultiplier tube	RB	Right bundle
PO	Per os	RBBB	Right bundle branch block
P_{O_2}	Partial pressure of oxygen	RBC	Red blood cell
POBT	Polyoxybutylene terephthalate	RBE	Relative biologic effectiveness
POM	Polyoxymethylene	RBF	Rose bengal fecal excretion
POMC	Patient order management and communication system	RBI	Resting baseline impedance
POPRAS	Problem Oriented Perinatal Risk Assessment System	RCBD	Randomized complete block diagram
PP	Perfusion pressure; Polypropylene; Postprandial (after meals)	rCBF	Regional cerebral blood flow
PPA	Phonemic process analysis	RCC	Right coronary cusp
PPF	Plasma protein fraction	RCE	Resistive contact electrode
PPM	Pulse position modulation	R&D	Research and development
PPSFH	Polymerized phyridoxalated stroma-free hemoglobin	r.e.	Random experiment
PR	Pattern recognition; Pulse rate	RE	Reference electrode
PRBS	Pseudo-random binary signals	REM	Rapid eye movement; Return electrode monitor
PRP	Pulse repetition frequency	REMATE	Remote access and telecommunication system
PRO	Professional review organization	RES	Reticuloendothelial system
PROM	Programmable read only memory	RESNA	Rehabilitation Engineering Society of North America
PS	Polystyrene	RF	Radio frequency; Radiographic-nuoroscopic
PSA	Pressure-sensitive adhesive	RFI	Radio-frequency interference
PSF	Point spread function	RFP	Request for proposal
PSI	Primary skin irritation	RFQ	Request for quotation
PSP	Postsynaptic potential	RH	Relative humidity
PSR	Proton spin resonance	RHE	Reversible hydrogen electrode
PSS	Progressive systemic sclerosis	RIA	Radioimmunoassay
PT	Plasma thromboplastin	RM	Repetition maximum; Right masseter
PTB	Patellar tendon bearing orthosis	RMR	Resting metabolic rate
PTC	Plasma thromboplastin component; Positive temperature coefficient; Pressurized personal transfer capsule	RMS	Root mean square
PTCA	Percutaneous transluminal coronary angioplasty	RN	Radionuclide
PTFE	Polytetrafluoroethylene	RNCA	Radionuclide cineangiogram
PTT	Partial thromboplastin time	ROI	Regions of interest
PUL	Percutaneous ultrasonic lithotripsy	ROM	Range of motion; Read only memory
		RP	Retinitis pigmentosa
		RPA	Right pulmonary artery
		RPP	Rate pressure product
		RPT	Rapid pull-through technique
		RPV	Right pulmonary veins
		RQ	Respiratory quotient

RR	Recovery room	SEBS	Surgical isolation barrier system
RRT	Recovery room time; Right posterior temporalis	SID	Source to image reception distance
RT	Reaction time	SIMFU	Scanned intensity modulated focused ultrasound
RTD	Resistance temperature device	SIMS	Secondary ion mass spectroscopy; System for isometric muscle strength
RTT	Revised token test	SISI	Short increment sensitivity index
r.v.	Random variable	SL	Surgical lithotomy
RV	Residual volume; Right ventricle	SLD	Sublethal damage
RVH	Right ventricular hypertrophy	SLE	Systemic lupus erythemotodes
RVOT	Right ventricular outflow tract	SMA	Sequential multiple analyzer
RZ	Return-to-zero	SMAC	Sequential multiple analyzer with computer
SA	Sinoatrial; Specific absorption	SMR	Sensorimotor
SACH	Solid-ankle-cushion-heel	S/N	Signal-to-noise
SAD	Source-axis distance; Statistical Analysis System	S:N/D	Signal-to-noise ratio per unit dose
SAINT	System analysis of integrated network of tasks	SNP	Sodium nitroprusside
SAL	Sterility assurance level; Surface averaged lead	SNR	Signal-to-noise ratio
SALT	Systematic analysis of language transcripts	SOA	Sources of artifact
SAMI	Socially acceptable monitoring instrument	SOAP	Subjective, objective, assessment, plan
SAP	Systemic arterial pressure	SOBP	Spread-out Bragg peak
SAR	Scatter-air ratio; Specific absorption rate	SP	Skin potential
SARA	System for anesthetic and respiratory gas analysis	SPECT	Single photon emission computed tomography
SBE	Subbacterial endocarditis	SPL	Sound pressure level
SBR	Styrene-butadiene rubbers	SPRINT	Single photon ring tomograph
SC	Stratum corneum; Subcommittees	SPRT	Standard platinum resistance thermometer
SCAP	Right scapula	SPSS	Statistical Package for the Social Sciences
SCE	Saturated calomel electrode; Sister chromatid exchange	SQUID	Superconducting quantum interference device
SCI	Spinal cord injury	SQV	Square wave voltammetry
SCRAD	Sub-Committee on Radiation Dosimetry	SR	Polysulfide rubbers
SCS	Spinal cord stimulation	SRT	Speech reception threshold
SCUBA	Self-contained underwater breathing apparatus	SS	Stainless steel
SD	Standard deviation	SSB	Single strand breaks
SDA	Stepwise discriminant analysis	SSD	Source-to-skin distance; Source-to-surface distance
SDS	Sodium dodecyl sulfate	SSE	Stainless steel electrode
S&E	Safety and effectiveness	SSEP	Somatosensory evoked potential
SE	Standard error	SSG	Solid state generator
SEC	Size exclusion chromatography	SSP	Skin stretch potential
SEM	Scanning electron microscope; Standard error of the mean	SSS	Sick sinus syndrome
SEP	Somatosensory evoked potential	STD	Source-tray distance
SEXAFS	Surface extended X-ray absorption fine structure	STI	Systolic time intervals
SF	Surviving fraction	STP	Standard temperature and pressure
SFD	Source-film distance	STPD	Standard temperature pressure dry
SFH	Stroma-free hemoglobin	SV	Stroke volume
SFTR	Sagittal frontal transverse rotational	SVC	Superior vena cava
SG	Silica gel	SW	Standing wave
SGF	Silica gel fraction	TAA	Tumor-associated antigens
SGG	Spark gap generator	TAC	Time-averaged concentration
SGOT	Serum glutamic oxaloacetic transaminase	TAD	Transverse abdominal diameter
SGP	Strain gage plethysmography; Stress-generated potential	TAG	Technical Advisory Group
SHE	Standard hydrogen electrode	TAH	Total artificial heart
SI	Le Système International d'Unités	TAR	Tissue-air ratio
		TC	Technical Committees
		TCA	Tricarboxylic acid cycle
		TCD	Thermal conductivity detector
		TCES	Transcutaneous cranial electrical stimulation

TCP	Tricalcium phosphate	UHMWPE	Ultra high molecular weight polyethylene
TDD	Telecommunication devices for the deaf	UL	Underwriters Laboratory
TDM	Therapeutic drug monitoring	ULF	Ultralow frequency
TE	Test electrode; Thermoplastic elastomers	ULTI	Ultralow temperature isotropic
TEAM	Technology evaluation and acquisition methods	UMN	Upper motor neuron
TEM	Transmission electron microscope; Transverse electric and magnetic mode; Transverse electromagnetic mode	UO	Urinary output
TENS	Transcutaneous electrical nerve stimulation	UPTD	Unit pulmonary oxygen toxicity doses
TEP	Tracheoesophageal puncture	UR	Unconditioned response
TEPA	Triethylenephosphoramidate	US	Ultrasound; Unconditioned stimulus
TF	Transmission factor	USNC	United States National Committee
TFE	Tetrafluoroethylene	USP	United States Pharmacopeia
TI	Totally implantable	UTS	Ultimate tensile strength
TICCIT	Time-shared Interaction Computer-Controlled Information Television	UV	Ultraviolet; Umbilical vessel
TLC	Thin-layer chromatography; Total lung capacity	UVR	Ultraviolet radiation
TLD	Thermoluminescent dosimetry	V/F	Voltage-to-frequency
TMJ	Temporomandibular joint	VA	Veterans Administration
TMR	Tissue maximum ratio; Topical magnetic resonance	VAS	Visual analog scale
TNF	Tumor necrosis factor	VBA	Vaginal blood volume in arousal
TOF	Train-of-four	VC	Vital capacity
TP	Thermal performance	VCO	Voltage-controlled oscillator
TPC	Temperature pressure correction	VDT	Video display terminal
TPD	Triphasic dissociation	VECG	Vectorelectrocardiography
TPG	Transvalvular pressure gradient	VEP	Visually evoked potential
TPN	Total parenteral nutrition	VF	Ventricular fibrillation
TR	Temperature rise	VOP	Venous occlusion plethysmography
tRNA	Transfer RNA	VP	Ventriculoperitoneal
TSH	Thyroid stimulating hormone	VPA	Vaginal pressure pulse in arousal
TSS	Toxic shock syndrome	VPB	Ventricular premature beat
TTD	Telephone devices for the deaf	VPR	Volume pressure response
TTI	Tension time index	VSD	Ventricular septal defect
TTR	Transition temperature range	VSWR	Voltage standing wave ratio
TTV	Trimming tip version	VT	Ventricular tachycardia
TTY	Teletypewriter	VTG	Vacuum tube generator
TUR	Transurethral resection	VTS	Viewscan text system
TURP	Transurethral resections of the prostate	VV	Variable version
TV	Television; Tidal volume; Tricuspid valve	WAIS-R	Weschler Adult Intelligence Scale-Revised
TVER	Transscleral visual evoked response	WAK	Wearable artificial kidney
TW	Traveling wave	WAML	Wide-angle mobility light
TxB ₂	Thromboxane B ²	WBAR	Whole-body autoradiography
TZ	Transformation zone	WBC	White blood cell
UES	Upper esophageal sphincter	WG	Working Groups
UP	Urea-formaldehyde	WHO	World Health Organization; Wrist hand orthosis
UffIS	University Hospital Information System	WLF	Williams-Landel-Ferry
UHMW	Ultra high molecular weight	WMR	Work metabolic rate
		w/o	Weight percent
		WORM	Write once, read many
		WPW	Wolff-Parkinson-White
		XPS	X-ray photon spectroscopy
		XR	Xeroradiograph
		YAG	Yttrium aluminum garnet
		ZPL	Zero pressure level

CONVERSION FACTORS AND UNIT SYMBOLS

SI UNITS (ADOPTED 1960)

A new system of metric measurement, the International System of Units (abbreviated SI), is being implemented throughout the world. This system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

Base Units	
length	meter [†] (m)
mass [‡]	kilogram (kg)
time	second (s)
electric current	ampere (A)
thermodynamic temperature§	kelvin (K)
amount of substance	mole (mol)
luminous intensity	candela (cd)
Supplementary Units	
plane angle	radian (rad)
solid angle	steradian (sr)

Derived Units and Other Acceptable Units

These units are formed by combining base units, supplementary units, and other derived units. Those derived units having special names and symbols are marked with an asterisk (*) in the list below:

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
*absorbed dose	gray	Gy	J/kg
acceleration	meter per second squared	m/s ²	
*activity (of ionizing radiation source)	becquerel	Bq	1/s
area	square kilometer	km ²	
	square hectometer	hm ²	ha (hectare)
	square meter	m ²	

[†]The spellings “metre” and “litre” are preferred by American Society for Testing and Materials (ASTM); however, “-er” will be used in the Encyclopedia.

[‡]“Weight” is the commonly used term for “mass.”

[§]Wide use is made of “Celsius temperature” (*t*) defined $t = T - T_0$ where *T* is the thermodynamic temperature, expressed in kelvins, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvins.

<i>Quantity equivalent</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable</i>
* capacitance	farad	F	C/V
concentration (of amount of substance)	mole per cubic meter	mol/m ³	
* conductance	siemens	S	A/V
current density	ampere per square meter	A/m ²	
density, mass density	kilogram per cubic meter	kg/m ³	g/L; mg/cm ³
dipole moment (quantity)	coulomb meter	C·m	
* electric charge, quantity of electricity	coulomb	C	A·s
electric charge density	coulomb per cubic meter	C/m ³	
electric field strength	volt per meter	V/m	
electric flux density	coulomb per square meter	C/m ²	
* electric potential, potential difference, electromotive force	volt	V	W/A
* electric resistance	ohm	Ω	V/A
* energy, work, quantity of heat	megajoule	MJ	
	kilojoule	kJ	
	joule	J	N·m
	electron volt [†]	eV [†]	
	kilowatt hour [†]	kW·h [†]	
energy density	joule per cubic meter	J/m ³	
* force	kilonewton	kN	
	newton	N	kg·m/s ²
* frequency	megahertz	MHz	
	hertz	Hz	1/s
heat capacity, entropy	joule per kelvin	J/K	
heat capacity (specific), specific entropy	joule per kilogram kelvin	J/(kg·K)	
heat transfer coefficient	watt per square meter kelvin	W/(m ² ·K)	
* illuminance	lux	lx	lm/m ²
* inductance	henry	H	Wb/A
linear density	kilogram per meter	kg/m	
luminance	candela per square meter	cd/m ²	
* luminous flux	lumen	lm	cd·sr
magnetic field strength	ampere per meter	A/m	
* magnetic flux	weber	Wb	V·s
* magnetic flux density	tesla	T	Wb/m ²
molar energy	joule per mole	J/mol	
molar entropy, molar heat capacity	joule per mole kelvin	J/(mol·K)	
moment of force, torque	newton meter	N·m	
momentum	kilogram meter per second	kg·m/s	
permeability	henry per meter	H/m	
permittivity	farad per meter	F/m	
* power, heat flow rate, radiant flux	kilowatt	kW	
	watt	W	J/s
power density, heat flux density, irradiance	watt per square meter	W/m ²	
* pressure, stress	megapascal	MPa	
	kilopascal	kPa	
	pascal	Pa	N/m ²
sound level	decibel	dB	
specific energy	joule per kilogram	J/kg	
specific volume	cubic meter per kilogram	m ³ /kg	
surface tension	newton per meter	N/m	
thermal conductivity	watt per meter kelvin	W/(m·K)	
velocity	meter per second	m/s	
	kilometer per hour	km/h	
viscosity, dynamic	pascal second	Pa·s	
	millipascal second	mPa·s	

[†]This non-SI unit is recognized as having to be retained because of practical importance or use in specialized fields.

<i>Quantity</i>	<i>Unit</i>	<i>Symbol</i>	<i>Acceptable equivalent</i>
viscosity, kinematic	square meter per second	m ² /s	
	square millimeter per second	mm ² /s	
	cubic meter	m ³	
	cubic decimeter	dm ³	L(liter)
	cubic centimeter	cm ³	mL
wave number	1 per meter	m ⁻¹	
	1 per centimeter	cm ⁻¹	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

<i>Multiplication factor</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Note</i>
10 ¹⁸	exa	E	
10 ¹⁵	peta	P	
10 ¹²	tera	T	
10 ⁹	giga	G	
10 ⁸	mega	M	
10 ³	kilo	k	
10 ²	hecto	h ^a	^a Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.
10	deka	da ^a	
10 ⁻¹	deci	d ^a	
10 ⁻²	centi	c ^a	
10 ⁻³	milli	m	
10 ⁻⁶	micro	μ	
10 ⁻⁹	nano	n	
10 ⁻¹²	pico	p	
10 ⁻¹⁵	femto	f	
10 ⁻¹⁸	atto	a	

For a complete description of SI and its use the reader is referred to ASTM E 380.

CONVERSION FACTORS TO SI UNITS

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger (†). A more complete list is given in ASTM E 380-76 and ANSI Z210.1-1976.

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
acre	square meter (m ²)	4.047 × 10 ³
angstrom	meter (m)	1.0 × 10 ^{-10†}
are	square meter (m ²)	1.0 × 10 ^{2†}
astronomical unit	meter (m)	1.496 × 10 ¹¹
atmosphere	pascal (Pa)	1.013 × 10 ⁵
bar	pascal (Pa)	1.0 × 10 ^{5†}
barrel (42 U.S. liquid gallons)	cubic meter (m ³)	0.1590
Btu (International Table)	joule (J)	1.055 × 10 ³
Btu (mean)	joule (J)	1.056 × 10 ³
Bt (thermochemical)	joule (J)	1.054 × 10 ³
bushel	cubic meter (m ³)	3.524 × 10 ⁻²
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184 [†]
centimeters of water (39.2 °F)	pascal (Pa)	98.07
centipoise	pascal second (Pa·s)	1.0 × 10 ^{-3†}
centistokes	square millimeter per second (mm ² /s)	1.0 [†]

<i>To convert from</i>	<i>To</i>	<i>Multiply by</i>
cfm (cubic foot per minute)	cubic meter per second (m ³ /s)	4.72 × 10 ⁻⁴
cubic inch	cubic meter (m ³)	1.639 × 10 ⁻⁴
cubic foot	cubic meter (m ³)	2.832 × 10 ⁻²
cubic yard	cubic meter (m ³)	0.7646
curie	becquerel (Bq)	3.70 × 10 ^{10†}
debye	coulomb-meter (C·m)	3.336 × 10 ⁻³⁰
degree (angle)	radian (rad)	1.745 × 10 ⁻²
denier (international)	kilogram per meter (kg/m)	1.111 × 10 ⁻⁷
	tex	0.1111
dram (apothecaries')	kilogram (kg)	3.888 × 10 ⁻³
dram (avoirdupois)	kilogram (kg)	1.772 × 10 ⁻³
dram (U.S. fluid)	cubic meter (m ³)	3.697 × 10 ⁻⁶
dyne	newton(N)	1.0 × 10 ^{-6†}
dyne/cm	newton per meter (N/m)	1.00 × 10 ^{-3†}
electron volt	joule (J)	1.602 × 10 ⁻¹⁹

ECHOCARDIOGRAPHY AND DOPPLER ECHOCARDIOGRAPHY

PETER S. RAHKO
University of Wisconsin Medical
School
Madison, Wisconsin

INTRODUCTION

Echocardiography is a diagnostic technique that utilizes ultrasound (high frequency sound waves above the audible limit of 20 kHz) to produce an image of the beating heart in real time. A piezoelectric transducer element is used to emit short bursts of high frequency, low intensity sound through the chest wall to the heart and then detect the reflections of this sound as it returns from the heart. Since movement patterns and shape changes of several regions of the heart correlate with cardiac function and since changes in these patterns consistently appear in several types of cardiac disease, echocardiography has become a frequently used method for evaluation of the heart. Echocardiography has several advantages over other diagnostic tests of cardiac function:

1. It is flexible and can be used with transducers placed on the chest wall, inside oral cavities such as the esophagus or stomach, or inside the heart and great vessels.
2. It is painless.
3. It is a safe procedure that has no known harmful biologic effects.
4. It is easily transported almost anywhere including the bedside, operating room, cath lab, or emergency department.
5. It may be repeated as frequently as necessary allowing serial evaluation of a given disease process.
6. It produces an image instantaneously, which allows rapid diagnosis in emergent situations.

The first echocardiogram was performed by Edler and Hertz in 1953 (1) using a device that displayed reflected ultrasound on a cathode ray tube. Since that time multiple interrogation and display formats have been devised to display reflected ultrasound. The common display formats are

M-mode: A narrow beam of reflected sound is displayed on a scrolling strip chart plotting depth versus time. Only a small portion of the heart along one interrogation line ("ice pick" view) is shown at any one time.

Two-Dimensional Sector Scan (2D): A sector scan is generated by sequential firing of a phased array transducer along different lines of sight that are swept through a 2D plane. The image (a narrow plane in cross-section) is typically updated at a rate of 15–200 Hz and shown on a video monitor, which allows real time display of cardiac motion.

Three-Dimensional Imaging (3D): Image data from multiple 2D sector scans are acquired sequentially or in real time and displayed in a spatial format in three dimensions. If continuous data is displayed, time becomes the fourth dimension. The display can be shown as a loop that continuously repeats or on some systems in real time. Software allows rotation and "slicing" of the display.

Doppler: The Doppler effect is used to detect the rate and direction of blood flowing in the chambers of the heart and great vessels. Blood generally moves at a higher velocity than the walls of cardiac structures allowing motion of these structures to be filtered out. Blood flow is displayed in four formats:

Continuous Wave Doppler (CW): A signal of continuous frequency is directed into the heart while a receiver (or array of receivers) continuously processes the reflected signal. The difference between the two signals is processed and displayed showing direction and velocity of blood flow. All blood velocities in the line of sight of the Doppler beam are displayed.

Pulsed Wave Doppler (PW): Many bursts of sound are transmitted into the heart and reflected signals from a user defined depth are acquired and stored for each burst. Using these reflected signals an estimate is made of the velocities of blood or tissue encountered by the burst of sound at the selected depth. The velocity estimates are displayed similar to CW Doppler. The user defined position in the heart that the signal is obtained from stipulate the time of the acquisition of the reflected signal relative to transmission and length of the burst, respectively. The difference between transmitted and reflected signal frequencies is calculated, converted to velocity, and displayed. By varying the time between transmission and reception of the signal, selected velocities in small parts of the heart are sampled for blood flow.

Duplex Scanning: The 2D echo is used to orient the interrogator to the location of either the CW or PW signal allowing rapid correlation of blood flow data with cardiac anatomy. This is done by simultaneous display of the Doppler positional range gate superimposed on the 2D image.

Color Doppler: Using a complex array of bursts of frequency (pulsed packets) and multiple ultrasound acquisitions down the same beam line, motion of blood flow is estimated from a cross-correlation among the various acquired reflected waves. The

data is combined as an overlay onto the 2D sector scan for anatomical orientation. Blood flow direction, and an estimate of flow velocity are displayed simultaneously with 2D echocardiographic data for each point in the sector.

CLINICAL FORMATS OF ULTRASOUND

Current generation ultrasound systems allow display of all of the imaging formats discussed except 3D/4D imaging that is still limited in availability to some high end systems.

Specialized transducers that emit and receive the ultrasound have been designed for various clinical indications. Four common types of transducers are used (Fig. 1):

Transthoracic: By far the most common, this transducer is placed on the surface of the chest and moved to different locations to image different parts of the heart or great vessels. All display formats are possible (Fig. 2).

Transesophageal: The transducer is designed to be inserted through the patient’s mouth into the esophagus and stomach. The ultrasound signal is directed at the heart from that location for specialized exams. All display formats are possible.

Intracardiac: A small transducer is mounted on a catheter, inserted into a large vein and moved into the heart. Imaging from within the heart is performed to monitor specialized interventional therapy. Most display formats are available.

Intravascular: Miniature sized transducers are mounted on small catheters and moved through arteries to examine arterial pathology and the results of selected interventions. Limited 2D display formats are available some being radial rather than sector based. The transducers run at very high frequencies (20–30 MHz).

Ultrasound systems vary considerably in size and sophistication (Fig. 3). Full size systems, typically found in hospitals display all imaging formats, accept all types of

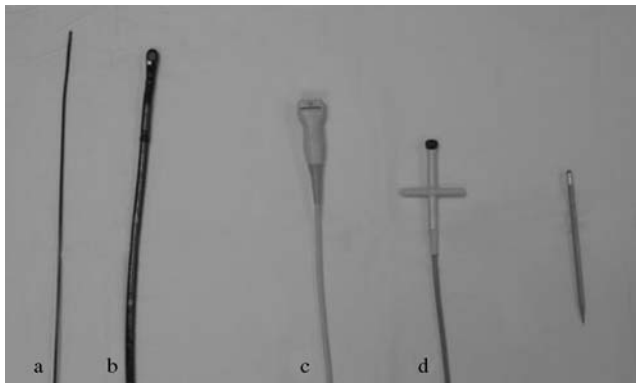

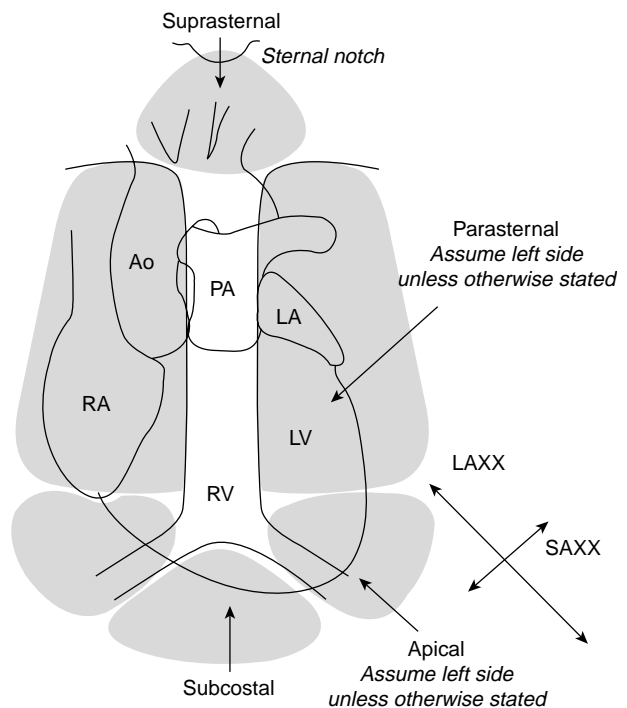

Figure 1. Comparative view of commonly used ultrasound transducers: (a) intracardiac, (b) transesophageal, (c) transthoracic, and (d) Pedof (special Doppler) transducer. A pencil is shown for size reference.

(a)

(b)

Figure 2. (a) Phased array transducer used for transthoracic imaging. The patient is shown, on left side, on exam table, typical for a transthoracic study. The transducer is in the apical position. (b) Diagram of the chest showing how the heart and great vessels are positioned in the chest and the locations where transthoracic transducers are placed on the chest wall. The four common positions for transducer placement are shown. The long axis (LAXX) and short axis (SAXX) orientations of the heart are shown for reference. These orientations form a reference for all of the views obtained in a study. Abbreviations are as follows: aorta (Ao), left atrium (LA), left ventricle (LV), pulmonary artery (PA), right atrium (RA), and right ventricle (RV).

Figure 3. Picture showing various types of ultrasound systems. At left a large “full-size” system is shown that can perform all types of imaging. At center is a miniaturized system that has most of the features of the full service system, but limited display, analysis and recording formats are available. The smallest “hand-held” system shown at right has basic features and is battery operated. It is designed for rapid screening exams integrated into a clinical assessment at the bedside, clinic, or emergency room.

transthoracic and transesophageal transducers, allow considerable on line image processing and support considerable analytic capacity to quantify the image.

Small imaging systems accept many but not all transducers and produce virtually all display formats, but lack the sophisticated array of image processing and analysis capacity found on the full systems. These devices may be used in ambulatory offices or other specialized circumstances requiring more basic image data. A full clinical study is possible.

Portable hand-held battery operated devices are used in limited circumstances, sometimes for screening exams or limited studies. Typically transducers are limited, image processing is rudimentary and analysis capacity very limited.

PRINCIPLES OF ULTRASOUND

Prior to discussing the mechanism of image production some common terms that govern the behavior of ultrasound in soft tissue should be defined. Since ultrasound is

propagated in waves, its behavior in a medium is defined by

$$\lambda = \frac{c}{f}$$

where f is the wave frequency, λ is the wavelength, and c is the acoustic velocity of ultrasound in the medium. The acoustic velocity for most soft tissues is similar and remains constant for a given tissue no matter what the frequency or wavelength (Table 1). Thus in any tissue frequency and wavelength are inversely related. As frequency increases, wavelength decreases. As wavelength decreases, the minimum distance between two structures, that allows them to be characterized as two separate structures, also decreases. This is called the *spatial resolution* of the instrument. One might conclude that very high frequency should always be used to maximize resolution. Unfortunately, as frequency increases, penetration of the ultrasound signal into soft tissue decreases. This serves to limit the frequency and, thus, the resolving power of an ultrasonic system for any given application.

Sound waves are emitted in short bursts from the transducer. As frequency rises, it takes less time to emit the same number of waves per burst. Thus, more bursts of sound can be emitted per unit of time, increasing the spatial resolution of the instrument (Fig. 4). The optimal image is generated by using a frequency that gives the highest possible resolution and an adequate amount of penetration. For transthoracic transducers expected to penetrate up to 24 cm into the chest, typical frequencies used are from 1.6 to 7.0 MHz. Most transducers are broadband in that they generate sound within an adjustable range of frequency rather than at a single frequency. Certain specialized transducers such as the intravascular transducer may only need to penetrate 4 cm. They may have a frequency of 30 MHz to maximize resolution of small structures.

The term *ultrasonic attenuation* formally defines the more qualitative concept of tissue penetration. It is a complex parameter that is different for every tissue type and is defined as the rate of decrease in wave amplitude per distance penetrated at a given frequency. The two important properties that define ultrasonic attenuation are reflection and absorption of sound waves (2). Note in Table 1 that ultrasound easily passes through blood and soft tissue, but poorly penetrates bone or air-filled lungs.

Acoustic impedance (z) is the product of acoustic velocity (c) and tissue density (ρ); thus this property is tissue specific but frequency independent. This property is important because it determines how much ultrasound is

Table 1. Ultrasonic Properties of Some Selected Tissues^a

Tissue	Velocity of Propagation, $10^3 \text{ m} \cdot \text{s}^{-1}$	Density, $\text{g} \cdot \text{mL}^{-1}$	Acoustic Impedance, 10^6 rayl^b	Attenuation at 2.25 MHz, $\text{dB} \cdot \text{cm}^{-1}$

^b1 rayl = $1 \text{ kg} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$.

Figure 4. Upper panel Two depictions of an emitted pulse of ultrasound. Time moves horizontally and amplitude moves vertically. Note the high frequency pulse of three waves takes less time. Lower panel Effect of pulse duration on resolution. One echo pulse is delivered toward two reflectors and reflections are shown. In the top panel, the reflectors are well separated from each other and distinguished as two separate structures. In the middle panel, pulse frequency and duration are unchanged, but the reflectors are close together. The two returning reflections overlap, the instrument will register the two reflectors as one structure. In the lower panel the pulse frequency is increased, thus pulse duration is shortened. The two objects are again separately resolved. (Reprinted from Zagzebski JA Essentials of Ultrasound Physics. St. Louis: Mosby-Year Book; copyright © 1996, p 28, with permission from Elsevier.)

reflected at an interface between two different types of tissue (Table 1). When a short burst of ultrasound is directed at the heart, portions of this energy are reflected back to the receiver. It is these reflected waves that produce the image of the heart. A very dense structure such as calcified tissue has high impedance and is a strong reflector.

There are two types of reflected waves: *specular reflections* and *diffuse reflections* (Fig. 5). Specular reflections occur at the interface between two types of tissue. The greater the difference in acoustic impedance between two tissues, the greater the amount of specular reflection and the lower the amount of energy that penetrates beyond the interface. The interface between heart muscle and blood produces a specular echo, as does the interface between a heart valve and blood. Specular echoes are the primary

Figure 5. Upper panel Comparison between specular and diffuse reflectors. Note the diffuse reflector is less angle dependent than the specular reflector. Lower panel Example of combined reflections (shown at bottom of figure) returning from a structure, typical of reflections coming back from heart muscle. The large amplitude specular echo corresponds to the border of the structure. The interior of the structure produces low amplitude scattered reflections. (Reprinted from Zagzebski JA, Essentials of Ultrasound Physics. St. Louis, Mosby-Year Book; copyright © 1996 p 12 with permission from Elsevier.)

echoes that are imaged by M-mode, 2D echo, and 3D echo and thus primarily form an outline of the heart. Diffuse reflected echoes are much weaker in energy. They are produced by small irregular more weakly reflective objects such as the myocardium itself. Scattered echoes “fill in the details” between the specular echoes. With modern equipment scattered echoes are processed and analyzed providing much more detail to tissue being examined.

Doppler echocardiography uses *scattered echoes* from red blood cells for detecting blood flow. Blood cells are Rayleigh scatterers since the diameter of the blood cells are much smaller than the typical wavelength of sound used to interrogate tissue. Since these reflected signals are even fainter than myocardial echoes, Doppler must operate at a higher energy level than M-mode or 2D imaging.

Harmonic imaging is a recent addition to image display made possible by advances in transducer design and signal processing. It was first developed to improve the display of contrast agents injected intravenously as they passed through the heart. These agents, gas filled microbubbles 2–5 μm in diameter, are highly reflective Rayleigh scatterers. At certain frequencies within the broadband transducer range the contrast bubbles resonate, producing a relatively strong signal at multiples of the fundamental interrogation frequency called harmonics. By using a high

pass filter (a system that blanks out all frequency below a certain level), to eliminate the fundamental frequency reflectors, selective reflections from the second harmonic are displayed. In second harmonic mode, reflections from the resonating bubbles are a much stronger than reflections from soft tissue and thus bubbles are preferentially displayed. This allows selective analysis of the contrast agent as it passes through the heart muscle or in the LV cavity (3).

Harmonic imaging has recently been applied to conventional 2D images without contrast. As the ultrasound wave passes through tissue, the waveform is modified by nonlinear propagation through tissue causing a shape change in the ultrasound beam. This progressively increases as the beam travels deeper into the heart. Electronic canceling of much of the image by filtering out the fundamental frequency allows selective display of the harmonic image, improving overall image quality by elimination of some artifacts. The spatial resolution of the signal is also improved since the reflected signal analyzed and displayed is double that of the frequency produced by the transducer (4).

ECHOCARDIOGRAPHIC INSTRUMENTATION

The transducer is a piezoelectric (pressure electric) device. When subjected to an alternating electrical current, the ceramic crystal (usually barium titanate, lead zirconate titanate, or a composite ceramic) expands and contracts producing compressions and rarefactions in its environment, which become waves. Various transducers produce ultrasonic waves within a frequency range of 1.0–40 MHz. The waves are emitted as brief pulses lasting $\sim 1 \mu\text{s}$ out of every 100–200 μs . During the remaining 99–199 μs of each interval the transducer functions as a receiver that detects specular and diffuse reflections as they return from the heart. The same crystal, when excited by a reflected sound wave, produces an electrical signal and sends it back to the echocardiograph for analysis and display. Since one heart-beat lasts somewhere from 0.3 to 1.2 s, the echocardiographic device sends out a minimum of several hundred impulses per beat allowing precise tracking of cardiac motion throughout the beat.

After the specular and diffuse echoes are received they must be displayed in a usable format. The original ultrasound devices used an A-mode format (Fig. 6) that displayed depth on the y axis and amplitude of the signal on the x-axis. The specular echoes from boundaries between cardiac chambers register as the strongest echoes. No more than 1D spatial information is obtained from this format.

In a second format, B-mode, the amplitudes of the returning echoes are displayed as dots of varying intensity on a video monitor in what has come to be called a gray scale (Fig. 6). If the background is black (zero intensity), then progressively stronger echoes are displayed as progressively brighter shades of gray with white representing the highest intensity. Most echocardiographic equipment today uses between 64 and 512 shades of gray in its output display. The B-mode format, by itself, is not adequate for cardiac imaging and must be modified to image a continuously moving structure.

Figure 6. Composite drawing showing the three different modes of display for a one-dimensional (1D) ultrasound signal. In the right half of the figure is a schematic drawing of a cross-section through the heart. The transducer (T) sits on the chest wall (CW) and directs a thin beam of ultrasonic pulses into the heart. This beam traverses the anterior wall (aHW) of the right ventricle (RV), the interventricular septum (IVS), the anterior (aML) and posterior (pML) leaflets of the mitral valve, and the posterior wall of the left ventricle (LVPW). Each dot along the path of the beam represents production of a specular echo. These are displayed in the corresponding A-mode format, where vertical direction is depth and horizontal direction is amplitude of the reflected echo and B-mode format where again vertical direction is depth but amplitude is intensity of the dot. If time is added to the B-mode format, an M-mode echo is produced, which is shown in the left panel. This allows simultaneous presentation of motion of the cardiac structures in the path of the echo beam throughout the entire cardiac cycle; measurement of vertical depth, thickness of various structures, and timing of events within the cardiac cycle. If the transducer is angled in a different direction, a distinctly different configuration of echoes will be obtained. In the figure, the M-mode displayed is at the same beam location as noted in the right-side panel. Typical movement of the AML and PML is shown. ECG = electrocardiogram signal. (From Pierand L., Meltzer RS., Roelandt J, Examination techniques in M-mode and two-dimensional echocardiography. In: Kraus R editor, *The Practice of Echocardiography*, New York: John Wiley & Sons; copyright © 1985, p 69. This material is used by permission of John Wiley & Sons, Inc.)

To image the heart, the M-mode format (M for motion) was devised (Fig. 6). With this technique, the transducer is pointed into the chest at the heart and returning echoes are displayed in B-mode. A strip chart recorder (or scrolling video display) constantly records the B-mode signal with depth of penetration on the y-axis and time the parameter displayed on the x-axis. By adding an electrocardiographic signal to monitor cardiac electrical activity and to mark the beginning of each cardiac cycle, the size, thickness, and movement of various cardiac structures throughout a cardiac cycle are displayed with high resolution. By variation of transducer position, the ultrasound beam is directed toward several cardiac structures (Fig. 7).

The M-mode echo was the first practical ultrasound device for cardiac imaging and has produced a considerable amount of important data. Its major limitation is its limited field of view. Few spatial relationships between cardiac structures can be displayed that severely limits diagnostic capability. The angle of interrogation of the heart is also

Figure 7. Upper panel Schematic diagram of the heart as in Fig. 6. The principal M-mode views are labeled 1–4. The corresponding M-mode image from these four views is shown in lower panel. Abbreviations as in Fig. 6a. Additional abbreviations: AV = Aortic valve, AAOW = anterior aortic wall, LA = left atrial posterior wall, LVOT = left ventricular outflow tract, RVOT = right ventricular outflow tract. (From Pierand L, Meltzer RS, Roelandt J, Examination techniques in M-mode and 2D echocardiography. In: Kraus R editor, *The Practice of Echocardiography*, New York, John Wiley & Sons; copyright © 1985, p 71. This material is used with permission of John Wiley & Sons, Inc.)

difficult to control. This can distort the image and render size and dimension measurements unreliable.

Since the speed of sound is rapid enough to allow up to 5000 short pulses of ultrasound to be emitted and received each second at depths typical for cardiac imaging, it was recognized that multiple B-mode scans in several directions could be processed rapidly enough to display a “real-time” image. Sector scanning in two dimensions was originally performed by mechanically moving a single element piezoelectric crystal through a plane. Typically, 128 B-mode scan lines were swept through a 60–90° arc 30 times · s⁻¹ to form a video composite B-mode sector (Fig. 8). These mechanical devices have been replaced by transducer arrays that place a group of closely spaced piezoelectric elements, each with its own electrical connection to the ultrasound system, into a transducer. The type of array used depends on the structure

Figure 8. Diagram of a 2D echo mechanical transducer with three crystals. As each segment sweeps through the 90° arc, an element fires a total of 128 times. The composite of the 128 B-mode lines form a 2D echo frame. Typically there are 30 frames/s of video information, a rate rapid enough to show contractile motion of the heart smoothly. (From Graham PL, Instrumentation. In: Krause R. editor. *The Practice of Echocardiography*, New York: John Wiley & Sons; copyright © 1985, p 41. This material is used by permission of John Wiley & Sons, Inc.)

being imaged. For cardiac ultrasound, a phased array configuration is used, typically consisting of 128–1024 individual elements. In a phased array transducer, a portion of the elements are fired to produce each sector scan line. The sound beams are electronically steered through the sector by changing the time delay sequence of the array elements (Fig. 9). In a similar fashion, all elements are electronically sequenced to receive reflected sound from selected parts of the sector being scanned (5).

Use of a phased array device allows many other modifications of the sound wave in addition to steering. Further sophisticated electronic manipulations of the time of sound transmission and delays in reception allow selective focusing of the beam to concentrate transmit energy that enhance image quality of selected structures displaced in the sector. Recent design advances have markedly increased the sector frame rate (number of displayed sectors/second) to levels beyond 220 Hz, markedly increasing the time resolution of the imaging system. While the human visual processing system cannot resolve time at such a rapid rate, high frame rates allow for sophisticated quantitation based on the 2D image, such as high-resolution graphs of time based indexes.

DOPPLER ECHOCARDIOGRAPHY

Application of the Doppler effect allows analysis of blood flow within the heart and great vessels. The Doppler effect, named for its discoverer Christian Doppler, describes the change in frequency and wavelength that occurs with relative motion between the source of the waves and the receiver. If a source of sound remains stationary with respect to its listener, then the frequency and wavelength of the sound will also remain constant. However, if the

Figure 9. Diagram of a phased array transducer. Beam direction is varied by changing the delay sequence among the transmitted pulses produced by each individual element. (From Zagzebski JA. Essentials of Ultrasound Physics. St. Louis: Mosby-Year Book Inc.; copyright © 1996, with permission from Elsevier.)

sound source is moving away from the listener wavelength increases and frequency decreases. The opposite will occur if the sound source is moving toward the listener (Fig. 10).

The Doppler principle is applied to cardiac ultrasound in the following way: A beam of continuous wave ultrasound is transmitted into the heart and reflected off red blood cells as they travel through the heart. The reflected impulses are then detected by a receiver. If the red blood cells are moving toward the receiver, the frequency of the reflected echoes will be higher than the frequency of the transmitted echoes and vice versa (Fig. 10).

The difference between the frequency of the transmitted and received echoes (usually called the Doppler shift) can be related to the velocity of blood flow by the following equation:

$$V = \frac{c(f_r - f_t)}{2(f_t)(\cos \theta)}$$

where V is the blood flow velocity, c is the speed of sound in soft tissue ($1540 \text{ m} \cdot \text{s}^{-1}$), f_r is the frequency of the reflected echoes, f_t is the frequency of the transmitted echoes, and θ is the intercept angle between the direction of blood flow and the ultrasound beam. Thus, flow toward the transducer will produce a positive Doppler shift ($f_r > f_t$), while flow away from the transducer will produce a negative Doppler shift ($f_r < f_t$). The only variable that cannot be directly measured is θ . Since $\cos 0^\circ = 1$, it follows that maximal flow will be detected when the Doppler beam is parallel to blood flow. Since blood flow cannot be seen with 2D echo, at best, θ can only be estimated. Fortunately, if θ is within 20° of the direction of blood flow, the error introduced by angulation is small. Therefore,

Figure 10. Upper panel The Doppler effect as applied to ultrasound. The frequency increases slightly when the reflector is moving toward the transducer and decreases when the reflector is moving away from the transducer. Lower panel Relative magnitude of the Doppler shift caused by red blood cells moving between cardiac chambers. In this example the frequency shift corresponds to a movement rate of $1 \text{ m} \cdot \text{s}^{-1}$. (Reprinted from Zagzebski JA. Essentials of Ultrasound Physics. St. Louis: Mosby-Year Book Inc.; copyright © 1996, with permission from Elsevier.)

most investigators do not formally correct for θ . Instead, the Doppler beam is aligned as closely as possible in the presumed direction of maximal flow and then adjusted until maximal flow is detected (6).

Doppler echo operates in two basic formats. Figure 10 depicts the CW method. An ultrasound signal is continuously transmitted into the heart while a second crystal (or array of crystals) in the transducer continually receives reflected signals. All red blood cells in the overlap region between the beam patterns of the transmit and receive crystals contribute to the calculated signal. The frequency

Figure 11. Example of a continuous wave Doppler signal taken from a patient. Flow toward the transducer is a positive (upward) deflection from the baseline and flow away from the transducer is downward. ECG = electrocardiogram signal.

content of this signal, combined with an electrocardiographic monitor lead, is then displayed on a strip chart similar to an M-mode echo (Fig. 11).

The advantage of the CW method is that it can detect a wide range of flow velocities encompassing every possible physiologic or pathologic flow state. The main disadvantage of the CW format is that the site of flow cannot be localized. To overcome the lack of localization of CW Doppler, a second format was developed called pulsed Doppler (PW). In this format, similar to B-mode echocardiographic imaging, brief bursts of ultrasound are transmitted at a given frequency followed by a silent interval (Fig. 12). Since the time it takes for a reflected burst of sound waves to return to the receiving crystal is directly related to the distance the reflecting structure is from the receiver, the position in the heart from which blood flow is sampled can be precisely controlled by limiting the time interval during which reflected ultrasound is received. This is known as range gating and allows the investigator to limit the area sampled to small portions of the heart or great vessel. There is a price to be paid for sample selectivity, however. The maximal detectable velocity PW Doppler is able to display is equal to one-half the pulse repetition frequency (frequently called the Nyquist limit). This reduces the number of situations in which flow velocity samples unambiguously display the flow phenomenon. A typical PW Doppler display shows flow both toward and away from the transducer (Fig. 13).

As one interrogates deeper structures progressively further from the transducer, the pulse repetition frequency must, of necessity, be decreased. As a result, the highest detectable velocity of the PW Doppler mode becomes progressively smaller. Due to attenuation, the sensitivity for detecting flow becomes progressively lower at greater distances from the transducer. Despite these limitations, selective sampling of blood flow allows interrogation of a wide array of cardiac structures in the heart.

When a measured flow has a velocity in a particular direction greater than the Nyquist limit, not all of the

Figure 12. Pulsed Doppler echocardiography. In place of a continuous stream of ultrasound, brief pulses are emitted similar to M-mode or 2D imaging. By acquiring reflected signal data over a limited time window following each pulse, reflections emanating only from a certain depth may be received. (From Feigenbaum H, Echocardiography (5th ed), Philadelphia, PA: Lea & Febiger; 1994, p 29, with permission from Lippincott Williams & Wilkins ©.)

Figure 13. Example of a pulsed wave Doppler tracing. The study was recorded in duplex mode from the LVOT. The small upper insert shows the 2D image which guides positioning of the sample volume (arrow). The Doppler signal is shown below and has been traced by the sonographer using electronic analysis system. Data automatically detected from tracing the signal are shown on the left and include the peak velocity (PV) of flow and the integral of flow velocity (VTI) that can be used for calculations of cardiac output.

spectral envelope of the signal is visible. Indeed, the velocity estimates “wrap-around” to the other side of the velocity map and the flow appears to be going in the opposite direction. This phenomenon where large positives velocities are displayed as negative velocities is called aliasing. There are two strategies to mitigate or eliminate aliasing. The zero shift line (no velocity) may be moved upward or downward, effectively doubling the display range in the desired direction. This may be sufficient to “un-wrap” the aliased velocity and display it entirely in the appropriate direction. Some velocities may still be too high for this strategy to work. To display these higher velocities an alternative method called high pulse repetition frequency (high PRF) mode is employed. In this mode, sample volumes at multiples of the main interrogation sample volume are also interrogated. This is accomplished by sending out bursts of pulse packets at multiples of the burst rate necessary to sample at the desired depth. The system displays multiple sites from which the displayed signal might originate. While this creates some ambiguity in the exam, the anatomy displayed by the 2D exam usually allows a correct delineation as to which range gate is creating the signal (Fig. 14).

By itself, Doppler echo is a nonimaging technique that only produces flow patterns and audible tone patterns (since all Doppler shifts fall within the audible range). Phased array transducers, however, allow simultaneous display of both 2D images and Doppler in a mode called duplex Doppler echocardiography. By using this combination, the PW Doppler sample volume is displayed as an overlay on the 2D image and is moved to a precise area in the heart where the flow velocity is measured (Fig. 13). This combination provides both anatomic and physiologic information about the interrogated cardiac structure. Most commonly, Duplex mode is used with the PW wave format of Doppler echo. However, it is also possible to position the continuous wave beam anywhere in the 2D sector by superimposing the Doppler line of interrogation on top of the 2D image.

Just as changing from an M-mode echo to a 2D sector scan markedly increases the amount of spacial data simultaneously available to the clinician, Doppler information can be expanded from a single a PW wave sample volume or CW line to a full sector array. Color Doppler echocardiography displays blood flow within the heart or blood vessel as a sector plane of velocity information. By itself, a color flow scan imparts little information so the display is always combined with the 2D image as an overlay so blood flow may be instantly correlated with anatomic structures within the heart or vessel.

Color Doppler uses the same transmission principles as B-mode 2D imaging and PW Doppler. Brief transmit pulses of sound are steered along interrogation lines in a sector simultaneously with usual B-mode imaging pulses (Fig. 15). In place of just one pulse of sound, multiple pulses are transmitted. The multiple bursts of sound, typically 4–8 in number, are referred to as packets or ensembles of pulses. The first signal stores all reflected echoes along each scan line. Reflectors from subsequent pulses in the packet are received, stored, and rapidly compared to the previous packets. Reflected waves that are identical during each burst in the packet are canceled

Figure 14. Example of high PFR mode of pulsed Doppler. The signal is used for velocity detected at the main gate because pulse packets are sent out more frequently at multiples of the frequency needed to sample at the main gate. Information can also be acquired at other gates that are multiples of the main gate. While the Nyquist limit is higher due to a higher sampling rate some signal ambiguity may occur due to information acquired from the unwanted gates. (Reprinted from Zagzebski JA. *Essentials of Ultrasound Physics*. St. Louis: Mosby-Year Book Inc. copyright © 1996 with permission from Elsevier.)

out and designated as stationary. Reflected waves that progressively change from burst to burst are acquired and processed rapidly for calculation of the phase shift in the ultrasound carrier. Both direction and velocity of movement are proportional to this phase change. Estimates for the average velocity are assigned to a pixel location on the video display. The velocity is estimated by an auto correlator system. On the output display, velocity is typically displayed as brightness of a given color similar to B-mode gray scale with black meaning no motion and maximum brightness indicating the highest velocity detected. Two contrasting colors are used to display direction of flow, typically a red-orange group for flow toward the transducer and a blue group away from transducer. Since the amount of data processed is markedly greater than a typical B-Mode, maximum frame rates of sector scan displays tend to be much lower. This limitation is due both to the speed of sound and the multiple packets of ultrasound evaluated in each interrogation line. To maximize

Figure 15. Diagram showing method of transmission of color flow Doppler ultrasound signals. Packets or ensembles of pulses represented by the open circles in the figure are sent out along some of the scan lines of the image. The reflected waves are analyzed in an autocorrelation circuit to allow display of the color flow image. (Reprinted from Zagzebski JA. *Essentials of Ultrasound Physics*. St. Louis: Mosby-Year Book Inc. copyright © 1996, with permission from Elsevier.)

time resolution, the color flow sector used to display data during a 2D echo may be considerably reduced in size compared to a usual 90° 2D sector scan. Some systems can only display color flow data at relatively slow frame rates of 6–10 Hz. Recent innovations, in which there are multiple receive lines for each transmit line allow much higher frame rates giving excellent time resolution on some systems (7).

Clinically, precise measurement of flow velocity is usually obtained with PW or CW Doppler. Color is used to rapidly interrogate a sector for the presence or absence of blood flow during a given part of the cardiac cycle. Another important part of the color exam is a display of the type of flow present. Normal blood flow is laminar; abnormal blood flow caused by valve or blood vessel pathology is turbulent. The difference between laminar and turbulent flow is easily displayed by color Doppler. With laminar flow, the direction of flow is uniform and variation in velocity of adjacent pixels of interrogation is small. With turbulent flow, both parameters are highly variable. The auto correlation system analyzing color Doppler compares the variance in blood flow between different pixels. The display can be set to register a third color for variance such as green, or the clinician may look for a “mosaic” pattern of flow in which non uniform color velocities and directions are scattered through the sector areas of color interrogation (Figs. 16 and 17).

As with pulsed Doppler there is a Nyquist limit restriction on maximal velocity than can be displayed. The zero flow position line may be adjusted as with PW Doppler to maximize the velocity limit in a given direction. High PRF is not possible with color Doppler. The nature of the color display is such that aliasing results in a shift from one color sequence to the next. Thus, in some situations a high velocity shift can be detected due to a clear shift in color (e.g., from a red-orange sequence to a blue sequence). This phenomenon has been put to use clinically by purposely manipulating the velocity range of color display to force aliasing to occur. By doing this, isovelocity lines are displayed outlining a velocity border of flow in a particular direction and a particular velocity (8).

Thus far, all discussion of Doppler has been confined to interrogation and display of flow velocity. Alternate modes of interrogation are possible. One mode, called power Doppler (or energy display Doppler) assesses the amplitude of the Doppler signal rather than velocity. By evaluating amplitude in place of velocity, this display becomes proportional to the number of moving blood cells present in the interrogation field rather than the velocity. This application is particularly valuable for perfusion imaging when the amount of blood present in a given area is of primary interest (9).

ULTRASOUND SIGNAL PROCESSING, DISPLAY, AND MANAGEMENT

Once each set of the reflected ultrasound data returns to the transducer, it is processed and then transmitted to video display. The information is first processed by a scan converter, which assigns video data to a matrix array of picture elements, “pixels.” Several manipulations of the image are possible to reduce artifacts, enhance information in the display, and analyze the display quantitatively.

The concept of attenuation has been introduced earlier. In order to achieve a usable signal, the returning reflections must be amplified. The amplification can be done in multiple ways. Similar to a sound system, overall gain may be adjusted to increase or decrease the sensitivity of the received signal. More important, however, is the progressive loss of signal strength that occurs with reflections from deeper structures due to attenuation. To overcome this issue, ultrasound systems employ a variable gain circuit that selectively allows gain control at different depths. The applied gain is changed as a function of time (range) in the gain circuit, hence the term time gain compensation (TGC) is used to describe the process. This powerful tool can “normalize” the overall appearance of the image helping make much weaker returning echoes from great depth appear equal to near-field information (Fig. 18). The user also has slide pot control of gain as a function of depth. Some of this user-defined adjustment is applied as part of the TGC function or later as part of digital signal processing.

Manipulation of data prior to writing into the scan converter is called preprocessing. An important part of preprocessing is data compression. The raw data received by the transducer encompasses such a broad energy range

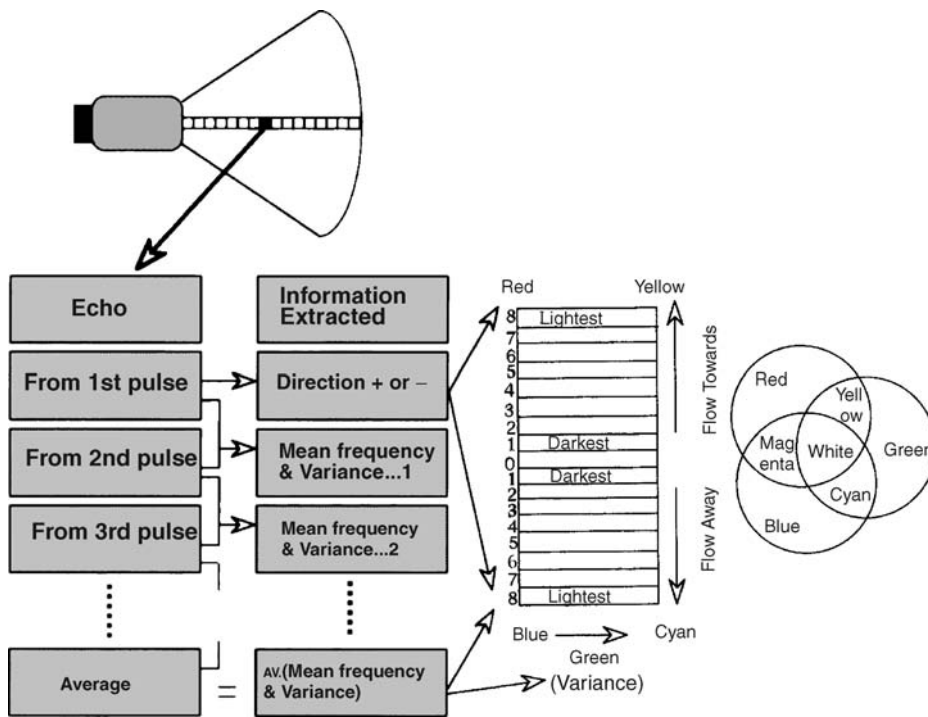

Figure 16. Diagram of color Doppler signal processing. At top, each box in the insonification line indicates a pulse of sound. A packet is made up of 4–8 pulses. The steps in the analysis cycle of a packet are shown in the “Echo” column and represent the comparison function of the autocorrelation system. From the first pulse the analysis determines the appropriate color representing direction. Comparisons between subsequent packets detect the velocity of blood flow. The brightness of the color selected corresponds to velocity. Comparisons of the variability of velocity are also done. Green is added proportional to the amount of variance. The final pixel color represents an average of the packet data for direction, velocity and variance. The right-hand column is the “color bar” that summarizes the type of map used, displays the range of color and brightness selected, and depicts how variance is shown. (From Sehgal CM, Principles of Ultrasound and Imaging and Doppler Ultrasound. In: Sutton, MG et al. editors: Textbook of Echocardiography and Doppler Ultrasound in Adults and Children (2nd ed). Oxford: Blackwell Science Publishing; 1996. p 29. Reprinted with permission of Blackwell Publishing, LTD. p 29)

that it cannot be adequately shown on a video display. Therefore, the dynamic range of the signal is reduced to better fit visual display characteristics. Selective enhancement of certain parts of the data is possible to better display borders between structures. Finally, persistence may be added to the image. With this enhancement, a fraction of data from the previous video frames at each pixel location may be added and averaged together. This helps define weaker diffuse echo scatterers and may work well in a static organ. However, with the heart in constant motion, only modest amounts of persistence add value to the image. Too much persistence reduces motion resolution of the image.

Once the digital signal is registered in the scan converter, further image manipulation is possible. This is called postprocessing of the image. Information in digital memory has a 1:1 ratio between ultrasound signal amplitude and video brightness. Depending on the structure imaged, considerable information may not be discernible in the image. With postprocessing, the relationship of video brightness to signal strength can be altered, frequently to enhance weaker echos and suppress high amplitude echoes. This may result in a better appreciation of less echogenic structures such as myocardium and the edges of the myocardium. The gray scale image may be transformed to a pseudo-color display that adds color to video amplitude data. In certain circumstances this may allow differentiation of pathologic changes from normal. Selective magnification of the image is also possible (Fig. 19).

Figure 17. Color Doppler (here shown in gray scale only) depicting mitral valve regurgitation. The large mosaic mitral insufficiency jet is caused by turbulent flow coming through the mitral valve. The turbulent flow area has been traced to measure its area. The more uniform flow in the left atrium is caused by normal flow in the chamber. It is of uniform color and of much lower velocity.

Figure 18. Processing steps during transmission of sound data to the scan converter. Raw data emerges from the transducer (a) that is imaging two objects that produce specular border echoes at points 1, 2, 3, and 4 and scattered echoes in between. (b) Specular echo raw data. (c) Low noise amplification is applied. Both specular and scattered echoes are now shown. Relative signal strength declines with depth due to attenuation of the signal, making signal 4 weaker than signal 1 even though the material border interface at borders 1 and 4 are identical. (d) Time gain compensation is applied proportionally by depth to electronically amplify signals received progressively later after the pulse leaves the transducer. This helps equalize perceived signal strength (e). The signal is then rectified (f) and smoothed (g) before entering the scan converter. (h) The process is repeated several times per second, in this case all new data appears every 1/30 of a second. The end result is a “real-time” video display of the two structures. (From Sehgal SH, Principles of Ultrasound Imaging and Doppler Ultrasound. In: Sutton MG et al. editors. Textbook of Echocardiography and Doppler Ultrasound in Adults and Children. Oxford: Blackwell Science; 1996. p 11. Reprinted with permission of Blackwell Publishing, LTD.)

Signal processing of PW and CW Doppler data includes filtering and averaging, but the most important component of the analysis is the computation of the velocity estimates. The most commonly used method of analysis is the fast Fourier transform analyzer, which estimates the relative amplitude of various frequency components of the input signal. This system (Fig. 20) divides data up into discreet time segments of very short duration (1–5 ms). For each segment, amplitude estimates are made for each frequency that corresponds to different velocity components in the flow and the relative amplitude of each frequency is recorded on gray scale display. Laminar flow typically has a narrow, discrete velocity range on PW Doppler while turbulent flow may be composed of the entire velocity range. Differentiation of laminar from turbulent flow may help define normal from abnormal flow states. Similar analysis is used to display the CW Doppler signal. Color Doppler displays can be adjusted by using multiple types of display maps. Each manufacturer has basic and special proprietary maps available to enhance color flow data.

All Doppler data can be subjected to selective band pass filters. For conventional Doppler imaging, signals coming from immobile structures or very slow moving structures such as chamber walls and the pericardium, are effectively blanked out. The range of velocity filtered can be changed

Figure 19. B-mode post processing occurs in which signal input intensity varies from 0 to 127 units. On the left side of the figure a linear output is equally amplified, the signal intensity range is now 0–255. On the right, nonlinear amplification is applied. The output is manipulated to enhance or compress the relative video intensity of data. In this example high energy specular reflection video data is relatively compressed (high numbers) while low energy data (from scattered echoes and weak specular echoes) is enhanced. Thus relatively more of the video range is used for relatively weaker signals in the final product. This postprocessing is in addition to time gain compensation done during preprocessing. (From Sehgal SH, Principles of Ultrasound Imaging and Doppler Ultrasound, In: Sutton MG et al. editors: Textbook of Echocardiography and Doppler Ultrasound in Adults and Children. Oxford: Blackwell Science; 1996. p 12. Reprinted with permission of Blackwell Publishing, LTD.)

Figure 20. Upper panel Build-up of a spectral Doppler signal by Fast-Fourier analysis. The relative amplitude of the signal at each pixel location is assigned a level of gray. With laminar flow, the range of velocities is narrow resulting in a narrow window of displayed velocity. Lower panel As flow becomes more turbulent the range of velocities detected increases to the point that very turbulent signals may display all velocities. (Reprinted from Zagzebski JA. Essentials of Ultrasound Physics. St. Louis: Mosby-Year Book Inc. copyright © 1996, p 100,101, with permission from Elsevier.)

Figure 21. Example of tissue Doppler imaging. Duplex mode is used; the 2D image is shown in the upper insert. The sample volume has been placed outside the left ventricular cavity over the mitral valve annulus and is being used to detect movement of that structure. The three most commonly detected waveforms are shown: (S) systolic contraction wave, (E) early diastolic relaxation wave, and (A) atrial contraction wave.

for different clinical circumstances. In some situations, not all of the slower moving structures can be fully eliminated without losing valuable Doppler data, resulting in various types of artifact.

New techniques of Doppler analysis focus on analyzing wall motion with Doppler and displaying the data either in color or with Fourier transform analysis. In this setting, the band pass filters are set to eliminate all high velocity data from blood flow and only analyze very low velocity movement coming from the wall of the ventricles or other structures such as valve tissue. Analysis of tissue motion measures the velocity of wall movement at selected locations in the heart using the typical PW sample volume. Conventional strip chart display is used and velocity can be displayed to represent both the velocity of contraction and the velocity of relaxation (Fig. 21). Color Doppler uses the auto correlator system to calculate velocity of large segments of myocardium at once. Systems that record data at high color Doppler frame rates store sufficient information to allow selective time—velocity plots to be made at various locations of the cardiac chamber walls. Color Doppler may also be utilized to calculate strain and strain rate, another alternate display mode being investigated as a parameter of ventricular function (10,11).

Once the video signal processing is complete, it is displayed on a monitor. Until recently, most monitors were analogue and used standard NTSC video display modes. The composite (or RGB) signal was sent to a videocassette recorder for long-term storage and playback. The study could then be played on a standard video playback system for review and interpretation. Many laboratories continue to use this method of recording and storage of images.

Figure 22. Organization chart showing a digital echo image storage system. Images generated by the ultrasound systems in the hospital and remote sites are input via high speed links through a switch to the server. The server has on line digital storage and is linked to a jukebox mass storage device. From the server, data may be viewed at any workstation either in the hospital or remotely. The hospital information system is linked to the system. This can allow electronic ordering of studies, downloading of demographic data on patients and interface with the workstations. Typically, images are reviewed at a workstation; a report is composed and is electronically signed. The report is stored in the server but may also be sent to the Hospital Information System electronic record or put out on paper as a final report.

Recently, many echo laboratories have changed to digital image display and storage. In some labs, the ultrasound system directly records the study in digital format, storing data on a large hard disk in the ultrasound system. The data is then output, typically using a DICOM standard signal to a digital storage and display system. Other laboratories may attach an acquisition box to the ultrasound system that digitally records and transmits the RGB signal to a central image server.

A digital laboratory set up is shown in Fig. 22. It has several advantages over videotape. Image data is sent to a server and on to a digital mass storage device. Depending on the amount of digital storage and volume of studies in the lab, days to months of image data may be instantly available for review. More remote data is stored in a mass storage system (PACS system) on more inexpensive media such as digital tape. Data in this remote storage may be held online in a second “juke box” server or be fully off line in storage media that must be put back on line manually.

Digital systems link the entire lab together and are typically integrated with the hospital information system. Common studies may be organized by patient and displayed on multiple workstations within the laboratory, hospital, and at remote clinics. This is a marked improvement compared to having each study isolated to one videotape. The quality of the image is superior. High-speed fiber optic links allow virtually simultaneous image retrieval at remote sites. Lower speed links may need several minutes to transmit a full study. To reduce the amount of storage, studies are typically compressed. Compression ratios of 30:1 can be used without evidence of any significant image degradation.

THE ECHOCARDIOGRAPHIC EXAMINATION

The Transthoracic Exam

A full-featured cardiac ultrasound system is designed to allow the operator to perform an M-mode echo, 2D echo, CW Doppler, PW Doppler, color Doppler, and tissue Doppler examination. Except for the specialized CW Doppler transducer, the entire exam is usually performed with a broadband multipurpose transducer. Occasionally, a specialized transducer of a different frequency or beam focus must be utilized to interrogate certain types of suspected pathology. The examination is performed in a quiet, darkened room with the patient supine or lying in a left lateral position on a specialized exam bed. The transducer is covered with a coupling medium (gel-like substance) that allows a direct interface between the transducer head and the patient's skin. If this coupling is broken the signal will be lost since ultrasound reflects strongly from tissue-air interfaces (Table 1). The transducer is then placed between the ribs, angled in the direction of the heart (ultrasound penetrates bone poorly and bone causes image artifacts), and adjusted until a satisfactory image is obtained (Fig. 2a). Electrodes for a single channel electrocardiogram are applied to the patient. The electrocardiogram signal is displayed continuously during the exam.

A standard examination begins in the left parasternal position (i.e., in the fourth and fifth rib interspaces just left of the sternum) (Fig. 2b). By orienting the 2D plane parallel to the long axis of the heart, an image of the proximal aorta, aortic valve, left atrium, mitral valve, and left ventricle can be obtained (Fig. 23). The standard M-mode echocardiographic views for dimension measurement are also obtained from this view (Fig. 6). Color Doppler is activated to examine flow near the mitral and aortic valves. By angulation from this position the tricuspid valve and portions of the right atrium and right ventricle are brought into view (Fig. 24). By rotation of the transducer $\sim 90^\circ$ from the long axis, the parasternal short-axis view is obtained.

Figure 23. Parasternal long axis view of the heart (LAXX) similar to orientation shown in Fig. 6. Abbreviations are as follows: aorta (Ao), left ventricle (LV), left atrium (LA), and right ventricle (RV). This is a 2D image.

Figure 24. Parasternal long axis view angled toward the right ventricle. Right-sided structures are shown: right atrium (RA), right ventricle (RV) and tricuspid valve (TV).

By progressively changing the angle of the transducer it is possible to obtain a series of cross-sectional views through the left ventricle from near the apex to the base of the heart at the level of the origin of the great vessels (Figs. 25 and 26). In an optimal study, several cross-sections through the left ventricle, mitral valve, aortic valve, and to a lesser degree the tricuspid valve, pulmonic valve, and right ventricular outflow tract can be obtained. Since conventional 1D arrays yield only 2D images, only small slices of the heart are examined at any one time.

The transducer is then moved to the mid-left chest slightly below the left breast where the apex of the heart touches the chest wall (Fig. 2). The 2D transducer is then angled along the long axis toward the base of the heart. The result is a simultaneous display of all four chambers of the heart and the mitral and tricuspid valves (Fig. 27). No M-mode views are taken from this position. Using duplex

Figure 25. Parasternal short axis view at the level of the great vessels. Shown is the aorta (Ao), a portion of the left atrium (LA), the origin of the left (LCA), and right (RCA) coronary arteries, and a part of the right ventricular outflow tract.

Figure 26. Short axis orientation at the transducer (SAXX) showing a cross-sectional view of the left ventricle (LV). The muscle appears as a ring. The septum (IVS) separates the LV from the right ventricle (RV).

mode, PW Doppler samples of blood flow are taken to show the forward flow signal across the mitral and tricuspid valves (Fig. 28). By further anterior angulation, the left ventricular outflow tract and aortic valve are imaged (Fig. 29) and forward flow velocities are sampled at each site. The 2D image allows precise positioning of the Doppler sample volume. By rotation of the transducer, further selective portions of the walls of the left ventricle are obtained (Fig. 30). Color Doppler is then used to sample blood flow across each heart valve, screening for abnormal turbulent flow, particularly related to valve insufficiency (leakage during valve closure). The transducer is then moved to a location just below the sternum (Fig. 2b) and aimed up toward the heart where the right atrium and atrial septum can be further interrogated, along with partial views of the other chambers (Fig. 31). In some

Figure 27. The transducer is placed in the apical position. The view shown is the apical "four chamber" view since all four chambers of the heart can be imaged simultaneously. Abbreviations are as follows: left ventricle (LV), left atrium (LA), right atrium (RA), and right ventricle (RV).

Figure 28. By using the same transducer orientation as Fig. 27, several other types of data are obtained. In this case, the system has been switched to Duplex mode. The 2D echo is used as a guide to position the mitral sample volume (small upper image). Flow is obtained across the mitral valve (MV) with waveforms for early (E), and atrial (A) diastolic flow shown.

patients, cross-sectional views equivalent to the short-axis view may be obtained.

However, this view in most patients is less useful because the heart is further from the transducer causing reduced resolution and increased attenuation of the echo signals. Finally, the heart may be imaged from the suprasternal approach (Fig. 2b), which generally will allow a view of the ascending aorta and aortic arch (Fig. 32).

Figure 29. From the view shown in Fig. 27, the transducer has been tilted slightly to show the outflow region of the left ventricle (LV) where blood is ejected toward the aorta (Ao). Abbreviations are as follows: left atrium (LA), right atrium (RA), and right ventricle (RV).

Figure 30. From the position shown in Fig. 27, the transducer is rotated to show a different perspective from the apical view. The “two-chamber” view shows only the left-sided chambers and the mitral valve (MV) that controls flow between these two chambers. Abbreviations are as follows: left ventricle (LV) and left atrium (LA).

The Transesophageal Exam

About 3–10% of hospital-based echocardiograms are performed using a specialized transesophageal (TEE) device. The ultrasound transducer, smaller but otherwise of virtually equal capability to the transthoracic device, is attached to the end of an endoscope. The patient is prepared using a topical anesthetic agent in the mouth and pharynx to eliminate the gag reflex and given conscious sedation to increase patient comfort. Patient status is monitored by a nurse, the ultrasound system operated by a sonographer

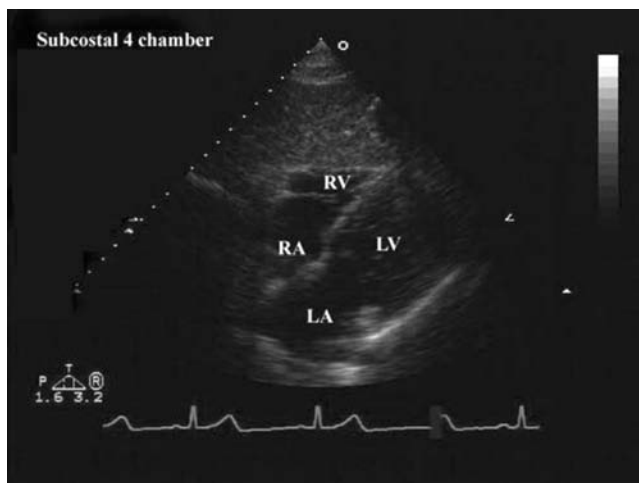

Figure 31. The transducer is moved to the subcostal position (see Fig. 2b). Portions of all four chambers are visible. Abbreviations are as follows: left atrium (LA), left ventricle (LV), right atrium (RA), and right ventricle (RV).

Figure 32. The transducer is positioned at the suprasternal notch (see Fig. 2b). A portion of the aorta (Asc Ao and Dsc Ao) is visible along with the origins of three branches coming off of this structure: innominate artery (IA), left common carotid artery (LCCA) and left subclavian (LSC).

and the transducer inserted by a physician who personally performs the exam. As the transducer is passed down in the esophagus, multiple imaging planes are obtained. These planes are obtained by a combination of movement of the transducer to different levels of the esophagus, changing the angle of the transducer and controlling the transducer head. Originally, the transducer was fixed in one location on the endoscope. Virtually all devices now made allow the operator to rotate the transducer through a 180° arc markedly increasing the number of imaging planes in the exam (Figs. 33–35). Using this method multiple views of structures in both a long and short axis configuration are possible. The transducer may also be passed into the stomach where additional views are possible.

Figure 33. Image generated by a transducer placed in the esophagus. Abbreviations are as follows: left ventricle (LV) and left atrium (LA).

Figure 34. Image from a transesophageal transducer. This is a magnified view of the mitral valve leaflets (arrows).

The exam is performed in a similar fashion to the transthoracic exam in that multiple views of cardiac chambers and valves are taken in an organized series of views to achieve a complete examination of the heart. Many planes are similar to the transthoracic exam except for location of the transducer. Other views are unique to the TEE exam and may be the clinical reason the exam was performed. Once the exam is complete, the transducer is removed, and the patient is monitored until recovered from the sedation and topical anesthesia.

The Intracardiac Exam

During specialized procedures it may be valuable to examine the heart from inside. This is usually done during specialized sterile cardiac procedures when a transthoracic transducer would be cumbersome or impossible to use and a TEE also would be impractical.

Figure 35. Image from a transesophageal transducer. The septal structure (IAS) that separates the two atrial chambers is shown (arrow).

A catheter with a miniaturized transducer is passed under fluoroscopic guidance up large central veins from the groin to the right side of the heart. For most applications, the device may be placed in the right atrium, or infrequently, in the right ventricle. The transducer is a miniature phased array device that can provide 2D and Doppler information. In most cases, the clinical diagnosis is already known and the patient is undergoing a specialized cardiac procedure in the catheterization laboratory to close a congenital defect or monitor radio frequency ablation during a complex electrophysiologic procedure, attempting to eliminate a cardiac rhythm disorder. The device contains controls that allow change of angle in four directions. This, combined with positional placement of the catheter in different parts of the cardiac chambers, allows several different anatomic views of cardiac structures (Fig. 36).

The Stress Echo Exam

Combining a transthoracic echo with a stress test was first attempted in the 1980s, became widely available in the mid-1990s, and is now a widely utilized test for diagnosis of coronary artery disease. The echo exam itself is purposely brief, usually confined to 4–6 2D views.

A patient having a stress echo is brought to a specialized stress lab that contains an ultrasound system set up to acquire stress images, an exam table, and a stress system that most commonly consists of a computerized electrocardiography system that runs a motorized treadmill (Fig. 37). The patient is connected to the 12-lead electrocardiogram stress system and a baseline electrocardiogram is obtained. The baseline echo is next performed, recording 2D views (Fig. 38). Then the stress test is begun. It can be performed in two different formats:

1. **Exercise:** If the patient is able to walk on a treadmill (or in some labs, pedal a bike), a standard maximal exercise test is performed until maximum effort has been achieved. Immediately upon completion of exercise, the patient is moved back to the echo exam table and repeat images are obtained within 1–2 min of completion of exercise.
2. **Pharmacologic stimulation:** If the patient is unable to exercise, an alternative is stimulation of the heart with an intravenous drug that simulates exercise. Most commonly, this is dobutamine, which is given, in progressively higher doses in 3–5 min stages. The patient remains on the exam table the entire time, connected to the electrocardiographic stress system. 2D echo images are obtained; at baseline, low dose, intermediate dose, and peak dose of drug infusion during the exam.

In both types of tests, clinical images are recorded and then displayed so that pretest and posttest data can be examined side by side. Comparisons of cardiac function are carefully made between the prestress and poststress images. The test relies on perceived changes in mechanical motion of different anatomic segments of the heart. Both inward movement of heart muscle and thickening of the walls of the ventricles are carefully evaluated. The normal

Figure 36. (a) Image of the atrial septum in a patient with an atrial septal defect (arrow). This image was taken with an intracardiac transducer placed in the right atrium (RA). The image is of similar quality to that seen in Fig. 35. (b) Image of same structure as (a) demonstrating color flow capabilities at the intracardiac transducer. Color Doppler (seen in gray scale) confirms the structure is a hole with blood passing through the hole (ASD shunt). (c) Image taken from same position as (a) and (b). The atrial septal defect has been closed with an occluder device (arrow). Doppler was used (not shown) to confirm that no blood could pass through the previously documented hole.

Figure 37. Typical set-up of a laboratory to perform stress echocardiograms. Shown are the echocardiographic examination table (ET), the treadmill (T), the treadmill computer control system (TC), and the ultrasound system (US).

heart responds by augmenting inward motion and wall thickening in all regions. If blood supply to a given segment is not adequate, mechanical motion and wall thickening either fails to improve or deteriorates in that segment, but improves in other segments. This change defines an abnormal response on a stress echo (Fig. 38). The location and extent of abnormal changes in wall motion and thickening are reported in a semiquantitative manner. In addition, the electrocardiogram response to stress is also compared with the baseline exam and reported along with patient symptoms and exercise capacity.

Figure 38. Quad screen format of view obtained from a stress echocardiography examination. Four views are displayed simultaneously, and the particular views shown can be changed to accommodate direct comparison of pre- (images on the left) and posttest images on the right views of the same part of the heart as shown in the example. The arrow indicates an area of the heart that failed to respond normally.

CLINICAL USES OF ECHOCARDIOGRAPHY

M-Mode Echocardiography

The M-mode echo was the original cardiac exam and for years was the dominant cardiac ultrasound study performed. The 2D echo has superseded M-mode echo as the primary examination technique and in most circumstances is superior. However, many laboratories continue to perform at least a limited M-mode exam because dimension measurements are well standardized. In addition, due to its high sampling rate, M-mode echo is superior to 2D echo for timing of events within the cardiac cycle and for recording simultaneously, with other physiologic measurements such as phonocardiograms and pulse tracings. Certain movement patterns of heart valves and chamber walls are only detected by M-mode, thus providing unique diagnostic information (Fig. 39).

Most M-mode echo data is obtained from multiple different “ice pick” views, all obtained from the parasternal position (Fig. 7). The 2D image is used to direct the cursor position of these views. The first view angles through a small portion of the right ventricle, the ventricular septum, the left ventricular chamber, the posterior wall of the left ventricle, and the pericardium. From this view, left ventricular wall thickness and the short-axis dimensions of this chamber can be measured. By calculating the change in dimension between end diastole (at the beginning of ejection) and end systole (at the end of ejection), the fractional shortening can be measured using the equation:

$$\frac{LVEDD - LVESD}{LVEDD} = \text{fractional shortening}$$

where LVEDD is the left ventricular end diastolic dimension and LVESD is the left ventricular end systolic dimension.

Figure 39. Example of an M-mode echocardiogram of the mitral valve showing abnormal motion, in this case a “B-bump” indicating delayed closure of the valve. DCM = dilated cardiomyopathy.

sion. This measurement estimates left ventricular function (Fig. 40). Dimension measurements give a relatively precise estimate of left ventricular chamber size to calculate whether the ventricle is inappropriately enlarged. In a similar manner wall thickness measurements can be utilized to determine if the chamber walls are inappropriately thick (left ventricular hypertrophy), asymmetrically thickened (hypertrophic cardiomyopathy), or inappropriately thin (following a myocardial infarction).

The second ice pick view passes through the right ventricle, septum, mitral valve leaflets, and posterior wall. This view is used primarily to evaluate motion of the mitral valve. Certain types of mitral valve disease alter the pattern of motion of this valve (Fig. 39). Other abnormal patterns of leaflet motion may indicate dysfunction elsewhere in the left ventricle.

The third ice pick view passes the echo beam through the right ventricle, aortic valve, and left atrium. From this view, analogous to the mitral valve, the pattern of aortic valve motion will change in characteristic ways allowing the diagnosis of primary aortic valve disease or diseases that cause secondary aortic valve motion changes. Also, from this view the diameter of the left atrium is measured and whether this structure is of normal size or enlarged can be of considerable importance in several circumstances. Other views are possible, but rarely used.

Measurements taken from M-mode may be performed during the exam by the sonographer. Usually, the scrolling M-mode video display is saved in digital memory on the system. The saved data is then reviewed until the best depiction of the various views discussed above is displayed. The sonographer then uses electronic calipers, automatically

Figure 40. Example of an M-mode echocardiogram of the left ventricle. The typical measurements of wall thickness (IVSed and LVPWed) and chamber dimensions (RVIDed, LVIDed and LVIDes) are shown. Several calculated parameters are possible from these values.

calibrated by the system, to record dimension measurements (Fig. 40). Basic measures are made and formulas for derived data such as the % FS are automatically calculated. Measurements can also be made “off line” using special workstations that display the video information at the time the study is interpreted by the physician.

Two-Dimensional Echocardiography

The 2D exam gives information about all four cardiac chambers and all four cardiac valves. It also serves as the reference point for positioning all Doppler sample volumes and the color Doppler exam. The heart is imaged from multiple positions, which not only improves the chance of useful information being obtained, but also allows better characterization of a given structure because the structure is seen in several perspectives. The primary role of a 2D echo is to characterize the size of the left and right ventricles as normal or enlarged, and if enlarged, estimate the severity of the problem. Second, the 2D exam evaluates pump function of the two ventricles. Function is characterized globally (i.e., total ventricular performance) or regionally (i.e., performance of individual parts of each ventricle). Some types of disease affect muscle function relatively equally throughout the chambers. Other forms of disease, most notably coronary artery atherosclerosis, which selectively changes blood supply to various parts of the heart, cause regional changes in function. In this disease, some portions of the heart may function normally while other areas change to fibrous scar and decrease or stop moving entirely. Global function of the left ventricle can be characterized quantitatively. The most common measurements of function use calculations of volume during the cardiac cycle. This is quantified when the heart is filled maximally just before a beat begins and minimally just after ejection of blood has been completed. The volume calculations are used to determine of ejection fraction. The equation is

$$\text{Ejection fraction} = \frac{\text{LVEDV} - \text{LVESV}}{\text{LVEDV}} \times 100$$

where LVEDV = left ventricular end diastolic volume and LVESV = left ventricular end systolic volume.

The 2D echo is sensitive for detecting abnormalities within the chambers, such as blood clots or vegetations (infectious material attached to valves). Abnormalities surrounding the heart, such as pericardial effusions (fluid surrounding the heart), metastatic spread of tumors to the heart and pericardium, and abnormalities contiguous to the heart in the mediastinum or great vessels can be readily imaged. Most of this information is descriptive in nature (Figs. 41 and 42).

The ability to directly and precisely make measurements from 2D echo views for quantitative measurements of dimensions, areas, and volumes is built into the ultrasound system and is typically done by the sonographer during the exam in a similar fashion to M-mode. Further measurements may be performed off line on dedicated analysis computers. Many parts of the interpretation of the exam, however, remain primarily descriptive and are usually estimated by expert readers.

Figure 41. Example of detection of a blood clot (thrombus) in the left ventricular chamber.

Doppler Echocardiography

While the 2D echo has considerably expanded the ability to characterize abnormalities of the four heart valves, it has not been possible to obtain direct hemodynamic information about valve abnormalities by imaging alone. Doppler imaging provides direct measurement of hemodynamic information.

By using Doppler, six basic types of information can be obtained about blood flow across a particular region:

1. The direction of the blood flow.
2. The time during the cardiac cycle during which blood flow occurs.
3. The velocity of the blood flow.
4. The time the peak velocity occurs.
5. The rate at which velocity changes.

Figure 42. Example of a patient with fluid surrounding the heart. The dark area surrounding the heart (pericardial effusion) is shown. In this case, increased pressure caused by the effusion compresses part of the right atrium (RA).

- 6. The pressure drop or gradient across a particular valve or anatomic structure.

Data about pressure gradients is derived from the velocity measurement using the Bernoulli equation:

$$P_1 - P_2 = \underbrace{1/2\rho(V_2^2 - V_1^2)}_{\text{Convective acceleration}} + \underbrace{\rho \int_1^2 \frac{dv}{dt} ds}_{\text{Flow acceleration}} + \underbrace{R(v)}_{\text{Viscous friction}}$$

where $P_1 - P_2$ is the pressure drop across the structure V_2 and V_1 being blood flow velocity on either side of the structure, and ρ is the mass density of blood ($1.06 \times 10^3 \text{ kg/m}^3$). For applications in the heart, the contributions by the flow acceleration and viscous friction terms can be ignored. In addition, V_1 is generally much less than V_2 (thus, V_1 can usually be ignored), and ρ is a constant for the mass density of blood (6). Combining all these changes together results in the final “simplified” form of the Bernoulli equation:

$$P_1 - P_2 = 4V^2$$

Cardiac Output. When the heart rate, blood flow velocity integral, and cross-sectional area of the region across which the blood flow is measured are known, cardiac output can be estimated using the following equation:

$$CO = A \times V \times HR$$

where CO is the cardiac output, A is the cross-sectional area, V is the integrated blood flow velocity, and HR is the heart rate.

The Character of the Blood Flow. The differentiation between laminar and turbulent blood flow can be made by observation of the spectral pattern. In general, laminar flow (all recorded velocities similar) occurs across normal cardiac structures of the heart, while disturbed or turbulent flow (multiple velocities detected) occurs across diseased or congenitally abnormal cardiac structures (Fig. 20).

Doppler is most valuable in patients with valvular heart disease and congenital heart disease. In the case of valve stenosis (abnormal obstruction to flow), use of Doppler echocardiography allows quantification of the pressure gradient across the valve (Fig. 43). Using the continuity principle, which states that the product of cross-sectional area and flow velocity must be constant at multiple locations in the heart, it is possible to solve for the severity of valve stenosis. The equation may be written as noted and then manipulated to solve for the area at the stenotic valve (A_2).

$$A_1 V_1 = A_2 V_2$$

$$\frac{A_1 V_1}{V_2} = A_2$$

For valvular insufficiency, Doppler echocardiography is most useful when the color Doppler format is used in

Figure 43. Example of a continuous wave Doppler signal through the aortic valve (AoV). Two tracings are shown along with measurement technique also demonstrated.

conjunction with 2D echo. Since an insufficient valve (i.e., a valve that allows backward leakage of blood when closed) produces turbulent flow in the chamber behind the valve, color Doppler immediately detects its presence. The extent to which turbulent flow can be detected is then graded on a semiquantitative basis to characterize the amount of valve insufficiency (Fig. 17). Since only 2D are interrogated at any given time, the best results are obtained when Doppler sampling is done from more than one view.

In patients with congenital heart disease, Doppler echocardiography allows the tracing of flow direction and velocity across anatomic abnormalities, such as holes between various cardiac chambers (i.e., atrial or ventricular septal defects). It can also display gradients across congenitally malformed valves and great vessels and also determine the direction and rate of flow through anatomically mal positioned chambers and great vessels.

In addition to direct interrogation of heart valves for detection of primary valve disease, Doppler flow sampling is used to evaluate changes in flow across normal valves that may indicate additional pathology. For example, the systolic blood pressure in the lungs (pulmonary artery pressure) may be estimated by quantifying the velocity of flow of an insufficiency jet across the tricuspid valve (another application of the Bernoulli equation). This calculated value, when added to the estimated central venous pressure (obtained in a different part of the exam) gives an excellent estimate of pulmonary artery pressure.

A second important measurement involves characterizing the way the left ventricle fills itself after ejecting blood into the aorta. There is a well-described set of changes in the pattern of flow across the mitral valve, changes in flow into the left atrium from the pulmonary veins and changes in the outward movement in the muscle itself characterized

by tissue Doppler that can help categorize the severity of changes in filling of the left ventricle.

SPECIALIZED CLINICAL DATA

Transesophageal Echocardiography

The TEE exam is used when a transthoracic exam either cannot be performed or gives inadequate information. One limitation of echo is the great degree of variability in image quality from patient to patient. In some circumstances, particularly in intensive care units, the TEE exam may provide superior image quality since its image quality is not dependent on patient position or interfered with by the presence of bandages, rib interfaces, air or other patient dependent changes. Similarly, during open heart surgery a TEE is routinely used to assess cardiac function pre- and postintervention and pre- and postheart valve replacement or repair. Since the TEE probe is in the esophagus, outside of the surgeon’s sterile field images are obtained even when the patient’s chest is open. This capability allows the surgeon to evaluate the consequences of, for example, a surgical repair of a heart valve, when the heart has been restarted, but before the chest is sutured closed. The TEE exam also visualizes parts of the heart not seen by any transthoracic view. A particular example of this is the left atrial appendage, a part of the left atrium. This structure sometimes develops blood clots that can only be visualized by TEE.

Three-Dimensional Reconstruction

While the 2D exam displays considerable data about spatial relationships between structures and quantification of volume, there is still considerable ambiguity in many circumstances. One way to further enhance the exam is to use 3D reconstruction.

Figure 44. Example of on-line 3D reconstruction. The heart is imaged at the level of the aortic valve where all three leaflets are shown.

Its use has been a significant challenge. All early methods developed computerized routines that characterized the movement of the transthoracic transducer in space. Images were acquired sequentially and then reconstructed first using geometric formulae and later using more flexible algorithms without geometric assumptions. The data, while shown to be useful for both adding new insight into several cardiac diseases and improving quantitation, did not achieve practical acceptance due to the considerable operator time and effort required to obtain just one image (12).

Recently innovations in image processing and transducer design have produced 3D renditions of relatively small sections of the heart in real time. Use remains limited at present but further development is expected to make 3D imaging a practical reality on standard ultrasound systems (Fig. 44).

(a)

(b)

Figure 45. (a) Example of injection of agitated saline into systemic veins. The contrast moves into the right atrium (RA) and right ventricle (RV), causing transient full opacification. The left-sided chambers are free of contrast. (b) Similar to (a). However, some of the contrast bubbles have crossed to the left ventricle (LV), proving a communication exists between the right and left sides of the heart.

Figure 46. Example of contrast use to improve visualization of the walls of the left ventricle. The contrast agent used in this case is a gas-filled microbubble that fills the left ventricle during a stress test. The entire chamber is white with full contrast enhancement.

Contrast Imaging

Contrast agents are combined with certain 2D echo exams to enhance the amount of diagnostic information available on the exam, or improve the quality of the exam.

There are two types of contrast agents. One type is made from normal saline solution. An assistant generates the contrast for injection during regular 2D imaging. Typically 0.5 mL of air is added to a 10 mL syringe of saline and vigorously hand agitated between 2 syringes for about 15 s. This agitation causes production of several million small bubbles. The bubbles are too large to pass through capillaries, thus when injected into a vein, they are all filtered out by the passage of venous blood through the lungs. Thus when injected into a normal heart, saline contrast passes into the right atrium and right ventricle, produces a transient intense response and disappears, not making it to the left ventricle. This property makes saline injection ideal for detecting an abnormal hole, or shunt passage across the atrial septum or ventricular septum. When a communication of this type is present bubbles cross directly from the right side to the left side of the heart. This is an extremely sensitive method for making this diagnosis (Fig. 45).

A second type of contrast agent, developed and now commercially marketed, is a gas filled microbubble smaller than a red blood cell. This type of agent, made from perfluorocarbons covered by an albumen or lipid shell, when intravenously injected passes through the lungs and opacifies the left side of the heart as well as the right side. The bubbles are gradually destroyed by ultrasound and blood pressure, lasting for several minutes in ideal circumstances. When combined with harmonic imaging these contrast agents markedly improve the quality of the 2D image, particularly for the evaluation of left ventricular wall motion (Fig. 46). The contrast agent markedly enhances the border between blood and the chamber wall. Use of these agents is variable among laboratories, but its use substantially decreases the number of nondiagnostic

studies. Still under investigation is whether these same contrast agents can be used for evaluation of blood flow within the heart muscle. This information could be of particular value for patients with coronary artery disease either during acute episodes of ischemia when a new coronary stenosis is suspected or as an enhancement to the stress echocardiogram (13).

INTRODUCTION

Electroanalgesia, electroanesthesia, neurostimulation, neuromodulation, and other physical methods of producing analgesia, anesthesia, and/or decreased sensitivity to painful stimuli are old concepts that are beginning to be revitalized in the recent past. For > 40 years, there has been a revival of electrotherapy in the treatment of pain. Analgesia by electrical current is now based on transcutaneous or percutaneous nerve stimulation, deep stimulation, posterior spinal cords stimulation, and transcutaneous cranial electrical stimulation (1–8). One reason for this has been the increased awareness of spinal and supraspinal opioid analgesic mechanisms, including the precise pathways,

receptors, and neurotransmitters involved in pain perception, recognition, modulation, and blockade. Another reason is the renewed belief that nonpharmacological manipulation of these receptors and transmitters should be possible with electricity since numerous progress have been made in the development of electric current waveforms that result in significant potentiation of the analgesic and hypnotics action of many intravenous and inhaled anesthetics without producing significant side effects (9–20). Finally, recent successes of transcutaneous electrical nerve stimulation (TENS) in the treatment of pain and transcutaneous cranial electrical stimulation (TCES) as a supplement during anesthesia to obtain postoperative analgesia by potentiating the anesthetic agents used during the intra- and postoperative phases. The popularity of electroacupuncture in a variety of pain and pain related areas have focused the attention of investigators and the public on electricity as a beneficial medical therapy. In this article, some of the most recent developments in nerve and brain stimulatory techniques using electrical stimulation to produce analgesia are addressed.

HISTORY

Alteration of pain perception utilizing forms of electrical stimulation dates back to the Greco-Roman period. Electrostimulation to decrease the pain started with the “electric fish” (torpedo marmorata), as 46 years after Jesus Christ, Scribonius Largus, physician to emperor Claudius, recommended the analgesic shock of the Torpille in the treatment of the pain (21,22). Unfortunately, in those days attempts were crude and success was limited for many reasons none-the-least of which was a poor understanding of the fundamentals of electricity. Interest in electroanalgesia was renewed in the seventeenth century when Von Guericke built the first electrostatic generator to apply locally to relieve pain; however, results were still marginal. At the beginning of the twentieth century, Leduc reawakened interest in the idea of producing sleep and local and general anesthesia with low frequency impulsional electrical current. He used unidirectional rectangular intermittent current of 100 Hz with an ON-time of 1 ms and OFF-time of 9 ms with a moderate amperage (0.5–10 mA) on a variety of animals and on himself to evaluate the effects of electricity on the central nervous system (23,24). Electrodes were placed on the forehead and kidney areas and electrostimulation resulted in apnea, cardiac arrhythmias, cardiac arrest, and convulsions in dogs and a “nightmarelike state” in which the subject was aware of pain. Despite these inauspicious beginnings, studies continued. In 1903, Zimmern and Dimier produced postepileptic coma with transcerebral currents, and in 1907, Jardy reported the first cases of surgery in animals with electroanesthesia. Between 1907 and 1910, Leduc and other performed a number of surgical operations on patients with electricity as an anesthetic supplement (1–5).

In the early decades of the twentieth century, electroanalgesia was always associated with intense side effects including muscle contractures, prolonged coma (cerebral shock), cerebral hemorrhage, hyperthermia, cardiac

arrhythmias, and convulsions. Because of these difficulties, interest waned. In 1944, Frostig and Van Harveld began experimenting with an alternating current from 50 to 60 mA and a variable voltage bitemporally. The advantage of this more complex method of stimulation was less muscular spasm and contraction (4,5). Unfortunately, these approaches still resulted in transient periods of apnea, cardiac arrhythmias, and standstill as well as fecal and urinary soilage. These problems could be reduced, but not eliminated, by decreasing amperage. Numerous other investigators began using many diverse currents without much success. The most interesting results were obtained in 1951 by Denier (25,26) and in 1952 by Du Cailar (4). Denier began experimenting with high frequency (90 kHz) rectified sinusoidal current with a pulse duration of 3 ms (on time) and a resting time of 13 ms (OFF time), knowing that the effects of modulation at a high frequency current are those of the envelope of its waves. Du Cailar introduced the idea of electropharmaceutical anesthesia by utilizing a premedication of morphin-lobelin in association with a barbituric induction, along with the electrical current. This idea of electropharmaceutical anesthesia that was taken up again in the Soviet Union in 1957 by Ananev et al. using the current of Leduc combined with a direct current (1-3), and in the United States by Hardy et al. using an alternating sinusoidal current of 700 Hz current of Knutson (27-29), and during the same period by Smith using the current of Ananev (1). But with these currents the experimenters were always bothered by side effects (muscle contractions of the face with trismus, of the body with apnea, etc.) that required the use of curare and for all practical purposes made this approach to anesthesia more complicated than conventional anesthesia.

Other investigators began studying mixtures of pharmaceutical agents, including opioids, barbiturates, and later benzodiazepines and butyrophenones in combination with electric currents to reduce and hopefully eliminate these problems, which were often attributed to "the initial shock of the electric current". Others began studying the shape of the current waveform and its frequency. Sances Jr., in United States, used the current of Ananev associated with white noise (5,30) while Shimoji et al. in Japan, used a medium frequency (10 kHz) monophasic or biphasic current with sinusoidal or rectangular waves (31,32). Many were able to produce impressive analgesia and anesthesia in animals, but significant problems (apnea, hypersialorrhea, muscular contractures, convulsions, cardiac arrhythmias) continued to occur in humans. As a result, from the 1950s until the present time, many investigators focused on appropriate electrode placement. It was Djourno who thought that the principal problem to resolve was to find the ideal position for the electrodes to determine the trajectory of the electric current so as to touch precise zones of the brain. This is why he advocated electrovector anesthesia applied with three electrode pairs (vertex-palate, temporal-temporal, fronto-occipital) (4,33). During this time the Soviets Satchov et al. preferred interferential currents of middle frequencies (4000-4200 Hz) associated with barbiturates transmitted by two pairs of crossed electrodes (left temporal-right retromastoid and right

temporal-left retromastoid). Others suggested that the problems can be minimized by using mixtures of sedative, hypnotic, and analgesic drugs, plus low amperage electrical currents to produce the ideal effect.

The result of all this activity is that there is still no general agreement on the importance of electrode placement (although frontal and occipital are probably most popular), waveform, wave frequency, current strength, interference currents, or the role of supplemental pharmacotherapy (4,34-38). What was agreed was that it appeared impossible to reliably produce problem-free "complete anesthesia" in humans using any available electrical generators and associated apparatus. Instead, the most successful approaches to electroanesthesia have used waveforms, frequencies, and currents that produce few, if any, side effects (and result in significant analgesia), but must be supplemented with pharmacological therapies to be a "complete anesthetic". While some may scoff at these modest gains, others remain optimistic because using a variety of neurostimulatory approaches, reproducible and quantifiable analgesia was now possible without pharmaceutical supplementation.

Analgesia and Electroneurostimulation

The advancement of the spinal gate control theory of pain by Melzack and Wall (39,40), the discovery of central nervous system opiate receptors, and the popularity and apparent effectiveness of acupuncture in some forms of pain management have given support to the basis that neurostimulatory techniques can produce analgesia via readily understandable neurophysiological changes rather than mysterious semimetaphysical flows of mysterious energy forces (41,42). It is now clear that electrical stimulation of the brain and peripheral nerves can markedly increase the concentration of some endogenous opiates (β -endorphin, δ -sleep producing factor, etc.) in certain areas of the brain and produce various degrees of analgesia. It is proposed that pain relief from electrical stimulation also results from a variety of other mechanisms including alteration in central nervous system concentrations of other neurotransmitters (serotonin, substance P), direct depolarization of peripheral nerves, peripheral nerve fatigue, and more complex nervous interactions (43-46).

Whatever the mechanisms producing analgesia with electrical stimulation, many clinicians are beginning to realize the advantages of these techniques. Neurostimulatory techniques are relatively simple, devices are often portable, their parameters (controls) are easy to understand and manipulate, and application usually requires minimal skills. Moreover, there are few, if any, side effects, addiction is unheard of, if a trial proves unsuccessful little harm is done, the techniques reduce requirements for other analgesics, and usually the stimulation itself is pleasant.

Transcutaneous Electrical Nerve Stimulators

Transcutaneous electrical nerve stimulation, currently called TENS, is the most frequently used device for treatment of acute postoperative and chronic pain of most etiologies. The first portable transcutaneous electrical stimulators were produced in the 1970s with controllable

wave forms and modulable patterns of stimulation. The goal was to produce a compact, lightweight, portable miniaturized current generator to provide stimulation by means of skin contacting electrodes, and able to be used as the patient went about normal daily activities. To that end, as well as safety reasons, the devices were battery powered. A plethora of electrical nerve stimulators can be found on the market. Dimensions are approximately the size of a pack of cigarettes and can be worn by the patient by use of straps or belts. These stimulators, that have one or more adjustable electric parameters that provide no ease of operation, deliver biphasic waves of low frequency of 1–250 Hz with current intensity from 50 to 100 mA. These electrical stimulations result in a tingling or vibrating sensation. Patients are able to adjust the dial settings with respect to frequency and intensity of the stimulus.

The stimulation electrodes must permit uniform current density and have a stimulation surface $> 4 \text{ cm}^2$ in order to avoid cutaneous irritation caused by elevated current densities. The material must be hypoallergenic, soft, and flexible to allow maximal reduction of any discomfort while providing for lengthy stimulation in diverse situations. The impedance at the biologic electrode–skin interface can be minimized by the choice of material as well as the use of a conducting gel. Materials used to make the electrodes can be carbon-based elastomeres as well as malleable metals. Most recent developments use adhesive-type ribbons impregnated with silver and are activated by a solvent and provide improved conductivity. For a clinician who is inexperienced in electronics or electro-neurophysiology, it is difficult to choose wisely as parameters available for use are created by inventors or producers with absolutely no scientific basis. Analysis of results obtained with the majority of these devices is based on subjectivity of the physician or the patient. The domain is merely empiric. It is a pity that the parameters chosen in the production and use of these devices is by researchers that have not taken advantage of the available scientific works in electrophysiology, notably those of Willer (47,48) on the nociceptive reflex of exercise in humans. A neurostimulator must be selected that will provide proper nerve excitation that is reproducible and durable and that does not cause lesions from burns or electrolysis. Consequently, all those stimulators that deliver direct or polarized current should be used carefully as well as those that deliver a radio frequency (RF) in excess of 800 kHz. One must choose stimulators that deliver a constant biphasic asymmetric current, that is, one that delivers a positive charge that is equal to the negative charge providing an average intensity of zero. To guide the clinician, it must be recalled that current always takes the path of least resistance, and therefore a current of low frequency can only be peripheral the more one increases the frequency. Otherwise, undesirable effects will be produced under electrodes. It is known that a sensation of numbness appears from 70 to 100 Hz and that a motor action appears from 1 to 5 Hz.

Implantable Electrical Nerve Stimulators

Other forms of stimulation consist of implanted neurostimulators, spinal cord stimulation (SCS) (dorsal column

stimulators), and deep brain stimulation (DBS). Peripheral nerve neurostimulation implants are also often used for chronic pain but may be employed for acute ulnar, brachial plexus, or sciatic pain in critically ill patients (8).

There are two types of implantable electrical stimulators: Passive-type stimulator with RF made up of a totally implantable element (receptor) and an external element (transmitter) that supplies the subcutaneous receiver through the skin using an RF modulated wave (500 kHz–2 MHz). Active-type totally implantable stimulator, supplied by two mercury batteries (which lasts for 2–4 years) or a lithium battery, which lasts for 5 or 10 years. These devices enable several parameters to be controlled (amplitude peak, wave width, frequency gradient). The variation of these parameters obviously depends on the patient, the region stimulated and the symptom which it is desired to modify.

ACTUAL CLINICAL NEUROSTIMULATORY TECHNIQUES

Certain precautions must be taken and the patient must be well advised as to the technique, the principles of stimulation, and all desired effects. These techniques should not be used on patients wearing a cardiac pacemaker, pregnant women, or in the vicinity of the carotid sinus. The methods demand the utmost in patience, attention to detail, and perseverance. It must be regularly practiced by medical or paramedical personnel.

The most important application of neurostimulatory techniques in clinical use today is in management of acute postoperative and chronic pain, however, since 1980 numerous terms are used in the articles to describe the diverse techniques for electrical stimulation of nervous system. Certain words do not harmonize with reality, such as TransCranial Electrostimulation Treatment (TCET) or Transcranial Electrostimulation (TE). In reality, the microamperage and low frequency used do not enable penetration of the current into the brain, they correspond to a peripheral electrostimulation, which is a bad variant of Transcutaneous Electrical Nerve Stimulation, now being used for certain painful conditions.

Transcutaneous Electrical Methods

Transcutaneous Electrical Nerve Stimulation (TENS). The purpose of this method is to achieve sensitive stimulation, by a transcutaneous pathway, of the tactile proprioceptive fibers of rapid conduction with minimal response of nociceptive fibers of slow conduction and of efferent motor fibers. Numerous studies have documented that TENS in the early postoperative period reduces pain, and thus the need for narcotic analgesics, and improves pulmonary function as measured by functional residual capacity. TENS is also frequently applied in chronic unremitting pain when other approaches are less effective or ineffective. This method is the simplest technique, and appears to be effective by alleviating the appreciation of pain (6,49).

The points of stimulation and the stimulation adjustments must be multiple and carefully determined before concluding that the effect is negative. Different stimulation points are used by the various authors: One can stimulate

either locally by placing the electrodes in the patient at the level of the painful cutaneous area and more particularly on the trigger point that may be at times some distance from the painful zone (50), or along a nerve pathway “upstream” away from the painful zone to cause parasthesia in the painful area, or an acupuncture point corresponding to the points depicted in an acupuncture chart (41,42). The stimulation time is usually 20–30 min and repeated at fixed hourly intervals, and discontinued when the pain is relieved. Whatever method is used, one must avoid the production of harmful stimulations or muscle contractions and the stimulation must be conducted with the patient at rest.

In acute injury states where pain is localized, TENS can produce analgesia in up to 80% of patients (51), but this percentage decreases to ~20% effectiveness at the end of a year. In order to obtain this result, this stimulation has the sensation of “pins and needles” in the area of the cutaneous stimulation. This phenomenon appears to be in part similar to a placebo effect estimated at 33% regardless of the type of current employed or the location of applied current. As the affected area increases in size, TENS is less likely to be sufficient and is also less effective in chronic pain, especially if the cause of the pain itself is diffuse.

The mechanism by which TENS suppresses pain is probably related to spinal and/or brain modulation of neurotransmitter and/or opiate or other γ -aminobutyric acid (GABA) receptor function. This method works best with peripheral nerve injuries and phantom and stump pains. Transcutaneous nerve stimulators are usually less effective in low back pain or in patients who have had multiple operations. It is often totally unsatisfactory for pain (particularly chronic pain) that does not have a peripheral nerve cause such as pain with a central nervous system etiology or an important psychological component (depression and anxiety) (52–55).

Transcutaneous Acupoint Electrical Stimulation (TAES). Acupuncture, in its traditional form, depends on the insertion of needles into specific acupuncture points in the body as determined by historical charts. Electrical Acupuncture (EA) or TAES employs Low Frequency (LF) stimuli of 5–200 Hz in the needles inserted at the classical acupuncture points. Occasionally, nontraditional acupuncturists use the needles at or near the painful area. Usually these types of treatments produce mild degrees of analgesia. Electrical acupuncture is essentially as benign as TENS and produces its effects by similar mechanisms (42,53,56). Unfortunately, EA is more expensive to perform than TENS because it necessitates the presence of an acupuncturist clinician. Thus, it is likely that EA will not become as popular as TENS for treatment of most pain problems.

Transcutaneous Cranial Electrical Stimulation (TCES). This method is a special form of electrical stimulation that employs a stimulator that gives a complex current (specific waveforms and high frequency). It was developed by a French group headed by Limoge (35–38,57–59). The TCES method has been used for analgesia during labor pain and before, during, and after surgery, and has recently been shown to be effective to potentiate the analgesic drugs for

major surgery, and cancer pain (60). With TCES two electrodes are placed in back of the ear lobe and behind the mastoid bone and one electrode at intersection of the line of the eyebrows and the sagittal plane. The resulting analgesia is systemic rather than regional (see the section Electrical Anesthesia for a more complete description of the current).

Neurosurgical Methods

Percutaneous Electrical Nerve Stimulation (PENS). This method consists of an electric stimulation by means of a surgically implanted electrode (subcutaneous) coupled by RF induction to an external stimulator nerve. This surgical technique produces long-term positive results of ~70% (61,62). It is possible to carry out this procedure quite simply by temporarily implanting needle electrodes at the acupuncture points or auriculotherapy points. This technique produces results similar to those of classic TENS (63,64).

Spinal Cord Stimulation (SCS). This is a neurosurgical method utilized in cases of failure of simple pharmacological or physical treatment where the percutaneous test was positive. As with PENS an RF stimulator is implanted, which this time is connected to electrodes at a level with the posterior spinal cord. The electrodes are actually placed in the epidural space, to provide a percutaneous pathway, under local anesthesia and radiological control. It is often difficult to obtain good electrode position and electrodes can easily become displaced. This technique is reserved for desperate cases as the results are of long term. Approximately 30% are discouraging results (8).

Deep Brain Stimulation (DBS). This method is a complicated and awkward procedure bringing to mind stereotaxis (8). It consists of implanting electrodes at the level of the Ventral Postero-Lateral (VPL) nucleus of the thalamus, which is in relation to afferent posterior cords at the level of PeriAqueductal Grey Matter (PAGM) or at the level of the PeriVentricular Grey Matter (PVG), where endorphin and serotonin neurons are found at the motor cortex, which is the start of the pyramidal fascia (10–13). Results obtained are encouraging in cases of consecutive pains at the deafferentation (72%), but of no value in case of pains of nociception. Deep brain stimulation is employed in patients when pain is severe, when other approaches have failed, and when there is a desire to avoid a “drugged existence” and life expectancy is at best a few months. It is often an approach to patients with metastatic cancer. This method is less successful when pain originates from the central nervous system (secondary to stroke, trauma, quadriplegia). The DBS-stimulating probes are usually targeted for the periaqueductal grey matter when pain is deep seated, or for the sensory thalamus or medial lemniscus when is superficial.

Electrical Anesthesia

As mentioned previously, it has never been nor is not now possible to produce, “complete anesthesia” with electricity alone in humans without producing serious side effects. On

the other hand, work by numerous investigators has demonstrated that one or more methods of electropharmaceutical anesthesia (anesthesia consisting of a combination of an electric current with anesthetic agents) is not only possible, but also desirable because of the lack of side effects and reduced requirements for neurodepressants. During past years, progress in chemical anesthesia has been so successful that the objective was not to replace classical anesthesia, but to more precisely confirm studies performed on animals, potentiation of anesthetic drugs by Transcutaneous Cranial Electrical Stimulation (TCES) to obtain postoperative electromedicinal analgesia, to the end that toxicity induced by chemical drugs could be dramatically reduced. The use of TCES is not without considerable supporting data, as from 1972 to 2000, many clinical trials involving TCES had been carried out on patients under electromedicinal anesthesia and provide >20 specific references (7). During those clinical trials, anesthetists noticed that complaints of patients operated under TCES were less numerous in the recovery room than complaints of patients operated with chemical anesthesia. It seems that a state of indifference and reduction of painful sensation persisted in TCES-treated patients. These observations were scientifically confirmed in a study (59) in which 100 patients operated under electroanesthesia (EA) was compared to another 100 patients submitted to narco-neurolept-analgesia, a classical anesthesia (CA): the head nurses were ordered to administered 15 mg (i.m.) of pentazocine in case of patient complaints. It is worth noting that the first 16 postoperative hours, the average intake of pentazocine for the patients of the EA group was 8.1 mg/patient, whereas it was 29.7 mg/patient (3.67 time higher) for the patients of the CA group. This difference between groups is highly statistically significant ($p < 0.001$) (Fig. 1).

This residual and prolonged analgesia is surely one of the most important advantages of TCES, but few clinicians benefit from its advantages at the present time. The most likely reason that few clinicians benefit from TCES is that it is not yet approved for use in the United States, Canada, and many countries in Europe by the respective regulatory agencies. Recent research carried on in numerous laboratories has increased our knowledge of the neurobiological

Figure 1. Comparison of two groups receiving pentazocin during the first 16 h after surgery.

effects of these currents, and allowed the establishment of serious protocols dedicated to new clinical applications (7).

Nature of the Limoge's Current. Limoge et al. demonstrated that complex currents of their design are capable of producing profound analgesia without provoking initial shock, pain, or unpleasant sensations, burns, other cutaneous damage, muscular contractures, cerebral damage or convulsions, and respiratory or circulatory depression (58). The Limoge current consists of high frequency (HF) biphasic asymmetrical wave trains composed of modulated high frequency (166 kHz) pulse trains, regularly interrupted with a repetition cycle of 100 Hz (7,57). These wave trains are composed of successive impulsional waves of a particular shape: one positive impulse of high intensity and short duration (2 μ s), followed by a negative impulse of weak intensity and long duration (4 μ s) adjusted in such a way that the positive surface is equal to the negative surface. The average intensity of this current equals 0 mA. The use of such a negative phase makes it possible to eliminate all risk of burns. The "on-time" of the low frequency (LF) wave trains is 4 ms, followed by a 6 ms "OFF-time" (Fig. 2).

Figure 2. The Limoge waveform pattern: a modulated HF (166 kHz) pulse trains (top) regularly interrupted with a repetition cycle of 100 Hz. Concerning the high frequency, note the exponential ascent and acute fall of the waveform, and also note the area of the positive deflection is equal to that of negative deflection.

Figure 3. Application of the device on a patient during post operative period. See the placement of the frontal electrode.

This type of current was gradually developed over ~20 years through numerous human clinical studies. The shape and cyclic ration of the HF waves are felt to be of utmost importance in the production of analgesia. Various shapes of waves have been tested (triangular, rectangular, exponential). Clinical impressions suggest that the most profound analgesia occurs with HF waveforms having an exponential ascent and acute fall. The most effective cyclic ratios are 2:5 with LF waves and 1:3 with HF waves with peak-to-peak intensity between 250 and 300 mA and peak-to-peak voltage between 30 and 40 V.

Electrodes. Three electrodes are used. One frontal electrode is placed between the eyebrows and two posterior electrodes are placed behind the mastoid process on each side of the occiput (Fig. 3). It is hoped that the intracerebral electric field thus obtained spreads on each side of the median line and it thus successful in stimulating opioid receptors surrounding the third and fourth ventricles and the paraventricular areas of the brain. In addition, some of the electric current spreads over the scalp, thus provoking peripheral electrostimulation (Fig. 4). The use of HF biphasic current permits employment of self-sticking electrodes made of silver (active diameter 30 mm), without risk of burns and without unpleasant sensations under electrodes.

Transcutaneous Cranial Electrical Stimulators Using Limoge Currents. Until now three types of devices only give Limoge currents: two American devices called Foster Biotechnology Neurostimulation Device (FBND) and Electro-Analgesia Stimulation Equipment (EASE) and one French device called Anesthelec (Fig. 5). The electrical stimulator must abide by general safety rules. The use of electrosurgical units during TCES requires excellent electrical isolation of the generator to avoid any risk of return of the current or skin burns under electrodes, a fault in the electrosurgical unit. These portable devices of type LF with isolated output are composed of one HF oscillator, one oscillator with LF relaxation with internal power supply generating HF (166 kHz), and LF (100 Hz) currents for

Figure 4. Location of the electrodes and shape of wave on the scalp. The center of the frontal electrode is situated at the intersection of the line of the eyebrows and the sagittal plane. The center of the two retromastoid electrodes is localized in the retromastoid fossa. On the scalp the amplitude of HF waves diminish in measurement as the point O (occipital line) is approached, and behind that point there is an inversion of the wave form. The lines joining the frontal electrode to retromastoid electrodes represent the projected distribution of Limoge currents through the brain with action at the level of the periaqueductal gray matter and the limbic system.

therapeutic use and one delay circuit, to stop output when its level is too high. The battery pack must be protected against short circuit as well as polarity inversion and detachable as it is rechargeable. The patient cable must

be an interlocking type preventing accidental disconnection and the functioning of the device must be simplified with detectors to measure the intensity of the current and the voltage applied to the patient to confirm proper contact between skin and electrodes. Concerning electromagnetic compatibility, the device must be autonomous with no possible direct or indirect link mains supplies. Mini box and manipulation components must be made in isolated material and the patient cables must be shrouded and the applied elements must be protected against overvoltage.

Clinical Usage of TCES

The TCES method being used with increasing frequency in France, and many other European countries, in Russia, in Mexico, and in Venezuela. It is not yet approved for use in the United States, but is being evaluated both in patients and in volunteers. Numerous studies have demonstrated that TCES is particularly effective in urologic, thoracic, and gastrointestinal surgery, but is not limited to these types of operative procedures. Patients receiving TCES require less nitrous oxide (N_2O) (30–40% less) to prevent movement in response to a pain stimulus. This method potentiates both the amnesic and analgesic effects of N_2O and prolongs residual postanesthetic analgesia at sites of trauma. The mechanism of analgesia resulting from TCES during administration of N_2O is unknown. Volunteers getting TCES without N_2O for 1 h are not sleepy or amnesic, but do report a warm and tingling sensation all over their body, and are objectively analgesic to many forms of painful stimulation (14–16). Similar results have been obtained with some TENS units in patients with chronic pain and after operation in patients with acute postoperative pain (54,55). As mentioned previously, some have suggested that receptor sites situated in the central gray area of the brain, the spinal cord, and other areas in the central nervous system regulate the effects of painful stimulation, analgesia, and the perception of somatic pain. Electrical stimulation of these receptor sites has been shown to result in relief from pain and can be antagonized by narcotic antagonists. Furthermore, the analgesic actions of TENS can be reversed with antagonists like naloxone (9,10). This suggests that TENS and TCES may be producing analgesia by stimulating increased production and/or release of the body's endogenous analgesics, the endorphins, enkephalins, serotonin and/or other neurotransmitters and neuromodulators (5,11–13,43–46,63–65).

To separate facts from empiricism and anecdotal information for several years, teams of researchers and clinicians attempted to show in animals and in humans what are the neurobiological mechanisms brought into play by the TCES with currents of Limoge. For that reason, a study was conducted in France on rats on TCES potentiation of halothane-induced anesthesia and the role of endogenous opioid peptides was addressed (19). Carried out in double blind for 10 h prior to tracheotomy and the inhalation of halothane, the TCES provoked in the stimulated rats (TCES group, $n = 10$), a significant decrease ($p < 0.001$) in the Minimum Alveolar Concentration of Halothane (MACH) in comparison with the nonstimulated rats (con-

Figure 6. Effects of TCES on halothane requirements in rats. *** indicate significant difference between TCES and CONTROL groups (ANOVA, $p < 0.001$).

control group, $n = 10$). This effect was completely inhibited by a subcutaneous injection of 2 mg/kg of naloxone (antagonist of morphine), which restored the MACH to its initial value in the TCES group without affecting the control group (Fig. 6). Moreover, TCES potentiation of halothane-induced anesthesia was dramatically increased by inhibition of enkephalin degradation. Thus the decrease of the MACH is associated with the potentiation the analgesic action of enkephalins released in the cellular space by TCES. These results demonstrate the direct involvement of endogenous opioid peptides on therapeutic effects of TCES.

In addition, a double-blind study carried out during labor and delivery on parturients to provide evidence of a mode of action of TCES on maternal plasma secretion of β -endorphins (66). To evaluate the rate of β -endorphins, blood samples were drawn from two groups of voluntary women in parturition (a TCES group, $n = 23$, and a control group, $n = 17$) at four precise stages: at the moment the electric generator was attached, after 1 h of the current application, at the time of complete dilatation, and finally after the delivery. The dosages were achieved by the radio-immuno enzymatic method. The plasmatic rate of β -endorphins was identical in the beginning for the two groups as those described in the literature, but this rate was progressively augmented in a significant fashion during the course of the labor from the first hour ($p < 0.05$) for the TCES group (Table 1).

It is more interesting to know the rate of endorphins produced in the cerebral structures known for their abundance of opiate receptors, more so than in the plasma. The exploration of the effects of TCES on brain opioid peptides was conducted at the Vishnevski Institute in Moscow by dosing endorphins in the cerebral spinal fluid (CSF) before cardiac surgery and after 30 min of TCES. The dosage showed that TCES augmented significantly ($p < 0.01$) the rate of β -endorphins in the CSF when compared to the control group and the effects of TCES reversed by naloxone (49,67,68).

These studies can partially explain the mode of action of TCES with currents of Limoge in the brain and permit not only rectification of protocols for clinical trials already carried out, but also provide better indication for utilization of TCES.

For all clinical applications, it must be kept in mind that the currents of Limoge provoke endogenous neurosecretions (7), which are not immediate, they require a certain

amount of time for their induction, and then are maintained all along the stimulation application. In consequence, the utilization of this technique in classical anesthesia is not the best indication except for major interventions of long duration. One must also remember that during > 10,000 major surgical interventions carried out under classical anesthesia combined with TCES it has been proven that the Limoge currents has a potentiation effect on opioid and non-opioid analgesics, morphinomimetics, psychotropes, and psycholeptics, (14–20) and this potentiation allows a decrease in drug doses, and therefore a decrease in toxicity. But one must admit objectively that, during past years, progress in chemical anesthesia has been so successful that the TCES will not replace classical anesthesia. The potentiation of drugs nevertheless by TCES can open new perspectives in the treatment of pain whether postoperative or chronic. To be precise the potentiation of opioid analgesia by TCES under specific conditions, was demonstrated by Stinus et al. (17). The authors showed that potentiation was a function of (a) the intensity of the stimulation, (b) the opioid dose administered, (c) the duration of TCES applied preceding opioid administration, and (d) the position and the polarity of the electrodes. This experimental approach was of prime importance as it allowed determination of the most efficient parameters, studied the therapeutic effects of TCES in humans, and increased our knowledge of the effects of TCES on neurobiological substrates.

Taking account of animal experimentation and clinical trials, one must know that to be successful in clinical applications, a correct basal protocol for TCES use should be followed. The main parameters are, the correct placement of the electrodes, starting electrostimulation no < 2 h

prior to the introduction of drugs and continuation of TCES delivery during the pharmacokinetic action of drugs.

Abolition of Postoperative Pain (Fig. 3). Patients operated under TCES associated with pharmaceutical anesthesia complain strikingly less often about pain than those operated with a classical anesthesia. The TCES method induces a postoperative analgesia for an average of 16 h. A double-blind study has been made during per and postoperative period on 39 patients (TCES group *n* = 20 and control group *n* = 19) undergoing an abdominal surgery (20). Upon arrival in the recovery room, patients were given a computerized, patient-controlled analgesia (PCA) device to deliver IV buprenorphine (50 μ g boluses, 30 min lock-out) during the first four postoperative hours. The recorded variables included postoperative requirements, pain scores with pain visual analogue scale (VAS) (from 0 = no pain to 10 = worst), sedation, (from 0 = not arousable to 4 = awake) and were collected hourly from the first to the sixth postoperative hour by a blinded investigator. There was a highly significant reduction of cumulative buprenorphine requirements in the TCES group compared with the control group (2.36 \pm 0.19 vs. 3.43 \pm 0.29 μ g · kg⁻¹ · h⁻¹; $p < 0.01$) (Table 2). At each postoperative hour, patients required less buprenorphine in the TCES group. These results indicate that TCES reduces narcotic requirements for postoperative analgesia. TCES may have potential to facilitate early postoperative analgesia in patients undergoing major surgery. Therefore this technique allows a maximal restriction of pharmaceutical contribution.

Obstetric Electroanalgesia (66,69). In order to test the analgesic efficacy of TCES with Limoge currents during

labor and delivery, a double-blind study was performed with "anesthelec" on 20 cases for whom analgesia was necessary (TCES group I, current "on", $n = 10$, and control group II, current "off", $n = 10$). Labor and delivery were carried out by a medical team different from those using the anesthelec. The results showed that TCES, with or without nitrous oxide inhalation, decreases by 80% the number of epidural analgesia or general anesthesia that would otherwise have been unavoidable. To define the effects of TCES, maternal and fetal parameters of 50 deliveries carried out under TCES were compared with 50 deliveries carried out under epidural analgesia (70).

TCES was used only if analgesia was required. These clinical trials were a retrospective comparison between two similar nonpaired series. Despite the fact that analgesia obtained with TCES was less powerful than with epidural analgesia, this method showed many advantages: total safety for the child and the mother, easy utilization, shorter labor time, decreased number of instrumental extractions and potentially reduced costs. Good acceptance and satisfaction for the mother should stimulate a rapid evolution and acceptance of this new method.

The TCES method should be applied following the first contractions. Analgesia is established after 40 min of stimulation. A diminution of pain is achieved that is comparable to that obtained after an injection (IV) of morphine (but it is less profound than with epidural analgesia), a decrease in vigilance with euphoria is obtained without inducing sleep, but allowing compensatory rest between contractions. The pupils are enlarged. Stimulation is applied throughout the birthing procedure and residual analgesia persists for several hours following delivery. Results are best if the expectant mother participates in a preparatory course for the birthing experience or if she uses musicotherapy in conjunction with TCES. If analgesia is insufficient it is possible to have patients breath nitrous oxide and oxygen (50:50) or to administer an epidural analgesia for the remainder of procedure. Thus obstetrical analgesia utilizing the currents of Limoge allows a reduction of labor time in all primapares ($p < 0.001$) and is without risk to the mother or child. Mothers in labor appreciate this simple, nonmedicinal, nonpainful technique that allows them to actively participate in the delivery.

Electropharmaceutical Anesthesia in Long Duration Microsurgery. For major operations and those of long duration the results are most encouraging as TCES permits a reduction of anxiolytics and neuroleptics by 45% and reduction of morphinomimetics by 90% and demonstrates the possibilities of drug potentiation to prolong analgesia while at the same time providing a less depressive general anesthetic (7,58,59,68). Early results have improved thanks to animal research and revision of protocols more particularly (17–19). In 1972, it was not known to begin electrostimulation three hours prior to medicinal induction (4).

Potentiation of Morphine Analgesia for Patients with Chronic Pain and Associate Problems (71). For all neurophysiological applications, a basic protocol must be followed. This protocol is as follows: If the patient is being treated pharmacologically, for the first time, never stop the che-

mical medication but diminish the dosage each day until a threshold dose is obtained according to the particular pathology and the patient. Begin TCES at least 1 h before medication whether it be on awakening in the morning or 2 h prior to going to bed. (There is no contraindication in maintenance of stimulation all-night long.)

If the patient is not being treated chemically, the effect of the current is best if there is a "starter dosage" of medicine. It is therefore recommended that a weak medicinal dose be prescribed according to the pathology and begin the TCES 1 h before the patient takes the dose, and continue stimulation during the time of pharmacokinetic action of the medicine.

This protocol will permit treatment of cancer patients at home whenever possible under medical supervision: This is a less traumatizing course of action than having the patients come into hospital every day. In the beginning, one must maintain the standard pain medication therapy and the patient should be connected to the Limoge Current generator for 12 h (during the night, if possible); the potentiometer is turned clockwise to a reading of 35 V and 250–300 mA, peak to peak. After this first treatment phase, the patient can use the machine for 3 h whenever they feel the need. The analgesic effect of TCES may not appear until the third day of treatment. Then TCES is initiated upon awakening. After 1 h, standard pain medication is given and TCES therapy is continued for another hour. Three hours before bedtime, TCES is again administered for 2 h, then standard pain medication is given and TCES therapy continued for another hour. The patient should enjoy restful sleep. After 8 days, the standard pain medication therapeutic dose should be decreased gradually, but not totally terminated. After this status has been achieved, patients may use the machine whenever they feel the need, for 3 h preferably with the reduced dose of the standard pain medication. The minimal therapeutic dose of the pain medication, however, may have to be adjusted upward somewhat due to individual differences in some patients.

CONCLUSION

All numerous and previous clinical trials have demonstrated that TCES reduces narcotic (fentanyl) requirements in patients undergoing urologic operations with pure neuroleptanesthesia (droperidol, diazepam, fentanyl, and air-oxygen) (20,36–38). Use of TCES in a randomized double-blind trial of these patients resulted in a 40% decrease in fentanyl requirements for the entire operation. Unfortunately, while available TCES units (using currents of 250–300 mA peak to peak, with an average intensity of zero) provide analgesia and amnesia, they do not produce complete anesthesia. Whether any form of TCES or the use of very high frequency (VHF) will provide more analgesia and amnesia, that is, amounts sufficient to result in complete anesthesia without need for pharmaceutical supplementation, without problems has yet to be carefully evaluated but obviously needs to be studied. Considerable research must continue in this area.

Theoretically, lower doses of narcotics or lower concentrations of inhalation anesthetics should result in fewer

alterations in major organ system function during anesthesia. This could mean that anesthesia with TCES produces less physiological insult than more standard anesthetic techniques and results in a shorter postoperative recovery period. It has been observed that TCES plus N₂O results in analgesia that persists after stimulation is terminated and N₂O is exhaled (7,14,15,20,58–60). This suggests that intraoperative use of TCES might reduce postanesthetic analgesic requirements, and that future clinical trials must be initiated to confirm this suggestion.

The 30,000 plus major interventions realized under TCES in France and in Russia since 1972 and the > 5000 drug withdrawals undertaken in opioid addicted patients at the Medical Center of the University of Bordeaux since 1979 without even the most minor incident permits us to conclude that the currents of LIMOGE are absolutely innocuous and cause no side effects. This simple technique reduced the use of sedative medicaments such as psychotropes or psycholeptics that often lead to "legal" addiction. The TCES is atoxic, reproducible, causes no personality change and is without habituation. Briefly, this technique fits perfectly into the domaine of all aspects of classical and alternative medicine as well as human ecology.

El Paso, Texas

INTRODUCTION

Digital computers have the ability to store tremendous amount of data and retrieve them with amazing speed for further processing and display. These attributes of computers make them extremely useful in a modern clinic or hospital environment. Computers play a central role in medical diagnosis and treatment as well as management of all processes and information in the hospital including patient data. Computers greatly facilitate the recording and retrieval of patient data in a simple way. All areas of hospital including patient admittance and discharge, the wards, all specialty areas, clinical and research laboratories are now interconnected through computer intranet and even nationally or globally connected through computer internet networks. This arrangement provides for better coordination of patient management throughout various hospital departments, and reduces patient waiting

times. Obviously, computers also play a very important role in all aspects of administration and management of the hospital like other sophisticated institutions. Therefore, they greatly facilitate the overall planning and operation of the hospital resulting in improved healthcare services.

As the electrocardiographic (ECG) signal is one of the most, if not the most, measured and monitored vital signs, computers have had a tremendous impact in electrocardiography. One of the most well known areas of application of computers in medical diagnosis is their use in recording, monitoring, analysis and interpretation of ECG signals. Computers reduce interpretation time and ensure improved reliability and consistency of interpretation. Computers assist cardiologists by providing cost-effective and efficient means in ECG interpretation and relieve them from the tedious task of reviewing large numbers of ECG recordings. Computers also increase the diagnostic potential of ECG signals. Of course, cardiologists consider patient history, the details of the morphology of the ECG signals and other pertinent patient data backed by their clinical knowledge and experience to make a complete diagnosis. It should be clearly stated and emphasized that computers do in no way relieve the physicians of forming a complete clinical decision. However, computers provide them with information on the ECG examination in a clearer fashion and save them from the burden of routine, repetitive, and subjective calculations. An additional advantage of using computers in electrocardiography is the ease of storage and retrieval of ECG data for further study and analysis.

Computer processing of ECG signals, which are analogue in nature with amplitudes in low millivolt range and low frequency content (0.05–150 Hz), involves digitization with a typical sampling frequency of 500 Hz and 12 bit resolution in analog-to-digital conversion process. Further processing involves digital filtering, removal of powerline and biological artifacts (like EMG interference), averaging and automatic measurement of amplitudes and durations of different parts of the ECG signal. Computer analysis programs developed based upon the interpretative experience of thousands of experts performed on millions of ECG records, provide important ECG waveform components, such as amplitude, duration, slope, intervals, transform domain features, and interrelationships between individual waves of the ECG signal relative to one another. These parameters are then compared with those derived from normal ECGs to decide whether there is an abnormality in the recordings. There are a wealth of algorithms and methods developed over several decades to assist with computer-aided analysis and interpretation of ECG signals.

Computer-assisted ECG analysis is widely performed in ECG monitoring and interpretation. This method is effectively deployed in routine intensive care monitoring of cardiac patients, where the ECGs of several patients are continuously monitored to detect life-threatening abnormalities. The purpose of monitoring is not only to detect and treat ventricular fibrillation or cardiac arrests, but also to detect the occurrence of less threatening abnormalities like heart blocks and arrhythmias. The occurrence of such episodes and their timely detection helps clinicians to make early diagnostic decisions and take appropriate therapeutic measures. The accurate detection of trends resulting in

dangerous cardiac abnormalities by visual inspection of ECG displays or chart recorders is a difficult task. Computer-assisted analysis of ECG signals to extract base-lines, amplitudes, slopes, and other important parameters to establish minimum and maximum values for these parameters provides an efficient and accurate means to track the nature of the ECG rhythms.

The ECG acquisition and analysis systems like many other biomedical devices are designed to measure physiological signals of clinical relevance and significance. To design and effectively use appropriate instrumentation to measure and process such signals, an understanding of the origin and properties of these signals are of prime importance. This article starts off with an attempt to present a distilled overview of the origin of bioelectric signals in general, and the electrocardiographic signal in particular. This overview sets the basis to briefly describe the cardiac vector and its projection along specific directions (leads) providing the surface ECG recordings and review the basic instrumentation necessary to record these signals. A detailed description of a high end computer-based 12 lead clinical ECG acquisition and analysis system provides an example to appreciate the role of computers in diagnostic electrocardiography. An overview of the role of computers in high resolution electrocardiography (body surface potential mapping) and other ECG-based diagnostic devices then follows. A brief introduction to computer-based ECG monitoring systems and a block diagram description of a QRS detection algorithm illustrate how computer programming serves as a basis to detect cardiac arrhythmias. The article ends with a web-based ECG telemonitoring system as an example.

REVIEW OF BASIC CONCEPTS

From cellular physiology, we recall that biopotentials are produced as a consequence of chemical activity of excitable or irritable cells. Excitable cells are components of the neural, muscular, glandular as well as many plant tissues. More specifically, biopotentials are generated as a consequence of ionic concentration difference of electrolytes (mainly Na^+ , K^+ , Cl^- ions) across the cellular membrane of excitable cells. Ionic differences are maintained by membrane permeability properties and active transport mechanisms across the cellular membrane (ionic pumps.)

The cellular membrane is a semipermeable lipid bilayer that separates the extracellular and intracellular fluids having different ionic concentrations. As a consequence of semipermeability and differences in concentration of ions, electrochemical gradients are set up across the membrane. Ionic transfer across the membrane by diffusion and active transport mechanisms results in the generation of a voltage difference (membrane potential), which is negative inside. The resting membrane potential is mainly established by the efflux of K^+ ions due to diffusion and is balanced by the consequent inward electric field due to charge displacement. This equilibrium voltage can be estimated by the Nernst equation (1), which results from application of electric field theory and diffusion theory. If we consider the effects of the three main ions, potassium

(K⁺), sodium (Na⁺), and chloride (Cl⁻), the Goldman-Hodgkin and Katz equation can be used to calculate the resting membrane potential (1).

The smallest sources of bioelectric signals (biosources) are single excitable cells. These cells exhibit a quiescent or resting membrane potential across the cellular membrane of several millivolts (mV) (-90 mV with several hundred milliseconds in duration for ventricular myocytes). When adequately stimulated, the transmembrane potential in excitable cells becomes positive inside with respect to outside (depolarization) and action potentials are generated (at the peak of the action potential in ventricular

myocytes, the membrane potential reaches about +20 mV). Action potentials are produced by sudden permeability changes of cellular membrane to ions: primarily sodium and potassium ions. Action potentials are all-or-none monophasic waves of depolarization that travel unattenuated with a constant amplitude and speed along the cellular membrane (Fig. 1).

The excitable cells function in large groups as a single unit and the net effect of all stimulated (active) cells produces a time-varying electric field in the tissue surrounding the biosource. The surrounding tissue is called a volume conductor. The electric field spreads in the volume

Figure 1. The monophasic action potential, direction of conduction of the action potential, and movement of ions across the cellular membrane. (Courtesy of Ref. 2.)

conductor and can be detected as small voltages by means of bioelectrodes or simply electrodes placed in the tissue or on the skin. Electrodes are sensors, which convert ionic current flow in the living tissue to electronic current flow in the electromedical instrument.

To understand the origin (electrogenesis) of biopotential signals like ECG, we should consider the following:

1. Electrical activity (bioelectric phenomena) at the cardiac cellular level and the extracellular potentials generated as the result of the electrical activity of single cardiac cells placed in a large homogeneous bathing (conducting) medium with the same composition as body fluids (volume conductor fields of simple bioelectric sources).
2. Extracellular potentials generated as the result of the electrical activity of a large number of myocardial cells (tissues) placed in a large conducting medium with the ionic composition of body fluids (volume conductor fields of complex bioelectric sources).
3. The relationship between these extracellular potentials and the gross electrical activity recorded on the body surface as ECG signals.

A simplified version of the volume conductor problem at the cellular level can be considered as follows. If a single excitable cell is placed in a bathing conductive medium, it acts like a constant current source. When the biosource becomes adequately depolarized, an action potential is generated across its membrane and it injects a current to the surrounding medium. The conductive medium presents as a load with a long range of loading conditions depending on its geometry, temperature, and so on. The lines of current flowing out of the excitable cell into the volume conductor with a specific resistance r , gives rise to an extracellular field potential proportional to the transmembrane current (i_m) and the medium resistance (r) according to Ohm's law. Obviously, the extracellular field potential increases with higher values of membrane current or tissue resistance.

There has been considerable debate about the exact relationship between the action potential across the cellular membrane and the shape of the extracellular field potential. However, the work of many researchers with different types of excitable cells has confirmed that the extracellular field potential resembles the second derivative of the transmembrane action potential. This means that a monophasic action potential creates a *triphasic* extracellular field potential (1). It has also been shown that the extracellular field potential is shorter in duration and much smaller in magnitude (μV compared to mV). Of course, this relationship has been established for cases when the geometry of the biosource and its surrounding environment is simple and the volume conductor is isotropic (uniform in all directions).

More realistically, when a piece of excitable tissue in the living organism becomes electrically active it becomes depolarized, acts like a point current source and injects a current into the anisotropic volume conductor comprised of tissues

and body fluids surrounding it with different conductances (resistances). Consequently, the spatial distribution of current will not resemble that of a simple dipole placed in an isotropic volume conductor. However, it has been shown that an active nerve trunk (comprised of thousands of sensory and motor nerve fibers simultaneously stimulated) placed in a large homogeneous volume conductor generates an extracellular field potential which is quite similar in shape to that of a single nerve fiber (1). It is concluded that, the extracellular field potential is formed from the contributions of superimposed electric fields of the component biosources in the nerve trunk. The general form of the extracellular field potential of a nerve trunk in response to electrical stimulation is triphasic, it has amplitude in the microvolt range and it loses both amplitude and high frequency content at large radial distances from the nerve trunk. It is observed that the major contribution to the triphasic extracellular field potential is from the motor nerves in the trunk. It has also been shown that with a change in the volume conductor load (e.g., an increase in the specific resistance of the volume conductor or a decrease in the radial distance from the complex biosource) the amplitude of the recorded extracellular field potential increases (1).

The concepts discussed above are directly applicable to explain the relationship between the extracellular field potentials generated by complex and distributed biosources (current generators) like the cardiac tissue, the muscles, and the brain and their electrical activities recorded on the body surface as ECG, electromyogram (EMG) and electroencephalogram (EEG) signals.

In summary, excitable cells and tissues (biosources), when adequately stimulated, generate monophasic action potentials. These action potentials cause the injection of constant currents into a large bathing medium surrounding the biosource (considered as a point current source). As a result of the current flow in the volume conductor with specific resistance, extracellular field potentials are generated in the medium. These field potentials are triphasic in shape, of shorter duration and smaller amplitude compared to the transmembrane action potential. As the resistivity of the medium increases and the radial distance from the biosource decreases, the field potential increases. These field potentials are recorded as clinically useful signals on the body surface.

The biopotentials most frequently measured and monitored in modern clinics and hospitals are electrocardiogram (ECG: a recording of the electrical activity of the heart), electromyogram (EMG: a recording of the electrical activity of the muscle), electroencephalogram (EEG: a recording of the electrical activity of the brain), and others. Based on the physiological concepts reviewed above, now we present a brief overview of the electrogenesis of the ECG signals that carry a wealth of information about the state of health and disease of the heart. Having done this, we look at basics of electrocardiography.

BASICS OF ELECTROCARDIOGRAPHY

The conduction system of the heart consists of the sinoatrial (SA) node, the internodal tracts, the atrioventricular

Figure 2. Waveforms of action potentials in different specialized cells in the conductive pathway of a normal heart and their contribution with color coding to the surface ECG. (Courtesy of Ref. 2.)

(AV) node, the bundle of His, the right bundle branch (RBB), the left bundle branch (LBB), and the Purkinje network. The rhythmic electrical activity of the heart (cardiac impulse) originates in the SA node. This node is known as the natural pacemaker of the heart, approximately the size of the tip of a pencil, located at the junction of the superior vena cava and the right atrium. The impulse then propagates through internodal and interatrial (Bachmann's bundle) tracts. As a consequence, the pacemaker activity reaches the AV node by cell-to-cell atrial conduction and activates the right and left atrium in an organized manner. The pacemaker action potential has a fast activation phase, a very short steady recovery phase, followed by a fairly rapid recovery phase and a characteristic slow depolarization phase leading to self-excitation (Fig. 2). The pacemaker cells of the SA node act as a biological oscillator.

As atria and ventricles are separated by fibrous tissue, direct conduction of cardiac impulse from the atria to the ventricles can not occur and activation must follow a path that starts in the atrium at the AV node. The cardiac impulse is delayed in the AV node for ~ 100 ms. It then proceeds through the bundle of His, the RBB, the LBB, and finally to the terminal Purkinje fibers that arborize and invaginate the endocardial ventricular tissue. The delay in the AV node is beneficial since electrical activation of cardiac muscle initiates its successive mechanical contraction. This delay allows enough time for completion of atrial contraction and pumping of blood into the ventricles. Once the cardiac impulse reaches the bundle of His, conduction

is very rapid, resulting in the initiation of ventricular activation over a wide range. The subsequent cell-to-cell propagation of electrical activity is highly sequenced and coordinated resulting in a highly synchronous and efficient pumping action by the ventricles.

Essentially, an overall understanding of the genesis of the ECG waveform (cardiac field potentials recorded on the body surface) can be based on a cardiac current dipole model placed in an infinite (extensive) volume conductor. In this model, an active (depolarizing) region of the tissue is considered electronegative with respect to an inactive (repolarizing) region. Therefore, a boundary or separation exists between negative and positive charges. This is regarded as a current dipole: a current source and sink separated by a distance. According to the dipole concept, a traveling excitation region can be considered as a dipole moving with its positive pole facing the direction of propagation. Thus a nearby recording electrode placed in the surrounding volume conductor (referenced to an indifferent electrode placed in a region of zero potential) will detect a positive-going field potential as excitation approaches and a negative-going field potential as it passes away. Repolarization (recovery) is considered as a dipole with its negative pole facing the direction of propagation. Therefore, the propagation of excitation can be considered as the advance of an array of positive charges with negative charges trailing and the recovery could be considered as the approach of negative charges with positive ones trailing. Consequently, an upward deflection in the biopotential recording indicates the approaching of excitation

Figure 3. Isochrone surfaces in ventricular activation color coded to show spatiotemporal propagation. (Courtesy of Ref. 2.)

(depolarization) toward the positive (recording) electrode and a downward deflection indicates a recovery (depolarization) in the recorded signal.

As the wave of excitation (depolarization) spreads throughout the conductive pathways and tissues, specific excitation regions called isochrones are synchronously excited. In the ventricles, these synchronous activation regions propagate in a temporally and spatially orderly fashion from the endocardial to the epicardial direction (Fig. 3.)

In a localized region of the heart many cells are simultaneously activated because of the high electrical and mechanical coupling (functional syncytium) between the myocardial cells. Each activation region can be viewed as an elementary dipole, and all elementary dipoles could be vectorially added to all others to form a single net dipole. (For more details on simple and multiple dipole models see the section Electrocardiography.) Therefore, at each instant of time, the total cardiac activity can be represented by a net equivalent dipole current source. The electric field produced by this dipole source represents the total electrical activity of the heart and is recorded at the body surface as the ECG signal (Fig. 4). (For quantitative details see chapter 6 in Ref. 2.)

In the early 1900, Einthoven postulated that the cardiac excitation could be viewed as a vector. He drew an equilateral triangle with two vertices at two shoulders and one at the navel (representing the left leg). With the cardiac vector representing the spread of cardiac excitation inside the triangle, the potential difference measured between two vertices of the triangle (known as the limb leads) with respect to right leg, is proportional to the projection of the vector on each side of the triangle (Fig. 5).

In summary, based on the aforementioned concepts, electrocardiographers have developed an oversimplified model to explain the electrical activity of the heart. In this model, the heart is considered as an electric dipole (points of equal positive and negative charges separated from one

another by a distance), denoted by a spatiotemporally changing dipole moment vector \mathbf{M} . This dipole moment (amount of charge times distance between positive and negative charges) is called the cardiac vector. As the wave of depolarization spreads throughout the cardiac cycle, the magnitude and orientation of the cardiac vector changes and the resulting bioelectric potentials appear throughout the body and on its surface. The potential differences (ECG signals) are measured by placing electrodes on the body surface and connected to biopotential amplifier. (For details, see the section Bioelectrodes, and Electrocardiographic Monitors.) In making these potential measurements, the amplifier has a very high input impedance to minimally disturb the cardiac electric field that produces the ECG signal. As it was discussed before, when the depolarization wavefront points toward the recording positive electrode (connected to the + input terminal of the bioamplifier), the output ECG signal will be positive going, and when it points toward the negative electrode, the ECG signal will be negative going. The time varying cardiac vector produces the surface ECG signal with its characteristics P wave, QRS complex, and T wave during the cardiac cycle. These field potentials are measured by using bioelectrodes and biopotential amplifiers to record the ECG tracings.

BASIC INSTRUMENTATION TO RECORD ECG SIGNALS

As the electrical events in the normal heart precede its mechanical function, ECG signals are of great clinical value in diagnosis and monitoring of a wide variety of cardiac abnormalities including myocardial infarction and chamber enlargements. Therefore, ECG signal acquisition systems are widely used in cardiology, cardiac catheterization laboratories, intensive and cardiac care units, and at patient's bedside, among other areas.

As it was described earlier, the electrical activity of the heart can be best modeled and characterized by vector quantities. However, it is easier to measure scalar

Figure 4. The total cardiac electrical activity represented by the net dipole (cardiac vector) during different phases of the cardiac cycle and its projection along the frontal plane electrocardiographic leads (I, II, and III). (Courtesy of Ref. 3.)

quantities, such as potential differences between specified points on the torso known as surface ECGs. These ECG signals have a diagnostically significant frequency content between 0.05 and 150 Hz. To ensure stability of the baseline, a good low frequency response is required. The instabilities in the baseline recordings originate from changes in the electrode–electrolyte interface at the point of contact of the bioelectrode with the skin. (For details see the section Bioelectrodes.) To faithfully record fast changes in the ECG signals and distinguish between other interfering signals of biological origin, adequate high frequency response is necessary. This upper frequency value is a compromise between several factors including limitation of mechanical recording parts of ECG machines using direct writing chart recorders.

To amplify the ECG signals and reject nonbiological (e.g., powerline noise) as well as biological interferences (e.g., EMG), differential amplifiers (DAs) with high gains (typically 1000 or 60 dB) and excellent common mode rejection capabilities must be used. Typically, common mode rejection ratios (CMRRs) in the range of 80–120 dB with 5 KΩ imbalance between differential amplifier input leads provide a desirable level of environmental and biological noise and artifact rejection in ECG acquisition systems. In addition to this, in very noisy environments it becomes necessary to engage a notch (band-reject) filter centered at 60 Hz or 50 Hz (in some countries) to reduce powerline noise further. A good review of adaptive filtering method applied to ECG powerline noise removal is given in Adaptive Filter Theory by Simon Haykin (4).

Figure 5. Einthoven equilateral triangle. The vertices are LA (left arm), RA (right arm), and LL (left leg). The RL (right leg) is used as a reference for potential difference measurements and is not shown. I, II and III represent electrocardiographic frontal limb leads. The + and - represent connection to the terminals of an ECG (biopotential) amplifier. Lead I is the potential difference between LA and RA. Lead II is the potential difference between LL and RA. Lead III is the potential difference between LL and LA. (The input polarity of the amplifier shown is for recording: III limb.)

Many modern biomedical instruments use instrumentation amplifiers (IAs). These amplifiers are advanced versions of differential amplifiers enhanced with many additional desirable characteristics such as very high input impedance $> 100 \text{ M}\Omega$ to prevent loading the small ECG signals to be picked up from the skin. The final stages of the ECG amplifier module limit the system's response (band pass filtering) to the desirable range of frequencies for diagnostic (i.e., 0.05–150 Hz) or monitoring (i.e., 0.5–40 Hz) purposes. A more limited bandwidth in the monitoring mode provides improved signal to noise ratio and removes ECG baseline drift due to half-cell potentials generated at the electrode/electrolyte interface and motion artifacts. Driven right-leg amplifiers improve the CMRR. The amplified and adequately filtered ECG signals are then applied to display, recording or digitization modules of a computer-based ECG acquisition system. Detailed specifications for diagnostic ECGs have been developed by the American National Standards Institute (5). For more detailed specification and design as well as other aspects of ECG instrumentation and measurements, see the Appendix, Bioelectrodes, Electrocardiography, and Electrocardiographic Monitors.

COMPUTER SYSTEMS IN ELECTROCARDIOGRAPHY

Diagnostic Computer-Based ECG Systems

Heart diseases cause a significant mortality rate in the world. Accurate diagnosis of heart abnormalities at an early stage could be the best way to save patients from disability or death. The ECG signal has considerable diagnostic value and ECG monitoring is a very well established and commonly used clinical method. Diagnostic ECG testing is performed in a doctor's office, in a clinic or hospital as a routine check up. In this test, a full 12-lead ECG (to be described later) is acquired from a resting subject and displayed on a chart recorder or a computer screen to diagnose cardiac diseases. In cardiac care units (CCUs), a patient's single lead ECG may be continuously acquired and displayed on a cathode ray tube (CRT) or a computer screen for signs of cardiac beat abnormalities. The ECG

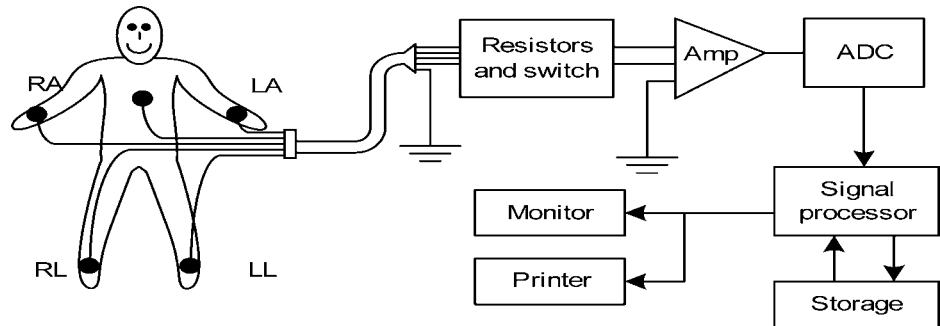

monitoring capabilities are now an integral part of a number of other medical devices, such as cardiometers, Holter monitors, cardiac pacemakers, and automatic defibrillators.

Most of the traditional clinical ECG machines used a single channel amplifier and recording system. The recording was achieved using a direct writing chart recorder. In modern systems, however, computer memory, display screen and printing capabilities are deployed to record, display and report the ECG data. Traditional single channel systems used a multiposition switch to select the desired lead connection (I, II, III, aV_R , aV_L , aV_F , V_1 , V_2 , V_3 , V_4 , V_5 , and V_6) and apply it to the biopotential amplifier and chart recorder. Only one ECG lead at a time could be selected and recorded with these machines. The block diagram of a modern single channel computer-based ECG acquisition system is shown in Fig. 6.

Most of the modern ECG machines are multichannel systems. They include several amplifier channels and record several ECG leads simultaneously. This feature enables them to considerably reduce the time required to complete a set of standard clinical ECG recordings. As the ECG leads are recorded simultaneously, they can be shown in their proper temporal relationship with respect to each other. These systems use microprocessors to acquire the cardiac signals from the standard 12-lead configuration by sequencing the lead selector to capture four groups of three lead signals, and switch groups every few seconds. The high end computer-based systems capture all 12-leads simultaneously and are capable of real-time acquisition and display of the standard 12-lead clinical ECG signals (see Example below.)

Modern ECG acquisition systems achieve certain desirable features, such as removal of artifacts, baseline wander, and centering of the ECG tracings by using specialized computer algorithms. These systems perform automatic self-testing on power up and check for lead continuity and polarity and indicate lead fall-off or reversal. They deploy digital filters implemented in software to considerably improve the ECG signal quality and automatically remove baseline drift and reduce excessive powerline and biological noise. Powerful software programs not only minimize

Figure 6. Block diagram of a three-lead electrocardiograph. The normal locations for surface electrodes are right arm (RA), right leg (RL = ground or reference), left arm (LA), and left leg (LL). In 12-lead electrocardiographs, six electrodes are attached on the chest of the patient as well. (Courtesy of Ref. 6.)

baseline drift without signal distortion during rest, they also produce high quality ECG tracings during patient monitoring, exercise and ambulation.

12-Lead Clinical Electrocardiography. The most commonly used or standard clinical ECG system is the 12-lead system. This system is comprised of three bipolar limb leads (I, II, III) connected to the arms and legs; three augmented leads (aV_R , aV_L , aV_F); and six unipolar chest or precordial leads (V_1 , V_2 , V_3 , V_4 , V_5 , V_6).

The connections to measurement points in the 12-lead system are shown in Fig. 7. Six of these 12 leads are frontal leads (the bipolar and the augmented leads) and six of them are transverse leads (the precordial leads). The frontal leads are derived from three measurement points RA, LA, LL with reference to RL. Therefore, any two of these six leads contain exactly the same information as the other four. The dipole source model can be used to explain the total electrical behaviour of the heart (See the section Electrocardiography and Ref. 2.)

Basically, any two of the three I, II, and III leads could represent the cardiac activity in the frontal plane and only one chest lead could be used to represent the transverse activity. Chest lead V_2 is a good representative of electrical activity in the transverse plane as it is approximately orthogonal (perpendicular) to the frontal plane. Overall, as the cardiac electrical activity could be modeled as a dipole, the 12-lead system could be considered to have three independent leads and nine redundant leads. However, since the chest leads also detect unipolar elements of the cardiac activity directed toward the anterior region of the heart, they carry significant diagnostic value in the transverse plane. As such, the 12-lead ECG system can be considered to have eight independent and four redundant leads. Now the question arises why all the 12-leads are recorded then. The main reason is that the 12-lead system enhances pattern recognition and allows cardiologists to compare the projections of the resultant vectors in the two orthogonal planes and at different angles. This facilitates and validates the diagnostic process. Figure 8 shows the surface anatomical positions for the placement of the bio-electrodes in 12-lead electrocardiography.

A Detailed Example: The Philips PageWriter Touch 12-Lead ECG System. Currently, there are a number of highly advanced 12-Lead ECG data acquisition, analysis and interpretative systems on the market. A detailed description and comparison of all these systems are beyond the scope of this chapter (for information on these systems see

manufacturers web sites). Due to space limitation, only one representative system will be described in detail as an example. The Philips PageWriter Touch (Philips Medical, MA) is an advanced 12-lead ECG acquisition and analysis system with many user-friendly features. It has a compact design and is best suited for busy hospitals and fast-paced clinical environments. It has an intuitive touch screen which is fully configurable and it has a powerful built-in interpretative 12-lead ECG signal analysis algorithm developed for rapid and accurate interpretation of ECG signals (Fig. 9).

The PageWriter supports a variety of ECG data acquisition modes, display settings and reporting schemes. It provides real-time color-coded ECG signals enabling the user to perform quality control checks on the acquired ECG data. Quality control features include surface anatomical diagrams that alert the user to the location of loose or inoperable electrodes (Fig. 8). It is equipped with a full-screen preview display of the ECG report before print out. It has an ergonomic design that facilitates ECG data collection from the patient bedside (Fig. 10).

The PageWriter Touch has an alphanumeric keyboard, an optional barcode scanner, and an optional magnetic card reader to increase the speed and accuracy of patient data entry and management. Data handling features include indexed ECG storage and quick transmission of stored ECG data to an ECG data management system. By using indexed thumbnail images of each ECG report the user can instantly view and print the stored reports. Multiple reporting formats may be applied to any saved ECG records.

In brief, the PageWriter Touch features accurate and fast 12-lead ECG signal acquisition and analysis capabilities for both adults and children patients. It has real-time color-coded display facilities and provides instantaneous snapshots of stored ECG data on the touch screen. It has a variety of ECG data review and printing capabilities. The touch screen provides easy and flexible configurability of features (Fig. 11). (For more details on Technical Specifications of PageWriter Touch see the Appendix.)

Overview of System Description. The PageWriter Touch electrocardiograph performs acquisition, analysis, presentation, printing, storage, and transfer of ECG signals as well as other patient data. A generalized block diagram of the system is shown in Fig. 12.

The system is comprised of three major subsystems equipped with an LCD display and touch screen module. A brief and high level description of these subsystems is as follows.

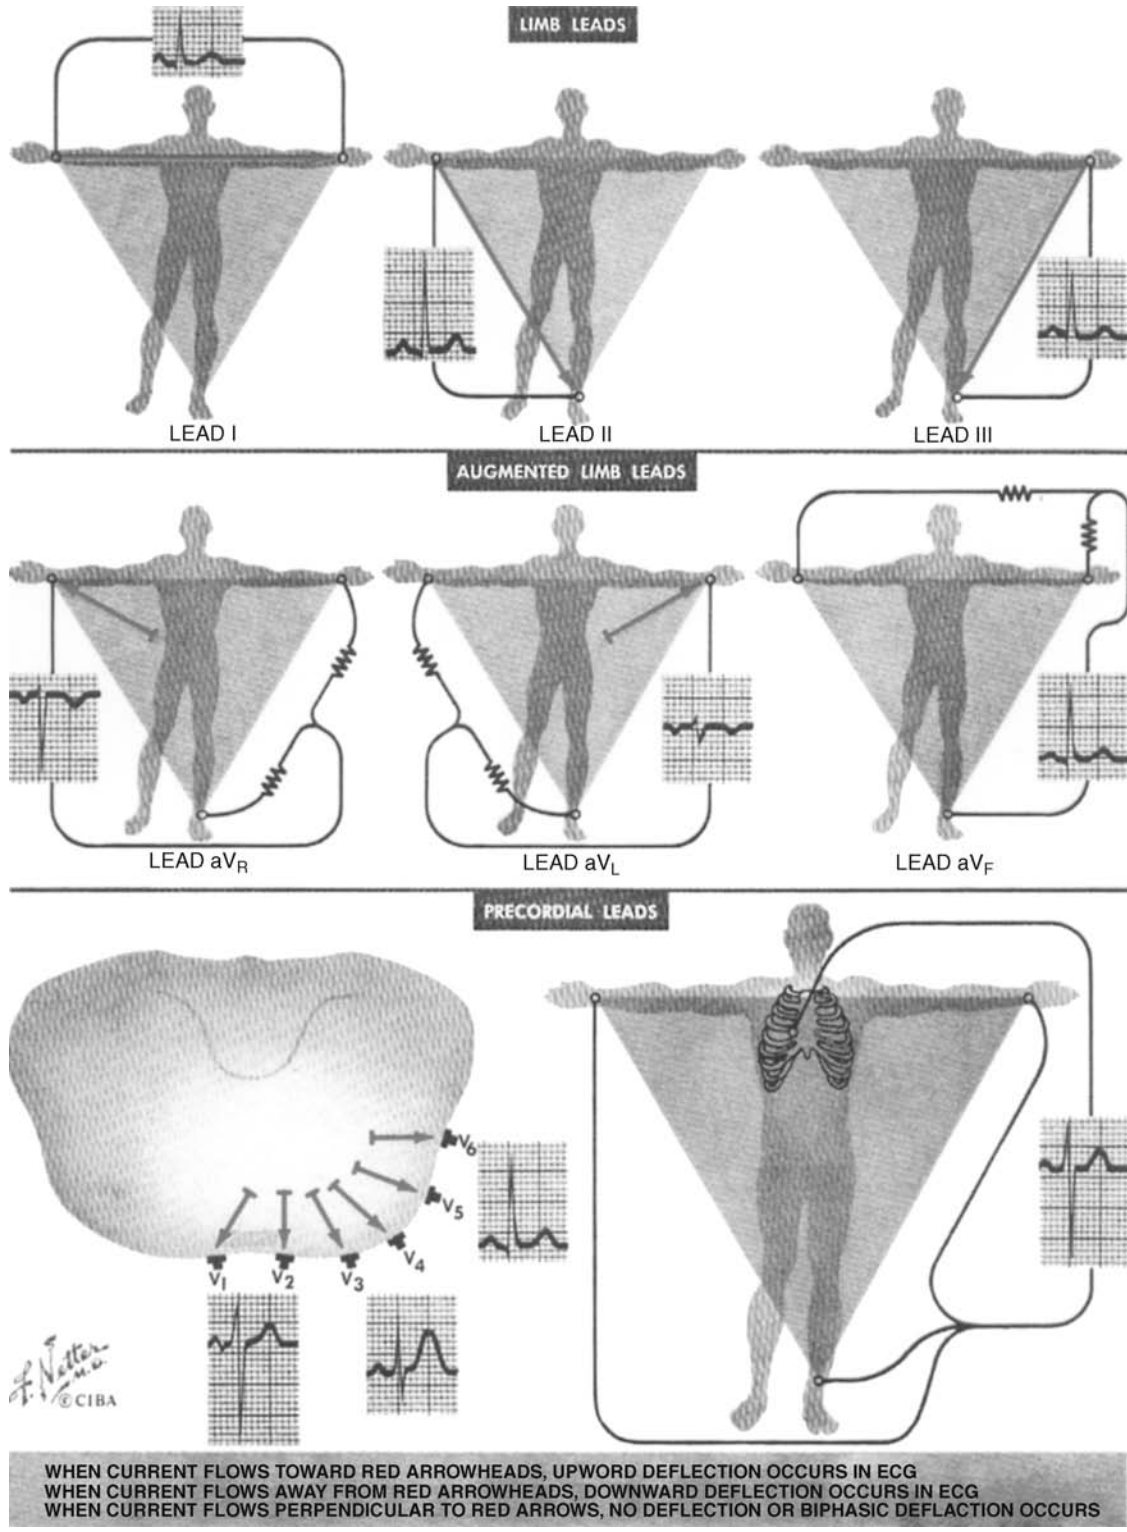

Figure 7. Lead connections in standard 12-lead electrocardiography. (Courtesy of Ref. 3.)

1. Main Controller Board. This is a single board computer (SBC) with extensive Input-Output facilities, running Windows CE 3.0. The PageWriter application software controlling the overall operation of the electrocardiograph runs on the Main Controller

Board, which includes the display and user-input subsystems. The application software interacts with numerous hardware and software subsystems. The Main Controller Board SBC contains loader software and Windows CE kernel image in its

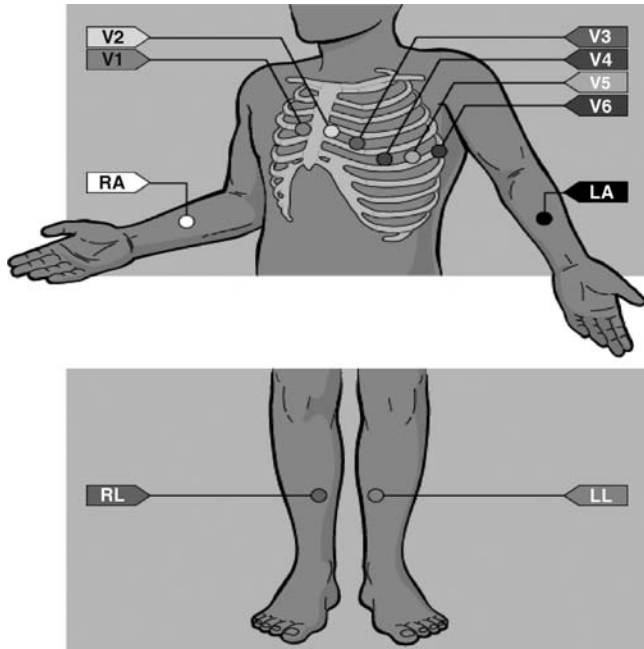

Figure 8. Surface anatomical positions for application of bioelectrodes in the 12-lead ECG system. (Courtesy of Philips Medical Systems, USA.) (Illustration courtesy of Mark Wing, Illustrator.)

internal flash memory (32 MB). At system boot, a system RAM test is performed by the loader (64 MB RAM onboard). The Windows CE kernel loads next. After loading of the CE, the application launcher runs, verifying system and executable images before loading the SierraGUI (Graphical User Interface) application. All interactions with the system operator (user) are implemented through the SierraGUI application. The application software and all ECG archives are stored on a separate 128 MB Compact-Flash (CF) card installed on the Main Controller Board (Fig. 12.)

Figure 9. PageWriter Touch, a high-end 12-lead electrocardiograph with built-in 12-lead ECG signal interpretation capabilities. (Courtesy of Philips Medical Systems, USA.)

Figure 10. Easy data collection set up at bedside. (Courtesy of Philips Medical Systems, USA.)

2. **Printer Controller Board.** This is a controller board that provides all the real-time management of the printer. The Printer Controller Board communicates with the Main Controller Board through a USB port. The Printer Controller Board is a micro-processor-based control board for the electrocardiograph thermal printer mechanism. This board is connected by a USB port to the Main Controller Board and is powered by the power circuit of the Main Controller Board. It provides ECG waveform rendering and basic bitmap imaging operations, and uses a PCL-like control language API for page description and feed control. It controls the print head, motor, and detects drawer-open and top-of-form.
3. **Patient Input Module (PIM).** This is a controller running Windows CE 3.0, coupled with a signal acquisition board employing mixed-signal Application Specific Integrated Circuit (ASIC) technology developed for ECG data acquisition. The PIM communicates with the Main Controller Board through a USB port (Fig. 12.)

Figure 11. PageWriter Touch electrocardiograph has a user-friendly interface. (Courtesy of Philips Medical Systems, USA.) (Illustration courtesy of Mark Wing, Illustrator.)

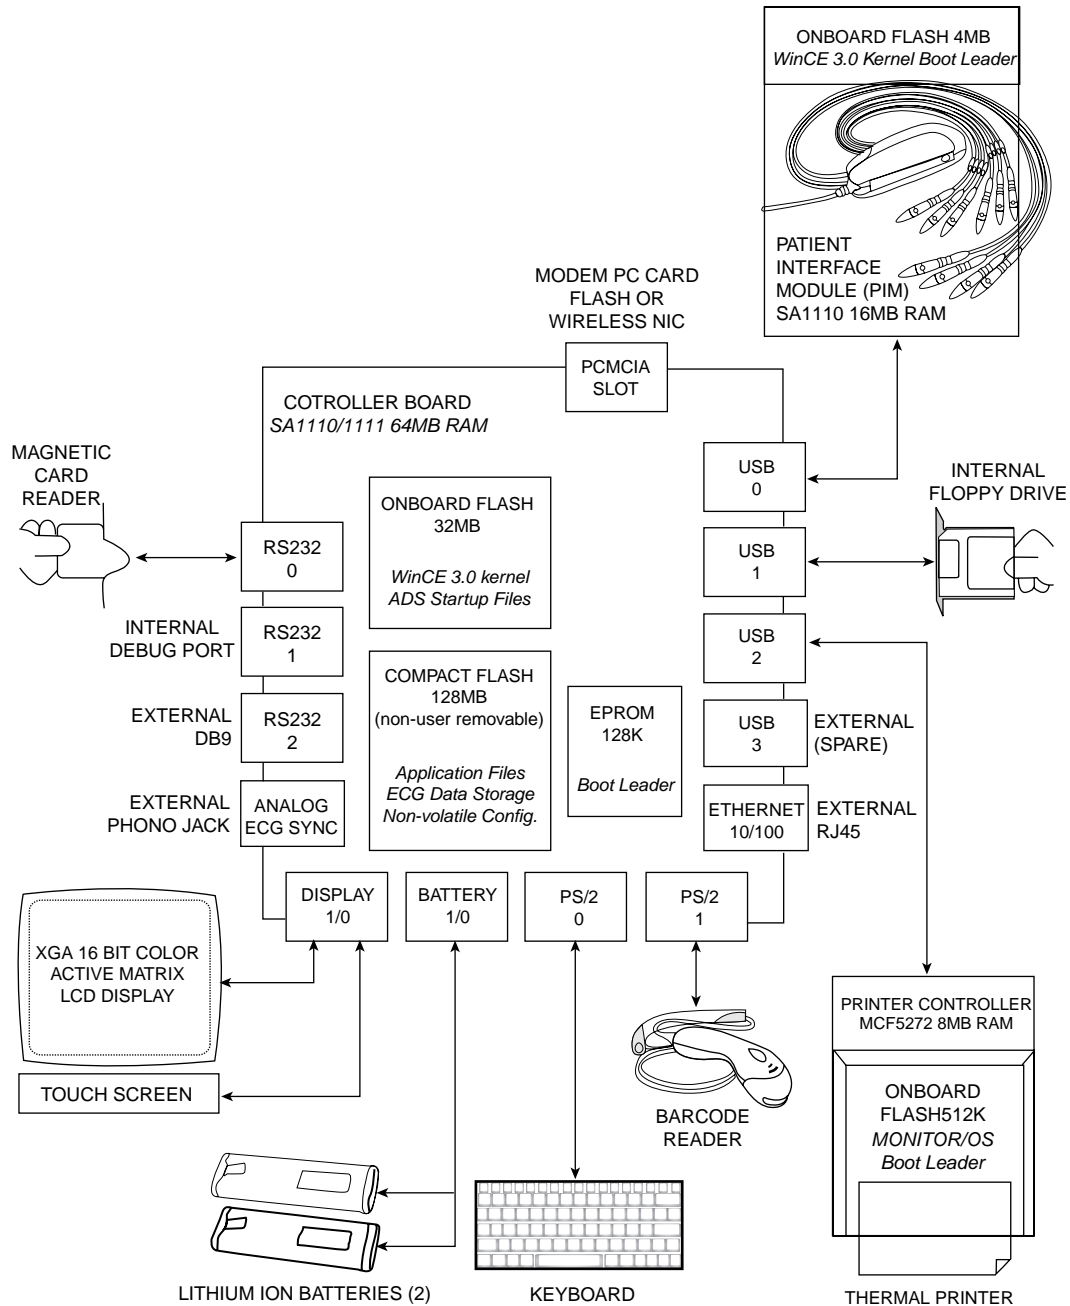

Figure 12. A generalized block diagram for PageWriter Touch. (Courtesy Philips Medical Systems, USA.)

The LCD display module for the PageWriter Touch electrocardiograph is an extended graphic array or XGA-compatible, full-color with backlight and overlaid touch screen (Fig. 9.) It is driven by the Main Controller Board using a graphics accelerator chip and dedicated touch screen support hardware. The touch screen provides finger-tap input substituting for the normal Win32 mouse-click input.

ECG Data Flow and Storage in PageWriter Touch. The ECG data flow and storage in the PageWriter Touch electrocardiograph is shown in Fig. 13.

The ECG signals are picked up at the body surface using electrodes attached to properly prepared skin at specified anatomical sites. The ECG data stream is then routed in real-time to the Main Controller Board, where it is written into the application buffers in RAM. These buffers are used to present the ECG data stream on the LCD screen in real-time. When the user initiates an AUTO report print, presses the ACTION button on the Patient Input Module or the Snapshot button on the display, or uses the Timed ECG acquisition, the corresponding 10 s segments of the ECG data are then copied to the temporary ECG storage in RAM. These 10 s segments are named ECG reports that

Figure 13. The ECG data flow and storage in PageWriter Touch electrocardiograph. (Courtesy of Philips Medical systems, USA.)

can be previewed and printed. In AUTO mode, the ECG report may be automatically printed after copying to storage. An ECG report contains waveforms, analysis information, patient demographics, and acquisition information, along with operator and device information. Figure 14 shows a rendered ECG report print sample.

The PageWriter Touch 12-Lead ECG Data Analysis Program. This program analyzes up to 12 simultaneously acquired ECG waveforms over a 10s period using interpretive criteria by patient-specific information. For examples of ECG diagnostic criteria see Ref. (7). The analysis algorithm analyzes ECG data and produces an interpretive report to assist the clinician make more informed patient

assessment in a broad range of clinical settings. The analysis program is developed to allow clinicians read and interpret ECG findings more quickly and efficiently, provide accurate, validated ECG measurements to facilitate physician overreading and improve treatment decision making, generate detailed findings that highlight areas of interest for physicians review, provide high levels of reproducibility for more consistent ECG interpretation.

The algorithm monitors the quality of the ECG waveforms acquired from 10 electrodes (12 leads), recognizes patterns, and performs basic rhythm analysis. Using advanced digital signal processing techniques, the algorithm removes biological and non-biological noise and artifacts while minimizing distortion of the ECG waveforms

Figure 14. A 12-lead ECG report sample for printing or copying. (Courtesy of Philips Medical systems, USA.)

and preserving their diagnostic quality. By using a set of diagnostic criteria, the 12-lead ECG analysis program generates interpretative statements, summarizes the findings for the ECG signals, and highlights key areas of concern for physician review. The analysis program has a built-in pacemaker pulse detector and paced rhythm classification routine. The program distinguishes a variety of atrial, ventricular and atrioventricular (AV) sequential pacing modes to recognize asynchronous pacing typically seen with a magnet in place. In addition to automated detection capabilities, the algorithm provides user selected configuration of “pacemaker patient” or “non-pacemaker patient” for more accurate analysis.

The 12-lead analysis program also incorporates factors, such as age and gender that impact a patient’s risk for developing specific forms of cardiac disease. It uses gender-specific interpretation criteria to take into account key physiological differences between males and females. For example, it applies gender-specific evaluation of Q waves for improved detection of Acute Myocardial Infarction (AMI), which is often missed in female patients. It also uses more gender-specific criteria for detection of axis deviation, Left Ventricular Hypertrophy (LVH), and prolonged QT segment.

The 12-lead algorithm also includes an advanced Pediatric Criteria Program, which uses age to select clinically relevant interpretative statements related to cardiac rhythm and morphology. If a patient’s age is < 16 years, the algorithm automatically uses pediatric ECG interpretation criteria, which accounts for higher rates and narrower QRS complexes in this patient population. The Pediatric Criteria Program recognizes 12 distinct age groups to ensure most relevant-age interpretation criteria are applied for analyzing the ECG data. In fact, patient age is used to define normal limits in heart rate, axis deviation, ECG segment time intervals, voltage values for interpretation accuracy in tachycardia, bradycardia, prolongation or shortening of PR and QT intervals, hypertrophy, early

repolarization, myocardial ischemia and infarct, as well as other cardiac conditions. The pacemaker detection and classification algorithm built into the Pediatric Analysis Program has the ability to reliably distinguish pacemaker pulses from the very narrow QRS complexes often produced by neonatal and pediatric patients. It also reduces the likelihood of false diagnosis in non-paced patients, while enabling more accurate paced rhythm analysis for the pediatric age group.

To improve on the classification accuracy of a diagnostic dilemma in pediatrics to distinguish between mild Right Ventricular Hypertrophy (RVH) and Incomplete Right Bundle Branch Block (IRBBB), the algorithm combines 12-lead synthesized vectorcardiogram transverse plane measurements with scalar ECG measurements. In addition, the pediatric analysis program provides improved QT measurements in pediatric patients.

The ST segment elevation in ECG tracings is an effective indicator of acute myocardial infarction. The Page-Writer Touch 12-Lead ECG Analysis Program provides advanced software for detection of ST Elevation Acute Myocardial Infarction (STEMI). This software feature provides clinicians with a valuable decision support tool when working with patients presenting symptoms that suggest accurate coronary syndromes.

Other cardiac conditions, such as benign early repolarization and acute pericarditis, tend to mimic the ECG diagnosis of STEMI, and degrade algorithm detection accuracy. To address this difficulty, the ECG Analysis Program separates the confounders by examining the patterns of ST elevation. Improved measurements in ST deviation enables the algorithm to achieve both high sensitivity and specificity in more accurate detection of STEMI condition.

Exercise (Stress) Electrocardiography. Exercise (Stress or Treadmill) electrocardiography is a valuable diagnostic and screening procedure primarily used to diagnose

coronary artery disease (CAD). Exercise on treadmill may induce ischemia that is not present at rest. Exercise electrocardiography is usually performed to screen for the presence of undiagnosed CAD, to evaluate an individual with chest pain, to clarify abnormalities found on a resting ECG test, and to assess the severity of known CAD.

Accurate interpretation of stress ECG is dependent on a number of factors including a detailed knowledge of any prior medical condition, presence of chest pain and other coronary risk factors. A modern exercise ECG system includes a 12-lead ECG diagnostic system with accurate and advanced ECG signal processing capabilities. It also includes appropriate interfaces for treadmills, ergometers as well as motion-tolerant noninvasive blood pressure (NIBP) monitors.

Vectorcardiography. In 12-lead clinical electrocardiography described above, the scalar ECG signals are recorded from 10 electrodes placed on specific sites on the body surface. These tracings show detailed projections of the cardiac vector as a function of time. However, they do not show the underlying cardiac vector. Vectorcardiography is a method in which the cardiac electrical activity along three orthogonal axes (x , y , z) in the principal planes (frontal, transverse, sagittal) are recorded and the activity of any two of the three is displayed on a CRT. This display is a closed loop showing the locus of the tip of the cardiac vector during the evolution of atrioventricular depolarization–repolarization phases in one cardiac cycle (Fig. 4.) These closed loops are known as vectorcardiogram

(VCG). Figure 15 shows the 3D representation of the cardiac electrical activity and its projections onto the principal planes recorded as vectorcardiogram. Figure 16 shows the basic principles of vectorcardiography and the VCG.

In contrast to ECG tracings that show the detailed morphology of the electrical activity of the heart in any one single lead direction, the VCG is the simultaneous plot of the same electrical events in two perpendicular (orthogonal) lead directions. This gives a detailed representation of the cardiac vector and produces loop-type patterns on the CRT. The magnitude and orientation of the P, QRS, and T loops are then determined from the VCG. The VCG plots provide a clear indication of the cardiac axis and its deviation from normal. Each VCG exhibits three loops, showing the vector orientation of the P waves, the QRS complex and the T wave during the cardiac cycle. The high amplitude of the QRS complex loop predominates the VCG recordings and sensitivity adjustments need to be made to adequately display the loops resulting from the P and T waves.

The VCG is superior to the clinical 12-lead scalar ECG in recognition of undetected atrial and ventricular hypertrophy and some cases of myocardial infarction and the capability to diagnose multiple infarctions in the presence of bundle branch blocks. For example, in most infarcts the cardiac vector orientation moves away from the area of infarction. The advantage of VCG is that it only requires three orthogonal leads to provide full information on cardiac electrical activity. This translates into simpler algorithms and less computation. However, the full 12-lead

Figure 15. The three-dimensional (3D) representation of the evolution of the cardiac vector for P, QRS, and T loops during one cardiac cycle and their projections onto the three principal planes. (Courtesy of Ref. 3.)

Figure 16. Vectorcardiography based on mutually orthogonal uniform lead fields set up by parallel electrode arrangements on opposite sides of the torso in three principal planes. (Courtesy of Ref. 2.)

scalar ECG provides detailed time plots of the ECG signals and highlights the changes in waveform morphology. Decades of clinical experience has made the 12-lead electrocardiography the standard method of practice in diagnosis of heart disease and favors that method over vectorcardiography. For a comprehensive and detailed description of Vectorcardiography see Refs. 2 and 8.

High Resolution Electrocardiography (Body Surface Potential Mapping). The electrical activity of the heart triggering its pumping action is a spatiotemporally distributed process. As discussed above, electrocardiography provides temporal information on timing of cardiac cycle. It can provide information on chamber enlargement and is an established tool for diagnosis of cardiac arrhythmias. Exercise testing using 12-lead clinical electrocardiography is the most common means of clinical investigation in evaluation of patients with chest pain. Even though clinical 12-lead ECG provides excellent temporal resolution in assisting clinical diagnosis of heart disease, it is limited in providing spatial information on the evolution of the electrical activity during the cardiac cycle.

The 12-lead ECG is now a standard diagnostic tool in clinical practice, but it is limited in detecting some cardiac abnormalities due to its sparse spatial sampling of the cardiac vector. Cardiac electrical imaging or enhanced electrocardiography alleviates this limitation by acquiring more information through deployment of a larger array (hundreds) of electrodes installed in a jacket to record more spatial samples of cardiac electrical activity.

As discussed in the sections above, the heart is a spatially and temporally distributed biosource embedded in an irregularly shaped volume conductor with conductivity inhomogeneities. In standard electrocardiography one can measure heart rate and detect arrhythmias, determine the location of cardiac ischemia and infarction, localize some sites of conduction disorders between atria and ventricles or areas of transient ischemia or even detect chamber hypertrophy or congenital heart defect. However, standard ECG is specifically limited in the following: accurate detection of events in the non-anterior regions of the heart, underestimation of the deflections of the ST segment during ischemia if they are weak or nonexistent on the regions of the torso sampled by the ECG leads, inaccuracy of ECG amplitudes in reflecting the extent of physiological alterations due to the spatial integration effects of many simultaneous events, some of which partially cancel so that small defects can result in large changes in the ECG signal or vice versa.

Simply stated, standard ECG is limited in spatial resolution as it is used to describe the complex cardiac fields generated by the electrical activity of a spatiotemporally distributed biosource like the heart. Therefore, the need for enhanced resolution electrocardiography exists. Recent developments in cardiac imaging techniques have been largely driven by this need. A number of active research centers around the world are dedicated to the development of this technology (9–12). As with other imaging methods used in medicine, recent developments in cardiac electrical imaging have greatly benefited from better data

Figure 17. Color-coded BSPMs and computed potential distributions at the surface of the heart during the peak of the QRS complex using 120 ECG electrodes. The surface on the right shows the computed potential distribution on the surface of the heart at the same instant. The relative size of the two surfaces is distorted but their orientations are aligned as in the geometric model used for the inverse calculation. The scaling and isopotential contours are local to each surface. Scale bars on both sides indicate the voltage (in microvolt) to color mapping. (Courtesy of Dr. Robert MacLeod, Scientific and Imaging Institute, University of Utah, Ref. 9.)

acquisition capabilities and advancements in electronics and computer hardware and software capabilities. Figure 17 shows color-coded BSPMs and computed potential distributions at the surface of the heart during the peak of the QRS complex using 120 ECG electrodes as an example of how advanced computing methods can improve the spatial resolution of electrocardiography.

In summary, a popular modern approach to extend the capabilities of the standard 12-lead ECG system in mapping the electrical activity of the heart is high resolution electrocardiography or body surface potential mapping (BSPM). This approach attempts to provide spatial information by including a larger number of recording electrodes covering the entire torso. The BSPM facilitates the spatial visualization of the cardiac electrical activity. It has been shown that BSPM is superior to 12-lead electrocardiography in detection and localization of acute and remote myocardial infarction (MI). However, the full capability of BSPM to localize acute MI is as yet, not established.

Computers play a central role in fast acquisition and real-time processing of a large number of ECG signal channels, as well as in modeling and visualization of the electrical images of the heart and eventual construction of 3D animated representations of body surface potential maps. These topics are active areas of research and deserve separate chapters in their own right.

Computer-Based Monitoring ECG Systems

All modern diagnostic and monitoring ECG acquisition and analysis systems are equipped with state-of-the-art computer technology. ECG monitoring devices constitute an essential part of the patient monitoring systems. Patient monitoring systems are used to continuously or intermittently measure the vital signs (generally

ECG, heart rate, pulse rate, blood pressure, and temperature) and perform automatic analysis on them. Monitoring is carried out at the bedside, or a central station. Bedside monitors are now widely used in intensive care, cardiac care and operating rooms. Computer-based bedside monitors perform ECG analysis and generate alarms if life-threatening arrhythmias occur. The ECG monitoring systems can be networked to share common computing and analysis resources. Telecommunication technologies are now used to transmit ECG signals back and forth between computing facilities. For a detailed discussion of ECG-based monitoring systems see Ambulatory (Holter) Monitoring and Electrocardiographic Monitors.

Computer-Based Heart Beat Detection. Computer-based arrhythmia detectors that provide accurate detection of prevalent heart diseases could greatly help cardiologists in early and efficient diagnosis of cardiac diseases. Such devices now constitute an integral part of computer-based cardiac monitoring systems. The morphologic and rhythmic character of the ECG signal can be interpreted from its patterns, which normally have periodic waveforms such as PQRSTU-waves. Rhythmical patterns deviating from normal ECG (cardiac arrhythmias) have correlation with heart injuries or its malfunction in pumping the blood, such as premature beats, flutter and fibrillation patterns. The most serious pattern is ventricular fibrillation, which may be life threatening due to deficient supply of oxygen by the blood to the vital organs, including the heart itself. Considering other factors influencing the ECG patterns such as medications taken by patients, their physiological and psychological condition as well as their health records, an accurate diagnosis can be made based on cardiac arrhythmia classification.

Accurate determination of the QRS complex and more specifically, reliable detection of the R-wave peak plays a central role in computer-based ECG signal analysis, Holter data analysis and robust calculation of beat-to-beat heart rate variability (13). Fluctuations in the ECG signal baseline drift, motion artifact due to electrode movement and electromyographic (EMG) interference due to muscular activity frequently contaminate the ECG signal. In addition, morphological variations in the ECG waveform and the high degree of heterogeneity in the QRS complexes make it difficult to distinguish them from tall peaked P and T waves.

Many techniques have therefore been developed to improve the performance of QRS detection algorithms. These techniques are mainly based on band pass filtering, differentiation techniques, template matching and others. Recently, it has been shown that the first differential of the ECG signal and its Hilbert Transform can be used to effectively distinguish the R-waves from large, peaked T and P waves with a high degree of accuracy (14). Even though this method provides excellent R peak detection performance, it lacks automatic missing-R-peak correction capability and has not been tested on pediatric ECG data. Manual correction of missing R peaks in the ECG signal is time consuming and tedious and could play a critical role in error-free derivation of HRV signal. Figure 18 shows the block diagram for an Enhanced Hilbert Transform-based (EHT) method with automatic missing-R-peak correction capability for error-free detection of QRS complexes in the ECG signals.

In this algorithm, filtered ECG signals are differentiated first to reduce baseline drift and motion artifacts. This step sets the ECG peaks to zero. Hilbert Transform of the differentiated signal is then calculated and the conjugate of the Hilbert Transform is obtained. With this operation, the zero crossings in the differentiated signal becomes prominent peaks in the Hilbert transformed conjugate of the differentiated signal. A threshold is then selected based upon the normalized RMS value (as it gives a measure of the noise content in the signal) of the Hilbert transformed ECG signal. The time instants for which the signal amplitude is greater than the threshold value are stored in an array. Peak detection is performed on the original signal. The peak values and the time at which they occur are stored in separate arrays. The R–R intervals are

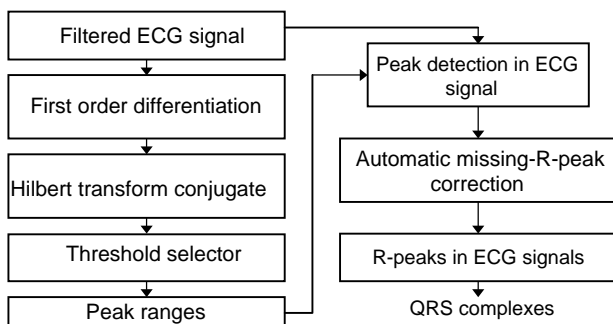

Figure 18. Block diagram for the Enhanced Hilbert Transform-based (EHT) QRS detection algorithm with automatic built-in missing R-peak correction capability. (Courtesy of Ref. 13.)

then calculated. If an R–R interval is $> 130\%$ of the previous R–R interval, then the algorithm is considered to have missed an R-peak from the ECG signal. Hence a correction for the missing beat is made based upon an updated moving average of the previous R–R intervals. The amplitude of the missing peak is estimated as the average of the two previous R-peaks adjacent to it (13).

ECG Signal Telemonitoring

With advancements in bioinstrumentation, computer, and telecommunications technologies now it is feasible to design vital sign telemonitoring systems to acquire, record, display, and transmit physiological signals (e.g., ECG) from the human body to any location. At the same time, it has become more practical and convenient for medical and paramedical personnel to monitor vital signs from any computer connected to the Internet.

Telemonitoring can improve the quality, increase the efficiency, and expand access of the healthcare delivery system to the under-staffed, remote, hard-to-access, or under-privileged areas where there is a paucity of medical practitioners and facilities. It seems reasonable to envision that a telemonitoring facility could significantly impact areas where there are needs for uniform healthcare access such as under-served populations of rural areas, developing countries, space flights, remote military bases, combat zones, and security healthcare facilities. Mobile patient telemonitoring (i.e., emergency medicine), posthospital patient monitoring, home care monitoring, patient education and continuing medical education all will benefit from telemonitoring. Figure 19 shows the graphical user interface of a Web-based vital sign telemonitor accessed from a client site (15).

Capacity

Typically 50 ECGs and copies on a single charge or 40 min of continuous rhythm recording

Recharge

Seven hours in standby mode to >90% capacity (typical)

Network Connections

10/100 Base-T IEEE 802.3 Ethernet Via RJ45 connector (standard)

Optional software required for Proxim Range LAN 27410 CE PC card wireless LAN connection

FAX Capability (optional)

Group 3, Class 1 or 2 fax

Modem (optional for USA & Canada)

V.90, K56 flex, enhanced V.34, V32 bits, V.32, V.22 bits and below

Barcode Reader (optional)

Reads Code 39 (standard and full ASCII)

Magnetic Card Stripe Reader (optional)

Reads cards adhering to ISO 7810, 7811-1, -2, -3, -4, and JIS X6301 and X6302

ECG Storage

XML File Format

150 ECGs to internal flash memory
 2–3 ECGs typical per 1.4 MB floppy disk
 150 ECGs per 128 MB PCMCIA card (optional)

ECG File Formats

XML and XML SVG

Power and Environment

Line Power 100–240 Vac, 50/60 Hz, 150 VA max

Environmental Operating Conditions

15–35°C (50–104°F)
 15–70% relative humidity (noncondensing)
 Up to 4550 m (15,000 ft.) altitude

Environmental Storage Conditions

0–40°C (32–122°F)
 15–80% relative humidity (noncondensing)
 Up to 4550 m (15,000 ft) altitude

Cardiograph Dimensions

~45 × 45.8 × 16 cm (17.7 × 18.0 × 6.34 in.)

Cardiograph Weight

~13 kg (28 lb.) including accessories

Patient Interface Module

Remote, microprocessor-controlled module

Safety and Performance

Meets the following requirements for safety and performance:

- IEC 60601-1:1988 + A1: 1991 + A2: 1995 General Requirements for Safety including all National Deviations
- IEC 60601-1-2: 1993 General Requirements for Safety Electromagnetic Compatibility
- IEC 60601-2-25: 1993 + A1: 1999 Safety of Electrocardiographs
- IEC 55011: 1998 Radio Frequency disturbance, Limits and Methods of Test
- AAMI EC11: 1991 Diagnostic Electrocardiographic Devices
- JIST 1202: 1998 Japanese Industrial Standard for Electrocardiographs

ACKNOWLEDGMENT

The excellent support of Ms Mary-Lou Lufkin with the Diagnostic ECG Division at Philips Medical Systems, USA is greatly appreciated.

ELECTROCONVULSIVE THERAPY

MILTON J. FOUST, JR
 MARK S. GEORGE
 Medical University of South
 Carolina
 Charleston, South Carolina

INTRODUCTION

Electroconvulsive therapy (ECT) is a technique for the treatment of severe psychiatric disorders, which consists of the deliberate induction of a generalized tonic-clonic seizure by electrical means. Contemporary ECT devices typically deliver bidirectional (alternating current) brief-pulse square-wave stimulation through a pair of electrodes that are applied externally to the patient's scalp. The procedure is now almost always performed under general anesthesia, although, in some unusual situations, such as in developing countries with limited medical resources, it

may be occasionally done without anesthesia (1). As with other convulsive therapies that historically preceded ECT, the goal is to produce a seizure. The presence of seizure activity appears to be essential; stimuli that are below the seizure threshold appear to be clinically ineffective. However, although the production of a seizure appears to be necessary, a seizure alone is not sufficient. Some forms of seizure induction are, in fact, clinically ineffective. A variety of psychiatric and neurological conditions exist that respond favorably to ECT, although the majority of patients treated with ECT have mood disorders, such as unipolar or bipolar depression, particularly when severe or accompanied by psychotic symptoms. Certain other conditions, such as mania, schizoaffective disorder, catatonia, neuroleptic malignant syndrome, Parkinson's disease, and intractable seizures, may respond to ECT as well. Schizophrenia has also been treated with ECT, although the results tend to be less favorable than those obtained in patients with mood disorders. Those patients with schizophrenia who also have a prominent disturbance of mood probably respond best to ECT (2,3). Typically, a series or a course of treatments is prescribed. By convention, ECT treatments are usually given two to three times per week. A course usually consists of around six to eight treatments, which may then be followed by maintenance treatment in the form of either medication, additional ECT given at less frequent intervals, or both. A number of questions still remain regarding the most effective methods for performing ECT, the mechanism of action of ECT, and what role there may be in the future for ECT and other forms of brain stimulation, such as repeated transcranial magnetic stimulation (rTMS), magnetic seizure therapy (MST), and vagus nerve stimulation (VNS).

HISTORY

ECT was first used by the Italian psychiatrists Ugo Cerletti (Fig. 1) and Lucio Bini to treat a disorganized, psychotic man found wandering the streets of Rome in 1938. The results were dramatic, with complete recovery reported (4). The treatment was developed as an alternative to other, higher risk forms of artificial seizure induction, specifically Ladislav von Meduna's convulsive therapy involving the use of stimulants such as camphor, strychnine, and Metrazol (pentylentetrazol) (4–6). ECT was welcomed due to its effectiveness with otherwise treatment-resistant and profoundly disabled patients. However, the procedure was at risk of being abandoned due to the incidence of fractures (up to 40%) caused by uncontrolled seizure activity. This problem was resolved by the introduction of muscle relaxation (originally in the form of curare, and later with depolarizing muscle relaxants such as succinylcholine) and general anesthesia (7). The use of anesthesia and muscle relaxation was one of the most important innovations in ECT treatment, another being the use of brief-pulse square-wave stimulation in place of sine-wave alternating current. Brief-pulse ECT was found to cause less cognitive impairment compared with sine-wave ECT, as well as less disruption of the EEG (8,9). The routine use of oxygen and monitoring of vital signs, cardiac rhythm, pulse oximetry,

Figure 1. Ugo Cerletti 1877–1963. Reprinted with permission from the American Journal of Psychiatry, (Copyright 1999). American Psychiatric Association.

electromyography (EMG), and electroencephalography (EEG) have also helped to reduce the risks associated with the procedure.

PRE-ECT EVALUATION

In order to receive ECT, a patient must first be evaluated by a physician (typically a psychiatrist) who is trained and credentialed in the procedure and who agrees that the patient is a suitable candidate, based on psychiatric history and examination, physical condition, and capacity to consent. If a patient is unable to consent, a suitable substitute decision-maker must be identified, usually a family member (in some states, a court-order may be required). The process of evaluation typically consists, at a minimum, of a psychiatric interview and mental status examination, a medical history (including a past medical history, family and social history, and review of systems) and physical examination (including a screening neurological examination and fundoscopic examination to exclude papilledema) (1,2,10). It is necessary to review the patient's current medications, including those that are prescribed for concurrent medical conditions as well as psychiatric medications, and to obtain some information about previous medication trials for the psychiatric condition under consideration. Usually, it is desirable to obtain some basic laboratory studies (such as complete blood count, serum electrolytes, BUN, glucose and creatinine, urinalysis, liver

function tests, and thyroid function tests) both to screen for medical conditions that may cause depressive or psychotic symptoms and to identify conditions of increased ECT or anesthesia risk. Most patients, and especially older patients or patients with a history of cardiovascular disease, should have an electrocardiogram (ECG). The use of brain imaging is controversial; many practitioners prefer some form of pre-ECT brain imaging to identify or exclude the possibility of an intracranial mass, one of the few conditions that may be associated with a high risk of mortality with ECT (11). However, it has been argued that a neurologic examination should be sufficient to screen for this particular risk factor (12).

CONSENT

Prior to undergoing ECT or any other procedure, the patient (or patient's surrogate decision-maker) must demonstrate a satisfactory understanding of the nature of the procedure, its risks, benefits, and alternatives. In some states, the physician may need to petition the court for permission to perform ECT on patients who lack the capacity to consent. The issue of consent is complex, as those patients who are most in need of ECT are generally those who are the most ill, and are often the most vulnerable and impaired. It is possible to have a severe psychiatric illness and yet still retain the capacity to rationally evaluate the necessary issues involved in making a decision as to whether to have ECT, but one can be seriously incapacitated as well. Evaluating the patient's capacity to give informed consent is one of the most important parts of the pre-ECT consultation process, along with establishing the presence or absence of an appropriate indication for treatment and identifying concurrent medical conditions and medications that may increase the risk of treatment. It is part of the consultant's responsibility to educate the patient about what is, for many, an unfamiliar or frightening treatment. Often, much of what a patient or family may understand of ECT consists of disturbing images, such as those presented in films like "One Flew over the Cuckoo's Nest" (13). In most cases, the patient will be able to understand the information presented and engage in a rational decision-making process despite their illness. However, some patients may be able to express a superficial understanding of the facts at hand and yet be impaired in the ability to make rational decisions (14), which may be demonstrated through self-destructive behavior, lack of self-care, or irrational refusal of necessary treatment. In these cases, it becomes necessary to seek a substitute, usually a family member, who can make medical decisions on the patient's behalf. State laws differ regarding the details and circumstances under which another person can make these types of treatment decisions, and it is necessary to become familiar with the particular local laws governing consent.

INDICATIONS

The most common indication for ECT is severe, treatment-resistant depression, either of the unipolar or bipolar type

Table 1. Indications for ECT

Unipolar or bipolar depression
Mania
Schizoaffective disorder
Schizophreniform disorder
Schizophrenia
Catatonia
Neuroleptic malignant syndrome

(Table 1). The syndrome of depression is characterized by a sad or depressed mood, as well as disturbances in energy level, sleep, and the capacity to experience pleasure (anhedonia) (15). It may include psychotic symptoms such as delusions (fixed, false beliefs that are held despite evidence to the contrary) or hallucinations. Patients with so-called "unipolar" depression exhibit one or more episodes of depression without episodes of mania. Such patients will usually be formally diagnosed as having a major depressive disorder (MDD). Patients with so-called "bipolar" depression have also suffered from one or more episodes of mania, frequently in a cyclical pattern of alternating mania followed by depression. Those patients who are most severely ill, particularly those who are delusional or catatonic, will typically respond best to ECT. Although usually reserved for those patients who have not had a successful response to one or more medication trials, ECT is an appropriate first treatment when the patient's life is threatened by severe illness in the form of aggressively self-destructive behavior, refusal or inability to eat or drink, or extreme agitation. Mania, a condition characterized by an abnormally elevated or irritable mood, hyperactivity, agitation, impulsivity, and grandiosity, also responds well to ECT. Schizophrenia is often treated with ECT, particularly in some European and Asian countries, but may respond less well, unless mood disturbance is a prominent component of the patient's illness. Neuroleptic malignant syndrome (an antipsychotic drug-induced syndrome that shares many of the characteristics of catatonia) is a less common indication for ECT and may be used when the syndrome persists despite the usual interventions such as discontinuing neuroleptics and treatment with dopamine agonists. Catatonia (which may be an expression of either a mood disorder or schizophrenia) is characterized by mutism and immobility, sometimes with alternating periods of agitation. These patients may respond to treatment with benzodiazepines, but if they do not, ECT is indicated and frequently effective. Recurrent, treatment-refractory seizures may respond to ECT as well, suggesting an anticonvulsant mechanism of action for ECT (16). Patients with Parkinson's disease may improve with ECT, possibly due to the dopaminergic effect of ECT.

Certain conditions exist, such as personality disorders, that do not respond well to ECT or may even reduce the likelihood of successful treatment when they coexist with a more suitable indication, such as a mood disorder (17–19). In some cases, the burden of disability and suffering may be so great (and the risk of serious complications so low) that ECT may reasonably be offered even if the patient's diagnosis is not one of those generally considered a standard indication for the treatment (20).

Table 2. Conditions of Increased Risk with ECT

Increased intra-cranial pressure
Recent myocardial infarction or stroke
Unstable angina
Severe cardiac valvular disease
Severe congestive heart failure
Unstable aneurysms
Severe pulmonary disease
Pheochromocytoma
Retinal detachment
Glaucoma

CONDITIONS OF INCREASED RISK

As will be discussed later in this article, ECT as currently practiced is a relatively low risk procedure. It can be safely used to treat all patient groups including children and adolescents (21–25), pregnant women (26,27), and the elderly (28). In particular, age alone should not be considered a barrier to treatment; elderly patients are among those who often have the most dramatic and favorable responses to ECT (29). However, certain medical conditions exist that may, to a greater or lesser degree, contribute to an increase in risk of morbidity or mortality with the procedure (Table 2). Most significant among these would be severe or unstable cardiac disease or the presence of a space-occupying lesion (such as a tumor) within the cranial cavity, resulting in increased intracranial pressure. Very small tumors without a visible mass effect on computerized tomography (CT) or magnetic resonance imaging (MRI) do not appear to pose a high risk with ECT (30). Detecting such masses and making the distinction between low and high risk lesions may help to support a rationale for pre-ECT brain imaging as a screening tool (11).

COMPLICATIONS

Serious complications with ECT are rare (Table 3). The risk of death has been estimated at 4 per 100,000 treatments (31). The risk of other potentially life-threatening complications, such as myocardial infarction and stroke, is also very low, although the risk of cardiac arrhythmias appears to be higher in persons with pre-existing cardiac disease (32,33). The introduction of general anesthesia and muscle relaxation has almost eliminated the risk of fractures with ECT. Both retrograde amnesia and anterograde amnesia are common, but it is unusual for cognitive impairment to be severe or prolonged. Minor side effects such as headaches, muscle aches, and nausea frequently occur; these side effects are usually transient and easily managed with symptomatic treatment.

The amnesia or memory loss that occurs with ECT typically takes two forms: loss of memory for past or previously learned information (retrograde amnesia) as well as difficulty in learning new information (anterograde amnesia). The retrograde amnesia associated with ECT tends to be greater for “public” or “impersonal” knowledge about the world than for autobiographical or personal memories. Memories for remote events also tend to be

Table 3. Side Effects and Complications with ECT

Common:
Cognitive side effects
Transient postictal confusion or delirium
Retrograde and anterograde amnesia
Headaches
Muscle soreness
Nausea
Less common or rare:
Death (1/10,000 patients)
Aspiration
Brochospasm or laryngospasm
Cardiovascular
Arrhythmias
Severe hypertension or hypotension
Cardiac ischemia
Myocardial infarction
Cardiac arrest
Neurological
Prolonged or tardive seizures
Nonconvulsive status epilepticus
Stroke
Prolonged apnea due to pseudocholinesterase deficiency
Malignant hyperthermia of anesthesia

better preserved than that for more recent events. Bilateral ECT appears to produce greater and more persistent memory deficits than right-unilateral ECT (34). ECT-induced anterograde amnesia is typically greatest immediately following treatment and tends to rapidly resolve in the weeks following the last treatment of a series. Recovery also typically occurs over time with retrograde amnesia, although patients may notice some persistent gaps in memory for past events. Although anecdotal, it may be reassuring to patients to be made aware of the stories of psychologists and physicians who have had ECT, benefited, and resumed their professional activities (35). Uncommon exceptions to these rules exist, however. A few patients complain of severe and persistent problems with memory that cause them much distress (36). No satisfactory explanation exists for this phenomenon of severe ECT-induced memory loss (37). No reliable evidence exists that ECT causes damage or injury to the nervous system.

MEDICATIONS AND ECT

Experts in the past have recommended stopping antidepressants prior to ECT (38), although a recent study now suggests that tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) may be safe in combination with ECT (39). Evidence exists that certain antipsychotic medications (such as haloperidol, risperidone, and clozapine) may have beneficial effects in combination with ECT (40–44). Many drugs that were originally developed and used as anticonvulsants (such as carbamazepine, valproic acid, and lamotrigine) are frequently used as either mood stabilizers or as adjunctive agents in antidepressant regimens. As these drugs, by definition, can be expected to inhibit seizure activity, they are generally tapered and discontinued prior to beginning

ECT. An exception would be those patients for whom these drugs are prescribed for a concurrent seizure disorder. In these cases, anticonvulsant drugs should usually be continued in order to minimize the risk of uncontrolled seizure activity between treatments. Lithium, a commonly used mood stabilizer, has been associated with prolonged delirium following ECT. In general, it should be avoided, but, in special circumstances and with careful monitoring, its use in combination with ECT may be justified (45,46). Both chlorpromazine and reserpine, an antipsychotic and antihypertensive agent that acts through the depletion of neuronal dopamine, have been associated with severe hypotension and death when combined with ECT (47).

Certain drugs that are prescribed for concurrent medical conditions (and not primarily for psychiatric conditions) help to reduce the risks associated with ECT and anesthesia. Patients who have gastro-esophageal reflux disease (GERD) should be treated with a suitable medication (such as a histamine-2 receptor blocker or proton pump inhibitor) in the morning prior to ECT to reduce the risk of reflux and aspiration. Patients who may be especially prone to aspiration can be treated with intravenous metoclopramide to accelerate gastric emptying. Pregnant women may be given sodium citrate/citric acid solution by mouth. Patients with known hypertension should receive their usual antihypertensive regimen prior to ECT; an exception would be made for diuretics, which should be delayed until after ECT to avoid bladder filling before or during the procedure. Some patients may have an exaggerated hypertensive response to the outpouring of catecholamines that occurs with seizure response to ECT, which can usually be controlled with intravenous beta-adrenergic antagonists such as esmolol or labetalol. A patient with a pheochromocytoma (catecholamine-secreting tumor) is at especially high risk of severe hypertension (48). Such a patient may require more aggressive measures (such as arterial blood-pressure monitoring and intravenous sodium nitroprusside) in order to maintain satisfactory blood pressure control (49). Patients with pulmonary disease should have their pulmonary status assessed prior to treatment and should receive their usual medications, including inhaled beta-agonists or steroids. As ECT and the resulting seizure produces a transient increase in intraocular pressure (50), patients with retinal detachment may be at risk of further eye injury and should have this condition treated prior to ECT. Similarly, patients with glaucoma should have their intraocular pressures controlled with suitable medications prior to ECT (51).

ANESTHESIA

Methohexital was previously a very popular anesthetic drug for ECT, but manufacturing problems made it essentially unavailable for several years, forcing changes in ECT anesthesia practice (52). Anesthesia for ECT may be induced with an intravenous injection of other short-acting anesthetic agents such as propofol and etomidate. Etomidate may be substituted for methohexital or propofol in an effort to produce seizures of longer duration (53) or to

stimulate seizures in those uncommon situations of no seizure activity despite maximum stimulus and bilateral electrode placement. Once anesthesia is induced (typically within seconds following the injection), a muscle relaxant is injected, typically succinylcholine, but a nondepolarizing muscle relaxant such as mivacurium may be used when there are coexisting medical conditions that increase the risk of exaggerated hyperkalemic response with succinylcholine, such as burns, renal failure, or neurologic disease, or if a history of malignant hyperthermia exists (54,55). The ECT stimulus may elicit a vagal (parasympathetic) response, which can lead to bradycardia, transient heart block, or even asystole, which has been explained as the result of forced expiration against a closed glottis during the stimulus, or it may be a direct effect of the stimulus on the central nervous system. Bradycardia and asystole have been observed in the postictal period as well (56). An anticholinergic compound such as glycopyrrolate or atropine may be injected proximate to the anesthetic to reduce the bradyarrhythmias that may occur with ECT (57). If the stimulus is successful in producing a seizure, it results in an outpouring of catecholamines and a sympathetic response with resulting tachycardia and hypertension as noted above, which is usually transient and without clinical significance, but in some patients, especially those with pre-existing hypertension or cardiovascular disease, it may be desirable to limit this response using an antihypertensive agent (54,55,58).

Patients are unable to breathe without assistance when anesthetized and fully relaxed; ventilation and oxygenation are provided by means of positive-pressure ventilation with 100% oxygen through a bag and mask. Endotracheal intubation is rarely required. In some patients (such as pregnant women), the risk of reflux may be higher and intubation may be the preferred option for airway management (27). Some patients may have abnormalities of the face and upper airway that interfere with mask ventilation. Other options for airway management including intubation, laryngeal mask airway (59,60), or even tracheostomy may be considered.

MONITORING

The type of medical monitoring that is used during ECT includes ECG blood pressure, pulse oximetry, EMG, and EEG. Modern ECT devices typically include the capacity to monitor and record ECG, EMG, and EEG; commonly, a paired right and left fronto-mastoid EEG placement is used. Two-channel EEG monitoring is helpful both to ensure that the seizure generalizes to both hemispheres and to evaluate the degree of inter-hemispheric EEG symmetry or coherence, as well as postictal EEG suppression, all factors that may predict the therapeutic efficacy of the seizure (61). Two EMG electrodes are placed on a foot, usually the right, which is isolated from the rest of the patient's circulation with a blood pressure cuff acting as a tourniquet, which minimizes the effect of the muscle relaxant and permits the observation and recording of motor seizure activity in the foot, even with complete paralysis otherwise.

Figure 2. Brief-pulse square-wave ECT stimulus.

ECT STIMULUS

As noted previously, the ECT stimulus itself typically consists of a series of brief electrical pulses. Early ECT devices provided stimulation with sine-wave alternating current; essentially the same type of current that is distributed through public utilities for use in household appliances and lighting. Most modern ECT devices now provide a stimulus that consists of brief pulses with a bidirectional square-wave pattern (Fig. 2). (One exception is the Ectron series 5A, manufactured by Ectron, Ltd, Letchworth, Hertfordshire, England. This device delivers unidirectional pulses.) The American Psychiatric Association has recommended the use of “constant-current” devices; so-called because a relatively constant (rather than continuously varying) current is maintained for the duration of the pulse. The advantage of using a constant-current rather than constant-voltage or constant-energy device is that the clinician is able to deliver a predetermined quantity of charge by varying the time interval of exposure to the current (62).

At 100% of available output, a typical ECT device such as the Thymatron System IV (Somatics, LLC, Lake Bluff, IL) can provide approximately 504 mC of charge (Table 4) (64), which will be delivered as brief pulses of 0.5 ms each at a frequency of 70 Hz for a total stimulus duration of 8 s. Members of the Thymatron (Fig. 3) series (DX, DGX, and System IV) and similar devices such as those of the Spectrum series (4000M, 4000Q, 5000M, and 5000Q manufactured by MECTA, Lake Oswego, OR) are calibrated in such a way

Table 4. ECT Device Specifications (Thymatron System IV)

Current:	0.9 A (fixed)
Frequency:	10 to 140 Hz
Pulsewidth:	0.25 to 1.5 ms
Duration:	0.14 to 7.99 s
Output:	approx. 25 to 504 mC (5 to 99.4J at 220 Ω) 1008 mC (188.8J at 220 Ω) with double-dose option
Input:	120 V AC, 60 Hz
Recording:	4 channel (2 EEG, EMG, ECG)

Figure 3. Somatics Thymatron system IV ECT device (Image provided courtesy of Somatics, LLC).

that the user can select incremental quantities of charge. The device labels and manuals will usually refer to these as increments of “percent energy,” although the energy required to deliver the charge is actually dependent on the particular impedance of the patient being treated. The user (clinician) may have the option of individually adjusting such parameters as “percent energy” (charge), pulse frequency, pulse-width, and total duration of pulse train. Both voltage and energy will be altered by the device to adjust for variations in impedance. The average impedance for a human receiving ECT is approximately 220 Ω, and the energy required to deliver 504 mC is 99.4 J (63).

Over an 8 s total stimulus duration, the average power for that interval is $99.4\text{ J}/8\text{ s} = 12.4\text{ W}$, although the power during each discrete electrical pulse is obviously much greater. Assuming a pulse frequency of 70 Hz (140 pulses/s with bidirectional current), delivered over a total stimulus duration (stimulus train) of 8 s, with a pulse-width of 0.5 ms (or 0.0005 s), then the power during each discrete electrical pulse of this stimulus would be:

$$99.4\text{ J}/(140\text{ pulses/s} \cdot 8\text{ s} \cdot 0.0005\text{ s/pulse}) = 99.4\text{ J}/0.56\text{ s} = 177.5\text{ W}$$

The stimulus is transmitted to the head of the patient (and, indirectly, to the brain) through externally applied scalp electrodes. These electrodes may either be stainless-steel discs held in place with an elastic band or self-adhesive flexible conductive pads. The stimulus electrodes can be applied in several configurations, including bilateral (also called bifronto-temporal), right unilateral, and bifrontal. In bilateral ECT, the electrodes are placed approximately 3 cm above the midpoint of a line between the canthus of the eye and tragus of the ear. With right unilateral ECT, the right electrode is placed in the conventional position for bilateral ECT, with the second electrode just to the right of the vertex of the skull. Bifrontal electrode placement is the newest of these various methods of performing ECT. Bifrontal placement is 5 cm above the angle of the orbit of the eye, which is usually found near the outer edge of the eyebrow. Comparative studies suggest that bilateral ECT may be more effective at lower energy levels, although right unilateral and bifrontal ECT may result in less cognitive impairment (64–68).

We consider the patient and device (including electrodes and cables) to be a circuit, and, for purposes of simplification, impedance in this circuit is usually treated as more or less equivalent to resistance. However, it should be recognized that impedance in the circuits being discussed has both resistive and reactive components (62). These reactive components are capacitance and inductance. Both inductance effects and capacitance in tissue are assumed to be low, but the treatment cables and electrode–skin interface may make a more significant contribution, altering both the amplitude and frequency of the stimulus. Complicating matters further, it should also be noted that the circuit impedance varies with the intensity of the stimulus. ECT devices typically provide a “static impedance” reading prior to treatment, which can vary widely, but is usually around 2000 Ω . The “dynamic impedance” can be measured during the stimulus and is substantially less, an average of about 200 Ω . The static impedance is measured with a very small test stimulus (insufficient to cause a seizure or even be detected by the patient). This static impedance is used primarily to test the integrity of the circuit. If the impedance is greater than 3000 Ω , it is assumed that either a break in the circuit occurred or inadequate contact exists at the skin-electrode interface. Similarly, an excessively low impedance suggests shunting through a very low impedance channel (short-circuit) such as saline, conductive gel, or skin between closely applied electrodes. Interestingly, the seizure threshold (quantity of charge required to stimulate a seizure) is typically lower for unilateral than for bilateral ECT, despite the lower interelectrode distance with potential for lower impedance and greater shunting through scalp tissues with unilateral placement, which is thought to be a result of differing patterns of charge density, with maximum charge density in the frontal region for bilateral electrode placement and maximum charge density for unilateral placement in the region of the motor strip, an area of lower intrinsic seizure threshold (62).

SEIZURE RESPONSE

A seizure is characterized neurophysiologically by the paroxysmal synchronous discharge of populations of neurons. It is recognized clinically as abnormal behavior associated with abnormal neuronal activity and may present in a variety of different forms such as simple partial seizures, complex partial seizures, or generalized tonic-clonic seizures (69). During ECT, the patient is anesthetized and relaxed, so many of the clinical characteristics are altered. However, the observable characteristics of the ECT seizure are consistent with the generalized tonic-clonic type of seizure. The ECT stimulus predictably results in a pattern of spike and slow-wave activity that is distinctive and recognizable on EEG (70). The seizure activity rapidly spreads throughout both hemispheres and usually lasts for less than 60 s. The immediate goal of ECT is to produce such a seizure; stimuli that do not result in seizure activity appear to lack therapeutic benefit. However, it is possible to produce seizures, specifically with right unilateral ECT at or only slightly above the seizure threshold, that have a

relatively weak therapeutic effect (64). Most experts recommend that right unilateral ECT be given with a stimulus that is at least five times the seizure threshold. Threshold may either be determined by titration (i.e., by giving a series of increasing stimuli), or the stimulus may be given at maximum energy. If bilateral or bifrontal electrode placement is used, energies just above the seizure threshold may be sufficient, and seizure threshold can be estimated based on the patient's age (71).

Certain characteristics of the seizure activity may be associated with therapeutic efficacy, including coherence or symmetry between hemispheres of high amplitude slow waves on EEG and marked postictal suppression following the end of the seizure (61). Adjustments can be made in technique to try to improve response based on these characteristics and other seizure characteristics, including overall seizure duration.

MECHANISM OF ACTION OF ECT

The precise mechanisms of action of ECT are not well understood. A number of biochemical and physiological changes exist that have been detected following both ECT in humans and electroconvulsive shock (ECS) in animals. Some of these parallel those of antidepressant drugs, but others do not. In vivo studies of long-term ECS (and repeated tricyclic antidepressant drug administration) show increases in postsynaptic 5-hydroxytryptamine type 1a (5-HT-1a) receptor sensitivity. Long-term ECS increases 5-HT-2a receptors, but antidepressant administration in animals decreases 5-HT-2a receptors. Both antidepressant treatment and ECS reduce beta-adrenergic receptors (72). Evidence for increased dopaminergic activity with ECS and ECT exists, probably as a result of increased dopamine synthesis (73). Proton magnetic resonance spectroscopy measurements following ECT have demonstrated increases in concentrations of cortical gamma-amino butyric acid (GABA), an inhibitory neurotransmitter (74). This observation, as well as the finding that increasing seizure threshold during a course of ECT is associated with clinical response, has led to the hypothesis that a linked anticonvulsant and antidepressant response to ECT exists (61).

Magnetic resonance imaging (MRI) scans obtained before and after ECT have failed to demonstrate any structural changes in the brain. Positron emission tomography (PET) and single-photon emission computerized tomography (SPECT) scans of the brain during the ECT seizure show marked increases in global and regional metabolic activity and blood flow (75). However, PET scans taken several hours or days following ECT have shown a marked reduction in absolute and prefrontal activity (76). The majority of functional imaging studies with depressed patients have shown pretreatment deficits in similar regions (77). Paradoxically, those subjects with the greatest post-ECT reduction in the left prefrontal cortex show the greatest clinical response (78,79). One possible explanation for this may be that specific areas of the brain exist that are hypermetabolic in the depressed state and are suppressed by the effects of ECT, although, as mentioned

above, most scans show resting prefrontal hypoactivity in depression.

At the level of gene expression, ECS appears to induce brain-derived neurotrophic factor (BDNF) and its receptor, protein tyrosine kinase B (TrkB). Using our current understanding of the effects of ECS and neurotransmitter signal transduction, a model can be constructed that traces the effects of ECS/ECT-induced neuronal depolarization through pathways of norepinephrine (NE), 5-HT and glutamate release, monoamine receptors and ionotropic glutamate receptor binding by these neurotransmitters, cyclic adenosine monophosphate (cAMP) and other second-messengers coupled to these receptors, and protein kinases stimulated by these second-messengers. Protein kinase A (PKA), protein kinase C (PKC), and calcium/calmodulin-dependent protein kinase (CaMK) phosphorylate and activate cAMP response element binding protein (CREB). CREB is a transcription factor for BDNF. BDNF then induces neuronal sprouting and may have other beneficial effects that reverse stress-induced neuronal atrophy (80) and, presumably, depression.

FUTURE DIRECTIONS FOR ELECTROMAGNETIC BRAIN STIMULATION

A number of unanswered questions regarding ECT still exist, including such questions as:

- What are the most effective methods of maintenance therapy (medications, ECT, or both) following an acute course of treatment?
- Which medications (including antidepressants, antipsychotics, and mood stabilizers) can be successfully and safely combined with ECT?
- What is the best electrode placement from a treatment efficacy and side-effect point of view?
- How can the ECT stimulus be modified to make it more therapeutically effective and diminish side effects (especially cognitive effects)?
- What is the actual mechanism (or mechanisms) by which ECT exerts its antidepressant, antipsychotic, and other beneficial effects?

ECT itself is no longer the only form of electromagnetic brain stimulation. Both rTMS (often referred to simply as TMS) and VNS have shown promise for the treatment of mood disorders (79,81). As it does not involve the production of seizures and therefore requires no anesthesia, TMS is a particularly attractive alternative to ECT, especially for mood disorders resistant to treatment with medication. MST involves magnetic stimulation at frequencies designed to provoke seizures. This technique obviously requires general anesthesia and muscle relaxation just as ECT does. The hope is that MST may be as effective as ECT, but with less cognitive impairment due to the more focal nature of the stimulus.

ECT will remain an important option for severe and treatment-refractory psychiatric illness for the foreseeable future. An improved understanding of the pathophysiology of psychiatric illness as well as the mechanism of action of

electromagnetic brain stimulation will lead to further refinements in technique that will make ECT and related therapies safer, more effective, and more acceptable to patients and their families. The availability of alternative methods of brain stimulation will provide a wider range of choices and will create opportunities for combining therapies in ways that will be more compatible with individual patients' needs. Although changing social and political conditions may affect its image and public acceptance, it is unlikely that ECT will disappear or be replaced for some time to come.

ACKNOWLEDGMENTS

The authors would like to express their appreciation to Carol Burns, RN, ECT Program Coordinator of the Medical University of South Carolina Department of Psychiatry and Behavioral Sciences and to Drs. Melinda Bailey and Gary Haynes of the Medical University of South Carolina Department of Anesthesiology for their helpful advice during the preparation of this article.

INTRODUCTION

The following section will give an overview of the electroencephalogram (EEG), its origin, and its validity for diagnosis in clinical use. Since Berger (1) demonstrated in 1929 that the activity of the brain can be measured using external electrodes placed directly on the intact skull, the EEG has been used to study functional states of the brain. Although the EEG signal is the most common indicator for brain injuries and functional brain disturbances, the complicated underlying process, creating the signal, is still not well understood.

Figure 1. The major portions of the human cerebrum called lobes. Areas external to the cerebrum include the midbrain areas such as the diencephalon and the hindbrain areas such as the cerebellum, medulla, and pons. (Adapted from Ref. 5.)

The section is organized as follows. The biophysical basis of the origin of the EEG signal is described first, followed by EEG recordings and classification. Afterward, the validity and scientific basis for using the EEG signal as a tool for studying brain function and dysfunction is presented. Finally, logistical and technical considerations as they have to be made in measuring and analyzing biomedical signals are mentioned.

ORIGIN OF EEG

Valid clinical interpretation of the electroencephalogram ultimately rests on an understanding of the basic electrochemical and electrophysical processes through which the patterns are generated and the intimate nature of the brain's functional organization, at rest and in action. Therefore, the succeeding parts of the following discussion deal with the gross organization of the cortex, which is generally assumed to be the origin of brain electrical activity that is recorded from the surface of the head (2–4), the different kinds of electrical activity and resulting potential fields developed by cortical cells. Figure 1 shows the general organization of the human brain.

Organization of the Cerebral Cortex

Even though different regions of the cortex have different cytoarchitectures and each region has its own morphological patterns, aspects of intrinsic organization of the cortex are general (6,7). Most of the cortical cells are

arranged in the form of columns, in which the neurons are distributed with the main axes of the dendritic trees parallel to each other and perpendicular to the cortical surface. This radial orientation is an important condition for the appearance of powerful dipoles. Figure 2 shows the schematic architecture of a cortical column. It can be observed that the cortex, and within any given column, consist of different layers. These layers are places of specialized cell structures and within places of different functions and different behaviors in electrical response. An area of very high activity is, for example, layer IV, which neurons function to distribute information locally to neurons located in the more superficial (or deeper) layers. Neurons in the superficial layers receive information from other regions of the cortex. Neurons in layers II, III, V, and VI serve to output the information from the cortex to deeper structures of the brain.

Activity of a Single Pyramidal Neuron

Pyramidal neurons constitute the largest and the most prevalent cells in the cerebral cortex. Large populations of these pyramidal neurons can be found in layers IV and V of the cortex. EEG potentials recorded from electrodes placed on the scalp represent the collective summation of changes in the extracellular potentials of pyramidal cells (2–4).

The pyramidal cell membrane is never completely at rest because it is continually influenced by activity arising in other neurons with which it has synaptic connections (8).

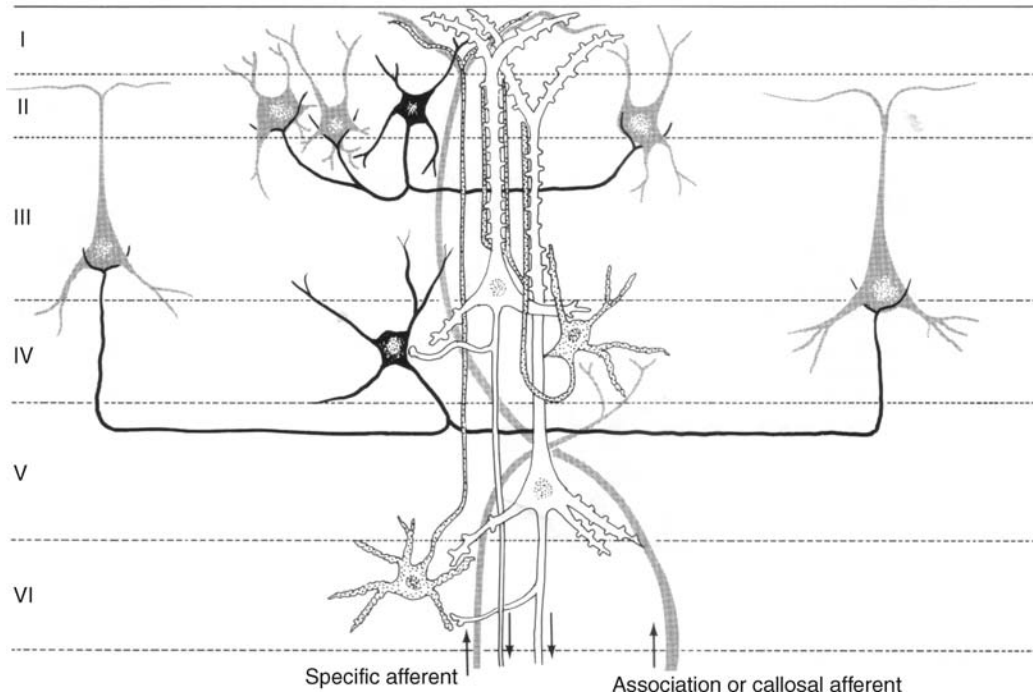

Figure 2. Schematic of the different layers of the cerebral cortex. Pyramidal cells that are mainly in layers III and V are mainly responsible for the generation of the EEG. (Adapted from Ref. 5.)

Such synaptic connections may be excitatory or inhibitory and the respective transmitter changes the permeability of the membrane for K^+ (and/or Cl^-), which results in a flow of current (for details, please see Ref. 8).

The flow of current in response to an excitatory post-synaptic potential at the site on the apical dendrite of a cortical pyramidal neuron is shown in Fig. 3. The excitatory postsynaptic potential (EPSP) is associated with an inward current at the postsynaptic membrane carried by positive ions and an outward current along the large expanse of the extra-synaptic membrane. For simplicity, only one path of outward current is illustrated through the soma membrane. This current flow in the extracellular space causes the generation of a small potential due to extracellular resistance (shown by R in Fig. 3).

As an approximation it is possible to estimate the extracellular field potential as a function of the transmembrane potential (9)

$$\phi_e = \frac{a^2 \sigma_i}{4 \sigma_e} \int \frac{\partial^2 v_m / \partial x^2}{r} dx \quad (1)$$

where ϕ_e is the extracellular potential, a is the radius of axon or dendrites, v_m is the transmembrane potential, σ_i is the intracellular conductance, and σ_e is the extracellular conductance. For a derivation of the above mentioned equation, please see Ref. 9.

Although these extracellular potentials individually are small, their sum becomes significant when added over many of cells. This is because the pyramidal neurons are more or less simultaneously activated by this way of synaptic connections and the longitudinal components of their extracellular currents will add, whereas their transversal components will tend to cancel out.

Figure 3. The current flow within a large pyramidal cell. Ionic flow is established to enable charge balance. (Adapted from Ref. 2.)

Generation of EEG Potentials

The bulk of the gross potentials recorded from the surface of the scalp results from the extracellular current flow associated with summated postsynaptic potentials in synchronously activated vertically oriented cortical pyramidal neurons. The exact configuration of the gross potential is related in a complex fashion to the site and the polarity of the postsynaptic potentials. Considering two cortical pyramidal neurons (shown in Fig. 3), the potential measured by a microelectrode at the location P is given by (4)

$$\begin{aligned} \Phi_p(t) = & \frac{1}{4\pi\sigma} \left[\frac{I_a}{R_1} \cos(2\pi f_a t + \alpha_a) - \frac{I_a}{R_2} \cos(2\pi f_a t + \alpha_a) \right. \\ & \left. + \frac{I_b}{R_3} \cos(2\pi f_b t + \alpha_b) - \frac{I_b}{R_4} \cos(2\pi f_b t + \alpha_b) \right] \\ & + \text{Similar contributions from other dipoles} \end{aligned} \quad (2)$$

where I_a and I_b are the peak magnitudes of current for each dipole with phases α_a and α_b , respectively, and is the conductivity of the medium. "Similar contribution from other dipoles" refers to the contribution of dipoles other than the two shown, most significantly from the dipoles physically close to the electrode. Dipoles that are farther from the recording electrode but in synchrony ($\alpha_a = \alpha_b = \dots = \alpha$), and aligned in parallel, contribute an average potential proportional to the number of synchronous dipoles $|\overline{\Phi}_p| \approx m$. Dipoles that are either randomly oriented or with a random phase distribution contribute an average potential proportional to the square root of their number $\overline{\Phi}_p| \approx \sqrt{m}$. Thus, the potential measured by a microelectrode can be expressed by the following approximate relation (4):

$$|\overline{\Phi}_p| \sim \frac{1}{8\pi\sigma} \left[\sum_{i=1}^l \frac{I_i}{R_i} + m \frac{I_s d}{R_s^2} + \sqrt{n} \frac{I_a d}{R_a^2} \right] \quad (3)$$

Here the subscripts i , s , and a refer to local, remote synchronous, and remote asynchronous dipoles. I_s and I_a are the effective currents for remote synchronous and remote asynchronous sources, which may be less than the total current, depending on the orientation of the sources with respect to the electrode. Also l , m , and n are the numbers of local, remote synchronous, and remote asynchronous sources, which are located at average distances R_i , R_s , and R_a respectively. Note that a microelectrode like the scalp electrode used for EEG recordings measures a field averaged over a volume large enough to contain perhaps 10^7 – 10^9 neurons.

Contribution of Other Sources

A decrease in the membrane potential to a critical level of approximately 10 mV less than its resting state (depolarization) initiates a process that is manifested by the action potential (10). Although it might seem that action potentials traveling in the cortical neurons are a source of EEG, they contribute little to surface cortical records, because they usually occur asynchronously in time in large numbers of axons, which run in many directions relative to the surface. Other reasons are that the piece of membrane that is depolarized by an action potential at any instant of time

is small in comparison with the portion of membrane activated by an EPSP and that action potentials are of short durations (1–2 ms) in comparison with the duration of EPSPs or IPSPs (10–250 ms). Thus, their net influence on potential at the surface is negligible. An exception occurs in the case of a response evoked by the simultaneous stimulation of a cortical input (11), which is generally called a compound action potential.

Other cells in the cortex like the glial cells are unlikely to contribute substantially to surface records because of their irregular geometric organization, such that produced fields of current flow sum to a small value when viewed from a relatively great distance on the surface. There is also activity in deep subcortical areas, but the resulting potentials are too much attenuated at the surface to be recordable.

The discussed principles show that the surface-recorded EEG can be observed as the result of many active elements, where the postsynaptic potentials from cortical pyramidal cells are the dominant source.

Volume Conduction of EEG

Recording from the scalp has the disadvantage that there are various layers with different conductivities between the electrode and the area of cortical potential under the electrode. Therefore, potentials recorded at the scalp are not only influenced by the above mentioned patterns, but also by regions with different conductivities. Layers lying around the brain are such regions. These include the cerebrospinal fluid (CSF), the skull, and the scalp. These layers account, at least in part, for the attenuation of EEG signals measured at the surface of the scalp, as compared with those recorded with a microelectrode at the underlying cortical surface or with a grid of electrodes directly attached to the cortex (ECOG). These shells surrounding the brain account for an attenuation factor of 10 to 20 (12). This attenuation mainly affects the high-frequency–low-voltage component (the frequency range above 40 Hz), which has been shown to carry important information about the functional state of the brain, but it is almost totally suppressed at the surface.

EEG SIGNAL

The EEG signal consists of spontaneous potential fluctuations that also appear without a sensory input. It seems to be a stochastic signal, but it is also composed of quasi-sinusoidal rhythms. The synchrony of cerebral rhythms may occur from pacemaker centers in deeper cortical layers like the thalamus or in subcortical regions, acting through diffuse synaptic linkages, reverberatory circuits incorporating axonal pathways with extensive ramifications, or electrical coupling of neuronal elements (13). The range of amplitudes is normally from 10 to 150 μ V, when recorded from electrodes attached to the scalp. The EEG signal consists of a clinical relevant frequency range of 0.5–50 Hz (10).

EEG Categories

Categorizing EEG signals into waves of a certain frequency range has been used since the discovery of the electrical

Figure 4. (a) Examples of EEG from different frequency bands. (b) The phenomenon of alpha desynchronization. (From Ref. 14).

activity of the brain. Therefore, these different frequency bands have been the most common feature in EEG analysis. Although this feature contains a lot of useful information as presented below, its use is not with criticism. It can be observed that there is some physiological and statistical evidence for the independence of these bands, but the exact boundaries vary between people and change with the behavioral state of each person (age, mental state, etc.). In particular, between human EEG and EEG signals recorded from different species of animals one can find different EEG patterns and frequency ranges. Nevertheless, the different frequency bands for human EEG are described below, because of their importance as an EEG feature. Most of the patterns observed in human EEG could be classified into one of the following bands or ranges:

Delta	below 3.5 Hz (usually 0.1–3.5 Hz)
Theta	4–7.5 Hz
Alpha	8–13 Hz
Beta	usually 14–22 Hz

A typical plot of these frequency bands is shown in Fig. 4, and the different bands are described below.

Delta Waves. The appearance of delta waves is normal in neonatal and infants' EEGs and during sleep stages in adult EEGs. When slow activity such as the delta band appears by itself, it indicates cerebral injury in the waking adult EEG. Dominance of delta waves in animals that have had sub-cortical transections producing a functional separation of

cerebral cortex from deeper brain regions suggests that these waves originate solely within the cortex, independent of any activity in the deeper brain regions.

Theta Waves. This frequency band was included in the delta range until Walter and Dovey (15) felt that an intermediate band should be established. The term "theta" was chosen to allude to its presumed thalamic origin.

Theta frequencies play a dominant role in infancy and childhood. The normal EEG of a waking adult contains only a small amount of theta frequencies, mostly observed in states of drowsiness and sleep. Larger contingents of theta activity in the waking adult are abnormal and are caused by various forms of pathology.

Alpha Waves. These rhythmic waves are clearly a manifestation of the posterior half of the head and are usually found over occipital and parietal regions. These waves are best observed under conditions of awakeness but during physical relaxation and relative mental inactivity. The posterior alpha rhythm can be temporarily blocked by mental activities, or afferent stimuli such as influx of light while eye opening (Fig. 4b). This alpha blocking response was discovered by Berger in 1929 (1). Mainly thalamocortical feedback loops are believed to play a significant role in the generation of the alpha rhythm (16).

Beta Waves. Beta activity is found in almost every healthy adult and is encountered chiefly over the frontal and central regions of the cortex. The voltage is much lower than in alpha activity (seldom exceeds 30 μV). Beta

Figure 5. (a) and (b) The side and top view of the layout of a standardized 10–20 electrode system. Adapted from Ref. 14.

activity shows considerable increase in quantity and voltage after the administration of barbiturates, some non-barbituric sedatives, and minor tranquilizers. It also appears during intense mental activity and tension.

Clinical EEG

To obtain EEG recordings, there are several standardized systems for electrode placement on the skull. The most common are those of the standard 10–20 system of the International EEG Federation, which uses 30 electrodes placed on four landmarks of the skull as observed in Fig. 5.

It is now possible to obtain unipolar (or monopolar) and bipolar derivations from these electrodes. Using a bipolar derivation, one channel is connected between a pair of electrodes and the resultant difference in the potential between these two electrodes is recorded. Therefore, bipolar derivations give an indication of the potential gradient between two cerebral areas. Unipolar (monopolar) derivations can either be obtained by recording the potential-difference between the “active” electrodes and one “indifferent” electrode, placed elsewhere on the head (ear, nose), or with respect to an average reference, by connecting all other leads through equal-valued resistances (e.g., 1 M Ω) to a common point (17). The advantages of unipolar derivations are that the amplitude of each deflection is proportional to the magnitude of the potential change that causes it and the demonstration of small time differences between the occurrence of a widespread discharge at several electrodes. Small, nonpolarizable, disk Ag-AgCl electrodes are used together with an electrode paste. Recorded potentials are amplified using a high gain, differential, capacitively coupled amplifier. The output signals are displayed on a chart recorder or a monitor screen. For more details about unipolar or bipolar derivations and EEG-amplifiers, please see (Ref. 11).

SCIENTIFIC BASIS FOR EEG MONITORING

The scientific basis for using EEG as a tool for studying brain function and dysfunction rests on the following four neurobiologic qualities of EEG.

Link With Cerebral Metabolism

The above presented discussion on the origin of potential-differences, recorded from the brain, shows that the EEG can be observed as a result of the synaptic and cellular activity of cortical pyramidal neurons. These neuronal and synaptic activities are directly linked to cerebral metabolism. Cerebral metabolic activity in turn depends on multiple factors including enzyme synthesis, substrate phosphorylation, axonal transport, and adenosine triphosphate (ATP) production from mitochondrial and glycolytic pathways (18). Thus, the EEG is a composite phenomenon reflecting complicated intracellular, intraneuronal, and neuro-glial influences. Although this multifaceted system makes it obvious that a selection of any single mechanism underlying the electrocortical manifestations may not be possible, the EEG is still a highly sensitive indicator of cerebral function (19).

Sensitivity to Most Common Causes of Cerebral Injury

The most common causes of cerebral injury are hypoxia and ischemia. It can be observed that hypoxia-ischemia causes a severe neuronal dropout in the cortical layers 3 and 5, leading to well-known histopathologic patterns of laminar necrosis. As pyramidal neurons that occupy the cortical layers are the main source for EEG, this loss of neuronal activity changes the cortical potentials and therefore makes EEG very sensitive to these common insults.

Correlation With Cerebral Topography

The standardized systems for electrode placement (Jung, international 10–20 system, etc.) establish a consistent relationship between electrode placement and underlying cerebral topography (20). Therefore, changes in EEG recorded from these electrodes of different areas of the skull reflect a consistent topographical relationship with underlying cerebral structures and allows useful inferences about disease localization from abnormalities in EEG detected at the scalp.

Ability to Detect Dysfunctions at a Reversible Stage

Heuser and Guggenberger (21) showed in 1985 that EEG deteriorates before the disruption of neuronal membrane and before significant reduction of cellular ATP levels. Siesjo and Wieloch (22) demonstrated in 1985 that during cerebral ischemia, changes in EEG correlate with elevated tissue lactate levels while ATP levels remain normal. Astrup (23) showed that a reduction in cerebral blood flow (CBF) affects EEG much before it causes neuronal death. These and several other reports make it clear that EEG offers the ability to detect injury at a reversible stage.

EEG also allows a prediction of recovery after brain dysfunctions like cerebral ischemia after cardiac arrest (24). Various studies in this report show that EEG recordings at several stages during recovery allow the prediction of whether the patient has a favorable outcome. Goel (25) showed that parameters obtained from EEG recordings may serve as an indicator for the outcome after hypoxic-asphyxic encephalopathy (HAE). These attributes make the EEG a very attractive neurologic observational tool.

LOGISTICAL AND TECHNICAL CONSIDERATIONS

Although the last sections have shown that EEG signal detection may serve as an important indicator for detection of neurological status and disorders, its clinical use and acceptance under a neurological care regime is limited. This is due to the complicated nature of the EEG signal and because of the difficulties regarding the interpretation of the signals. Some challenges of EEG analysis are as follows.

Artifacts

Recordings of physiological signals, especially from the surface of the body, have the problem that they are superimposed or distorted by artifacts. EEG signals are especially prone to artifact distortions due to their weak character. Therefore, a knowledge about the possible sources of distortion is necessary to estimate the signal-to-noise ratio (SNR). These artifacts are mostly generated from various kinds of sources. The sources of artifacts can be divided into two major groups: the subject-generated artifacts and the artifacts generated by the equipment. Subject-generated artifacts include EMG artifacts like body movement, muscle contraction of the neck, chewing, swallowing, coughing, involuntary movements (like myoclonic jerks, palatal myoclonus, nystagmus, asymmetric oculomotor paralysis, and decerebrate or decorticate posturing), and eye movements. Scalp edema can produce artifactual reductions in amplitude regionally or over an entire hemisphere. Pulse and EKG could also contribute as artifacts in EEG.

Artifacts generated by the equipment include ventilator artifacts that typically appear as slow wave like activity, vibrations of electrical circuitry around the subject, and power line interference. By taking the appropriate methods, a lot of these artifacts can be prevented [for more details, see Mayer-Waarden (10)].

Another method, to eliminate both artifacts generated by the equipment and the subject, is to use a differential amplifier for the recording between two electrodes. The

assumption here is that the transmission time of artifacts between two electrodes can be neglected, and therefore, the artifacts at both electrodes are in-phase. The signal to be recorded is assumed to have a time delay from one to another electrode, and taking the difference therefore eliminates the artifact but keeps the signals' nature.

Inter-User Variability

Interpreting physiological signals is difficult, even for specialists, because of their subject-specific nature. The complicated nature of EEG signals makes it even more difficult, and data generated by different EEG analysis methods (especially techniques like feature analysis, power spectral analysis, etc.) may be interpreted in different ways by different analysts. An analysis of inter-user-variability of clinical EEG interpretation was presented by Williams et al. (26), which showed that even EEG data interpretation by EEG analysts could be different. Therefore, more standardized and objective methods of EEG analysis are extremely desirable.

Inter-Individual Variability

As mentioned, the consistency of the human EEG is influenced by many parameters and makes EEG unique for a certain person and for a specific point-in-time. Intrinsic parameters are the age and the mental state of the subject (degree of wakefulness, level of vigilance), the region of the brain, hereditary factors, and influences on the brain (injuries, functional disturbances, diseases, stimuli, chemical influences, drugs, etc.). To detect deviations from "normal" EEG, it would be necessary to compare this "abnormal" EEG with the "normal" EEG as a reference. Therefore, attempts have been made to obtain normative EEG for each of the classes discussed above (i.e., normative EEG for various age groups, normative EEG under the influence of varying amounts of different drugs, etc.), but these databases of normative data are still not sufficient to cover the variety of situations possible in real-life recordings. On the other hand, these normative data vary too much for considering them as one person's "normal" EEG.

Labor-Intensive and Storage Problems

For patient monitoring in the operating room or for chronic monitoring tasks that are necessary for cases of gradual insults and injuries, the EEG recordings can be extremely labor intensive. This makes it necessary to have either efficient means of collecting, storing, and displaying the long-term recordings or to come up with new techniques of compressing the EEG data, while preserving its characteristic features. Better methods to overcome these problems have been developed in both directions, although primarily toward efficient storage and display techniques. Methods of compressed spectral array representation overcome the limitation of compressed display to a great extent.

DISCUSSION

The review presented above emphasizes that the EEG is sensitive to different states of the brain and therefore may

serve as a useful tool for neurological monitoring of brain function and dysfunction. In various clinical cases, the EEG has been used to observe patients and to make critical decisions. Nevertheless, its complicated nature and difficulty of interpretation has limited its clinical use. The following section should give an overview of the common techniques in analyzing EEG signals.

TECHNIQUES OF EEG ANALYSIS

Introduction

The cases presented above show that EEG has significant clinical relevance in detecting several diseases as well as in different stages of recovery. Still the complex nature of EEG has so far restricted its use in many clinical situations. The following discussion should give an overview of the state-of-the-art EEG monitoring and analysis techniques. The presented EEG analysis methods are divided into two basic categories, parametric and nonparametric, respectively, assuming that such a division is conceptually more correct than the more common differentiation between frequency and time-domain methods because they represent two different ways of describing the same phenomena.

NonParametric Methods

In most of these analysis methods, the statistical properties of EEG signals are considered realizations of a Gaussian random process. Thus, the statistics of an EEG signal can be described by the first- and second-order moments.

These nonparametric time-domain and frequency-domain methods have been the most common way in analyzing EEG signals. In the following description of the different methods, it is also mentioned whether the technique is still being used in clinical settings.

Clinical Inspection. The most prevalent method of clinically analyzing the EEG is the visual inspection of chart records obtained from EEG machines. It uses the features observed in real-time EEG (like low frequency-high amplitude activity, burst suppression activity, etc.) for diagnostic and prognostic purposes. Several typical deviations from the normal EEG are related to different stages of the brain. This method suffers from the limitations like inter-user variability, labor intensiveness, and storage problems. A detailed description of logistical and technical considerations faced with EEG analysis is given later in this section.

Amplitude Distribution. Amplitude distribution is based on the fact that a random signal can be characterized by the distribution of its amplitude and accompanying mean, variance, and higher order moments. It can be observed that the amplitude distribution of an EEG signal most of the time can be considered as Gaussian (27) and the deviations from Gaussianity and its time-varying properties have been clinically used to detect and analyze different sleep stages (28,29). This method is now less popular because of more powerful and sophisticated EEG analysis techniques.

Interval Distribution. This is one of the earliest methods of quantitating the EEG (30). The method is based on measuring the distribution of intervals between either zero or other level crossings, or between maxima and minima. Often, the level crossings of the EEG's first and second derivatives are also computed to obtain more information about the spectral properties of the signal. Due to its ease of computation, the method has been shown to be useful in monitoring long-term EEG changes during anesthesia or sleep stages. Although simple, some theoretical problems are associated with this technique: It is extremely sensitive to high-frequency noise in the estimation of zero crossings and to minor changes in EEG. Also the zero crossing frequency (ZXF), the number of times the EEG signal crosses the zero voltage line, is not unique to a given waveform. Very different waveforms could give rise to the same ZXF. Despite the limitations, modified versions of period analysis are still used for clinical applications (30).

Interval-Amplitude Analysis. Interval-amplitude analysis is the method by which the EEG decomposed in waves or half-waves, both defined in time, by the interval between zero crossings, and in amplitude by the peak-to-through amplitudes. The amplitude and the interval duration of a half-wave are defined by the peak through differences in amplitude and time; the amplitude and the interval duration of a wave are defined by the mean amplitude and the sum of the interval durations of two consecutive half-waves (31,32). This method has been used clinically for sleep monitoring and depth of anesthesia studies (33).

Correlation Analysis. The computation of correlation functions constituted the forerunner of contemporary spectral analysis of EEG signals (34,35). The correlation function for random data describes the general dependence of the values of the data at one time on the values of the same data in the case of autocorrelation analysis (or of different data in the case of cross-correlation analysis) at another time. The cross-correlation between two signals x and y is defined as

$$\Phi_{xy}(\tau) := E\{x(t)y(t+\tau)\} \quad (4)$$

where τ is the lag time (note that $\Phi_{xy}(\tau)$ becomes the autocorrelation function for $x=y$ and it can be estimated for discrete data by

$$\hat{\Phi}_{xy}(m) = \frac{1}{N-|m|} \sum_{n=0}^{N-|m|-1} x(n)y(n+m), \quad m \in \{0, 1, 2, \dots, M < N\} \quad (5)$$

and m is the lag number, M is the maximum lag number and $\hat{\Phi}_{xy}(m)$ is the estimate of the correlation function at lag number m . This estimation is unbiased but not consistent (36). The following modifications of this method have been used clinically:

1. Polarity coincidence correlation function: In this method, the signals are replaced by their signum equivalents, where $\text{sign}[x(t)] = +1$ for $x(t) > 0$ and $\text{sign}[x(t)] = -1$ for $x(t) < 0$. This modification achieves

computational simplification and has been shown (37) to be useful for EEG analysis.

2. Auto- or cross-averaging: This method consists of making pulses at a certain phase of the EEG (e.g., zero-crossing, peak, or trough) that are then used to trigger a device that averages the same signal (auto-averaging) or another signal (cross-averaging). In this way, rhythmic EEG phenomena can be detected (38,39).
3. Complex demodulation: This method is related to correlation functions and allows one to detect a particular frequency component and to follow it over time. This is done by multiplying EEG signals with a sine wave of a desired frequency to give a product at 0 Hz. The 0 Hz component is then retained using a low-pass filter, obtaining the frequency component of interest. This method has been used to analyze visual potentials (40) and sleep spindles (41). However, correlation analysis has lost much of its attractiveness for EEG analysis since the advent of the Fourier transformation (FT) computation of power spectra.

Power Spectra Analysis. The principal application for a power spectral density function measurement of physical data is to establish the frequency composition of the data, which in turn bears an important relationship to the basic characteristics of the physical or biological system involved. The power spectrum provides a statement of the average distribution of power of a signal with respect to frequency. The FT serves as a bridge between the time domain and the frequency domain by identifying the frequency components that make up a continuous waveform. An equivalent of the FT for discrete time signals is the discrete Fourier transform (DFT), which is given by

$$X(\omega) = \sum_{n=-\infty}^{+\infty} x(n)\exp(-j\omega n) \quad (6)$$

An approximation of this DFT can be easily computed using an algorithm, developed in 1965 by Cooley and Tukey (42) and known as the fast Fourier transform (FFT).

An estimation of the power spectrum can now be obtained by Fourier-transforming (using FFT/DFT) either the estimation of the autocorrelation function, as developed in the previous section (Correlogram), or the signal and calculating the square of the magnitude of the result (Periodogram). Many modifications of these methods have been developed to obtain unbiased and consistent estimates (for details, please see Ref. 43). One estimator for the power spectrum, developed by Welch (44), will be used in the last section of this work.

Based on the frequency contents, human EEG has been classified into different frequency bands, as described. Correlations of normal function as well as dysfunctions of the brain have been made with the properties (frequency content, powers) of these bands. Time-varying power spectra have also been used to analyze time variations in EEG frequency properties (45). One of the main advantages of this kind of analysis is that it retains almost all the information content of EEG, while separating out the low-frequency artifacts into a small band of frequencies.

On the other hand, it suffers from some of the limitations of feature analysis, namely, inter-user variability, labor intensiveness, and storage problems. There have been attempts to reduce the labor intensiveness by creating displays like linear display of spectral analysis and grayscale display of spectral analysis (30), which compromises the amount of information presented.

Cross-Spectral Analysis. This kind of analysis allows quantification of the relationship between different EEG signals. The cross-power spectrum $\{P_{xy}(f)\}$ is the product of the smoothed DFT of one signal and the complex conjugate of the other [see for details, Jenkins and Watts (46)]. As $P_{xy}(f)$ is a complex quantity, it has a magnitude and phase and can be written as

$$P_{xy}(f) = |P_{xy}(f)|\exp[j\phi_{xy}(f)] \quad (7)$$

where $j = \sqrt{-1}$, and $\phi_{xy}(f)$ is the phase spectrum. With the cross-power spectrum, a normalized quantity, the coherence function, can be defined as follows:

$$\text{coh}_{xy}(f) = \frac{|P_{xy}(f)|^2}{P_{xx}(f)P_{yy}(f)} \quad (8)$$

where $P_{xx}(f)$ and $P_{yy}(f)$ are the autospectral densities of $x(t)$ and $y(t)$. The spectral coherence can be observed as a measurement of the degree of the "phase synchrony" or "shared activity" between spatially separated generators. Therefore, unity in this quantity indicates a complete linear relationship between two electrode sites, whereas a low value for the coherence function may indicate that the two EEG locations are connected via a nonlinear pathway and that they are statistically mostly independent.

Coherence functions have been used in several investigations of the EEG signal generation and their relation to brain functions, including studies of hippocampal theta rhythms (47), on limbic structures in humans (48), on thalamic and cortical alpha rhythms (49), on sleep stages in humans (29), and in EEG development in babies (50).

A more generalized form of coherence is the so called "spectral regression-amount of information analysis" [introduced and first applied to EEG analysis by Gersch and Goddard (51)] which expresses the linear relationship that remains between two time series after the influence of a third time series has been removed by a partial regression analysis. If the initial coherence decreases significantly, one can conclude that the coherence between the two initially chosen signals is due to the effect of the third one. The partial coherence between the signals x and z , when the influence of y is eliminated, can be derived from

$$P_{zz,y}(f) = P_{zz}(f)(1 - \text{coh}_{zy}(f)) \quad (8)$$

and

$$P_{xx,y}(f) = P_{xx}(f)(1 - \text{coh}_{xy}(f)) \quad (9)$$

$P_{xz,y}(f)$ is the conditioned cross-spectral density and can be calculated as

$$P_{xz,y}(f) = P_{xz}(f)\left(1 - \frac{P_{xy}(f)P_{yz}(f)}{P_{yy}(f)P_{xz}(f)}\right) \quad (10)$$

This method has been mainly used to identify the source of EEG seizure activity (51,52).

Bispectrum Analysis. The power spectrum essentially contains the same information as autocorrelation and hence provides a complete statistical description of a process only if it is Gaussian. In cases where the process is non-Gaussian or is generated by nonlinear mechanisms, higher order spectra defined in terms of higher order moments or cumulants provide additional information that cannot be obtained from the power spectrum (e.g., phase relations between frequency components). There are situations, due to quadratic nonlinearity, in which phase coupling between two frequency components of a process results in a contribution to the power at a frequency equal to their sum. Such coupling affects the third moment sequence, and hence, the bispectrum is used in detecting such nonlinear effects. Although used in experimental settings (53,54), bispectral analysis techniques have not yet been used in clinical settings, probably due to both the complexity of the analysis and the difficulty in interpreting results.

The bispectrum of a third-order stationary process can be estimated by smoothing the triple product

$$B(f_1, f_2) = E\{F_{xx}(f_1)F_{xx}(f_2)^*F_{xx}(f_1 + f_2)\} \quad (11)$$

where $F_{xx}(f)$ represents the complex FT of the signal and $F_{xx}(f)^*$ is the complex conjugate of $F_{xx}(f)$ [for details, please see Huber et al. (55) and Dumermuth et al. (56)].

Hjorth Slope Descriptors. Hjorth (57) developed the following parameters, also called descriptors, to quantify the statistical properties of a time series:

$$\begin{aligned} \text{activity, } A &= a_0 \\ \text{mobility, } M &= \left[\left(\frac{a_2}{a_0} \right) \right]^{\frac{1}{2}} \\ \text{complexity, } C &= \left[\left(\frac{a_4}{a_2} \right) - \left(\frac{a_2}{a_0} \right) \right]^{\frac{1}{2}} \end{aligned}$$

where

$$a_n = \int_{-\infty}^{+\infty} (2\pi f)^n S_{xx}(df)$$

Note here that a_0 is the variance of the signal ($a_0 = \sigma^2$), a_2 is the variance of the first derivative of the signal, and a_4 is the variance of the signal's second derivative. Hjorth also developed a special hardware for real-time computation of these three spectral moments, which allows the spectral moments to vary as a function of time. Therefore, this form of analysis can be applied to nonstationary signals, and it has been used in sleep monitoring (58) and in quantifying multichannel EEG recordings (59). It should be noted that Hjorth's descriptors give a valid description of an EEG signal only if the signals have a symmetric probability density function with only one maximum. As this assumption cannot be made in general practice, the use of the descriptors is limited.

Parametric Methods

The motivation for parametric models of random processes is the ability to achieve better power spectrum density (PSD) estimators based on the model, than produced by classical spectral estimators. In the last section, the PSD was defined as the FT of an infinite autocorrelation sequence (ACS). This relationship may be considered as a nonparametric description of the second-order statistics of a random process. A parametric description of the second-order statistic may also be devised by assuming a time-series model of the random process. The PSD of the time-series model will then be a function of the model parameters (and not of the ACS). A special class of models, driven by white noise processes and processing rational system functions, is the autoregressive (AR), the moving average (MA), and the autoregressive moving average (ARMA) model.

One advantage of using parametric estimators is, for example, better spectral resolution. Periodogram and correlogram methods construct an estimate from a windowed set of data or ACS estimates. The unavailable data or unestimated ACS values outside the window are implicitly zero, which is an unrealistic assumption, that leads to distortions in the spectral estimate. Some knowledge about the process from which the data samples are taken is often available. This information may be used to construct a model that approximates the process that generated the observed time sequence. Such models will make more realistic assumptions about the data outside the window instead of the null data assumption. Thus, the need for window function can be eliminated. Therefore, a parametric PSD estimation method is useful in real-time estimation because a short data sequence is sufficient to determine the model. The following parametric approaches have been used to analyze EEG signals.

ARMA Model. The ARMA model is the generalized form of the AR and MA model, which represents the time series $x(n)$ in the following form:

$$\begin{aligned} x(n) + a(1)x(n-1) + a(2)x(n-2) \dots + a(p)x(n-p) \\ = w(n) + b(1)w(n-1) + b(2)w(n-2) \dots \\ + b(q)w(n-q) \end{aligned} \quad (12)$$

where $a(n)$ are the AR parameters, $b(n)$ are the MA parameters, $w(n)$ is the error in prediction, and p, q are the model orders for the AR and MA model, respectively.

The power spectrum $P_{xx}(z)$ of this time series $x(n)$ can be obtained by using the ARMA parameters in the following fashion:

$$P_{xx}(z) = \left| \frac{\sum_{i=0}^q 1 + b(1)z^{-1} + b(2)z^{-2} + \dots + b(q)z^{-q}}{\sum_{i=0}^p 1 + a(1)z^{-1} + a(2)z^{-2} + \dots + a(p)z^{-p}} \right|^2 W(z) \quad (13)$$

where $W(z)$ is the z -transform of $w(n)$. Note here that if we set all $b(q)$ equal to zero, we obtain an AR model, represented by poles close to the unit circle only and therefore an all-pole-system, and if we set all $a(p)$ equal to zero, we obtain an MA model. The ARMA spectrum can model both sharp peaks as they are obtained from an AR spectrum and

deep nulls as they are typical for an MA spectrum (60). Although ARMA is a more generalized form of the AR model, in most EEG applications, it is sufficient to compute the AR model because EEG signals have been found to be represented effectively by such a model (45). The AR model will be described in more detail in the following section.

Inverse AR Filtering. Assuming that an EEG signal results from a stationary process, it is possible to approximate it as a filtered noise with a normal distribution. Consequently, passing such an EEG signal through the inverse of its estimated autoregressive filter could be performed to obtain the generator noise (also called the residues) of the signals, which is normally distributed with mean zero and variance σ^2 . The deviation from a noise with a normal distribution can be used as an important tool to detect nonstationarity and nonlinearities in the original signal. This method has been used to detect transient nonstationarities present in epileptiform EEG (45).

Kalman Filtering. A method of analyzing time-varying signals consists of applying the so-called Kalman estimation method of tracking the parameters describing the signal (61,62). The Kalman filter recursively obtains estimates of the parametric model coefficients (such as those of an AR model) using earlier as well as current data. These data are weighted by the Kalman filter, depending on the signal-to-noise ratio (SNR) of the respective data. For the estimation of the parametric model, coefficients data with a high SNR are weighted higher than data with a lower SNR (37).

This method is not easy to implement due to its sensitivity to model order and initial conditions; it also tends to be computationally extensive. Despite these limitations, recursive Kalman filtering has been used in EEG analysis for deriving a measure of how stationary the signal is and for EEG segmentation signal (61,62). This segmentation of the EEG signal into quasi-stationary segments of variable length is necessary and useful in reducing data for the analysis of long EEG recordings under variable behavioral conditions. Adaptive segmentation based on Kalman filtering has been used to analyze a series of clinical EEGs to show a variety of normal and abnormal patterns (63).

BURST AND ANALYZING METHODS

Introduction

This article has shown that EEG signals are sensitive to various kinds of diseases and reflect different stages of the brain. Specific EEG patterns can be observed after ischemic brain damage and during deep levels of anesthesia with volatile anesthetics like enflurane, isoflurane, or halothane anesthesia (64). The patterns are recognized as periods of electrical silence disrupted by bursts of high-voltage activity. This phenomenon has been known since Derbyshire et al. (65) showed that wave bursts separated by periods of electrical silence may appear under different anesthetics. The term "burst suppression" was introduced to describe the occurrence of alternating wave bursts and blackout sequences in narcotized animals (66), in the iso-

lated cerebral cortex (67), during coma with dissolution of cerebral functions (68), after trauma associated with cerebral anoxia (69), and in the presence of a cortical tumor (70). Other bursting-like patterns in the EEG are seizures as they occur during epilepsy. Although also episodes of high voltage, the background EEG is not suppressed in the presence of seizures.

The knowledge about occurrence of these bursts and periods of electrical silence in the EEG is of important clinical value. Although burst suppression during anesthesia with modern anesthetics is reversible and harmless, it often is an ominous sign after brain damage (71). Frequently occurring seizures may indicate a severe injury state. Thus, it is of great interest to detect these burst and burst suppression sequences during surgery or in other clinical settings. We have already presented several methods to analyze EEG signals, their advantages and disadvantages. In the case of short episodes of burst suppression or spikes, however, methods that maintain the time-varying character of the raw EEG signal are necessary.

In this section, we want to present the mechanisms of the underlying processes, which cause burst-suppression or spiking. Methods that show the loss of EEG signal power during the occurrence of burst suppression and methods that can follow the time-varying character of the raw input signal are presented. Finally, we will present some methods that have been used to detect bursts and seizures based on detection of changes in the power of the signal.

Mechanisms of Bursts and Seizures

Bursts can be observed as abrupt changes in the activity of the entire cortex. These abrupt changes led to the assumption that a nonlinear (ON-OFF or bang-bang control system) inhibiting mechanism exists in the central nervous system (CNS) that inhibits the burst activity in the EEG. Recent studies confirm this theory and have shown that during burst-suppression, the heart rate also is decreased (72,73). At the end of the suppression, this inhibition is released abruptly, permitting burst activity in EEG and increase in heart rate. The task of such a control system in the CNS may be to decrease the chaotic activity in a possibly injured or intoxicated brain. As cortical energy consumption is correlated with the EEG, decreased cortical activity also avoids excessive, purposeless energy consumption (74). Studies on humans under isoflurane anesthesia have shown that increased burst-suppression after increased anesthesia concentration does correlate with cerebral oxygen consumption (75).

Another interesting observation is the quasi-sinusoidal character of the EEG signal during bursting. This has been shown by Gurvitch et al. (76) for the case of hypoxic and posthypoxic EEG signals in dogs. In contrast to anesthesia evoked bursts, which also contain higher frequency components up to 30 Hz, these hypoxic and posthypoxic bursts are high-voltage slow-wave signals, with frequency components in the delta range (77). Figure 6 shows two typical cortical EEG recordings from an isoflurane-anesthetized dog and a piglet after hypoxic insult. The power spectrum of the first burst in each recording is shown, respectively. Bispectral analysis as described has shown that there is

Figure 6. Burst suppression under the influence of isoflurane and after hypoxic insult. (a) Cortical EEG from a dog anesthetized with isoflurane/DEX. (b) Cortical EEG from a piglet during recovery from a hypoxic insult. Note the similarities in electrically silent EEG interrupted by high voltage EEG activity.

significant phase coupling during bursting (78). Due to these observations, we assume the EEG signal to be quasiperiodic during bursting and seizure sequences. Note that this observation is an important characteristic and will be used in the next section as a basic assumption for the use of an energy estimation algorithm.

The first cellular data on EEG burst suppression patterns were presented by Steriade et al. in 1994 (79). This study examined the electrical activity in cells in the thalamus, the brain stem, and the cortex during burst suppression in anesthetized cats. They showed that although the activity of intracellularly recorded cortical neurons matches the cortical EEG recording, the recording from thalamic neurons displays signs of activity during the periods of electrical silence in the cortex and the brain stem. But it has also been observed that the cortical neurons are not unresponsive during periods of electrical silence. Thalamic volleys delivered during the epochs of electrical silence were able to elicit neuronal firing or subthresholding depolarizing potentials as well as the revival of EEG activity. This observation led to the assumption that full-blown burst suppression is achieved through complete disconnection within the prethalamic, thalamocortical, and corticothalamic brain circuits and indicates that, in some instances, a few repetitive stimuli or even a single volley may be enough to produce recovery from the blackout during burst suppression. Sites of disconnection throughout thalamocortical systems are mainly inhibited synaptic transmissions due to an increase in GABAergic inhibitory processes at both thalamic and cortical synapses. Note that we showed that postsynaptic extracellular potentials at cortical neurons are the origin of the EEG signal. Therefore, this failure of synaptic transmission explains the flatness in the EEG during burst suppression. The spontaneous recurrence of cyclic EEG wave bursts may be observed as triggered by remnant activities in different parts of the affected circuitry, mainly in the dorsothalamic-RE thalamic network in which a sig-

nificant proportion of neurons remains active during burst suppression. However, it is still unclear why this recovery is transient and whether there is a real periodicity in the reappearance of electrical activity. According to the state of the whole system, the wave bursts may fade and be replaced by electrical silence or may recover toward a normal pattern.

Seizures are sudden disturbances of cerebral function. The underlying causes of these disorders are heterogeneous and include head trauma, lesions, infections, and genetic predisposition. The most common injury that causes seizures is epilepsy. Epileptic seizures are short, discrete episodes of abnormal neuronal activity involving either a localized area or the entire cerebrum. The abnormal time series may demonstrate abrupt decreases in amplitude, simple and complex periodic discharges, and transient patterns such as spikes (80) and large amplitude bursts.

Generalized seizures can be experimentally induced by either skull shocks to the animal or through numerous chemical compounds like pentylenetetrazol (PTZ). Several studies have shown that there are specific pathways through which the seizure activity is mediated from deeper cortical areas to the superficial cortex (81). Figure 7 shows a cortical EEG recording from a PTZ-treated rat. Nonconvulsive seizures are not severe or dangerous. In contrast, convulsive seizures like the seizures caused by epilepsy might be life threatening, and a detection of these abnormalities in the EEG at an early stage of the insult is desirable.

Reasons for Burst and Seizure Detection

We have seen in the previous section that there are various possible sources that can cause EEG abnormalities, like seizures or burst suppression interrupted by spontaneous activity outbreaks. In this section, now we want to describe why it is of importance to detect these events. Reasons for detecting bursts or seizures are as follows.

Figure 7. PTZ-induced generalized clonic seizure activity in the cortex and the thalamus of a rat. The figures from the top to the bottom show seizure activity recorded from the trans-cortex, the hippocampus, the posterior thalamus, and the anterior thalamus. Note the occurrence of spikes in the cortical recording before the onset of the seizure. At time point 40, one can see the onset of the seizure in the cortical recording, whereas the hippocampus shows increased activity already at time point 30. Such recordings can be used to study the origin and the pathways of seizures.

Confirmation of the Occurrence. In the case of seizures, it is obvious that it is desirable to detect these seizures as an indicator of possible brain injuries like epilepsy. Epileptic or convulsive seizures might be life-threatening, and detection at an early stage of the injury is necessary for medication. The frequency with which seizures occur in a patient is the basis on which the diagnosis of epilepsy is made. No diagnosis for epilepsy will be made based only on the occurrence of occasional seizures. Burst suppression under anesthesia is an indicator for the depth of anesthesia (82), and the relationship between the duration of burst suppression parts and bursting episodes is therefore desirable. In the case of hypoxia, however, burst suppression indicates a severe stage of oxygen deficiency and a possible risk of permanent brain damage or brain death. In the recovery period, in post-hypoxic analysis, the occurrence of bursts might be of predictive value whether or not the patient has a good outcome (83–85).

To Further Analyze Seizure or Burst-Episodes. Not only the presence of bursts or seizures can serve as a physiological indicator, furthermore special features or characteristics of these EEG abnormalities are of importance. Intracranial EEG patterns at seizure onset have been found to correlate with specific pathology (86), and it has been suggested that the different morphologies of intracranial EEG seizure onset have different degrees of localizing value (87).

In the case of anesthesia or hypoxia-induced bursts, the duration of the bursts and the burst suppression parts may

indicate the depth of anesthesia or the level of injury, respectively. Frequency or power analysis of these bursts may help discriminating these two kinds of bursts from one another (77). This is important, for example, in open heart surgery to detect reduced blood flow to the brain at a reversible stage.

Localization. Localization of the source of an injury or an unknown phenomenon is always desirable. This is valid especially in the case of epilepsy, where the injured, seizure-causing part of the brain can be operatively removed. Detecting the onsets of bursts or seizures in different channels from different regions of the brain may help us to localize the source of these events. In particular, recordings from different regions of the thalamus and the cortex have been used to study pathways of epileptic seizures.

Ability to Present Signal-Power Changes During Bursting

We have already mentioned that bursts can be observed as a sequence in the EEG signal with increased electrical activity and within sequences of increased power or energy. Therefore, looking at the power in the EEG signal can give us an idea about the presence of bursts and burst suppression episodes in the signal. Looking at the power in different frequencies of a signal is classically done by estimating the PSD. We will present three methods here that have already been used in EEG signal analysis. First is a method to estimate the PSD by averaging over a certain number of periodograms, which is known as the Welch method. After obtaining the power spectrum over the entire frequency range, the total power in some certain frequency bands can then be obtained by summing together the powers in the discrete frequencies that fall in this frequency band. For this method, the desired frequency bands have to be known in advance. One method to obtain the knowledge where the dominant frequencies may be found in the power spectrum is to model the EEG signal with an AR model. Beside the fact that this method calculates the dominant frequencies, we also obtain the power in these dominant frequencies and can use this method directly to follow the power in the dominant frequencies. The third method will be a method to perform time-frequency analysis as a method to obtain the energy of a signal as a function of time as well as a function of frequency. We will present the short-time Fourier transform (STFT) as such a time-frequency distribution. As mentioned, these methods have been already used in EEG signal processing.

Feature Extraction. One major problem with these methods is the large amount of data that become available. Therefore, attempts have been made to extract spectral parameters out of the power spectrum that for themselves contain enough necessary information about the nature of the original EEG signal. The classic division of the frequency domain in four major subbands (called alpha, beta, theta, and delta waves) as described in the first section, has been one possibility of feature extraction and data reduction. However, we have also observed that these subbands may vary among the population and the major frequency components of a human EEG might be

different from the predominant frequency components of an EEG recorded from animals. Furthermore, some specific EEG changes typically involve an alteration or loss of power in specific frequency components of the EEG (88) or a shift in power over the frequency domain from one frequency range to another. This observation led to the assumption that the pre-division of the frequency domain into four fixed subbands may not give features that are sensitive to such kinds of signal changes. We therefore propose the use of “dominant frequencies” as parameters; these are frequencies at which one can find a peak in the power spectrum, and therefore, these dominant frequencies can be observed as the frequencies with an increased activity. Recent studies (25) have shown that following the power in these dominant frequencies over time has a predictive value after certain brain injuries, whether or not the patient has a good outcome. In fact, detecting changes in power in dominant frequencies may be used as a method to visualize changes in the activity in certain frequency ranges. Another method to reduce some of the information of the power spectrum to one single value is to calculate the mean frequency of the spectrum at an instant point of time. This value can be used as a general indicator for changes in the power spectrum from one instant time point to another. Other spectral parameters that will not be described here are, for example, peak frequency or various different defined edge frequencies like the medium frequency. However, the effectiveness of these EEG parameters in detecting changes in the EEG, especially in detecting injury and the level at which they become sensitive to injury, has not been well defined. After the description of each method, we will present how we can obtain the power in the desired frequency bands and the mean frequency.

Power Spectrum Estimation Using the Welch-Method.

We have already observed the use of the FT and its discrete performance in the DFT in the first section. In this section, we now want to show how we can use the DFT to obtain an estimator for the PSD.

To estimate the PSD there are two classic possibilities. The first and most direct method is the periodogram built by using the discrete-time data sequence and transforming it with DFT/FFT. We describe the algorithm in detail:

$$I(N) = \frac{1}{N} \left| \sum_{n=1}^{n=N} x(n) \exp(-j\omega n) \right| \quad (14)$$

where $x(n)$ is the discrete time signal and N is the number of FFT points. It can be observed that this basic estimator is not statistically stable, which means that the estimation has a bias and is not consistent because the variance does not tend to be zero for large values of N . The second method to achieve the PSD estimation is more indirect, in which the autocorrelation function of the signal is estimated and transformed via DFT/FFT. This estimation is called a correlogram:

$$I_N(\omega) = \sum_{m=-(N-1)}^{N-1} \hat{\Phi}_{xx} \exp(-j\omega m) \quad (15a)$$

where $\hat{\Phi}_{xx}(m)$ is the estimated autocorrelation function of a time signal $x(n)$:

$$\hat{\Phi}_{xx}(m) = \frac{1}{N} \sum_{n=0}^{N-|m|-1} x(n)x(n+|m|) \quad (15b)$$

To avoid these disadvantages of the periodogram as an estimator for PSD, many variations of this estimator were developed, reducing the bias and variance of the estimation. The most popular method among these estimators is the method of Welch (44). The given time sequence is divided into k overlapping segments of L points each, and the segments are windowed and transformed via DFT/FFT. The estimator of the PSD is then obtained by the mean of these spectra. It can be observed that as more spectral samples are used to build this estimator, the more the variance is reduced. Assuming a given sequence length of N points, the variance of the estimate will decrease if the number of points in each segment decreases. Note that a decrease in number of points results in a loss of good spectral resolution. Therefore, a compromise has to be found to achieve a small variance and a sufficient spectral resolution. To increase the number of segments, which are used to build the mean, an overlap of the segments of 50% is used.

Use of a finite segment length, $n=0, \dots, N-1$, of the signal $x(n)$ for computation of the DFT is equivalent to multiplying the signal $x(n)$ by a rectangular window $w(n)$. Therefore, due to the filtering effects of the window function, sidelobe energy is generated where the spectrum is actually zero. The window function also causes some smoothing of the spectrum when N is sufficiently large. To reduce the amount of sidelobe leakage caused by windowing, a nonrectangular window that has smaller sidelobes may be used. Examples of such windows include the Blackman, Hamming, and Hanning windows. However, use of these windows for reduction of sidelobe leakage also causes an increase in smoothing of the spectrum. Figure 8 shows the difference of sidelobe leakage effects between a rectangular and a Blackman window. In our case, a Tukey window is used in respect to a sufficient suppression of sidelobes and to obtain sharp mainlobes at the containing frequencies (90):

$$u(x) = \begin{cases} 0.5(1 - \cos(\pi x/d)) & 0 \leq x \leq d \\ 1 & d \leq x \leq 1-d \\ 0.5(1 - \cos(\pi(1-x)/d)) & 1-d \leq x \leq 1 \end{cases}$$

The resultant estimator of PSD is obtained by using the equation:

$$\hat{S}_{xx}(\exp(j\Omega)) = \frac{1}{kA} \sum_{i=1}^K \frac{1}{L} \left| \sum_{k=0}^{L-1} x_i(k) f_L(k) \exp(-j\Omega k) \right|^2 \quad (16)$$

where k is the number of segments, L is the number of points in each segment, $f_L(k)$ is the data window function, and

$$A = \frac{1}{L} \sum_{k=0}^{L-1} f_L^2(k) \quad (17)$$

Figure 8. Comparison of sidelobe leakage effects in the spectrum using (a) rectangular window versus (b) Blackman window. Spectra are computed for a signal with (voltage spectrum $X(f)=1$, $\text{abs}(f) < 1$; $X(f)=0$ otherwise). The Blackman window reduces sidelobe effects and increases smoothing of the spectrum. (Adapted from Ref. 89.)

which is a factor to obtain an asymptotically unbiased estimation. Even if the PSD estimator (using the Welch method) is a consistent estimator, we have to note that it is only an approximation of the real PSD. Beside the above-mentioned limitations, unwanted effects also result from using DFT/FFT. These include aliasing, leakage, and the picket fence effect. Most of these effects may be avoided by using a window of appropriate characteristic and by fulfilling the Nyquist criterion, which is that the highest signal frequency component has to be less than one half the sampling frequency.

The FT and autocorrelation method can compute the power spectrum for a given segment of the EEG signal. The spectrum over this segment must therefore be assumed to be stationary. Loss of information will occur if the spectrum is changing over this segment, because temporal localization of spectral variations within the segment is not possible. Because burst suppression violates the assumptions (91) underlying power spectrum analysis and may cause misleading interpretations (92,93), it is necessary to increase time resolution. To track changes in the EEG spectrum over time, spectral analysis can be performed on successive short segments (or epochs) of data. Note that we used the spectral analysis of such epochs for our method above. We therefore may expect that the spectral analyses for the short segments are less consistent and that the effects of signal windowing will play a more important role.

Parameter Extraction. For selected sequences of EEG at each stage during a recording, spectral analysis might be

performed using the Welch method. To obtain the power in the dominant frequencies, the powers in the average power spectrum are summed together over the frequency range of interest. This summation is made because the dominant frequency may vary in a small frequency range:

$$P(f_d) = \sum_{k=n}^{n+1} S(k) n + \ell < N/2 \quad (18)$$

where $S(k)$ is the average power spectrum, N is the FFT length, f_d is the dominant frequency, and $\ell N/2f_s$ is the bandwidth of the frequency band. Following the power in these specific frequency bands over time, we obtain a trend-plot of the power in different dominant frequency bands. This is shown in Fig. 9, where three sequences of 30 s are presented, which are recorded from a dog during different stages of isoflurane anesthesia. The dominant frequencies have been found using an AR model and are in the range of 0.5–5 Hz, 10–14.5 Hz, and 18–22.5 Hz. The recorded data are sampled with $f_s = 250$, and the sampled sequence is divided into segments of 128 points each with an overlap of 50%. The PSD estimator is obtained as described in Eq. 16.

The mean frequency (MF) of the power spectrum is computed from the following formula:

$$\text{MF} = \frac{\sum_{K=1}^{N/2} S(K)(KF_s/N)}{\sum_{K=1}^{N/2} S(K)} \quad (19)$$

Figure 9. Trend in power in dominant frequency bands. The top row shows three input signals as they are obtained at different stages of anesthesia in a dog. The recordings show from left to right a baseline EEG followed by an EEG epoch obtained after administration of a sedative drug and finally the EEG after reversing the process. The three epochs were recorded in a distance of 1000 s to one another. The second row shows the averaged power spectra obtained with the Welch method, respectively. The data were sampled with $f = 250 \pi$ and the FFT length is 128 points. The bottom row shows the trend in the three dominant frequency bands 0.5–5, 10–14.5, and 18–22.5 Hz. Note that this method does not provide the possibility to visualize the bursts in the EEG recording, but it can give a trend in power changes in dominant frequency bands.

where $S(K)$ is the average power spectrum, N is the FFT length, and F_s is the sampling frequency. The mean frequency can be observed as the frequency instant at which one can find the “center of mass” in the power spectrum.

Short-Time Spectral Analysis

The Algorithm. The STFT is one of the most used time-frequency methods. Time-frequency analysis is performed by computing a time-frequency distribution (TFD), also called a time-frequency representation (TFR), for a given signal. The main idea of a TFD is to allow determination of signal energy at a particular time as well as frequency. Therefore, these TFDs are functions of two dimensions, time and frequency, which have an inherent tradeoff between time and frequency resolution that can be obtained. This tradeoff between time and frequency resolution arises due to the required windowing of the signal to compute the time-frequency distribution. For good time resolution, a short time window is necessary; meanwhile a good frequency resolution requires a narrowband filter, which corresponds to a long time window. But these two conditions, a window with arbitrarily small duration and arbitrarily small bandwidth cannot be fulfilled at the same time. Thus, a compromise has to be found to achieve sufficiently good time and frequency resolution.

The STFT as one possible realization of a TFD is performed by sliding an analysis window across the signal time series and computing the FT for the current time point. The STFT for a continuous-time signal $x(t)$ is defined as follows:

$$\text{STFT}_x^{(\gamma)}(t, f) = \int_{t'} [x(t')\gamma^*(t' - t)] e^{-j2\pi f t'} dt' \quad (20)$$

where $\gamma(t')$ is the analysis window and $*$ denotes the complex conjugate. As discussed the analysis window chosen for the STFT greatly influences the result. Looking at the two extremes shows this influence best. Consider the case of the delta function as analysis window: $\gamma(t) = \delta(t)$. In this case, the STFT = $\sum_{t=0}^{N-1} x(t) \exp(-j2\pi f t)$, which is essen-

tially $x(t)$ and yields perfect time resolution, but no frequency resolution. On the other hand, if the analysis window is chosen to be a constant value $\gamma(t) = 1$ for all time, then the STFT becomes the Fourier transform $X(f)$, with perfect frequency resolution but no time resolution. Therefore, an appropriate window to provide both time and frequency resolution lies somewhere between these two extremes. In our case, a Hanning window is chosen as the analysis window. Figure 10 shows a plot of the STFT as it is obtained by transforming segments of the data, sampled with 250 points. The segments of 128 points each and an overlap of 50% are transformed via a 256 point FFT.

Feature Extraction. Calculating the power of the three dominant frequency bands in each segment, as described in equation 18, we obtain a contour plot of the power in these bands as shown in Fig 11. Also the mean frequency can be calculated in each segment, as described in Eq. 19.

Power Spectrum Estimation using AR-Model

The Algorithm. In the last section, the PSD was defined as the FT of an infinite ACS. This relationship may be considered a nonparametric description of the second-order statistics of a random process. A parametric description of the second-order statistic may also be devised by assuming a time-series model of the random process. The PSD of the time-series model will then be a function of the model parameters (and not of the ACS). A special class of models, driven by white noise processes and processing rational system functions, is AR, ARMA, and MA. One advantage of using parametric estimators is, for example, better spectral resolution. Periodogram and correlogram methods construct an estimate from a windowed set of data or ACS estimates. The unavailable data or unestimated ACS values outside the window are implicitly zero, which is an unrealistic assumption that leads to distortion in the spectral estimate. Some knowledge about the process from which the data samples are taken is often available. This information may be used to construct a model that approximates the process that generated the observed time sequence. Such models will make more realistic

Figure 10. STFT. (a) Epoch of an EEG signal recorded from an isoflurane/DEX-treated dog. The time-varying character of this signal can be presented in the power spectrum using the STFT as shown in (b). STFT was performed with a 256 point FFT and a window length (Hamming window) of 128 points with an overlap of 50%. Data were sampled at $f = 250$ samples.

assumptions about the data outside the window instead of the null data assumption. In our case, the AR-modeling is used instead of AM or ARMA because of the advantage that the model parameter can be obtained by solving linear equations. The assumption is that if the model order p is chosen correctly, and the model parameters are calculated correctly, we obtain a PSD estimation with $p/2$ or $(p + 1)/2$ sharp peaks in the spectrum at the so-called dominant frequencies.

The AR parameters have been shown to follow a recursive relation (94):

$$a_p(n) = a_{p-1}(n) + K_p a_{p-1}^*(p - n) \quad \text{for } n = 1 \dots (p - 1) \quad (21)$$

where $a_p(n)$ are the parameters for model order p , and $a_{p-1}(n)$ for model order $(p - 1)$. K_p is the reflection coefficient for order p , and in Burg's maximum entropy method, K_p is determined by minimizing the arithmetic mean of the forward and backward linear prediction error power, i.e.,

Figure 11. Energy profile in dominant frequency bands using the STFT. (a) EEG epoch recorded from isoflurane/DEX-treated dog. Summing together the energy in the frequency bands 0.5–5, 9–14.5, and 17–22.5 Hz, we obtain the energy profiles in the dominant frequency bands as shown in (b). Note that burst sequences and sequences of electrical silence in the EEG signal can be clearly distinguished with this method.

minimizing

$$\rho_p^{\text{fb}} = \frac{1}{2N} \left(\sum_{n=p+1}^N |e_p^f(n)|^2 + \sum_{n=p+1}^N |e_p^b(n)|^2 \right) \quad (22)$$

where e^f and e^b are the forward and backward linear prediction errors. Minimizing this equation gives us the reflection coefficients K_p for model order p :

$$K_p = \frac{-2 \sum_{n=p+1}^N e_{p-1}^f(n) e_{p-1}^{b*}(n-1)}{\sum_{n=p+1}^N |e_{p-1}^f(n)|^2 + \sum_{n=p+1}^N |e_{p-1}^b(n)|^2} \quad (23)$$

To choose the right model order, we use the Akaike criterion (95), which is based on the maximum likelihood approach and is termed the Akaike Information Criterion (AIC) (95):

$$\text{AIC}(p) = N^* \ln(\rho_p) + 2p \quad (24)$$

where ρ_p is the error variance for model order p . The error variance follows the relation:

$$\rho_p = \rho_{p-1} (1 - |K_p^2|) \quad (25)$$

The optimum model order p has to minimize AIC. With the obtained model parameter, it is now possible to present the data sequence $x(n)$ in the following way (44):

$$\begin{aligned} x(n) &= w(n) - a(1)x(n-1) - a(2)x(n-2) \\ &\quad - \dots - a(p)x(n-p) \end{aligned} \quad (26)$$

where the $a(i)$ are the model parameters, p is the model order, and $w(n)$ is the error in prediction. If we now choose the model order and the model parameters correctly for our estimation, $w(n)$ turns out to be zero. Taking the z -transform of this equation, we obtain

$$X(z) = \frac{W(z)}{1 + a(1)z^{-1} + a(2)z^{-2} + \dots + a(p)z^{-p}} \quad (27)$$

where $W(z)$ is the z -transform of $w(n)$. Squaring the absolute value of $X(z)$, we obtain the estimated power spectrum:

$$P(z) = \left| \frac{W(z)}{1 + a(1)z^{-1} + a(2)z^{-2} + \dots + a(p)z^{-p}} \right|^2 \quad (28)$$

Parameter Extraction. From equation 27, we can now obtain the dominant frequencies in the estimated power spectrum. The poles of $X(z)$ are obtained from the equation:

$$z^p + a(1)z^{p-1} + \dots + a(p) \quad (29)$$

Evaluating this expression at the unit circle, we get frequencies ω at which there is a peak in the frequency spectrum of the data sequence and the analog frequencies of the spectral peaks are

$$F_{\text{do min ant}} = \frac{F_{\text{sampling}}}{2\pi} \omega_{\text{do min ant}} \quad (30)$$

It is now possible to evaluate the power in these frequencies either by integrating the power spectrum between desired frequencies or by the method of Johnsen and Anderson (96), which uses the residues to find the power in the peaks.

Thus, AR modeling provides the possibility to estimate the power spectrum of a signal, to calculate the frequencies at which we find a peak in the spectrum, and to obtain the power in these dominant frequencies. Note that an important assumption for a correct use of AR-modeling is a stationary signal. As this assumption cannot be made for EEG signals in long data sequences, the sample data have to be divided into small overlapping segments, in which the signal can be observed as quasi-stationary. The right segment length can be found using AIC criterion and that segment length is taken that minimizes the variance for the calculated model order. In our case for anesthetized dogs, a model order of eight was found to be appropriate. This leads to four dominant frequencies in the following frequency ranges: 0.5–5, 10–14.5, 18–22.5 Hz, and 27–31 Hz. However, it has been observed that the power in the highest dominant frequency is very small in comparison with the power in the lowest three dominant frequencies and this band is therefore ignored in our study.

Another problem with using AR models for single-channel EEG analysis during nonstationary events like burst suppression or seizures is the possibly change in model order (97). Therefore, AR models can be observed to be more appropriate for multichannel analysis.

Feature Extraction. The dominant frequencies and the power in the dominant frequencies are calculated in each segment, respectively. Therefore, a summation of power in a certain frequency band is not necessary. Figure 12 shows the power in the dominant frequencies over time. The input signal is sampled with 125 Hz and subdivided into segments of 50 points each. The segments are allowed to have an overlap of 50%.

Burst Detection Methods

The computerized detection of seizures and bursts requires differentiation of bursts from episodes of electrical silence and ictal (signal during seizure) from interictal (normal signal activity) parts. We already mentioned the characteristics of bursts and seizures, like high amplitude, high energy, and an increase in phase coupling. The change in energy at the onset and offset of bursts and seizures has been used to detect bursts in many applications. Babb et al. (98) constructed a circuit that signaled seizure detection when high amplitude–high frequency activity was observed for at least 5 s. Ives et al. (99) employed amplitude discrimination after summing and band pass filtering the EEG from 16 channels. Gotman (100) employs a detection paradigm based on measures of amplitude and time period obtained after a “half-wave decomposition” of the signals. Gotman has tested this method on numerous cases; many false positive are generated by this method. Murro et al. (101) used a discriminant function based on signal spectra. The advantage of this method is that it does not rely on visual determination of normal and abnormal signal characteristics. Recent studies have used wavelet analysis to detect the onset of bursts or seizures (102). The detection scheme is based on monitoring the variance structure of the wavelet coefficients over a selected scale range and power fluctuations in these scales individually. Webber et al. (103)

Figure 12. Energy profiles in dominant frequencies using an AR model. (a) EEG epoch recorded from an isoflurane/DEX-treated dog. An AR model (model order 8) was fitted to the EEG sample using segments of 50 points each and an overlap of 50%. The power in the three lowest dominant frequencies (ranges from 0.5–5, 10–14.5, and 18–22.5) was calculated with the residues. Note that this method provides the possibility to distinguish bursts from periods of electrical silence in the EEG signal.

presented in 1994 a detector for epileptiform discharges using an artificial neural network. The detector can detect seizure onsets and offsets in real time and was tested for raw EEG signals as well as for parametrized signals. Similar detectors have been developed by Oezdamer et al. (104) and Y aylali et al. (105). Bullmore et al. (106) presented in 1994 a detection method of ictal events based on fractal analysis of the EEG signal. The basic idea of this detector is that the EEG signal during bursts or seizures tends to have relatively low values for fractal dimensions. However, displaying the onsets and offsets of bursts and seizures very well, this method requires a visual inspection of the obtained image. Lehnerts and Elger (107) presented a detection algorithm in 1995 based on the neuronal complexity loss during ictal signal events. Alarkon et al. (108) presented a detector of seizure onsets in partial epilepsy based on feature changes extracted from the power spectrum. Features used were the total amplitude within specific frequency bands and the parameters activity, mobility, and complexity as developed by Hjorth (58) and presented earlier. The time course of these parameters was then displayed, and the onsets of ictal events were assessed when the parameter changes were above a preset threshold for more than four consecutive epochs. Franaszczuk et al. (109) presented a method in 1994, that allows not only the visualization of seizure onsets but also the flow of activity through different regions of the brain caused by epileptic discharges. The DFT method, a multichannel parametric method of analysis based on an AR model, was used for the analysis. Note that for localization of seizure onsets, this method requires recordings from different regions of the brain, especially recordings made with subdural grid and depth electrode arrays. A study that also used energy measurements in different frequency bands is that of Darcey and Williamson (110). The energy in different frequency bands is obtained from sequentially calculated power spectra, using short analysis windows to provide good time resolution. This method has been described in the previous section as STFT.

The energy ratio of the energy in the ictal EEG with respect to the energy of the preictal baseline EEG was calculated, and detection was performed by comparing this quantity with a threshold. However, it has also been observed in their study that the time resolution obtained with the STFT cannot be increased upon a certain limit, due to simultaneous decrease in frequency resolution.

Agarwal and Gotman present a method of segmentation and clustering based on the nonlinear Teager Energy algorithm or TEA (111). The Teager Energy algorithm is a critical advance in energy measurement methods; based on the nonlinear operators or the second order Volterra kernel (112), it measures the frequency-dependent energy in a signal. The method uses multipliers beyond the simple square law detector ($x^2(t)$) to capture the energy in a filtered portion of the signal. It is based on the energy in a spring concept. The TEA is a two-term time-domain Agarwal, and Gotman uses a TEA variant that does not depend on a square law term. This enables studying the energy function without the evident emphasis of the equivalent zero-lagged autocorrelation term. This would cause undo emphasis of apparent white noise contaminant. For sleep staging and burst detection studies, the TEA turns out to be an essential preliminary analysis component. Sherman et al. (113) use it for burst detection, burst counting, and burst duration calculation in a cardiac arrest (CA) and recovery model in fetal pigs. This study paralleled earlier results highlighting the fact that early bursting in the recovery EEG after CA is indicative of potentially favorable outcomes. High burst counts and time spent in bursting was shown to afford group separability based on a neuro-deficit score (NDS).

CONCLUSIONS

We have presented that bursts during burst-suppression and seizures are signals of short duration with high

amplitude and therefore episodes of high energy. This led to the assumption that a discrimination of bursting episodes from burst-suppression parts could be made based on detecting a change in the energy in dominant frequency bands. However, representing the energy of a time-varying signal has its difficulties. The abrupt change from bursting parts to burst-suppression parts and the possibly short duration of these sequences make it impossible to visualize the change in energy at a certain point of time in the average power spectrum. Other methods like the STFT or parametric methods like the AR model provide the possibility to obtain both a time and a frequency resolution. Nevertheless, both methods still require a certain window length to estimate the power spectrum, and the estimated energy in each window represents the averaged energy over a certain number of sampling points.

INTRODUCTION

Electrogastrography, a term similar to electrocardiography (ECG), is usually referred to as the noninvasive technique of recording electrical activity of the stomach using surface electrodes positioned on the abdominal skin (1–3). The cutaneous recording obtained using the electrogastrographic technique is called electrogastrogram (EGG). In this article, both electrogastrography and electrogastrogram are abbreviated to EGG. Due to the noninvasive nature and recent advances in techniques of EGG recording and computerized analysis, EGG has become an attractive tool to study the electrophysiology of the stomach and pathophysiology of gastric motility disorders and is currently utilized in both research and clinical settings (4–7).

Although there are now several commercially available hardware–software packages making recording and analysis of EGG relatively easy to perform, many centers still use home-built equipment because the interpretations of specific frequency and EGG amplitude parameters are still debated and the clinical utility of EGG is still under investigation (6–10). Therefore, there are definite needs for better definition of the normal frequency range of EGG and dysrhythmias as well as standardization of EGG recording and advanced analysis methods for extraction and interpretation of quantitative EGG parameters. More outcome studies of EGG are also needed to determine the usefulness of EGG in the clinical settings. This article covers the following topics: a brief historic review of EGG, basics of gastric myoelectrical activity, measurement and analysis of EGG including multichannel EGG, interpretation of EGG parameters, clinical applications of EGG and future development of EGG.

HISTORIC REVIEW OF EGG

Electrogastrography was first performed and reported by Walter Alvarez back in the early 1920s (1,11). On October 14, 1921, Walter Alvarez, a gastroenterologist recorded the first human EGG by placing two electrodes on the abdominal surface of “a little old woman” and connected them to a sensitive string galvanometer. A sinusoid-like EGG with a frequency of 3 cycles/min (cpm) was then recorded. As Alvarez described in his paper, “the abdominal wall was so thin that her gastric peristalsis was easily visible” (1). Alvarez did not publish any other paper on EGG probably because of a lack of appropriate recording equipment.

The second investigator to discover the EGG is I. Harrison Tumpeer, a pediatrician who probably performed the first EGG in children (12). In a note in 1926 (12) and in a subsequent publication (13), Tumpeer reported the use of limb leads to record the EGG from a 5 week old child who was suffering from pyloric stenosis and observed the EGG as looking like an ECG (electrocardiogram) with a slowly changing baseline (11).

However, it took ~30 years for EGG to be recovered by R.C. Davis, a psychophysiological in the mid-1950s (14). Davis published two papers on the validation of the EGG using simultaneous recordings from needle electrodes and a swallowed balloon (14,15). Although Davis made only slow progress in EGG research, his two papers had stimulated several other investigators to begin doing EGG research, such as Dr. Stern who started working in Davis’ lab in 1960 (11).

Stevens and Worrall (1974) were probably the first ones who applied the spectral analysis technique to EGG (16). They obtained simultaneous recordings from a strain gauge on the wall of the stomach and EGG in cats to validate the EGG. They not only compared frequencies recorded from the two sites visually in the old fashion way, but also used a fast paper speed in their polygraph and digitized their records by hand once per second, and then analyzed EGG data using Fourier transform (11).

Beginning in 1975, investigators in England published a number of studies on frequency analysis of the EGG signal and made numerous advances in techniques for analysis of the EGG, including fast Fourier transform (FFT) (17),

phase-lock filtering (18), and autoregressive modeling (19). In some of their studies, they compared the EGG with intragastric pressure recordings and reported their findings similar to those of Nelson and Kohatsu (20). They found that there was no 1:1 correlation between the EGG and the contractions. The EGG could be used to determine the frequency of the contractions, but could not be used to determine when contractions were occurring (21).

During this same time, Smout and co-workers at Erasmus University in Rotterdam, The Netherlands, conducted several validation studies of the EGG and made major contributions in the area of signal analysis. In their landmark 1980 paper (22), they were the first ones who showed that the amplitude of the EGG increases when contractions occur. In 1985, Dr. Koch and Dr. Stern reported their study on simultaneous recordings of the EGG and fluoroscopy (23). They repeatedly observed the correspondence between EGG waves and antral contractions during simultaneous EGG-fluoroscopy recordings.

To extract information about both the frequency of EGG and time variations of the frequency, a running spectral analysis method using FFT was introduced by van der Schee and Grashus in 1987 (24), later used by some others (2,25,26) and now still used in most laboratories (5). To avoid the averaging effect introduced by the block processing of the FT, Chen et al. (27,28) developed a modern spectral analysis technique based on an adaptive autoregressive moving average model. This method yields higher frequency resolution and more precise information about the frequency variations of the gastric electrical activity. It is especially useful in detecting dysrhythmic events of the gastric electrical activity with short durations (29).

In 1962, Sobakin et al. (30) performed the EGG in 164 patients and 61 healthy controls and reported that ulcers caused no change in the EGG, but that pyloric stenosis produced a doubling of amplitude, and stomach cancer caused a breakup of the normal 3 cpm rhythm. This was probably the first large-scale clinical use of the EGG. In the past two decades, numerous studies have been reported on the clinical use of the EGG including understanding the relationship between the EGG and gastric motility (22,23,31–37), gastric myoelectrical activity in pregnant women (38–40), gastric myoelectrical activity in diabetics or gastroparetic patients (41–44), gastric myoelectrical activity in patients with dyspepsia (45–50), and prediction of delayed gastric emptying using the EGG (42,46,47,49,51).

As Dr. Stern wrote in 2000, “the history of EGG can be described as three beginnings, a length period of incubation, and a recent explosion” (11). It is beyond the scope of this article to cover every aspect of EGG studies. For more information about the EGG, readers are referred to some excellent articles, reviews, dissertations, and chapters (2,5,6,21,27,52–56).

ELECTROPHYSIOLOGY OF THE STOMACH

Normal Gastric Myoelectrical Activity

Along the gastrointestinal tract, there is myoelectrical activity. *In vitro* studies using smooth muscle strips of

Figure 1. (a) Anatomy of the stomach (1–fundus, 2–body (corpus), 3–antrum, 4–pylorus) and the origin and propagation of the electrogastric signal from proximal (E1) to distal (E4) electrodes measured from the serosa of the human stomach. The dotted lines show the detection of a gastric slow wave traveling distally along the stomach wall. (b) Serosal recording obtained from the distal stomach in a patient. The trace shows slow waves of ~ 3 cpm with and without superimposed spike potentials.

the stomach have revealed independent gastric myoelectrical activity (GMA) from different regions of the stomach. The highest frequency of the gastric myoelectrical activity was recorded in the corpus and the lowest frequency in distal antrum. However, *in vivo* studies demonstrated a uniform frequency in the entire stomach under healthy conditions, because the myoelectrical activity in the corpus with the highest frequency drives or paces the rest of stomach into the same higher frequency (see Fig. 1).

Gastric myoelectrical activity is composed of slow waves and spike potentials. The slow wave is also called the pacesetter potential, or electrical control activity (57–59). The spike potentials are also called action potentials or electrical response activity (57–59). While slow waves are believed originated from the smooth muscles, recent *in vitro* electrophysiological studies suggest that interstitial cells of Cajal (ICC) are responsible for the generation and propagation of the slow wave (60). The frequency of normal slow waves is species-dependent, being ~ 3 cpm in humans and 5 cpm in dogs, with little day-to-day variations. The slow wave is known to determine the maximum frequency and propagation of gastric contractions. Figure 1 presents an example of normal gastric slow waves measured from a patient. Normal 3 cpm distally propagated slow waves are clearly noted.

Spike potentials are known to be directly associated with gastric contractions, that is, gastric contractions occur when the slow wave is superimposed with spike potentials.

Note, however, that *in vivo* gastric studies have failed to reveal a 1:1 correlation between spike potentials measured from the electrodes and gastric contractions measured from strain gauges although such a relationship does exist in the small intestine. In the stomach, it is not uncommon to record gastric contractions with an absence of spike potentials in the electrical recording. Some other forms of superimposed activity are also seen in the electrical recording in the presence of gastric contractions.

Abnormal GMA: Gastric Dysrhythmia and Uncoupling

Gastric myoelectrical activity may become abnormal in diseased states or upon provocative stimulations or even spontaneously. Abnormal gastric myoelectrical activity includes gastric dysrhythmia and electromechanical uncoupling. Gastric dysrhythmia includes bradygastria, tachygastria, and arrhythmia. Numerous studies have shown that gastric dysrhythmia is associated with gastric motor disorders and/or gastrointestinal symptoms (4–7,20,61,62).

A recent study has revealed that tachygastria is ectopic and of an antral origin (63). In $> 80\%$ of cases, tachygastria is located in the antrum and propagates retrogradely toward the pacemaker area of the proximal stomach. It may partially or completely override the normal distally propagating slow waves. However, most commonly it does not completely override the normal gastric slow waves. In this case, there are two different slow wave activities: normal slow waves in the proximal stomach and tachygastrial slow waves in the distal stomach. A typical example is presented in Fig. 2.

Unlike tachygastria, bradygastria is not ectopic and reflects purely a reduction in frequency of the normal pacemaking activity. That is, the entire stomach has one single frequency when bradygastria occur (63). Bradygastria is originated in the corpus and propagates distally toward the pylorus. The statistical results showing the origins of tachygastria and bradygastria are presented Fig. 3. The data was obtained in dogs and gastric dysrhythmias were recorded postsurgically or induced with various drugs including vasopressin, atropine and glucagon (63).

MEASUREMENT OF THE EGG

Gastric myoelectrical activity can be measured serosally, intraluminally, or cutaneously. The serosal recording can be obtained by placing electrodes on the serosal surface of the stomach surgically. The intraluminal recording can be acquired by intubating a catheter with recording electrodes into the stomach. Suction is usually applied to assure a good contact between the electrodes and the stomach mucosal wall. The serosal and intraluminal electrodes can record both slow waves and spikes, since these recordings represent myoelectrical activity of a small number of smooth muscle cells. These methods are invasive and their applications are limited in animals and laboratory settings.

The EGG, a cutaneous measurement of GMA using surface electrodes, is widely used in humans and clinical settings since it is noninvasive and does not disturb ongoing activity of the stomach. A number of validation studies have documented the accuracy of the EGG by

Figure 2. Origin and backward propagation of tachygastria and arrhythmia measured from the sorosa of the canine stomach. An ectopic pacemaker was located at the antrum (channel 8), which propagated both forward and backward. It changed the normal rhythm of original pacemaker that propagated down from the proximal part of the stomach (channel 1) to the distal part of the stomach (channel 8) and almost affected the entire rhythm of the stomach for a minute. A transient bradygastria was observed in all channels before normal rhythm changed back.

comparing it with the recording obtained from mucosal and serosal electrodes (19,22,31,61,64–66). Reproducibility of the EGG recording has been demonstrated, with no significant day-to-day variations (67). In adults, age and gender do not seem to have any influences on the EGG (68–71).

EGG Recording Equipment

The equipment required to record the EGG includes amplifiers, an analog-to-digital (A/D) converter and a personal computer (PC) (Figs. 4 and 5). The EGG signal must be amplified because it is of relatively low amplitude (50–500 μ V). An ideal EGG amplifier should be able to

enhance the gastric signal and effectively reduce interferences and noise. Abnormal frequencies of gastric slow waves may be as low as 0.5 and as high as 9 cpm. To effectively record the gastric slow wave, an appropriate recording frequency range is 0.5–18 cpm (5,6,72). It is recommended that a good choice of the sampling frequency should be three to four times of the highest signal frequency of interest (73,74). Therefore, a sampling rate for digitization of the EGG signal ≥ 1 Hz (60 cpm) is a proper choice.

A typical EGG recording system is shown in Fig. 4. It is composed of two parts: data acquisition and data analysis. Venders who currently offer or have offered EGG equipment in the past included 3CPM Company, Medtronic/Synectics, Sandhill Scientific, Inc., RedTech, and MMS (The Netherlands), and so on (2,6). To date, there are two U.S. Food and Drug Administration (FDA)-approval EGG systems: one from Medtronic Inc (Minneapolis, MN) and the other from 3CPM Company (Crystal Bay, NV). The 3CPM Company’s EGG device is a work station that consists of an amplifier with custom filters, strip chart recorder, and computer with proprietary software—the EGG Software Analysis System (EGGSAS). However, this device is only to record and analyze single-channel EGG.

The newly FDA-approved Medtronic’s ElectroGastrography system provides multichannel EGG recordings and analysis (75–78). It can be either running on Medtronic’s Gastro Diagnostic Workstation or consisting of the Medtronic’s Polygraf ID with a laptop to make a portable system (see Fig. 5). This system provides an Automatic Impedance Check function and optional Motion Sensor. With the Automatic Impedance Check, all EGG electrodes

Figure 3. Statistical results showed that bradygastria originated primarily from the proximal body of the stomach, while tachygastria originated primarily from the distal stomach.

Figure 4. (a) Position of abdominal electrodes for the measurement of one-channel EGG. (b) Block diagram of an EGG recording system.

are verified to be in good electrical contact with the skin within 10 s. The optional Motion Sensor can record respiration and patient movements during data capture. This assists physicians to more easily identify motion artifacts, which can then be excluded from subsequent analysis. Currently, this system has been configured to make four-channel EGG recordings with placement of six surface electrodes on the subject's abdomen (75–78) (see Fig. 5a).

An ambulatory recording device is also available and has been used frequently in various research centers (42,46,48,71,76). For example, the ambulatory EGG recorder (Digitrapper EGG) developed by Synectics Medical Inc. (Shoreview, MN) is of the size and shape of a “walkman” (79). It contains one channel amplifier, an A/D conversion

unit, and memories. It can be used to record up to 24-h one-channel EGG with a sampling frequency of 1 Hz. Information collected during recording can be downloaded into a desktop computer for data storage and analysis (42,79).

Procedures for Recording EGG

Due to the nature of cutaneous measurement, the EGG is vulnerable to motion artifacts. Accordingly, a careful and proper preparation before the recording is crucial in obtaining reliable data.

Skin Preparation. Since the EGG signals are very weak, it is very important to minimize the impedance between

Figure 5. (a) Electrogastragram electrodes placement for making four-channel EGG recordings consists of placing four active electrodes along the antral axis of the stomach, a reference electrode over the xyphoid process, and a ground electrode on the patient's left side. Table 1. List of Systems and Procedures for Recording EGG Used by Different Groups

References	Hardware System	Analysis Method	Procedure (Duration and Meal)
Dutch research groups (8,83)	Custom-built four-channels (band-pass filter: 0.01–0.5 Hz, sampling rate: 1 Hz)	Running spectral analysis by short-time Fourier transform (STFT)	2 h before and 3 h after meal (a pancake, 276 kcal)
McCallum and Chen (42,79), Parkman et al. (46,71) Chen et al. (75,76)	MicroDigitrapper (Synectics Medical, Inc.): single channel (cut-off frequency: 1–16 cpm, sampling rate: 1 or 4 Hz). Commercial four-channel EGG recording device (cut-off frequencies: 1.8–16 cpm) (Medtronic-Synectics, Shoreview, MN)	Running spectral analysis by STFT (Gastrosoft Inc., Synectics Medical) or adaptive analysis method)	(1) 30 min before and 2 h after meal (turkey sandwich, 500 kcal) (2) 60 min before and 60 min after meal (two scrambled egg with two pieces of toasted bread 200 mL water, 282 kcal)
Penn State groups (2,84)	An amplifier with custom filters, a strip chart recorder (cut-off frequency: 1–18 cpm, sampling frequency: 4.27 Hz)	Running spectral analysis by STFT and a data sheet with percentage distribution of EGG power in four frequency ranges	Water load test (45 min)

the skin and electrodes. The abdominal surface where electrodes are to be positioned should be shaved if necessary, cleaned and abraded with some sandy skin-preparation jelly (e.g., Ominiprep, Weaver, Aurora, CO) in order to reduce the impedance between the bipolar electrodes to $> 10 \text{ k}\Omega$. The EGG may contain severe motion artifacts if the skin is not well prepared.

Position of the Electrodes. Standard electrocardiographic-type electrodes are commonly used for EGG recordings. Although there is no established standard, it is generally accepted that the active recording electrodes should be placed as close to the antrum as possible to yield a high signal-to-noise ratio (80). The EGG signals can be recorded with either unipolar or bipolar electrodes, but bipolar recording yields signals with a higher signal-to-noise ratio. One commonly used configuration for recording one-channel EGG is to place one of two active electrodes on the midline halfway between the xiphoid and umbilicus and the other active electrode 5 cm to the left of the first active electrode, 30 cephalad, at least 2 cm below the rib cage, in the midclavicular line. The reference electrode is placed on the left costal margin horizontal to the first active electrode (42,81) (Fig. 4a). One commonly used configuration of electrodes for making four-channel EGG recordings is shown in Fig. 4a, including four active electrodes along the antral axis of the stomach, a reference EGG electrode over the xyphoid process, and a ground EGG electrode on patient's left side (75–78).

Positioning the Patient. The subject needs to be in a comfortable supine position or sit in a reclining chair in a quiet room throughout the study. Whenever possible, the supine position is recommended, because the subject is

more relaxed in this position, and thus introduces fewer motion artifacts. The subject should not be engaged in any conversations and should remain as still as possible to prevent motion artifacts (7,8,79).

Appropriate Length of Recording and Test Meal

The EGG recording is usually performed after a fast of 6 h or more. Medications that might modify GMA (prokinetic and antiemetic agents, narcotic analgesics, anticholinergic drugs, non-steroidal anti-inflammatory agents) should be stopped at least 48 h prior to the test (6,7). The EGG should be recorded for 30 min or more (no < 15 min in any case) in the fasting state and for 30 min or more in the fed state. A recording < 30 min may not provide reliable data and may not be reproducible attributed to different phases of migrating motor complex (82) in the fasting state.

The test meal should contain at least 250 kcal with no $> 35\%$ of fat (82). Solid meals are usually recommended although a few investigators have used water as the test "meal" (see Table 1).

EGG DATA ANALYSIS

In general, there are two ways to analyze EGG signals. One is time-domain analysis or waveform analysis, and the other is frequency-domain analysis. Numerous EGG data analysis methods have been proposed (18,19,24,27,53,55,56,84–97).

Time-Domain Data Analysis

Like other surface electrophysiological recordings, the EGG recording contains gastric signal and noise.

Table 2. Composition of the EGG

	Components	Frequency (cpm)
Signal	Normal slow wave	2.0–4.0
	Bradycastria	0.5–2.0
	Tachycastria	4.0–9.0
	Arrhythmia	NA ^a
Noise	Respiratory	12–24
	Small bowel	9–12
	ECG	60–80
	Motion artifacts	Whole range

^aNot available

Compared with other surface recordings, such as ECG, the quality of EGG is usually poor. The gastric signal in the EGG is disturbed or may even be completely obscured by noise (see Table 2). The frequency of gastric signals is from 0.5 to 9.0 cpm, including normal (regular frequency of 2–4 cpm) and abnormal frequencies. The gastric signals with abnormal frequencies may be divided further into bradycastria (regular frequency of 0.5–2.0 cpm), tachycastria (regular frequency of 4–9 cpm) and arrhythmia (irregular rhythmic activities) (62).

The noise consists of respiratory artifacts, interferences from the small bowel, ECG, and motion artifacts (see Table 2). The respiratory artifact has a frequency from 12 to 24 cpm. It is a common and thorny problem. It is superimposed upon almost every EGG recording if not appropriately processed. Occasionally, the slow wave of the small intestine may be recorded in the EGG. The frequency of intestinal slow waves is 12 cpm in duodenum and 9 cpm in the ileum. The intestinal slow wave is usually weaker than the gastric slow wave. One can avoid recording intestinal slow waves by placing electrodes in the epigastric area. The frequency of ECG is between 60 and 80 cpm. It can be eliminated using conventional low pass filtering because its frequency is much higher than that of the gastric signal component. The frequency of motion artifacts is in the whole recording frequency range. To

minimize motion artifacts, the subject must not talk and should remain still during recording.

The time-domain analysis methods with the aid of computers that were introduced to facilitate the EGG data analysis include (1) adaptive filtering. It is used to reduce noise such as respiratory artifacts with minimal distortion of the gastric signal component of interest (27,90,91), (2) coherent averaging. It is applied to filter out random noise by averaging a large number of EGG waves (85), (3) use of feature analysis and artificial neural networks to automatically detect and delete motion artifacts (93,94), and (4) use of independent component analysis to separate gastric signals from multichannel EGGs (97).

When noise level is low, it is possible to visually analyze the raw EGG tracing (3,6,84,98) to identify periods of artifact and provide a qualitative determination of recording segments with normal frequencies of ~ 3 cpm and those of abnormally high (tachycastria) or low (bradycastria) and the presence or absence of a signal power increase after eating a test meal. Artifacts usually are readily recognized visually as sudden, high amplitude off-scale deflections of the EGG signal (see Fig. 6). Artifactual periods must be excluded before analysis. This is because (a) they are usually strong in amplitude and may completely obscure the gastric signal; (b) they have a broad-band spectrum and their frequencies overlap with that of the gastric signal; therefore they are not separable using even spectral analysis method, and jeopardize any kind of quantitative analyses of the EGG data (79).

EGG Parameters (99)

Although a noise-free EGG signal is attainable by means of advanced signal processing techniques (27,86), the waveform analysis of the EGG has rarely been used, because the waveform of the EGG is related to many factors, including the thickness of the abdominal wall of the subject, skin preparation, position of the electrodes, and characteristics of the recording equipment (100). Furthermore, the number of specific characteristics of the EGG is limited. With single-channel EGG recording, only frequency and

Figure 6. The EGG data analysis. (a) A 30 min EGG recording. (b) The power spectra of the 30 min EGG data. The EGG dominant frequency (DF) and power at DF can be determined from the spectrum, (c) adaptive running spectra. Each curve (from bottom to top) is the spectrum of 2 min EGG data. The percentage of normal slow waves (or dysrhythmias) can be determined from the spectra by counting spectral peaks in each frequency band.

amplitude can be measured. Recent computer simulations and experiments have shown that the propagation of the gastric slow wave can be identified from the multichannel EGG recordings (27,100), it is, however, difficult to get this information from waveform analysis (27). Accordingly, quantitative data analyses of the EGG are mostly based on spectral analysis methods. Some important EGG parameters obtained by the spectral analysis methods are described as in the following sections.

EGG Dominant Frequency and Dominant Power. The frequency believed to be of gastric origin and at which the power in the EGG power spectrum has a peak value in the range of 0.5–9.0 cpm is called the EGG dominant frequency. The dominant power is the power at the dominant frequency. The EGG power can be presented in a linear or decibel (dB) unit. The dominant frequency and power of the EGG are often simplified as EGG frequency and EGG power. Figure 6 shows the definition of the dominant frequency and power of the EGG. Simultaneous cutaneous and serosal (13,17–19) or mucosal (11,16) recordings of GMA have shown that the dominant frequency of the EGG accurately represents the frequency of the gastric slow wave. The dominant power of the EGG reflects the amplitude and regularity of gastric slow waves. The gastric slow wave is regarded as abnormal if the EGG dominant frequency is not within a certain frequency range (e.g., 2–4 cpm). Although there is no established definition for the normal range of the gastric slow wave, it is generally accepted that the dominant frequency of the EGG in asymptomatic normal subjects is between 2.0 and 4.0 cpm (5,6,41,72). The EGG, or a segment of the EGG, is defined as tachygastrica if its frequency is > 4.0 cpm, but < 9.0 cpm, bradygastrica if its frequency is < 2.0 cpm and arrhythmia if there is a lack of a dominant frequency (see Table 2).

Power Ratio or Relative Power Change. As the absolute value of the EGG dominant power is related to many factors, such as the position of the electrodes, the preparation of skin and the thickness of the abdominal wall, it may not provide much useful information. One of the commonly used EGG parameters associated with the EGG dominant power is the power ratio (PR) or the relative power change after an intervention such as meal, water, or medication. Note that the power of the EGG dominant frequency is related to both the amplitude and regularity of the EGG. The power of the EGG dominant frequency increase when EGG amplitude increases. It also increases when the EGG becomes more regular. Previous studies have shown that relative EGG power (or amplitude) change reflects the contractile strength of the gastric contractions (22,33,37).

Percentage of Normal Gastric Slow Waves. The percentage of normal slow waves is a quantitative assessment of the regularity of the gastric slow wave measured from the EGG. It is defined as the percentage of time during which normal gastric slow waves are observed in the EGG.

Percentage of Gastric Dysrhythmias Including Bradygastrica, Tachygastrica, and Arrhythmia. The percentage of gas-

tric dysrhythmia is defined as the percentage of time during which gastric dysrhythmia is observed in the EGG. In contrast to the percentage of normal gastric slow waves in an EGG recording, this parameter represents the abnormality of the EGG or gastric slow waves.

Instability Coefficients. The instability coefficients are introduced to specify the stability of the dominant frequency and power of the EGG (99). The instability coefficient (IC) is defined as the ratio between the standard deviation (SD) and the mean:

$$IC = SD/\text{mean} \times 100\%$$

The clinical significance of the instability coefficient has been demonstrated in a number of previous studies (37,40,99). The instability coefficients defined by Geldof et al. is slightly different from the one defined above. More information can be found in Refs. 83,101.

Percentage of EGG Power Distribution. The percentage of EGG power distribution was introduced by Koch and Stern (102) and is defined as the percentage of total power in a specific frequency range in comparison with the power in the total frequency range from 1 to 15 cpm. For example;

$$\% \text{ of } (2.4\text{--}3.6 \text{ cpm}) = \frac{\text{the power within } 2.4\text{--}3.6 \text{ cpm}}{\text{the total power from } 1 \text{ to } 15 \text{ cpm}} \times 100\%$$

Using this parameter, Koch et al. (102) found that the percentage of power in the 3-cpm range was significantly lower in patients with idiopathic gastroparesis compared to patients with obstructive gastroparesis. They also found that the percentage of power in the tachygastrica range (3.6–9.9 cpm) correlated significantly with the intensity of nausea reported during vector-induced motion sickness (103). The advantage of this method is that it is easy for computation. We should be aware, however, that only relative values of this parameters in comparison with the control data should be used. Even in normal subjects, the percentage of normal EGG activity computed in this way will never be 100%. Note that this parameter is sensitive to noise, since any noise component in the frequency band of 1–15 cpm affects the computation of this parameter. Harmonics of the fundamental 3 cpm slow wave may be computed as tachygastrica (8,74).

Percentage of Slow Wave Coupling. Slow wave coupling is a measure of the coupling between two EGG channels. The percentage of slow wave coupling is defined as the percentage of time during which the slow wave is determined to be coupled. The slow waves between two EGG channels are defined as coupled if the difference in their dominant frequencies is < 0.2 (77,78,95) or 0.5 cpm (76).

Methods to Obtain EGG Parameters

Spectral analysis methods are commonly used for calculation of the EGG parameters, including power spectral analysis and running spectral analysis (RSA) or time-frequency analysis. The frequency and power of the EGG can be derived from the power spectral density. The periodogram is one of the commonly used methods for the calculation of

the power spectrum density (73). In this method, EGG data samples are divided into consequent segments with certain overlap. A FT is performed on each data segment, and the resultant functions of all segments are averaged. The periodogram method is more appropriate for the computation of the power spectrum of a prolonged EGG recording. Whenever there are enough data samples, the periodogram method instead of the sample spectrum should be used for the calculation of the dominant frequency and power of the EGG (21). Another method to estimate the frequency and power of EGG is to use a parametric method such as autoregressive modeling (AR) parameters (19). These AR parameters are initially set at zeros and are iteratively adjusted using the EGG samples. After a certain number of iterations, the EGG signal can be represented by these AR parameters. That is, the power spectrum of the EGG signals can be calculated from these parameters (19,27). The problem is the appropriate selection of the model order or the number of parameters. Too few parameters reduce the accuracy, and too many increasing the computing time (98). Although this method is somewhat time consuming, the advantage is that compared to FFT-based methods, the period over which the signal is analyzed can be much shorter (19).

To extract not only information about the frequency of the EGG, but also information about time variations of the frequency, a running spectral analysis method using FFT was first introduced by a Dutch group (24) and later used by others (25,26,39). This method consists of a series of sequential sample spectra. It is calculated as follows: For a given data set of EGG, a time window (e.g., Hanning window) with a length of D samples is applied to the first D samples, a FFT with the same length is calculated, and a sample spectrum is obtained for the first block of data. The sample spectrum of the next time step is obtained in the same way by shifting the windows of some samples forward. The advantage of this method is easy for implantation. Its drawback is that it may not be able to provide accurate time frequency estimations when the characteristics of the EGG signal change rapidly (72,104).

To avoid the averaging effect introduced by the FFT, Chen et al.(28) developed an adaptive spectral analysis based on the adaptive autoregressive moving average model (27). The main advantage of this method is that it is able to provide the instantaneous frequency of an EGG signal with short duration (29). Thus it is very useful for the detection of gastric dysrhythmias with brief duration, but may not be a good choice for the estimation of the EGG power (104). Recently, an exponential distribution (ED) method was also introduced for representation of EGG (92). The performance of the ED method is in between the RSA and the adaptive method. The cross-terms may deteriorate the performance of the ED method if the EGG signal contains several different frequency components (104). Time-frequency analysis methods other than those mentioned above have also been used, such as wavelet transform and fast Hartley transform (89). The description of these methods is mathematically complex and beyond the scope of this article. The detailed information can be found in (5) and (89).

An example of the calculation of the EGG parameters is shown in Fig. 6. The upper panel presents an EGG record-

ing obtained in a human subject. The power spectrum of this 30-min EGG is shown in the lower left panel. The lower right panel shows the power spectra of the 30-min EGG calculated by the adaptive spectral analysis method (28). Each line in Fig. 6c represents the power spectrum of 2-min nonoverlap data (from bottom to top). The percentage of normal slow wave and dysrhythmias can be calculated from these spectra. Of 15 spectra, 12 have peaks in the 2–4 cpm range, that is, 80% of the EGG recording has normal slow waves. Three spectra (two in the bradygastria range and one in the tachygastria range) have peaks outside the normal slow wave range. The percentage of dysrhythmias is then 20%.

EGG IN ADULTS

EGG in Healthy Subjects

Definitions of what constitutes a normal EGG have been provided by careful analysis of EGG recordings from normal volunteers (6).

Normal EGG Frequency Range. Several studies (4,41,49,68,70,71) in healthy adults have shown that EGG in the fasting state is characterized by a stable slow wave dominant frequency (DF) (median: 3.0 cpm; range: 2–4 cpm) with a relatively small amplitude. Immediately after the test meal, the EGG frequency decreases from the baseline for a short period [~ 5 min. (4)] and then gradually increases to above the baseline level (media: 3.2 cpm; range: 2–4 cpm). It has been shown that the postprandial EGG DF is also dependent on the type and specific qualities of the ingested test meal (99). Solid meals slightly, but significantly, increase EGG DF, whereas liquid meals temporarily reduce the EGG DF.

Based on the normal EGG frequency range of 2–4 cpm, the overall results of four studies in 189 normal subjects suggest that 70% is an appropriate lower limit of normal for the percentage of the recording time for the EGG rhythm to be in the 2.0–4.0-cpm range (4,41,49,68,70,71).

Note that the definition of normal EGG frequency range reported in the literature varies considerably (see Table 1). The Penn State group defined the percentage of normal EGG activity as the percentage of the power in the frequency range of 2.4–3.6 cpm compared to the total power from 1 to 15 cpm (84). Accordingly, dysrhythms are considered present when too much power is in the low frequency range (bradygastria) or in the high frequency range (tachygastria). This approach is debatable due to the following reasons: (1) The EGG is not sinusoid and thus its power spectrum contains harmonics that are related to the waveform, but not at all associated with gastric rhythmicity. In this method, however, the harmonics are considered as tachygastria (8). (2) The method is very sensitive to motion artifacts that can result in abnormal frequency spectra with significant power in the low frequency range (8,9). Apparently, the differences in the definitions of the normal frequency range of EGG or dysrhythmias are at least related the following two factors: (1) Relative small numbers of subjects were included in the above EGG studies; (2) different analysis methods were used to analyze the EGG

data. To establish better definitions of normal frequency range and dysrhythmias, an international multicenter EGG study with a relative large sample size is needed and the currently used analysis methods should be applied to compare the results.

EGG Power in the Fasting and EGG Power Ratio. Absolute values of EGG power during fasting and the postprandial period are affected by a number of variables including body habitus, electrodes placement, and body position (6,105). However, these factors do not influence the relative value in EGG power, that is, the power ratio between the pre- and postprandial powers. Depending on meals consumed, 90–95% of healthy volunteers exhibit increased postprandial power at DF (6,41,71). Note that different meals may have different effects on the EGG. The main results for the effects of different meals on the EGG power are summarized as follows (99):

Water: Water induces an increase in EGG dominant power and a decrease in EGG dominant frequency. In a study with 10 normal subjects drinking 140 mL water (106), it was found that the EGG dominant frequency was slightly, but significantly, lower than the baseline in the fasting state during the first 10 min after the drink (2.95 vs. 2.73 cpm, $p < 0.05$). The power of the EGG at the dominant frequency was significantly higher after the drink than the baseline. A 3 dB increase in EGG dominant power (equivalent to 41% increase in 3 cpm amplitude) was observed. Similar observations were reported by several other investigators (66,107). In a recently performed study, simultaneous EGG and serosal recordings of gastric myoelectrical activity were made in patients before and after a drink of water (66). Statistical analysis demonstrated that the EGG dominant power change after a drink of water was correlated with that observed in the serosal recording (Spearman's correlation coefficient: $r = 0.757$, $p = 0.007$) and the change of EGG dominant frequency was the same as that from serosal recordings.

Milk: To investigate whether there is a different effect between non-nutritive (water) and a nutritive liquid meal, Chen et al. repeated the study procedure mentioned above in Ref. 106 by asking volunteers to drink 140 mL of 2% milk. The results showed that milk decreases the amplitude of EGG. The average decrease in EGG power in the 10 subjects within the first 10 min was 3.8 dB (equivalent to ~50% decrease in amplitude (108).

Solid meal: The effects of solid meal on the EGG have been studied by numerous investigators (5,16,33,101,106). More significant increase in EGG dominant power was observed after the solid meal than after a drink of water. For example, the average EGG dominant power after a solid meal over 10 subjects was 6 dB higher than the preprandial value, equivalent to a 100% increase in amplitude (106) (see Fig. 7a and b). The actual amount of increase in EGG dominant power is believed to be associated with the volume and content of the meal (see next section). The dominant frequency of the EGG seems to increase as well after a test meal. Similar to the change in EGG dominant frequency after a drink of water, this increase is often small, but significant (106).

Figure 7. Pre- and postprandial EGG recordings in humans. (a) and (b): normal EGG patterns that show an increase in EGG amplitude postprandially; (c) and (d): dysrhythmic EGG pattern and a substantial decrease in EGG amplitude after the meal.

EGG IN PATIENTS

Abnormal EGG

A variety of abnormalities have been described on EGG recordings from patients with motility disorders. For example, abnormal EGGs are noted with nausea, vomiting, early satiety, anorexia, and dyspepsia including gastroparesis (41–44,102), nonulcer or functional dyspepsia (46–50,76,109), motion sickness (5,25,110), pregnancy (38–40), and eating disorders (35). Typical EGG abnormalities in patients with motility disorders or symptoms include (1) absence of normal slow waves, which is shown in the EGG power spectra as a lack of peaks in the 2–4 cpm frequency range; (2) gastric dysrhythmias, including bradycardia, tachycardia, and arrhythmia (see Fig. 8); (3) deterioration of the EGG after a test meal, which is shown as a decrease in EGG power in the 2–4 cpm frequency range (see Fig. 7c and d), (4) slow wave uncoupling between different gastric segments detected from a multichannel EGG recording (76–78,95,96).

Definition of an abnormal EGG is mainly determined by comparison of EGG findings in healthy volunteers and symptomatic patients (41). At present, it is widely accepted that an EGG is considered as abnormal if the DF is in the tachy- and/or bradycardic frequency ranges for > 30% of the time. This number takes into account the observation that healthy volunteers exhibit periods of time representing up to 30% of recording time in which recognizable EGG rhythms are not distinguishable from background electrical noise either on visual inspection or computer analysis.

Figure 8. The EGG recordings in a patient with gastroparesis: (a) 30-min preprandial EGG recording, (b) 30-min postprandial EGG. Lower left panel: Power spectra of preprandial EGG (solid line) and postprandial EGG (line with star) shows abnormal response to a meal (decrease in postprandial EGG power) and tachygastric after meal (EGG dominant frequency: 7.4 cpm). Lower right panel shows the running spectra of 30-min preprandial EGG and 30-min postprandial EGG demonstrating the presence of 7–8 cpm tachygastric peaks before meal and normal 3-cpm peaks after meal.

In addition, a decreased power ratio after a solid meal is also an indication of an abnormal EGG (6,7,41,68–71).

Some institutions have advocated the use of percentage distribution of EGG power in the three major frequency bands to summarize the absolute signal amplitude in the bradygastric, normal rhythm, and tachygastric ranges (2,84,111). For this parameter, an EGG is considered abnormal if the percentage distribution of total EGG power in the tachygastric range is $>20\%$ (6,112). Power distributions in the bradygastric frequency range are highly variable and may be affected by minor variations in the signal baseline or subtle motion artifacts. Thus the calculation of the percentage of the total EGG power in the bradygastric frequency range may not be reliable for the determination of bradygastric (6).

Clinical Role of EGG. The FDA approved EGG as a test for patient evaluation in 2000. The FDA statement on EGG concluded that EGG is a noninvasive test for detecting gastric slow waves and is able to differentiate adult patients with normal myoelectrical activity from those with bradygastric and tachygastric. The EGG can be considered as part of a comprehensive evaluation of adult patients with symptoms consistent with gastrointestinal motility disorders (6).

The members of the American Motility Society Clinical GI Motility Testing Task Force proposed the following indications for EGG as a diagnostic study to noninvasively record gastric myoelectrical activity in patients with unexplained persistent or episodic symptoms that may be related to a gastric motility and/or myoelectrical disorder (6). The EGG can be obtained: (1) to define gastric myoelectrical disturbances in patients with nausea and vomiting unexplained by other diagnostic testing or associated with functional dyspepsia and (2) to characterize gastric myoelectrical disturbances associated with documented gastroparesis.

The future clinical applications of EGG are in three main areas: (1) To assist in the clinical evaluation and diagnosis of patients with gastric motility disorders. (2) To determine the gastric response to either caloric stimuli or exogenous stimuli, such as pharmacologic and prokinetic agents or gastrointestinal hormones or gastric electrical stimulation or for patients before and after kidney-pancreas (KP) transplant (113–115). (3) To further evaluate the role of EGG in research and clinical work in infants and children (6,7,116).

EGG IN INFANTS AND CHILDREN

Although the majority of EGG studies are being performed in adults, there is an increased interest for the clinical application of EGG to pediatric patients. In infants, current diagnostic methods for the assessment of gastric motility, such as intraluminal manometry and radionuclide isotope study, are very much limited. Consequently, little is known on gastric myoelectrical in infants since mucosal-serosal recordings are not feasible, and much less information is available in infants than adults on gastric motility. The EGG is therefore an attractive noninvasive alternative to study gastric myoelectrical and motor activities in infants and children. In recent years, a small number of pediatric gastroenterologists and researchers, including Peter Milla, Alberto Ravelli, Salvatore Cucchiara, Giuseppe Riezzo, and Jiande Chen, et al. have begun to use the EGG to study the pathophysiology of gastric motility in infants and children (11).

Patterns of GMA in Healthy Pediatric Subjects with Different Ages

To investigate whether EGG patterns are associated with ages, Chen et al. (117) performed EGG studies in five groups of healthy subjects including 10 preterm newborns,

8 full-term newborns, 8 full-term infants (ages 2–6 months), 9 children (ages 4–11 years), and 9 adults. The Digitrpper EGG recorder was used to record EGG signals for 30 min before and 30 min after a test meal in each subject. Spectral analysis methods were applied to computer EGG parameters. The results showed that the percentage of 2–4 cpm slow waves was $26.6 \pm 3.9\%$ in the preterm newborns, $30.0 \pm 4.0\%$ in full-term newborns, $70 \pm 6.1\%$ in 2–6-months old infants ($P < 0.001$ compared with newborns), $84.6 \pm 3.2\%$ in 4–11-year old children ($P < 0.03$ compared with infants), and $88.9 \pm 2.2\%$ in the adults ($P > 0.05$ compared with children). This study has shown that regular gastric slow waves (2–4 cpm) are absent at birth, present at age of 2–4 months, and well developed at the age of 4–11 years. The EGG in healthy children is similar to that in healthy adults.

Using the percentage of total EGG power in the frequency range 2.5–3.6 cpm as a measure of normal gastric slow waves, Koch et al. reported similar findings in preterm and full-term infants with ages from 3 to 50 days: a low percentage of normal gastric slow waves, no difference between preterm and fullterm infants, and no difference between fasting EGG and fed EGG (111). These studies suggest that gastric slow waves are largely absent at birth, and there is a maturing process after birth.

To study the development or maturation of gastric slow waves in preterm infants, Liang et al. (118) performed a follow-up EGG study in 19 healthy preterm infants at postnatal ages of 1 and 2 weeks and 1, 2, 4, and 6 months (gestational age at birth: 33.5 ± 2.6 week). The results showed that the percentage of normal slow waves was low at birth and there was a progressive increase with age during the first 6 months of life (see Fig. 9). These results suggest that normative EGG data should be established for different age groups and age-matched controls

Figure 9. Preprandial and postprandial percentages of the normal 2–4-cpm slow waves in preterm infants at the ages of 1 and 2 weeks and 1, 2, 4, and 6 months. The P values resulted from comparison between paired fasting data or paired fed data.

are necessary for the interpretation of EGG from diseased neonates and infants.

EGG Norms in Healthy Children and Effects of Age, Gender, and BMI

As with any novel technique, the establishment of normal values is a prerequisite for reliable application across populations. Studies on EGG performed in healthy adults have found no major differences in EGG characteristics among age group (68,69,71). Using the same EGG recording and analysis system as utilized in healthy adults, Riezzo et al. performed EGG studies before and after a meal in 114 healthy children (age range: 6–12 years) (69) and Levy et al. conducted EGG studies in 55 healthy children (age range: 6–18 years) for a 1 h baseline preprandial period and a 1 h postprandial period after consumption of a standard 448 kcal meal (119). These studies have shown that the EGG patterns in the healthy children ages from 4 to 18 years are very similar to those in the healthy adults and the key normative values are not influenced by age and gender.

Applications in Pediatric Patients

Electrogastrogram has also been applied to evaluate pediatric patients with various diseases that are associated with gastric motility disorders. Functional dyspepsia presents as a challenge to clinicians with its debilitating features and no organic findings. Invasive diagnostic tests are limited in pediatric practice. Whereas, noninvasive EGG has been used and will be increasingly used to identify possible malfunctioning of the stomach, Cucchiara et al. (120) detected abnormal patterns of the EGG, encompassing all range of dysrhythmia, in 12 out of 14 patients with functional dyspepsia. Abnormalities in gastric myoelectrical activity were also observed from the EGG in pediatric patients with central nervous system disorders, chronic renal failure, and intestinal pseudoobstruction (98,121,122).

FUTURE PROSPECTS

The recording and analysis of the EGG are well established although not yet completely standardized. It is clear that the EGG is a reliable measurement of gastric slow waves and reflects relative contractile activity of the stomach. Clinical applications of the EGG are indicated in numerous studies. However, cautions should be made during recording to minimize motion artifact and in the interpretation of the EGG parameters. Future development in EGG methodology should be focused to reveal more information regarding spatial abnormalities of gastric slow waves and relevant information directly related to gastric contractility. In this regard, multichannel EGG may play a more important role in both electrophysiological studies of the stomach and clinical applications. Recently, several studies have been performed using a four-channel EGG system to derive spatial information from the multichannel EGG. These include spatial distribution of slow-wave frequency and amplitude, slow-wave coupling and propagation (75–78). The gastric slow wave propagation was measured by analyzing the phase shifts or time lags of

the EGG signal among different recording channels using cross-covariance analysis (75). Slow-wave coupling was defined as similar frequencies of the EGG signals in different channels and a cross-spectral analysis method has been established to compute the percentage of slow-wave coupling (93). Two single-center studies have suggested that patients with functional dyspepsia have impaired slow-wave propagation and coupling (76,78). Further multicenter studies are needed to determine how the expanded utility of the multichannel EGG.

The EGG is not only of great clinical significance in diagnosing gastric motility disorders, but may also play an important role in predicting and validating gastric electrical stimulation (GES) (116,123). Previous studies have established the efficacy of GES in reducing symptoms of gastroparesis. However, approximately one-third of the patients were shown to have poor response to GES therapy and the mechanism by which GES acts to improve gastroparetic symptoms is currently unclear (124,125). Physiological studies have demonstrated that gastric slow wave activity depends on the function of interstitial cells of Cajal (ICC) in the stomach (126–128). The ICC networks in the myenteric region of the gastric corpus and antrum (IC–MY) have been identified as the source of electrical slow waves that control the maximum frequency and propagation direction of gastric contractions. Ordog et al. (127) demonstrated that the loss of gastric IC–MY resulted in the loss of electrical slow waves and eliminated the ability the musculature to generate slow waves in response to depolarizing stimuli. Thus functional ICC is critical for the production and maintenance of normal slow wave activity and gastric motility. Degeneration of ICC is often found in some GI tract conditions characterized by ineffective motility of the affected segment. Recently, preliminary experiments have demonstrated (a) a normal baseline EGG is significantly correlated with an improved symptomatic outcome after chronic high frequency GES for refractory gastroparesis compared to an abnormal baseline EGG with which ~50% of patients were nonresponders to the high frequency GES therapy; (b) the absence of ICC was correlated with abnormal EGG and patients with an absence of ICC showed less symptom improvement (123,129). These data suggest that baseline EGG status could be used to predict long-term symptom improvement in gastroparetic patients treated with GES. Specifically, marked gastric dysrhythmias as determined by the baseline EGG study is a predictor to a poor response to high frequency GES. Further studies are required to determine the role of EGG in the management of GI motility disorders.

ELECTROMYOGRAPHY

CARLO DE LUCA
Boston University
Boston, Massachusetts

INTRODUCTION

Electromyography is the discipline that deals with the detection, analysis, and use of the electrical signal that emanates from contracting muscles.

This signal is referred to as the electromyographic (EMG) signal, a term that was more appropriate in the past than in the present. In days past, the only way to capture the signal for subsequent study was to obtain a “graphic” representation. Today, of course, it is possible to store the signal on magnetic tape, disks, and electronics components. Even more means will become available in the near future. This evolution has made the graphics aspect of the nomenclature a limited descriptor. Although a growing number of practitioners choose to use the term “myoelectric (ME) signal”, the term “EMG” still commands dominant usage, especially in clinical environments.

An example of the EMG signal can be seen in Fig. 1. Here the signal begins with a low amplitude, which when expanded reveals the individual action potentials associated with the contractile activity of individual (or a small group) of muscle fibers. As the force output of the muscle contraction increases, more muscle fibers are activated and the firing rate of the fibers increases. Correspondingly, the amplitude of the signal increases taking on the appearance and characteristics of a Gaussian distributed variable.

Figure 1. The EMG signal recorded with surface electrodes located on the skin above the first dorsal interosseous muscle in the hand. The signal increases in amplitude as the force produced by the muscle increases.

The novice in this field may well ask, why study electromyography? Why bother understanding the EMG signal? There are many and varied reasons for doing so. Even a superficial acquaintance with the scientific literature will uncover various current applications in fields such as neurophysiology, kinesiology, motor control, psychology, rehabilitation medicine, and biomedical engineering. Although the state of the art provides a sound and rich complement of applications, it is the potential of future applications that generates genuine enthusiasm.

HISTORICAL PERSPECTIVE

Electromyography had its earliest roots in the custom practiced by the Greeks of using electric eels to “shock” ailments out of the body. The origin of the shock that accompanied this earliest detection and application of the EMG signal was not appreciated until 1666 when an Italian, Francesco Redi, realized that it originated from muscle tissue (1). This relationship was later proved by Luigi Galvani (2) in 1791 who staunchly defended the notion. During the ensuing six decades, a few investigators dabbled with this newly discovered phenomenon, but it remained for DuBois Reymond (3) in 1849 to prove that the EMG signal could be detected from human muscle during a voluntary contraction. This pivotal discovery remained untapped for eight decades awaiting the development of technological implements to exploit its prospects. This interval brought forth new instruments such as the cathode ray tube, vacuum tube amplifiers, metal electrodes, and the revolutionary needle electrode which provided means for conveniently detecting the EMG signal. This simple implement introduced by Adrian and Bronk (4) in 1929 fired the imagination of many clinical researchers who embraced electromyography as an essential resource for diagnostic procedures. Noteworthy among these was the contribution of Buchthal and his associates.

Guided by the work of Inman et al. (5), in the mid-1940s to the mid-1950s several investigations revealed a monotonic relationship between the amplitude of the EMG signal and the force and velocity of a muscle contraction. This significant finding had a considerable impact: It dramatically popularized the use of electromyographic studies concerned with muscle function, motor control, and kinesiology. Kinesiological investigations received yet another impetus in the early 1960s with the introduction of wire electrodes. The properties of the wire electrode were diligently exploited by Basmajian and his associates during the next two decades.

In the early 1960s, another dramatic evolution occurred in the field: myoelectric control of externally powered prostheses. During this period, engineers from several countries developed externally powered upper limb prostheses that were made possible by the miniaturization of electronics components and the development of lighter, more compact batteries that could be carried by amputees. Noteworthy among the developments of externally powered prostheses was the work of the Yugoslavian engineer Tomovic and the Russian engineer Kobrinski, who in the late 1950s and early 1960s provided the first examples of such devices.

In the following decade, a formal theoretical basis for electromyography began to evolve. Up to this time, all knowledge in the field had evolved from empirical and often anecdotal observations. De Luca (6,7) described a mathematical model that explained many properties of the time domain parameters of the EMG signal, and Lindstrom (8) described a mathematical model that explained many properties of the frequency domain parameters of the EMG signal. With the introduction of analytical and simulation techniques, new approaches to the processing of the EMG signal surfaced. Of particular importance was the work of Graupe and Cline (9), who employed the autoregressive moving average technique for extracting information from the signal.

The late 1970s and early 1980s saw the use of sophisticated computer algorithms and communication theory to decompose the EMG signal into the individual electrical activities of the muscle fibers (10–12). Today, the decomposition approach promises to revolutionize clinical electromyography and to provide a powerful tool for investigating the detailed control schemes used by the nervous system to produce muscle contractions. In the same vein, the use of a thin tungsten wire electrode for detecting the action potential from single fibers was popularized for clinical applications (13,14). Other techniques using the surface EMG signal, such as the use of median and mean frequencies of the EMG signal to describe the functional state of a muscle and the use of the conduction velocity of the EMG signal to provide information on the morphology of the muscle fibers began to take hold. For a review, see De Luca (15).

The 1990s saw the effective application of modern signal processing techniques for the analysis and use of the EMG signal. Some examples are the use of time and frequency analysis of the surface EMG signal for measuring the relative contribution of low back muscles during the presence and absence of low back pain (16); the use of

Figure 2. Relationship among the various factors that affect the EMG signal. [Reproduced with Permission from C. J. De Luca, "The Use of Surface Electromyography in Biomechanics." In the Journal of Applied Biomechanics, Vol. 13(No 2): p 139, Fig. 1.]

systematic measurements of the muscle fiber conduction velocity for measuring the severity of the Duchenne Dystrophy (17); the analysis of motor unit action potential delay for locating the origin, the ending and the innervation zone of muscle fibers (18); and the application of time–frequency analysis of the EMG signal to the field of laryngology (19).

New and exciting developments are on the horizon. For example, the use of large-scale multichannel detection of EMG signals for locating sources of muscle fiber abnormality (20); application of neural networks to provide greater degrees of freedom for the control of myoelectric prostheses (21), and for the analysis of EMG sensors data for assessing the motor activities and performance of sound subjects (22) and Stroke patients (23). Yet another interesting development is the emerging use of sophisticated Artificial Intelligence techniques for the decomposing the EMG signal (24). The reader who is interested in more historical and factual details is referred to the book *Muscles Alive* (25).

DESCRIPTION OF THE EMG SIGNAL

The EMG signal is the electrical manifestation of the neuromuscular activation associated with a contracting muscle. The signal represents the current generated by the ionic flow across the membrane of the muscle fibers that propagates through the intervening tissues to reach the detection surface of an electrode located in the environment. It is a complicated signal that is affected by the anatomical and physiological properties of muscles and the control scheme of the nervous system, as well as the characteristics of the instrumentation used to detect and observe it. Some of the complexity is presented in Fig. 2 that depicts a schematic diagram of the main physiological, anatomical and biochemical factors that affect the EMG signal. The connecting lines in the diagram show the interaction among three classes of factors that influence the EMG signal. The causative factors have a basic or elemental effect on the signal. The intermediate factors represent physical and physiological phenomena that are

influenced by one or more of the causative factors and in turn influence the deterministic factors that represent physical characteristics of the action potentials. For further details see De Luca (26).

In order to understand the EMG signal, it is necessary to appreciate some fundamental aspects of physiology. Muscle fibers are innervated in groups called motor units, which when activated generate a motor unit action potential. The activation from the central nervous system is repeated continuously for as long as the muscle is required to generate force. This continued activation generates motor unit action potential trains. These trains from the concurrently active motor units superimpose to form the EMG signal. As the excitation from the Central Nervous System increases to generate greater force in the muscle, a greater number of motor units are activated (or recruited) and the firing rates of all the active motor units increases.

Motor Unit Action Potential

The most fundamental functional unit of a muscle is called the motor unit. It consists of an α -motoneuron and all the muscle fibers that are innervated by the motoneuron's axonal branches. The electrical signal that emanates from the activation of the muscle fibers of a motor unit that are in the detectable vicinity of an electrode is called the motor unit action potential (MUAP). This constitutes the fundamental unit of the EMG signal. A schematic representation of the genesis of a MUAP is presented in Fig. 3. Note the many factors that influence the shape of the MUAP. Some of these are (1) the relative geometrical relationship of the detection surfaces of the electrode and the muscles fibers of the motor unit in its vicinity; (2) the relative position of the detection surfaces to the innervation zone, that is, the region where the nerve branches contact the muscle fibers; (3) the size of the muscle fibers (because the amplitude of the individual action potential is proportional to the diameter of the fiber); and (4) the number of muscle fibers of an individual motor unit in the detectable vicinity of the electrode.

Figure 3. Schematic representation of the generation of the motor unit action potential.

The last two factors have particular importance in clinical applications. Considerable work has been performed to identify morphological modifications of the MUAP shape resulting from modifications in the morphology of the muscle fibers (e.g., hypertrophy and atrophy) or the motor unit (e.g., loss of muscle fibers and regeneration of axons). Although usage of MUAP shape analysis is common practice among neurologists, interpretation of the results is not always straightforward and relies heavily on the experience and disposition of the observer.

Motor Unit Action Potential Train

The electrical manifestation of a MUAP is accompanied by a contractile twitch of the muscle fibers. To sustain a muscle contraction, the motor units must be activated repeatedly. The resulting sequence of MUAPs is called a motor unit action potential train (MUAPT). The waveform of the MUAPs within a MUAPT will remain constant if the geometric relationship between the electrode and the active muscle fibers remains constant, if the properties of the recording electrode do not change, and if there are no significant biochemical changes in the muscle tissue. Biochemical changes within the muscle can affect the conduction velocity of the muscle fiber and the filtering properties of the muscle tissue.

The MUAPT may be completely described by its inter-pulse intervals (the time between adjacent MUAPs) and the waveform of the MUAP. Mathematically, the inter-pulse intervals may be expressed as a sequence of Dirac delta impulses $\delta_i(t)$ convoluted with a filter $h(t)$ that represents the shape of the MUAP. Figure 4 presents a graphic representation of a model for the MUAPT. It follows that the MUAPT, $u_i(t)$ can be expressed as

$$u_i(t) = \sum_{k=1}^n h_i(t - t_k)$$

Figure 4. Model for a motor unit action potential train (MUAPT) and the corresponding Fourier transform of the inter-pulse intervals (IPIs), the motor unit actions potentials (MUAP), and the MUAPT.

where

$$t_k = \sum_{l=1}^k x_l \quad \text{for } k, l = 1, 2, 3, \dots, n$$

In the above expression, t_k represents the time locations of the MUAPs, x represents the inter-pulse intervals, n is the total number of inter-pulse intervals in a MUAPT, and i, k , and l are integers that denote specific events.

By representing the inter-pulse intervals as a renewal process and restricting the MUAP shape so that it is invariant throughout the train, it is possible to derive the approximations

$$\begin{aligned} & \text{Mean rectified value} \\ &= E\{|u_i(t, F)|\} \cong \lambda_i(t, F) \int_0^\infty |h_i(t)| dt \\ & \text{Mean squared value} \\ &= MS\{|u_i(t, F)|\} \cong \lambda_i(t, F) \int_0^\infty h_i^2(t) dt \end{aligned}$$

where F is the force generated by the muscle and is the firing rate of the motor unit.

The power density spectrum of a MUAPT was derived from the above formulation by LeFever and De Luca [(27) and independently by Lago and Jones (28)]. It can be expressed as

$$S_{u_i}(\omega, t, F) = S_{\delta_i}(\omega, t, F) |H_i(j\omega)|^2 \frac{=\lambda_i(t, F) \{1 - |M(j\omega, t, F)|^2\}}{1 - 2 \cdot \text{Real}\{M(j\omega, t, F)\} + |M(j\omega, t, F)|^2} \{|H_i(j\omega)|^2\}$$

for $\neq 0$

where is the frequency in radians per second, $H_i(j\omega)$ is the Fourier transform of $h_i(t)$, and $M(j\omega, t, F)$ is the Fourier transform of the probability distribution function, $p_x(x, t, F)$ of the inter-pulse intervals.

Figure 5. An EMG signal formed by adding (superimposing) 25 mathematically generated MUAPTs.

The EMG Signal

The EMG signal may be synthesized by linearly summing the MUAPTs. This approach is expressed in the equation

$$m(t, F) = \sum_{i=1}^p u_i(t, F)$$

and is displayed in Fig. 5, where 25 mathematically generated MUAPTs were added to yield the signal at the bottom. This composite signal bears striking similarity to the real EMG signal.

From this concept, it is possible to derive expressions for commonly used parameters: mean rectified value, root-mean-squared (rms) value, and variance of the rectified EMG signal. The interested reader is referred to *Muscles Alive* (25).

Continuing with the evolution of the model, it is possible to derive an expression for the power density spectrum of the EMG signal:

$$S_m(\omega, t, F) = R(\omega, d) \left[\sum_{i=1}^{p(F)} S_{u_i}(\omega, t) + \sum_{\substack{i,j=1 \\ i \neq j}}^{q(F)} S_{u_i u_j}(\omega, t) \right]$$

where $R(\omega, d) = K \sin^2(\omega d / 2v)$ is the bipolar electrode filter function; d is the distance between detection surfaces of the electrode; ω is the angular frequency; v is the conduction velocity along the muscle fibers; $S_{u_i}(\omega)$ is the power density of the MUAPT, $u_i(t)$; $S_{u_i u_j}(\omega)$ is the cross-power density spectrum MUAPTs $u_i(t)$ and $u_j(t)$; p is the total number of MUAPTs that constitute the signal; and q is the number of MUAPTs with correlated discharges.

Lindstrom (8), using a dipole model, arrived at another expression for the power density spectrum:

$$S_m(\omega, t, F) = R(\omega, d) \left[1v^2(t, F) G(\omega d 2v(t, F)) \right]$$

This representation explicitly denotes the interconnection between the spectrum of the EMG signal and the conduction velocity of the muscle fibers. Such a relationship is implicit in the previously presented modeling approach because any change in the conduction velocity would directly manifest itself in a change in the time duration

of $h(t)$ as seen by the two detection surfaces of a stationary bipolar electrode.

ELECTRODES

Two main types of electrodes are used to detect the EMG signal: one is the surface (or skin) electrode and the other is the inserted (wire or needle) electrode. Electrodes are typically used singularly or in pairs. These configurations are referred to as monopolar and bipolar, respectively.

Surface Electrodes

There are two categories of surface electrode: passive and active. Passive electrode consists of conductive (usually metal) detection surface that senses the current on the skin through its skin electrode interface. Active electrodes contain a high input impedance electronics amplifier in the same housing as the detection surfaces. This arrangement renders it less sensitive to the impedance (and therefore quality) of the electrode–skin interface. The current trend is towards active electrodes.

The simplest form of passive electrode consists of silver disks that adhere to the skin. Electrical contact is greatly improved by introducing a conductive gel or paste between the electrode and skin. The impedance can be further reduced by removing the dead surface layer of the skin along with its protective oils; this is best done by light abrasion of the skin.

The lack of chemical equilibrium at the metal electrolyte junction sets up a polarization potential that may vary with temperature fluctuations, sweat accumulation, changes in electrolyte concentration of the paste or gel, relative movement of the metal and skin, as well as the amount of current flowing into the electrode. It is important to note that the polarization potential has both a direct current (dc) and an alternating current (ac) component. The ac component is greatly reduced by providing a reversible chloride exchange interface with the metal of the electrode. Such an arrangement is found in the silver–silver chloride electrodes. This type of electrode has become highly popular in electromyography because of its light mass (0.25 g), small size (< 10 mm diameter), and high reliability and durability. The dc component of the polarization potential is nullified by ac amplification when the electrodes are used in pairs. This point is elaborated upon in later sections of this article.

The active surface electrodes have been developed to eliminate the need for skin preparation and conducting medium. They are often referred to as “dry” or “pasteless” electrodes. These electrodes may be either resistively or capacitively coupled to the skin. Although the capacitively coupled electrodes have the advantage of not requiring a conductive medium, they have a higher inherent noise level. Also, these electrodes do not have long term reliability because their dielectric properties are susceptible to change with the presence of perspiration and the erosion of the dielectric substance. For these reasons, they have not yet found a place in electromyography.

An adequately large input impedance is achieved when resistance is on the order of 10 TΩ and capacitance is small

Figure 6. Examples of active surface electrode in bipolar configurations from Delsys Inc. The spacing between the bars is 10 mm, the length of the bars is 10 mm and the thickness is 1 mm. These electrodes do not require any skin preparation or conductive paste or gels.

(typically, 3 or 4 pF). The advent of modern microelectronics has made possible the construction of amplifiers housed in integrated circuitry which have the required input impedance and associated necessary characteristics. An example of such an electrode is presented in Fig. 6. This genre of electrodes was conceptualized and first constructed at the NeuroMuscular Research Laboratory at Children's Hospital Medical Center, Boston, MA in the late 1970s. They each have two detection surfaces and associated electronic circuitry within their housing.

The chief disadvantages of surface electrodes are that they can be used effectively only with superficial muscles and that they cannot be used to detect signals selectively from small muscles. In the latter case, the detection of "cross-talk" signals from other adjacent muscles becomes a concern. These limitations are often outweighed by their advantages in the following circumstances:

1. When representation of the EMG signal corresponding to a substantial part of the muscle is required.
2. In motor behavior studies, when the time of activation and the magnitude of the signal contain the required information.
3. In psychophysiological studies of general gross relaxation of tenseness, such as in biofeedback research and therapy.
4. In the detection of EMG signals for the purpose of controlling external devices such as myoelectrically controlled prostheses and other like aids for the physically disabled population.
5. In clinical environments, where a relatively simple assessment of the muscle involvement is required, for example, in physical therapy evaluations and sports medicine evaluations.
6. Where the simultaneous activity or interplay of activity is being studied in a fairly large group of muscles under conditions where palpation is impractical, for example, in the muscles of the lower limb during walking.
7. In studies of children or other individuals who object to needle insertions.

Figure 7. Examples of various needle electrodes: (a) A solid tip single-fiber electrode. If it is sufficiently thin, it can be inserted into a nerve bundle and detect neuroelectrical signals. (b) Concentric needle with one monopolar detection surface formed by the beveled cross-section of centrally located wire typically 200 μm in diameter. Commonly used in clinical practice. (c) Bipolar needle electrode with two wires exposed in cross-section, typically 100 μm in diameter. Used in clinical practice. (d) Single-fiber electrode with 25 μm diameter wire. Used to detect the activity of individual muscle fibers. (e) Macroelectrode with 25 μm diameter wire and with the cannula of the needle used as a detection surface. Used to detect the motor unit action potential from a large portion of the motor unit territory. (f) Quadrifilar planar electrode with four 50 μm wires located on the corners of a square 150 μm apart (center to center). Used for multiple channel recordings and in EMG signal decomposition technique. (g) Multifilar electrode consisting of a row of wires, generally used to study the motor unit territory.

Needle Electrodes

By far, the most common indwelling electrode is the needle electrode. A wide variety is commercially available. (see Fig. 7). The most common needle electrode is the "concentric" electrode used by clinicians. This monopolar configuration contains one insulated wire in the cannula. The tip of the wire is bare and acts as a detection surface. The bipolar configuration contains a second wire in the cannula and provides a second detection surface. The needle electrode has two main advantages. One is that its relatively small pickup area enables the electrode to detect individual MUAPs during relatively low force contractions. The other is that the electrodes may be conveniently repositioned within the muscle (after insertion) so that new tissue territories may be explored or the signal quality may be improved. These amenities have naturally led to the development of various specialized versions such as the multifilar electrode developed by Buchthal et al. (29), the planar quadrifilar electrode of De Luca and Forrest (30), the single fiber electrode of Ekstedt and Stålberg (13), and the macroelectrode of Stålberg (14). The single-fiber electrode consists of a thin, stiff, sharpened metal filament, usually made of tungsten. When inserted into a muscle it detects the action potentials of individual fibers. This electrode has

proven to be useful for neurological examinations of deinnervated muscles. Examples of these electrodes may be seen in Fig. 7.

Wire Electrodes

Since the early 1960s, this type of electrode has been popularized by Basmajian and Stecko (31). Similar electrodes that differ only in minor details of construction were developed independently at about the same time by other researchers. Wire electrodes have proved a boon to kinesiological studies because they are extremely fine, they are easily implanted and withdrawn from skeletal muscles, and they are generally less painful than needle electrodes whose cannula remains inserted in the muscle throughout the duration of the test.

Wire electrodes may be made from any small diameter, highly nonoxidizing, stiff wire with insulation. Alloys of platinum, silver, nickel, and chromium are typically used. Insulations, such as nylon, polyurethane, and Teflon, are conveniently available. The preferable alloy is 90% platinum, 10% iridium; it offers the appropriate combination of chemical inertness, mechanical strength, stiffness and economy. The Teflon and nylon insulations are preferred because they add some mechanical rigidity to the wires, making them easier to handle. The electrode is constructed by inserting two insulated fine (25–100 μm in diameter) wires through the cannula of a hypodermic needle. Approximately 1–2 mm of the distal tips of the wire is deinsulated and bent to form two staggered hooks (see Fig. 8 for completed version). The electrode is introduced into the muscle by inserting the hypodermic needle and then withdrawing it. The wires remain lodged in the muscle tissues. They may be removed by gently pulling them out: They are so pliable that the hooks straighten out on retraction.

In kinesiological studies, where the main purpose of using wire electrodes is to record a signal that is proportional to the contraction level of muscle, repositioning of the electrode is not important. But for other applications, such as recording distinguishable MUAPs, this limitation is counterproductive. Some have used the phrase “poke and hope” to describe the standard wire electrode technique for this particular application. Another limitation of the wire electrode is its tendency to migrate after it has been inserted, especially during the first few contractions of the muscle. The migration usually stops after a few contractions. Consequently, it is recommended to perform a half dozen or so short duration contraction before the actual recording session begins.

Figure 8. A bipolar wire electrode with its carrier needle used for insertion.

Electrode Maintenance

Proper usage of wire and needle electrodes requires constant surveillance of the physical and electrical characteristics of the electrode detection surfaces. Particular attention should be given to keeping the tips free of debris and oxidation. The reader is referred to the book *Muscles Alive* (25) for details on these procedures as well as suggestions for sterilization.

How to Choose the Proper Electrode

The specific type of electrode chosen to detect the EMG signal depends on the particular application and the convenience of use. The application refers to the information that is expected to be obtained from the signal; for example, obtaining individual MUAPs or the gross EMG signal reflecting the activity of many muscle fibers. The convenience aspect refers to the time and effort the investigator wishes to devote to the disposition of the subject or patient. Children, for example, are generally resistant to having needles inserted in their muscles.

The following electrode usage is recommended. The reader, however, should keep in the mind that crossover applications are always possible for specific circumstances.

Surface Electrodes

- Time force relationship of EMG signals.
- Kinesiological studies of surface muscles.
- Neurophysiological studies of surface muscles.
- Psychophysiological studies.
- Interfacing an individual with external electromechanical devices.

Needle Electrode

- MUAP characteristics.
- Control properties of motor units (firing rate, recruitment, etc.).
- Exploratory clinical electromyography.

Wire Electrodes

- Kinesiological studies of deep muscles.
- Neurophysiological studies of deep muscles.
- Limited studies of motor unit properties.
- Comfortable recording procedure from deep muscles.

Where to Locate the Electrode

The location of the electrode should be determined by three important considerations: (1) signal/noise ratio, (2) signal stability (reliability), and (3) cross-talk from adjacent muscles. The stability consideration addresses the issue of the modulation of the signal amplitude due to relative movement of the active fibers with respect to the detection surfaces of the electrode. The issue of cross-talk concerns the detection by the electrode of signals emanating from adjacent muscles.

For most configurations of needle electrodes, the question of cross-talk is of minor concern because the electrode

is so selective that it detects only signals from nearby muscle fibers. Because the muscle fibers of different motor units are scattered in a semirandom fashion throughout the muscle, the location of the electrode becomes irrelevant from the point of view of signal quality and information content. The stability of the signal will not necessarily be improved in any one location. Nonetheless, it is wise to steer clear of the innervation zone so as to reduce the probability of irritating a nerve ending.

All the considerations that have been discussed for needle electrodes also apply to wire electrodes. In this case, any complication will be unforgiving in that the electrode may not be relocated. Since the wire electrodes have a larger pickup area, a concern arises with respect to how the location of the insertion affects the stability of the signal. This question is even more dramatic in the case of surface electrodes.

For surface electrodes, the issue of cross-talk must be considered. Obviously, it is not wise to optimize the signal detected, only to have the detected signal unacceptably contaminated by an unwanted source. A second consideration concerns the susceptibility of the signal to the architecture of the muscle. Both the innervation zone and the tendon muscle tissue interface have been found to alter the characteristics of the signal. *It is suggested that the preferred location of an electrode is in the region halfway between the center of the innervation zone and the further tendon. See the review article by De Luca (12) for additional details.*

SIGNAL DETECTION: PRACTICAL CONSIDERATIONS

When attempting to collect an EMG signal, both the novice and the expert should remember that the characteristics of the observed EMG signal are a function of the apparatus used to acquire the signal as well as the electrical current that is generated by the membrane of the muscle fibers. The “distortion” of the signal as it progresses from the source to the electrode may be viewed as a filtering sequence. An overview of the major filtering effects is presented in Fig. 9. A brief summary of the pertinent facts follows. The reader interested in additional details is referred to *Muscles Alive* (25).

Figure 9. Block diagram of all the major aspects of the signal acquisition procedure. Note the variety of physical properties that act as filters to the EMG signal before it can be observed. The term “physiological EMG signal” refers to the collection of signals that emanate from the surface of the muscle fibers. These are not observable.

Electrode Configuration

The electrical activity inside a muscle or on the surface of the skin outside a muscle may be easily acquired by placing an electrode with only one detection surface in either environment and detecting the electrical potential at this point with respect to a “reference” electrode located in an environment that either is electrically quiet or contains electrical signals unrelated to those being detected. (“Unrelated” means that the two signals have minimal physiological and anatomical associations.) A surface electrode is commonly used as the reference electrode. Such an arrangement is called monopolar and is at times used in clinical environments because of its relative technical simplicity. A schematic arrangement of the monopolar detection configuration may be seen in Fig. 10. The monopolar configuration has the drawback that it will detect all the electrical signals in the vicinity of the detection surface; this includes unwanted signals from sources other than the muscle of interest.

The bipolar detection configuration overcomes this limitation (see Fig. 10). In this case, two surfaces are used to detect two potentials in the muscle tissue of interest each with respect to the reference electrode. The two signals are then fed to a differential amplifier which amplifies the

Figure 10. (a) Monopolar detection arrangement. (b) Bipolar detection arrangement. Note that in the bipolar detection arrangement, the EMG signals are considered to be different, whereas the noise is similar.

difference of the two signals, thus eliminating any “common mode” components in the two signals. Signals emanating from the muscle tissue of interest near the detection surface will be dissimilar at each detection surface because of the localized electrochemical events occurring in the contracting muscle fibers, whereas “ac noise” signals originating from a more distant source (e.g., 50 or 60 Hz electromagnetic signals radiating from power cords, outlets, and electrical devices) and “dc noise” signals (e.g., polarization potentials in the metal electrolyte junction) will be detected with an essentially similar amplitude at both detection surfaces. Therefore, they will be subtracted, but not necessarily nullified prior to being amplified. The measure of the ability of the differential amplifier to eliminate the common mode signal is called the common mode rejection ratio.

Spatial Filtering

1. As the signal propagates through the tissues, the amplitude decreases as a function of distance. The amplitude of the EMG signal decreases to approximately 25% within 100 μm . Thus, an indwelling electrode will detect only signals from nearby muscle fibers.
2. The filtering characteristic of the muscle tissues is a function of the distance between the active muscle fibers and the detection surface(s) of the electrode. In the case of surface electrodes, the thickness of the fatty and skin tissues must also be considered. The tissues behaves as a low pass filter whose bandwidth and gain decrease as the distance increases.
3. The muscle tissue is anisotropic. Therefore, the orientation of the detection surfaces of the electrode with respect to the length of the muscle fibers is critical.

Electrode Electrolyte Interface

1. The contact layer between the metallic detection surface of the electrode and the conductive tissue forms an electrochemical junction that behaves as a high pass filter.
2. The gain and bandwidth will be a function of the area of the detection surfaces and any chemical electrical alteration of the junction.

Bipolar Electrode Configuration

1. This configuration ideally behaves as a bandpass filter; however, this is true only if the inputs to the amplifier are balanced and the filtering aspects of the electrode electrolyte junctions are equivalent.
2. A larger interdetection surface spacing will render a lower bandwidth. This aspect is particularly significant for surface electrodes.
3. The greater the interdetection surface spacing, the greater the susceptibility of the electrode to detecting measurable amplitudes of EMG signals from adjacent and deep muscles. Again, this aspect is particularly significant for surface electrodes.

4. An interdetection surface spacing of 1.0 cm is recommended for surface electrodes.

Amplifier Characteristics

1. These should be designed and/or set for values that will minimally distort the EMG signal detected by the electrodes.
2. The leads to the input of the amplifier (actually, the first stage of the amplification) should be as short as possible and should not be susceptible to movement. This may be accomplished by building the first stage of the amplifier (the preamplifier) in a small configuration which should be located near (within 10 cm) the electrode. For surface EMG amplifiers the first stage is often located in the housing of the electrodes.
3. The following are typical specifications that can be attained by modern day electronics. It is worth noting that the values below will improve as more advanced electronics components become available in the future.
 - (a) Common-mode input impedance: As large as possible (typically $> 10^{15} \Omega$ in parallel with $< 7 \text{ pF}$).
 - (b) Common mode rejection ratio: $> 85 \text{ dB}$.
 - (c) Input bias current: as low as possible (typically $< 5 \text{ fA}$).
 - (d) Noise (shorted inputs) $< 1.5 \mu\text{V rms}$ for 20–500 Hz bandwidth.
 - (e) Bandwidth in hertz (3 dB points for 12 dB/octave or more rolloff):

Surface electrodes	20–500
Wire electrodes	20–2,000
Monopolar and bipolar needle electrodes for general use	20–5,000
Needle electrodes for signal decomposition	1,000–10,000
Single fiber electrode	1,000–10,000
Macroelectrode	20–5,000

An example of an eight-channel modern surface EMG amplifier is presented in Fig. 11. Such systems are

Figure 11. An eight-channel surface EMG system from Delsys Inc. The dimensions of this device ($205 \times 108 \times 57 \text{ mm}$) are typical for current day units. Note that the active electrodes connect to an input unit that is separate from the body of the amplifier and can be conveniently attached to the body of the subject.

available in configurations of various channels up to 32, but 8 and 16 channel versions are most common.

Recording Characteristics

The effective or actual bandwidth of the device or algorithm that is used to record or store the signal must be greater than that of the amplifiers.

Other Considerations

1. It is preferable to have the subject, the electrode, and the recording equipment in an electromagnetically quiet environment. If all the procedures and cautions discussed in this article are followed and heeded, high quality recordings will be obtained in the electromagnetic environments found in most institutions, including hospitals.
2. In the use of indwelling electrodes, great caution should be taken to minimize (eliminate, if possible) any relative movement between the detection surfaces of the electrodes and the muscle fibers. Relative movements of 0.1 mm may dramatically alter the characteristics of the detected EMG signal and may possibly cause the electrode to detect a different motor unit population.

SIGNAL ANALYSIS TECHNIQUES

The EMG signal is a time and force (and possibly other parameters) dependent signal whose amplitude varies in a random nature above and below the zero value. Thus, simple average aging of the signal will not provide any useful information.

Rectification

A simple method that is commonly used to overcome the above restriction is to rectify the signal before performing mode pertinent analysis. The process of rectification involves the concept of rendering only positive deflections of the signal. This may be accomplished either by eliminating the negative values (half-wave rectification) or by inverting the negative values (full-wave rectification). The latter is the preferred procedure because it retains all the energy of the signal.

Averages or Means of Rectified Signals

The equivalent operation to smoothing in a digital sense is averaging. By taking the average of randomly varying values of a signal, the larger fluctuations are removed, thus achieving the same results as the analog smoothing operation. The mathematical expression for the average or mean of the rectified EMG signal is

$$\overline{|m(t)|}_{t_j-t_i} = 1/t_j - t_i \int_{t_i}^{t_j} |m(t)| dt$$

where t_i and t_j are the points in time over which the integration and, hence, the averaging is performed. The shorter the time interval, the less smooth the averaged value will be.

The preceding expression will provide only one value over the time window $T = t_j - t_i$. To obtain the time varying average of a complete record of a signal, it is necessary to move the time window T duration along the record. This operation is referred to as moving average.

$$\overline{|m(t)|} = 1/T \int_t^{t+T} |m(t)| dt$$

Like the equivalent operation in the analogue sense, this operation introduces a lag; that is, T time must pass before the value of the average of the T time interval can be obtained. In most cases, this outcome does not present a serious restriction, especially if the value of T is chosen wisely. For typical applications, values ranging from 100 to 200 ms are suggested. It should be noted that shorter time windows, T , yield less smooth time dependent average (mean) of the rectified signal.

Integration

The most commonly used and abused data reduction procedure in electromyography is integration. The literature of the past three decades is swamped with improper usage of this term, although happily within the past decade it is possible to find increasing numbers of proper usage. When applied to a procedure for processing a signal, the term integration has a well-defined meaning that is expressed in a mathematical sense. It applies to a calculation that obtains the area under a signal or a curve. The units of this parameter are volt seconds (V·s). It is apparent that an observed EMG signal with an average value of zero will also have a total area (integrated value) of zero. Therefore, the concept of integration may be applied only to the rectified value of the EMG signal.

$$I\{|m(t)|\} = \int_t^{t+T} |m(t)| dt$$

Note that the operation is a subset of the procedure of obtaining the average rectified value. Since the rectified value is always positive, the integrated rectified value will increase continuously as a function of time. The only difference between the integrated rectified value and the average rectified value is that in the latter case the value is divided by T , the time over which the average is calculated. If a sufficiently long integration time T is chosen, the integrated rectified value will provide a smoothly varying measure of the signal as a function of time. There is no additional information in the integrated rectified value.

Root-Mean-Square (rms) Value

Mathematical derivations of the time and force dependent parameters indicate that the rms value provides more a more rigorous measure of the information content of the signal because it measures the energy of the signal. Its use in electromyography, however, has been sparse in the past. The recent increase is due possibly to the availability of analog chips that perform the rms operation and to the increased technical competence in electromyography. The time-varying rms value is obtained by performing the

operations described by the term in reverse order; that is,

$$\text{rms}\{m(t)\} = \left(1T \int_t^{t+T} m^2(t)dt\right)^{1/2}$$

This parameter is recommended above the others.

Zero Crossings and Turns Counting

This method consists of counting the number of times per unit time that the amplitude of the signal contains either a peak or crosses a zero value of the signal. It was popularized in electromyography by Williston (32). The relative ease with which these measurements could be obtained quickly made this technique popular among clinicians. Extensive clinical applications have been reported, some indicating that discrimination may be made between myopathic and normal muscle; however, such distinctions are usually drawn on a statistical basis.

This technique is not recommended for measuring the behavior of the signal as a function of force (when recruitment or derecruitment of motor units occurs) or as a function of time during a sustained contraction. Lindström et al. (33) showed that the relationship between the turns or zeros and the number of MUAPTs is linear for low level contractions. But as the contraction level increases, the additionally recruited motor units contribute MUAPTs to the EMG signal. When the signal amplitude attains the character of Gaussian random noise, the linear proportionality no longer holds.

Frequency Domain Analysis

Analysis of the EMG signal in the frequency domain involves measurements and parameters that describe specific aspects of the frequency spectrum of the signal. Fast Fourier transform techniques are commonly available and are convenient for obtaining the power density spectrum of the signal.

Three parameters of the power density spectrum may be conveniently used to provide useful measures of the spectrum. They are the median frequency, the mean frequency, and the bandwidth of the spectrum. Other parameters, such as the mode frequency and ratios of segments of the power density spectrum, have been used by some investigators, but are not considered reliable measures given the inevitably noisy nature of the spectrum. The median frequency and the mean frequency are defined by the equations:

$$f_{\text{med}} = \int_0^{f_{\text{med}}} S_m(f)df = \int_{f_{\text{med}}}^{\infty} S_m(f)df$$

$$f_{\text{mean}} = \int_0^f fS_m(f)df \int_0^f S_m(f)df$$

where $S_m(f)$ is the power density spectrum of the EMG signal. Stulen and De Luca (34) performed a mathematical analysis to investigate the restrictions in estimating various parameters of the power density spectrum. The median and mean frequency parameters were found to be the most reliable, and of these two the median frequency was found to be less sensitive to noise. This quality is particu-

larly useful when a signal is obtained during low level contractions where the signal to-noise ratio may be < 6 .

The above discussion on frequency spectrum parameters removes temporal information from the calculated parameters. This approach is appropriate for analyzing signals that are stationary or nearly stationary, such as those emanating from isometric, constant-force contractions. Measurement of frequency parameters during dynamic contractions requires techniques that retain the temporal information. During the past decade time–frequency analyses techniques have evolved in the field of Electromyography, as they have in the realm of other biosignals such as ECG and EEG. Early among the researchers to apply these techniques to the EMG signal were Contable et al. (35) who investigated the change in the frequency content of EMG signals during high jumps, and Roark et al. (19) who investigated the movement of the thyroarytenoid muscles during vocalization. In both these applications, the time–frequency techniques were essential because they investigated muscles that contracted dynamically and briefly.

Much of the work presented here is adapted, with permission, from Refs. 25, pp. 38, 58, 68, 74, and 81. The author thanks Williams & Wilkens for permission to extract this material.

INTRODUCTION

Recording techniques developed over the past three decades have made it possible to study the peripheral and central nervous system (CNS) in detail and often during unconstrained conditions. There have been many studies using the ElectroNeuroGram (ENG) to investigate the physiology of the neuromuscular system, in particular, chronic studies in freely moving animals (1,2). Other studies relate to monitoring the state of the nerve (e.g., in relation to axotomized nerves and regeneration of nerve fibers). Clinically, the ENG is used to measure the conduction velocities and latencies in peripheral nerves by stimulating a nerve at different points along the nerve. Extracellular potentials can be recorded by either con-

centric needle electrodes or surface electrodes. The potentials can be derived from purely sensory nerve, from sensory components of mixed nerve, or from motor nerves (3). The study of extracellular potentials from sensory nerves in general has been shown to be of considerable value in diagnosing peripheral nerve disorders. For an indebt description of the ENG in clinical neurophysiology see Ref. 4. Several studies pertain to the use of sensory signals as feedback information to control neuroprosthetic devices. Studies (5) have shown that the application of *closed-loop* control techniques can improve the regulation of the muscle activation. Techniques using an electrical interface to nerves innervating natural sensors (6-12), such as those found in the skin, muscles, tendons, and joints are an attractive alternative to artificial sensors. Since these natural sensors are present throughout the body, remain functional after injury, and are optimally placed through evolution to provide information for natural feedback control, a rich source of information that could be used to control future FES devices exists as long as a method can be found to access them.

Interestingly, much of the peripheral sensory apparatus in spinal and brain-injured human individuals is viable. This means that the natural sensors are transmitting relevant nerve signals through the peripheral nervous system. Therefore, if the body's natural sensors are to provide a suitable feedback signal for the control of FES systems in paralyzed subjects, the challenge is to be able to extract reliable and relevant information from the nerve innervating the sensors over extended periods.

The nerve cuff electrode still has an unrivaled position as a tool for recording ENG signals from peripheral nerves in chronic experiments (13,14) and as means to provide information to be used in neural prosthesis systems (9,15,16). Other kinds of electrodes are to challenge the cuff electrode, such as intra-fascicular electrodes (6,10,18) or multisite electrodes with hundreds of contacts within a few cubic millimeters (2,10,11,17-19). These types of nerve-interface provide advantages with respect to selectivity and number of sensors.

This article describes the characteristics of the peripheral nerve signals, principals of neural recordings, and the signals obtained with different electrodes in long-term implants. An essential part in the success of recording peripheral neural signals or activating peripheral neural tissue is the neural interface.

THE PERIPHERAL NERVOUS SYSTEM

A peripheral nerve contains thousands of nerve fibers, each of them transmitting information, either from the periphery to the CNS or from the CNS to the periphery. The efferent fibers transmit information to actuators; mainly muscles, whereas afferent fibers transmit sensory information about the state of organs and events (e.g., muscle length, touch, skin temperature, joint angles, nociception, and several other modalities of sensory information). Most of the peripheral nerves contain both afferent and efferent fibers, and the peripheral nerve can thus be seen as a bidirectional information channel.

Figure 1. Figure showing the structure and components of the peripheral nerve trunk. (Adapted from Crouche, 1969, with permission.)

Anatomical Definitions and Structures

If the CNS is defined as the tissues and neural circuitry that comprise the brain and spinal cord, the peripheral nervous system can be defined as the part of the nervous system that lies outside of the CNS. Given some generalization of this definition, the peripheral nervous system consists of the spinal roots, dorsal root ganglions, axons/dendrites, support cells, and sensory end organs. The structure of the peripheral nerve trunk is illustrated below showing the following: nerve trunk, nerve fascicle, axon, schwann cells, epineurium, perineurium, and endoneurium. Though not generally considered part of the peripheral nerve, the nerve can also contain resident macrophages, leucocytes, and other cell types involved in the inflammatory response (Fig. 1).

THE NEURO-ELECTRONIC INTERFACE

The ENG can be described as the extracellular potential of an active peripheral nerve recorded at some distance from the nerve or from within the nerve trunk. The extracellular potential is formed from the contributions of the superimposed electrical fields of the active sources within the nerve. The general form of the extracellular response of a whole nerve to electrical stimulation is triphasic, it is in the lower end of the microvolt scale in amplitude, and loses both amplitude and high frequency content at larger radial distances from the nerve trunk (20).

Principles of Nerve Recordings

All cells of the body have a membrane potential. The membrane potential is a consequence of the cell membrane being selectively permeable to different ion species, resulting in different ion concentrations at the intracellular and extracellular space. The difference in ion concentrations causes an electrochemical voltage difference across the membrane, called the membrane potential. Under normal physiological conditions, the interior of the cell is negative with respect to the extracellular space without a net electric current flowing through the membrane. Therefore, if a

macroscopic view of the cell membrane is justified (i.e., at distances that are large with respect to the thickness of the membrane), the existence of the resting membrane potential cannot be detected at the extracellular space.

Action Potentials. The change in membrane permeability is achieved by opening and closing of ion channels. The kinetics of the opening and closing of the channels determines the shape of the membrane current, which is characteristic for different types of nerve and muscle cells. The membrane potential changes as current flows through the membrane. The course of the membrane potential, from its resting state over an entire cycle of opening and closing of ion channels back to the initial state, is called the action potential. The associated current flowing through the membrane is the action current (Fig. 2).

A widely used model of peripheral myelinated nerve fibers is based on the model of single action potentials of fibers from rabbit sciatic nerve by Chiu et al. (22), comprising only sodium current and a leakage current. This model was adapted to 37°C and to human peripheral nerve conduction velocity by Sweeney et al. (23).

An extensive review of different membrane models can be found in Varghese (24). More recent modeling work of human fibers includes Wesselink et al. (25) and McIntyre et al. (25).

Extracellular Currents and Potential Distribution. During the action potential, current is entering and leaving the cell through the membrane. Since there are no sources or sinks of electricity in the nerve fibers, the current flows in closed loops, and the current entering the cell at one site has to leave at a remote location. Likewise, the current leaving the cell has to reenter at a distant location, resulting in the redistribution and conduction of the current through the extracellular space. The extracellular conduction current (or, more precisely, its associated electric or magnetic field) can be detected and measured. The electroneurogram measures the electric potential field generated by the ensemble of extracellular conduction currents originating from active sites at many different fibers.

Figure 2. Action potential and action current of the squid giant axon (unmyelinated nerve fiber). Time course of the propagating action potential V_m and action current I_m according to the Hodgkin and Huxley model (21). After initial depolarization, the sodium channels open, resulting in a 100-fold increase of sodium conductance, and thus inflow of sodium ions, which depolarizes the membrane potential even further. The delayed opening of the potassium channels (potassium outflow) and closing of sodium channels repolarizes the membrane potential, with a phase of hyperpolarization (below resting potential).

For the case of a single active myelinated fiber in an unbound homogeneous medium, the fiber can simply be modeled as a series of point current sources, representing the nodes of Ranvier, where current is entering and leaving the fiber (if myelin is assumed to be a perfect insulator). The extracellular potential φ of an active fiber can then easily be calculated by superposition of the electric potential fields of point current sources as follows (26):

$$\varphi(x, y, t) = \frac{1}{4\pi\sigma} \sum_n \frac{I_m(t - x_n/v)}{\sqrt{y^2 + (x - x_n)^2}}$$

where σ is the conductivity, I_m the action current (Fig. 2), v the propagation velocity, and $(x_n, 0)$ the position of the node of Ranvier n .

Figure 2 shows the extracellular potential $\varphi(0, y, t)$ of a single active myelinated fiber (10 μm) in unbound homogeneous medium for different distances y from the fiber. For very short distances from the fiber ($y = 1 \text{ mm}$, corresponding to one internodal distance), the extracellular potential follows mostly the shape of the action current from the closest node of Ranvier. With increasing distance from the fiber, not only does the amplitude of the extracellular potential drop rapidly down, but also its shape changes as the potential is averaged over increasingly numbers of active nodes. The influence of fiber diameter and distance from the fiber on the amplitude and duration of the extracellular potential has been discussed in detail in Struijk (26).

The amplitude and shape of the extracellular potential are also strongly influenced by inhomogeneities in the surrounding medium, called the volume conductor (e.g., the highly resistive perineurium, surrounding tissue, or cuff electrodes). For a more realistic (complex) volume conductor than the above infinitely large, homogeneous case, numerical methods are required to calculate the distribution of the

extracellular potential, such as harmonic series expansion, finite difference, or finite element methods.

Electrodes measure the extracellular potential by physically sampling the electric potential in the extracellular space. Depending on the electrode type, this yields either point-wise information (intrafascicular electrodes, needle electrodes, electrode arrays) or measurements averaged over a larger volume (cuff electrodes, surface electrodes). The configuration (monopolar, bipolar, tripolar) and spacing of the electrodes further affect the recording characteristics (e.g., noise rejection, spatial selectivity, diameter selectivity). Computer models are helpful in understanding these recording characteristics and for the development of electrodes with improved selectivity (27–29).

Neural Signals

Neural Signal Characteristics. The previous section, gives the theoretical basis of how the action potential is generated, and how this, in turn, results in a change in the electric field in the extracellular space. These potentials can be detected using electrodes in various recording configurations to maximize the neural signal detected and minimize the noise pickup. These configurations will be discussed in the next section. Here, the ENG signal is characterized. A starting point is to take recordings made by electrodes placed within the nerve fascicle, such as a longitudinal intra-fascicular electrode (LIFE).

Intrafascicular electrodes place their recording sites within the nerve fascicle, but outside of the nerve fiber. The site can be potentially adjacent to an active nerve fiber. An ENG record from an intrafascicular electrode placed in a branch of the tibial nerve in the rabbit model is shown Fig. 3. The record shows the activity from many active nerve fibers firing asynchronously from one another and superimposed upon one another.

Figure 3. (a) Shows the raw record from a LIFE implanted in a medial gastrocnemius nerve branch of the tibial nerve in response to ankle flexion and extension. (b) Shows the spectral composition of the modulated LIFE activity for three different levels of activity starting from baseline, the lowest, to maximum, the highest. It illustrates that the amplitude of the spectral composition varies with the amount of activity, but the distribution remains constant.

If a closer look is taken of this multiunit activity recording, it is possible to see the spiking activity of single nerve fibers, or single unit activity. Analysis on the largest of these single spikes reveals that the amplitude of the activity is on the order of $\sim 10\text{--}100 \mu\text{V}_{\text{pp}}$. The spectral components of intrafascicular ENG records show that, similar to extrafascicular ENG records, the activity has energy starting at ca. ~ 100 Hz. However, unlike the unimodal extrafascicular ENG spectrum, the intrafascicular ENG spectrum is bimodal, with higher frequency components in the $5\text{--}\sim 10$ kHz range (30) (Fig. 4).

Whether the ENG signals are recorded from extrafascicular or intrafascicular electrodes, it can be seen that ENGs are low amplitude signals and require amplification of between $1000\times$ and $100000\times$ to bring the amplitude into the ~ 1 V range where they can be adequately digitally sampled and stored, or recorded on analog tape. Approximate orders of magnitudes of various signals and their approximate spectral frequencies that might appear in an ENG record are shown in the Table 1.

Given the amount of amplification required and the relative amplitudes of the ambient noise that could be

picked-up by the recording electrodes, recording configurations and filtering must be considered to minimize the noise pick-up and maximize the neural signals.

Recording Configurations

Components of a Recording Setup. The previous section gave the theoretical basis of how the action potential is generated and how this, in turn, results in a change in the electric field in the extracellular space. These potentials can, in turn, be detected using a combination of electrodes placed in or around the nerve, and recording instrumentation. A typical recording setup consists of the following components starting (from the input biological input end and working toward the data storage or output):

- Electrodes: The active electrode(s), the ground electrode.
- Differential preamplifier.
- Main-amplifier and signal conditioning.
- Digitization, Interpretation, and storage.
- Visualization and audio monitoring.

Figure 4. The figure shows an ENG recording in response to repeated mechanical activation of muscle afferents by stretching the muscle at various time scales. The amplitudes in all three traces are the same. (Left panel) Trace is the lowest time resolution and the right trace has the highest time resolution. The darker portion of the left trace is shown in the middle trace, which is zoomed in time by a factor of 12.5. The highlighted portion of the middle trace is represented in the right trace, which is zoomed in time by a factor of 20. (Right panel) Trace single spikes are now resolved, while in the other two traces only the gross mass activity can be resolved.

Table 1. Relative Amplitudes and Frequency Ranges of Components of Signals and Noise that Could Be Present in ENG Records

Source	Amplitude Order	Frequency Range
Electrochemical potential	1 V	dc ^a
Motion artefact	100 mV	Broad
Line noise	10 mV	50–60, 100–120
Thermal (electronics)	10 μ V	Broad
Electrocardiogram (ECG)	1 mV	0.1–100 Hz
Electromyogram (EMG)	1 mV	1–1 kHz
Electroneurogram (ENG)	10 μ V	100–10 kHz
Electroencephalogram (EEG)	1 μ V	dc–1 Hz

^aDirect current = dc.

This instrumentation chain is represented schematically below in Fig. 5.

The components of the instrumentation chain can be blocked into four blocks: Preamplifier, Universal Amplifier/Filter, Computer, and Monitor. The preamplifier accepts signals from the electrode. Its function and configuration will be discussed in detail below. The Universal Amplifier/Filter block performs the analog filtering and main amplification, to reduce out of band noise, antialias and further amplify the signal and prepare the signal for the next block. The Computer block performs the digitization interpretation and depending on the application, storage of the neural data. It extracts and stores the information in the neural signal. Parallel to this is a monitoring block, which provides real-time feedback to the experimenter on the quality of the data being collected. In some cases, the monitoring block could be part of the Computer block. Neural signals are conveniently in the audio range, and the quality of the recording can be very effectively evaluated by simply listening to the signal through an audio monitor.

Differential Preamplifier. The differential preamplifier is a key component used in all measurement schemes. This component can also be called the headstage amplifier, preamplifier, or bioamplifier, and so on. In the context of biopotential recordings, the preamplifier is a low noise amplification stage used to amplify biopotentials to voltage levels in which signal conditioning can be performed using standard filters, amplifiers, discriminators, and so on. It

also serves the purpose of impedance matching between the relatively high impedance electrodes at its input and the relatively low impedance input of standard instrumentation.

Differential preamplifiers can be described as an active (powered), three input (\pm reference), one output device. Its main function is to measure a potential at each of its two active input relative to a reference potential measured at the ground input terminal, take the difference of the measured potentials and multiply by a fixed gain. In equation form, it performs the following function:

$$v_{\text{out}} = A_2 \times [A_1(v_+ - v_{\text{ref}}) - A_1(v_- - v_{\text{ref}})]$$

A typical differential preamplifier fitted with a standard connector is shown in Fig. 6 (b), though in practice packaging, connector and form factor for different preamplifiers vary widely. Common to differential preamplifiers are the three input terminals, and one output terminal. Although they can be realized using discrete components, most differential preamplifiers are realized using low noise instrumentation amplifier chips. Since the electrodes attached to the v_+ , v_- , and v_{ref} terminals of the instrumentation amplifier are physically located in different places; this equation implies that a spatial derivative is performed. It can also be seen that the voltage at the reference terminal is common to both active input terminals and should ideally be rejected along with the common mode rejection capabilities of the amplifier, measured by the common mode rejection ratio, CMRR.

One factor, which has a strong influence on the recording performance, is the impedance match of the electrodes at the active input terminals. In voltage controlled voltage source amplifiers the input impedance is much larger than the impedance of components (the electrode + tissue) preceding it so that most of the voltage drops across the input impedance of the preamplifier, and the voltage is adequately measured without attenuation. At the same time, there must be a finite dc current path from the input of the amplifier to ground to supply the required bias current to the input of the amplifier. Since there are no dc components in the extracellular nerve action potential, a commonly used scheme is to capacitively decouple the input to the amplifier. However, mismatches in the impedance of the electrode seen at each terminal of the amplifier can result in degradation of the CMR capacity of the amplifier.

Figure 5. A generic instrumentation chain consisting of a preamplifier that impedance matches the recording electrode to the relatively low impedance filter–amplifier chain, a bandpass filter, main amplifier, data storage and monitoring. Shown also is the grounding configuration of the instrumentation attached to a ground electrode in the tissue.

Figure 6. (a) Shows a schematic representation of the differential preamplifier and its electrode connections when used as a bioamplifier on tissues. (b) Shows a low noise differential preamplifier that could be used to record neural activity with a low impedance electrode.

Though the voltage, the controlled voltage source pre-amplifier scheme is the most commonly used type in current systems, current mode amplifiers, such as the application of microphone transformers have also been successfully used (31). The main limitations to the transformer amplifier scheme are the physical size of the transformer, which precludes their use in multichannel recording systems, and the necessity to carefully match the electrode impedance and transformer bandwidth.

Monopolar. Figure 7 shows the simplest recording configuration, the monopolar recording configuration where the activity recorded from the + terminal of the preamplifier is amplified relative to a common reference electrode. Though the recording configuration is commonly used for recording EEG, *in vitro* electrophysiological preparations and implanted cortical signals, the monopolar recording configuration would be sufficient to record activity from the peripheral nerve only in the ideal noise-free case.

In practice, peripheral nerve electrodes, unlike the surface EEG electrodes on the scalp, or intracortical electrodes, are implanted and used on or in nerves that are

generally surrounded by large biological noise sources, such as nearby skeletal muscles or the heart. As seen in the previous section, these bioelectrical sources have amplitudes that are orders of magnitude larger than the nerve signal, whose spectral domain can overlap that of the nerve activity making it difficult to filter the unwanted EMG activity out of the recording. Altering the recording configuration can reduce the pick-up of these unwanted activities. The monopolar recording configuration could be modified so that the reference electrode is place very close to the recording electrode, but far enough away from the nerve so that it only samples the unwanted EMG activity in the vicinity of the recording electrode.

The pick-up of unwanted radio-frequency (RF) noise, such as line noise, through the lead wires between the electrode and the amplifier, is a second problem. To adequately ground the recording system, the reference must have a low impedance dc path between the tissue and the electronic ground points. By necessity, the reference electrode should have a large area. The recording electrode, on the other hand, must sample the electric potential from a small area of nerve in order not to short out the nerve activity. The relative impedance of the recording and reference electrodes is not balanced, making the RF pick-up in each of these two electrodes leads different, and not cancelled by the CMR of the differential amplifier.

Another problem with the monopolar recording configuration arises when one wants to record from more than one channel. To minimize the pick-up of local EMG activity, one might use multiple recording and ground electrodes. However, in general, it is not good practice to have multiple ground electrodes in a single recording set-up (see Fig. 12). Each ground electrode represents a low impedance electrical pathway, through which large stray ground loop currents might pass. Such currents could exist during electrical stimulation or accidental electrocution.

Figure 7. The monopolar recording configuration consisting of a recording electrode on or in the peripheral nerve and a common indifferent/ground electrode.

Bipolar. The bipolar recording configuration overcomes many of the problems of the monopolar recording configuration and is the most commonly used recording configuration for most neural electrodes excluding cuff

Figure 8. Bipolar recording configurations. (a) Shows a standard bipolar configuration where the signals from one recording electrode are amplified with respect to a second electrode that samples the ambient noise, the indifferent electrode. A separate ground electrode is placed somewhere in the tissue. The differential bipolar recording configuration (b) places a second recording electrode in or on the nerve and the difference of the signals from two active electrodes is amplified.

electrodes. The bipolar recording configuration requires two recording electrodes and a low impedance reference electrode. The second recording electrode is matched to the first recording electrode and is introduced to sample the local noise in the vicinity of the first recording electrode. The two recording electrodes are attached to a differential preamplifier, which amplifies the relative difference of the potentials seen by the first electrode and those seen by that of the second electrode. Thus, the local EMG activity is seen by the differential preamplifier as common mode and is rejected. Similarly, since the two recording electrodes are matched, the RF noise induced on their lead wires is similar and is rejected by the preamplifier. The second electrode effectively samples the noise, but not the neural signal, and is referred to as the indifferent electrode (Fig. 8).

A variation on the bipolar recording configuration is the differential bipolar recording configuration. In this configuration, a second active recording electrode is introduced in or on the nerve instead of an indifferent electrode reducing the total number of electrodes that needs to be implanted. Additional channels can be introduced with the addition of matched recording electrode pairs and their associated preamplifier. Each additional preamplifier shares a common reference electrode to maintain only one low impedance path to ground, and minimizing the hazards of ground loops (see below).

The neural component of the potentials recorded by the electrodes is generated by a traveling waveform, which appears at the different recording sites along the nerve at different times. Thus, there are some consequences in using the differential bipolar recording configuration to the shape of the recorded action potential. Because the action potential is a traveling waveform, measuring the action potential at two different locations along the nerve and taking the difference, $v(t_1, s_1) - v(t_1, s_2)$, can be related to measuring the action potential measured at one location but at two different times, $v(t_1, s_1) - v(t_2, s_1)$. This relationship assumes that the two electrodes record the action potential equally, and the distance between the recording

sites are appropriate. $v(t_1, s_1) - v(t_1, s_2)$ is $\Delta v / \Delta s$, while $v(t_1, s_1) - v(t_2, s_1)$ is $\Delta v / \Delta t$. The relationship between the space interval, Δs , and the time interval, Δt , is the conduction velocity of the action potential, $\Delta s / \Delta t$. Therefore, the shapes of action potentials recorded using the differential bipolar configuration are roughly the derivative of the action potential recorded using the monopolar configuration. This alters the generally monophasic action potentials recorded by monopolar recordings to biphasic action potentials.

There is a dependence on the amplitude of the recorded action potential with the spacing between electrodes. The amplitude increases with electrode spacing until the spacing approaches the wavelength of the action potential. The wavelength of the action potential is dependent on the conduction velocity, which is related to the caliber of the nerve fiber. In general, distances should be kept > 1 cm for cuff electrode recordings (32), and > 2 mm in the case of differential bipolar recordings with LIFE (33).

Tripolar. The tripolar configuration is the most commonly used recording configuration with the nerve cuff electrode. The nerve cuff electrode is an extrafascicular recording configuration which places the active recording sites outside of the nerve fascicle. Since the perineurium has a relatively high impedance, most of the current generated by the nerve fiber during an action potential is restricted to within the fascicle. To maximize the signals, the nerve cuff design surrounds the nerve bundle with an insulating silicone tube that restricts whatever current leakage from the nerve bundle to the space between the nerve bundle and the insulating cuff. Let us first consider a cross sectional schematic of the electrode structure with a bipolar recording scheme as shown in Fig. 9.

One particular advantage of the cuff electrode is that the electrode is generally immune to noise sources that are lateral to the nerve and cuff electrode since they produce electrical fields that are shielded by the nerve cuff and shorted by the circumferential recording site of the electrode. However, noise sources producing electrical fields

Figure 9. Bipolar differential recording scheme used with the cuff electrode. The insulating cuff restricts the current from the nerve bundle to within the cuff to maximize the voltage generated from the nerve.

that are perpendicular produce a gradient through the nerve cuff, which is amplified by the bipolar recording configuration.

The tripolar recording configuration is a means to reduce or eliminate the longitudinal potential gradients of noise sources outside of the cuff. Two variants of the tripolar configuration are shown below in Fig. 10.

Longitudinal potentials from sources outside of the nerve cuff are influenced by the insulating cuff and linearized within the cuff. The tripolar recording configuration takes advantage of this property and averages the potentials seen by the outer two electrodes to predict the extra-cuff noise potential seen at the central electrode, either by directly measuring and averaging the signals, as in the True Tripolar configuration, or by shorting the contacts of the outer two electrodes, as in the Pseudo-Tripolar configuration (shown below in Fig. 11).

The tripolar recording configuration introduces another differentiation operation on the shape of the action potentials recorded, and action potentials recorded with the tripolar recording configuration are triphasic.

Cabling. The cabling between the electrode active site and preamplifier is a major source of noise that can be minimized by taking care during cabling. Line noise and RF noise is induced in the leads between the electrode and the preamplifier since they act as antennae. The effect is similar to that with high impedance wired microphones.

Figure 11. Tripolar recording configuration in a cuff electrode.

Similar strategies could be used to reduce noise pickup. Lead lengths should be kept as short as possible, though, in the case of implanted electrodes, this may not always be practical or possible since cables from multiple locations are often bundled together and routed to a common percutaneous connector to minimize the number of holes through the skin. Another strategy is to twist the differential lead pairs together so that the noise induced in each pair is nearly the same and can be reduced using the CMR of the differential pre-amplifier. When appropriate, shielded cabling could be further be used, though care should be taken to minimize ground loops when multiple shielded cables are used.

Grounding. A critical factor influencing the quality of the ENG recording is how the system is grounded. A low impedance path to ground must be established between the preamplifier and tissue to keep the input stage of the preamplifier stable and out of saturation. In acute animal preparations, the experiment is commonly performed on a conductive metal surface, which is tied to ground to a common internal ground electrode to reduce line noise. In chronic animal experiments as well as in human implanted systems, this means to reduce noise is not an option since the subject is autonomous and freely moving. In this case, a ground electrode with large surface area, such as braided stainless steel shields, can be used to establish a single ground point to the tissue. Because the ground electrode is intended to provide a low impedance pathway to a ground potential, the ground electrode

Figure 10. Tripolar recording configurations. (Left panel) Shows the true tripolar recording configuration consisting of a double differential amplification circuit. (Right panel) Shows a pseudo-tripolar recording technique, which approximates the true tripolar recording configuration by shorting the outer two electrodes 1 and 3.

provides a reference 0 potential in the tissue, and the potential of the tissues immediately surrounding the ground electrode forms a 0 isopotential. Multiple ground points to the tissue are typically not a good idea since each ground electrode would have a different chemoelectric potential even if they are made of the same material, and currents would flow from ground electrode to ground electrode to maintain a 0 isopotential at each ground point.

The issue of ground loop currents is particularly a problem when stimulation is performed at the same time as recording and if the stimulator shares the same ground with the recording circuit. Since each ground electrode is at the same potential, the current from a stimulator can flow into one ground electrode and out of another ground electrode, as shown in Fig. 11, making it nearly impossible to predict the current flow and location of stimulation. If the magnitude of stimulation is large, such as with surface stimulation, a significant portion of the current could flow through the ground electrodes since the impedance of the tissue and stimulating electrodes can be considerably higher than the impedance of the ground electrode and ground line. Current flow through the ground line can result in large artifacts and potential damage to high gain amplifiers.

One strategy to reduce ground loop currents especially during stimulation is to electrically isolate different circuits from one another. Circuits, such as the analog amplifier chain that demand low noise, are kept physically in different subcircuits from circuits that are noise-producing, such as stimulator circuits or digital circuits. If these different types of circuits must reside on a common PCB or ASIC, Parallel or Mecca grounding schemes with ground planes surrounding each circuit type can be established to prevent noise from spilling over and interfering with noise sensitive parts of the circuit (34). The strategy applied to Functional Electrical Stimulation (FES) systems where stimulation and recording sites are in close proximity to one another is to electrically isolate the stimulating circuit from the recording circuit. This makes each circuit independent from the other so that currents originating from the stimulation circuit see a high impedance pathway with no return current path in the recording system (Fig. 12).

Figure 12. Illustrates potential ground loop currents that can be induced during stimulation if multiple ground electrodes (shown as triangles) are used. Since each ground electrode represents the same potential, the nearest ground electrode can draw current, which passes through the ground plane and out of the other ground electrodes, increasing the uncertainty of the point of stimulation.

Figure 13. Schematic of a typical optoisolator using diode–diode coupling.

Optoisolators. An effective means to isolate circuits is with optoisolators. Optoisolators consist of two electrically independent halves: a transmitter, and a receiver. The basic analog optoisolator transmitter translates electrical currents into light intensity, typically through an LED. The transmitted light is detected with a phototransistor or photodiode receiver, which gates a current in the receiver that is mapped to the transmitter light intensity (Fig. 13).

If the transmitter and receiver are independently grounded and powered, this combination of optical transmitter/receiver electrically isolates the circuits at its input and output. This, of course, implies that when using optocouplers, each isolated circuit must have its own power supply and ground. The unisolated receivers can share a single power supply. A point should be made here about the number of ground electrodes in a recording set-up using multiple isolated recording/stimulation circuits. Since each isolated circuit must have its own ground, if several optoisolated recording/stimulation circuits are used, then each independent circuit must have its own single ground electrode. Ground loops between the circuits cannot form because the grounds are independent from one another, and there is no low impedance return path for ground loop currents to follow.

The optocoupler shown in the above Fig. 13 is a non-linear device that is dependent on the coupling of the diode characteristics of the transmitter and receiver. Linear analog optocouplers also exist that linearizes the diode characteristics using feedback with a diode–transistor coupling instead of the diode–diode coupling. The diode–diode coupling, though nonlinear, has a relatively fast response time, with rise and fall times on the order of $2\ \mu\text{s}$. The diode–transistor coupling scheme, however, is bandwidth limited to considerably $< 10\ \text{kHz}$. Newer linear optocouplers attempt to overcome the bandwidth limitation by sampling and flash converting the input voltage to a digital value, transmitting the digital value and reconstructing the analogue value with a DAC (Fig. 14).

Electrode Impedance

Frequency Dependence of the Impedance. The impedance of the electrode is a function of the electrochemical properties of the electrochemical interface. Further discussion on the electrochemical interface and impedance can be

Figure 14. Use of optoisolated amplifiers and an optoisolated stimulator eliminates the ground loops shown in Fig. 8 by eliminating low impedance return paths to the tissue or stimulator circuit. Note that each isolated subcircuit has its own independent ground. Moreover, since there is no current flowing through the main ground from the tissue (shown as a dashed triangle), the main ground does not need to be grounded to the tissue.

found in other sections of this volume and in Grimnes and Martinsen (35).

A typical impedance spectrum for a platinum electrode is shown in Fig. 13. Though the absolute magnitudes of the impedance will vary depending on the total area of the electrode active site and the material used, this figure shows the general shape and characteristics of the impedance spectrum. Depending on the type of electrode used, the upper corner frequency and the lower corner frequency can be shifted. Similarly, the low frequency and high

frequency segments (the segment < 1 Hz, and > 1 kHz, respectively, in Fig. 15) can be higher or lower than shown.

As seen earlier, most recording configurations rely on the common mode rejection ratio, CMRR, of the differential preamplifier to reduce noise pick-up and maintain stability of their neural recording. One consequence of the frequency dependence on the electrode impedance is that it influences the common mode rejection ratio. The differential preamplifier and its input can be represented by the following, where V_{cm} represents the common mode noise, which is to be rejected, and V_{dm} represents the differential nerve signal, which is to be amplified (Fig. 16).

Assuming an ideal preamplifier where the two input resistances R_{in+} and R_{in-} are equal, and applying the differential preamplifier equation given earlier, the common mode rejection ratio can be represented by

$$CMRR = \frac{|A_{dm}|}{|A_{cm}|} = \left| \frac{Z_+ + Z_- + 2R}{Z_+ - Z_-} \right|$$

In the ideal case, where the electrode and tissue impedances are matched, then the CMRR for an ideal differential preamplifier becomes infinite. However, real electrodes are relatively difficult to match, especially when dealing with small, high selectivity active site electrodes. A 10% error in electrode impedance at 1 kHz is common even with matched electrodes. Based on the CMRR equation and typical impedance shown earlier, the CMRR dependence versus, frequency can be calculated (Fig. 17).

It shows that because of the relatively high R_0 impedance at low frequency, there can be degradation in the CMRR, which results in inclusion of some of the relatively

Figure 15. (a) Shows a typical metal electrode impedance spectrum and its fit to the Cole model shown in (c). (b) is the Warburg representation of the impedance spectrum where the real Z is plotted with respect to the negative of the imaginary Z .

Figure 16. Shows a model of the differential preamplifier and its connections to input impedance loads, common mode, and differential mode inputs. The common mode input can represent noise that we hope to exclude from the ENG while the differential mode input represents the neural signal. The input Z represents the tissue, electrode, and whatever input network is used between the amplifier input and the signal sources.

high amplitude noise that exists at these frequencies. Similarly, not all of the ECG and EMG will be rejected. Therefore, inclusion of noise components from these sources should be expected in the raw ENG record and must be filtered before analysis and use of the ENG can be considered. High pass filtering the output of the differential preamplifier can remove much of the out of band noise not rejected by the CMR of the differential amplifier, but care should be taken to ensure that the differential preamplifier is operating within its linear dynamic range.

EXAMPLES OF LONG-TERM PERIPHERAL NERVE INTERFACES

Peripheral neural electrodes can be grouped according to the way that they interface with the peripheral neural tissue. They can be grouped into three main types: *regenerating*, *intra-neural*, and *extra-neural electrodes*. Common for all electrode interfaces presented here are that they

Figure 17. The frequency dependence of the CMRR is shown for an ideal preamplifier using electrodes that are mismatched by 10%. The frequency dependence of the electrodes has a large influence in the CMRR, which resembles the inverse of the electrode impedance.

record the extracellular potential from one or more peripheral nerve axons simultaneously (also referred to as extracellular electrodes). A fourth electrode group aims instead to record the intracellular potential of individual cells (also referred to as intracellular electrodes). In this case, the active recording site is placed inside a cell, so the electrode must therefore be carefully positioned and held in place during the entire duration of the recording. With their use, there is the risk of permanently breaking the membrane and injuring or killing the cell. As such, intracellular electrodes can be used acutely *in vitro*, *in situ*, or *in vivo*, however, they are not suitable for chronic animal, human or clinical use because of mechanical stability issues and the unavoidable damage to the cells that they record from. These electrodes are therefore not considered further here.

The choice of an optimal peripheral neural electrode largely depends on the application or the experimental design. One electrode might prove useful for one purpose, but not for suitable for another. A vast number of parameters have been used in the literature to describe, characterize, and compare neural interfaces. Most electrode interfaces can not only be used for recording from peripheral nerves, but also for applying electrical stimulation to the nervous tissue. However, the focus here will be on peripheral neural interfaces for recording. To provide a base for comparison between electrode types, the discussion will focus on the following issues:

- Design parameters, including: The rationale for design, the ease of use and the cost of manufacturing and ease of implantation.
- Application of the electrode, including: Recording selectivity and recording stability, expected lifespan, biocompatibility and robustness, and application examples.

Regenerating Electrodes

Introduction. Peripheral nerve axons spontaneously regrow after dissection or traumatic injury. The working principle of a *regenerating electrode* is to fit an electrode in the path between a proximal and distal nerve stump after a deliberate cut or traumatic nerve injury, and to guide the neural regrowth through perforations in the electrode structure. Ideally, the axons will grow through the perforations and allow very high resolution (single axon) recordings.

Sieve Electrodes

Design. Regenerating electrodes are often referred to as *Sieve electrodes*, inspired from their appearance. The structures are typically based on a sieve-shaped or perforated diaphragm, which contains an array of holes. The active sites are placed inside the sidewalls of the hole or in their immediate surroundings (similar to a printed circuit board via) to make physical contact with an axon growing through the hole. They are often designed incorporating a used small flexible tube made of a biocompatible material (e.g., polyimide or silicone) that is used to hold the two ends of the transected nerve stumps in place with the sieve

Figure 18. (a) Sketch of a Sieve electrode. The proximal and distal nerve stumps are fed into a guide tube. Neural axons must grow through holes in the Sieve electrode to reconnect with the neural axons on the other side. (b,c) Examples of Sieve electrodes. (d) shows the Sieve electrode *in situ*. (Reproduced with permission from T. Stieglitz, Fraunhofer Inst., Germany.)

electrode structure fixed in place between them. The tubes work to help guide the growing axons and to hold the electrode structure in place (36) (see Fig. 18). The first generations of Sieve electrodes were developed more than two decades ago (37). With the development of micromachining techniques, the devices have become considerably smaller and further enabled more suitable connections between the electrode and the surrounding world (38). These newer generations of sieve devices are made of silicon (39–41), polyimide or silicone substrates (38,42). Sieve electrodes have been designed with various shapes of the holes [round (40), squares (43), or longitudinal slots (39)]. The shape of the hole does not seem to have a major effect on the regrowth of the axons (36), but other design parameters, (such as the hole size, the thickness of the sieve diaphragm, and the relative amount of open versus closed space (also referred to as the *transparency factor*) have been found to be important. The thickness of the sieve diaphragm is typically in the order of 4–10 μm (36,40,41). Several findings suggest that 40–65 μm diameter Sieve holes work well (41,43,44), however, Bradley et al. (41) found that the holes could be as small as 2 μm . This may be explained by the difference in transparency factors of the electrodes. A high transparency factor is needed if the holes are small to secure regrowth (45). Major effort has also been put in to researching the use of neural growth factors (NGF) and how these may assist in promoting the spontaneous regeneration, and this may become an important factor in the future success of the *Sieve* electrodes.

Application. Bradley et al. (46) was among the first that obtained long-term recordings using sieve electrodes in mammals. They recorded from the rat glossopharyngeal nerve, which is mainly sensory, mediating somatosensory and gustatory information from the posterior oral cavity. Spontaneous activity was observed up to 7 weeks after implant. Evoked compound sensory responses were recorded up to 17 weeks after implantation. Other long-term evaluation studies have been reported by, for exam-

ple, Mesninger et al. (42,47,48). Despite the growing number of reports on long-term usage of Sieve electrodes, they have not yet been tested in humans. An ideal axon-to-axon reconnection through a *Sieve electrode* could provide the ultimate interface to monitoring peripheral neural activity, but to date, this concept has not been proven in humans. Deliberate transection of a peripheral nerve to allow implant of a sieve electrode is a highly invasive procedure, and the success of the implant can only be evaluated several weeks after implantation (36). The current designs are not optimal since some axons may stop grow when they meet a wall and not a hole (36). Furthermore, it is currently not possible to control what fiber types regenerate. It has been shown that myelinated fibers are more likely to grow through than unmyelinated fibers, and large fibers are more likely to grow through than small fibers (49). It will be necessary to obtain a detailed map of what kind of sensory or motor axons have reconnected in order to interpret the peripheral neural signals properly (Fig. 19).

Intraneural Electrodes

Introduction. Intraneural electrodes are defined as electrodes that penetrate the endoneurium and perineurium of a peripheral nerve or the dorsal root ganglion (DRG) neuropil. The active sites are placed in the extracellular space in close proximity with the nerve fibers, and therefore the electrodes aim to record from one single axon or from a small population of axons. The intraneural, penetrating electrodes are dependent on the insulating properties of the epineurium/perineurium to record.

Microneurography. Microneurography is a procedure in which a small needle electrode is placed directly inside a nerve fascicle. The aim is to record from one axon or a small population of axons to study basic neural coding in the animal or human subjects, or as a diagnostic tool in clinical practice. Sketches of two types of microneurography electrodes are depicted in Fig. 19.

Figure 19. Microneurography electrodes. (a) A drawing of the geometry of a typical, commercially available tungsten needle electrode. A separate ground or indifferent electrode must be placed in the close surroundings (Drawings appear courtesy of Dr. K. Yoshida.) (b) A drawing of a concentric needle electrode. One or two fine wires are threaded through a hypodermic needle and attached

Design. A classic needle electrode is manufactured from a stiff core material (e.g., tungsten, stainless steel, or carbon fiber) surrounded by a layer of insulating material. The Tungsten needle electrode typically has a 200–300 μm base diameter and a 2–4 μm tip diameter to ensure that the material is stiff enough to be pushed through the skin and muscle tissue and enter the perineurium without damaging the tip. The needle tip is uninsulated to create the active site. A separate ground wire must be placed subcutaneously in the close surroundings of the recording electrode (50,51).

A variation of the classic needle electrode was developed to allow more recording sites to be placed inside the nerve. The concentric needle electrode consists of one or more fine recording wires threaded through a hypodermic needle. The fine wires are glued in place with an epoxy adhesive. The wires are typically made from tungsten, platinum, or platinum–iridium, and have a 20–25 μm diameter that provides a smaller, and thereby more selective recording, site than with the Tungsten needle electrode. An active site is made at the end of the wire by simply cutting the wire at a straight or slightly oblique angle. The hypodermic needle has a typical outer diameter of 200–250 μm and an inner diameter of 100 μm . The hypodermic needle tip provides a cutting edge for easy insertion of the electrode. Further, the needle shaft works as the ground during recording (52).

The microneurography electrodes are implanted perpendicular to the nerve trunk, and they are typically inserted by hand or using a micromanipulator. These electrodes are inexpensive, and they are typically and both types are easily manufactured by hand.

Application. Since Vallbo and colleagues developed the microneurography technique for more than three decades ago, the technique has proved to be a powerful tool in

clinical experiments on conscious humans in hundreds of studies (51). However, the technique has a number of clear limitations. Placement of one single recording electrode may be extremely time consuming, and the delicate placement may easily be jeopardized if the animal or human subject moves. The microneurography needle electrodes are considered safe for short-term experiments, but they are not applicable for long-term implant and recording in animals or humans.

Longitudinal Intrafascicular Electrodes. The longitudinal intrafascicular electrodes (LIFE) are implanted parallel to the main axis of the peripheral nerve, and the active site of the electrode is placed along recording wires and not at the tip. The active sites typically record from a small population of axons.

Design. One of the first LIFE designs consisted of a simple 300 μm coiled stainless steel wire that was implanted into the nerve using a 30G hypodermic needle (53). The size of the hypodermic needle and implanted electrode may cause unnecessary injury to the nerve, and it also made it unsuitable for implantation in small nerves. Pioneering work was later done at University of Utah, as an attempt to solve these problems. A metal-wire LIFE was developed, see Fig. 21b (54). Here the 1–2 mm recording sites are created on 25 μm insulated, platinum–iridium wire. The recording wires are soldered to larger stainless steel lead-out wires, and the connections are protected by sliding a silicone tube over the solder joint. A polyaramid strand is threaded through this loop and glued to a 50–100 μm electrosharpened Tungsten needle (much similar to the tungsten needle electrode shown in Fig. 19). The needle is used to penetrate the perineurium/epineurium and pull the recording wires into place. The large lead-out wires remain outside the nerve. The electrode is sutured to the epineurium to hold it in place. The lead-out wires are then tunneled subcutaneously through the body to a chosen exit point. These metal-based LIFEs are relatively low cost, and they can be hand built. One of the disadvantages is the limited number of fine wires that can be fitted into one nerve. Further, the hand-building procedure does induce some variability in the size of the recording site, which influences the impedance and signal/noise ratio.

Later generations include polymer-wire LIFEs. Instead of using platinum–iridium wire, the recording wires are here based on 12 μm kevlar fibers. A metal is first deposited onto the kevlar to make the wire conductive, and a layer of silicone insulation is then added only leaving the recording sites exposed (55,56). The purpose of decreasing the intrafascicular wire size was to make the wires more flexible.

Application. The development of the LIFE has mainly been driven by the need for alternative and safe neural interfaces for clinical neuroprosthetic systems. Goodall et al. implanted the 25 μm platinum–iridium wire LIFEs in cat radial nerves and demonstrated that it was possible to obtain selective recordings of afferent activity from up to 6 months (59). Yoshida et al. used the same types of LIFES for recording neural activity in chronically

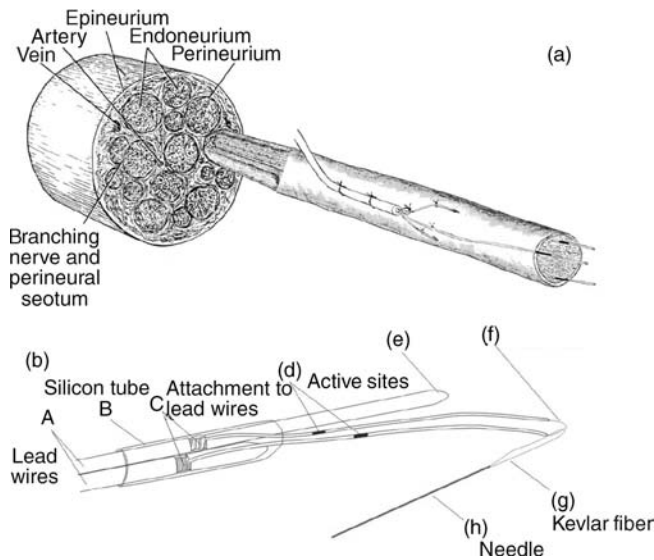

Figure 20. (a) Placement of a metal-wire LIFE electrode inside a whole nerve fascicle. Only the fine wires with the active sites are threaded through the nerve whereas the remaining part of the LIFE is located outside the epineurium. (b) is a line drawing of a two-channel metal-wire LIFE electrode. (a) Lead-out wires are located outside the body and tunneled through the body to a chosen exit point. (b,c) A silicone-tube is placed over the connection point for protection. (d) Active sites on the recording wires. (f-h) A polyaramid fiber links the recording wire to a tungsten needle. implanted cats. These studies characterized the effect of electrode spacing for rejecting EMG and stimulus artifacts and explored the possibility of using multichannel recordings for noise reduction. Yoshida and Stein (33) also explored the possibility of extracting joint angle information from muscle afferent signals recorded with LIFEs (6). The information was used as feedback in closed-loop control of the ankle joint in the cats. The chronic recording stability and biocompatibility of the polymer-wire LIFES have been demonstrated by Malstrom et al. (58) in dorsal rootlets and in peripheral nerve (59) (Fig. 20).

Silicon-Based electrodes. The design and manufacturing of silicon-based electrodes take advantage of often sophisticated microfabrication techniques. These electrodes may be inserted transversely into the peripheral nerve as the microneurography needle electrodes, or they may be inserted longitudinally as the LIFE electrodes. Many groups around the world have designed, developed, and tested different silicon-based electrodes, however, the vast majority of those are developed for interfacing with the cerebral cortex tissue. Many of these designs are currently considered unsuitable as chronic peripheral nerve implants because of the risk of mechanical failure of the rigid base structure or small, thin electrode shafts. A notable exception to this view is the Utah array. One electrode that has been used for both peripheral nerve and cerebral cortex implantation is presented here.

Figure 21. The 100-channel UTAH array. The electrode was originally developed at University of Utah, by Dr. R. A. Normann and colleagues. The electrode is commercially available through Cyberkinetics Inc. (Courtesy of Dr. R. A. Normann, University of Utah.)

Design. The UTAH array was originally developed by Normann and colleagues at University of Utah, and this electrode is now commercially available through Cyberkinetics Inc. The UTAH array is a three-dimensional (3D) silicon structure usually consisting of 100 penetrating electrodes arranged in a 10×10 array (see Fig. 21). Each needle is a long, tapered structure that is 1.5 mm long and has an $80 \mu\text{m}$ diameter at the base. The distance between the needles is $400 \mu\text{m}$. The base substrate for this electrode is silicon, and glass is used as insulation material. Only the very tip of each needle is deposited with gold, platinum, or iridium to form the active site (59). Fig. 22 shows an array with equal height needles, which was originally designed for recording from the cerebral cortex where the neurons of interest are often located at the same depth. A slanted UTAH array was designed with different lengths of the needles to better target different layers in the cerebral cortex or to accommodate for the fact that fascicles in a peripheral nerve are located at different depths. Implantation of the UTAH array requires a special insertion tool that shoots the electrode into the neural tissue in a controlled manner. This is necessary because the high density of the needles increases the amount of force that is necessary to penetrate the dura or the epineurium. Further, the insertion tool avoids the elastic compression of the neural tissue and possibly damage of the neural tissue that was found during manual insertion (60).

Application. The recording properties of the Slanted UTAH array was first tested by Branner and colleagues in acute cat model (61,62) and later in similar chronic cat implants (2). The 100-electrode array was inserted in the cat sciatic nerve using the pneumatic insertion tool (described above). The acute work demonstrated that it was possible to achieve highly selective recordings with the array. In the chronic experiments, the array was held in place using a silicone cuff (self-spiraling or simply oval shaped) to protect the implant and surrounding tissue, to hold the implant in place, and to electrically shield the electrode. This containment was found to be important for the long-term survival of the electrode. In the chronic experiments, electrodes with lead wires were implanted

up to 7 months, however, it was only possible to obtain stable recordings for a few days after implant.

The slanted UTAH array has also been implanted in dorsal root ganglions (through the dura) in acute cat model to evaluate the neural coding of the lower leg position (10). In this work, it was possible to obtain selective recordings from the UTAH arrays over the duration of the experiment. The UTAH array has recently been implanted in a human volunteer (in a peripheral nerve in the lower arm), however, the results are pending (63). The UTAH array is also currently under clinical evaluation as a cortical interface in humans by Cyberkinetic, Inc.

Extraneural Electrodes

Introduction. The extraneural electrodes are the least invasive interfacing technique presented here. They are defined as electrodes that encircle the whole nerve or are placed adjacent to the nerve without penetrating the epineurium or dorsal root ganglion neuropil. The electrodes record from a large number of nerve fibers at the same time.

Circumferential Cuff Electrodes. The cuff electrode is probably the peripheral nerve interface that appears with the largest number of variations in designs and configurations. Only the main designs will be presented here. It is the most mature and widely used chronically implanted electrode for use in neuroprosthetics and has been used in a large number of animal studies and implants in human subjects (see section below).

Design. A circumferential cuff electrode consists of a tube or cuff that is placed around the whole nerve. The active sites are attached to the inside of the cuff wall to make contact with the epineurium (see Fig. 22). The tube wall works as an insulating barrier keeping extracellular currents emerging from the nerve within the cuff and blocking electric currents from other surrounding tissue (predominantly muscle activity, but also activity from other nerves) outside of the cuff. The tube wall has found to be essential to obtain measurable voltages from the

nerve trunk and to achieve a good signal/noise ratio. The cuff tube or wall is made of a flexible, biocompatible material, such as silicone, (1,64,65) or polyimide (66,67). The cuffs may be handmade or microfabricated. The microfabrication technique has the advantage that thinner walls can be obtained.

The shape and number of active sites placed inside the cuff wall vary. The active sites are typically made of inert metals, such as platinum or platinum-iridium. In the classic configuration, a cuff electrode consists of a silicone tube lined with two or more thin conductive rings that are displaced from one another along their common axis (69). In this design, the number of active sites is usually three, but more may be fitted into the cuff depending on the application. The large conductive rings record from a large number of fibers within the nerve they encircle. Later designs placed several, smaller active sites around the inner cuff wall in an attempt to interface individual fascicles within the nerve trunk, and thereby increase the selectivity of the cuff recording (68,69). The number and size of the active sites have a large impact on the recording and stimulation selectivity, which will be discussed in the next section.

The cuff electrode is fitted onto a nerve by sliding the nerve into a longitudinal slit in the cuff wall while traction is placed on the cuff wall to keep the slit open. The procedure may be made easier for the experimenter/surgeon by gluing a number of sutures to the outside of the cuff wall (see Fig. 22a). The experimenter/surgeon can grab onto these sutures, pull the cuff open, and slide the cuff in place around the nerve. Knots are tied to close the cuff and secure that extracellular current is contained inside the cuff, which is important to achieve good recordings. Other closure mechanisms have been attempted.

1. A hinge or zipper-like closure has been suggested by Dr. M. Haugland, Aalborg University, Denmark [see Fig. 22c and patented by (70)]. Here the cuff is cut open and integrated with a piano hinge structure, that can be zipped up and threaded with a suture for closure. The disadvantage of this

Figure 22. The sketch representation of the cuff (around the nerve) electrodes (left) and the newly designed 12-contact circular cuff electrode (with a longitudinal slit) for selective stimulation with a four-channel stimulator. In order to minimize contamination of the neural signal from the surrounding biological signals, the electrode must fit tightly around the nerve and close well. An electrode can be closed with the flap covering the longitudinal slit, and kept in position by means of the surgical threads around the cuff (left side). It can be closed by using a “zipper” method where the ends of the cuff have little holes, through which a plastic baton can be pulled (right side). A self-wrapping polyimide multipolar electrode for selective recording/stimulation of the whole nerve is shown in (c). (Part a is courtesy of Dr. W. Jensen, Aalborg University, Denmark.) (Parts b and c are courtesy of Dr. T. Sinkjær and Dr. M. Haugland, Aalborg University, Denmark.)

Figure 23. Sketches of two cuff-electrode types that reshape the nerve. (a) The flat-interface electrode (FINE) has a rectangular shape and flattens the peripheral nerve in order to make selective contact with individual fascicles in the nerve. The active sites are placed on the cuff-wall. (b) The slowly penetrating interfascicular electrode (SPINE) is designed with a number of beams holding the active sites. A closure tube is moved over the beams to force the beams into position. The nerve will reshape around the beams and thereby make selective contact with the fascicles in the nerve. (Redrawn with permission from Dr. Durand, Case Western Reserve University.)

closure mechanism is that it adds several steps to the fabrication process. Furthermore, greater skill is required from the experimenter/surgeon for correct implantation and closure.

2. A second cuff is placed over the first cuff. This is an easy way to securely cover the longitudinal slit, and it is easy to implant. The disadvantage of this method is that overall implant diameter and stiffness increases.

The diameter of a fixed-sized cuff is an important design parameter. The inner diameter cannot be too large since the cuff wall works an electrical shield, and the active sites must make contact with the epineurium. It has been suggested that the fixed-sized cuff should have an inner diameter of $\sim 20\text{--}50\%$ larger than the nerve to avoid post-implant nerve damage caused by edema or swelling of the nerve (1,32).

A spiral cuff or a self-wrapping cuff design was originally suggested by Naples et al. (71) to circumvent some of the problems with the fixed-sized cuff. The spiral cuff electrode consists of a planar silicone or polyimide sheeting containing the active sites. The planar sheeting is flexible and is designed to automatically coil around a peripheral nerve (see Fig. 22b). These electrodes are generally handmade, but also have been manufactured by microfabrication techniques. The electrode will make a tight connection with the epineurium, leaving no space between the nerve and the contact sites. The self-sizing property of this design provides several advantages; (1) It is not necessary to determine the cuff diameter in advance as it is with the fixed-sized cuff electrodes. (2) The coiling will automatically and easily close the cuff and hold the cuff into place, and it is therefore very easy to implant. (3) The coiling will provide the necessary constriction of the extracellular current emerging from the nerve fibers without any possible leakages. (4) The coiling will allow the electrode to change size to accommodate for possible edema in the days after implantation.

An example of a cuff-electrode design that incorporates a number of the already discussed principles is a design referred to as the polyimide-hybrid cuff electrode (69) (see Fig. 22d). The electrode is based on a polyimide spiral cuff design containing multiple, platinum contacts on the inner wall. The polyimide-hybrid cuff is manufactured using microfabrication techniques that makes it possible to place a relatively high number of contacts inside the cuff and at

the same time allow space for lead-out wires, which was a problem with the first multicontact cuffs. The microfabrication technique further secures high repeatability in the manufacturing process. Several patents on this type of hybrid fabrication has been issued (72,73).

Application. The first circumferential cuff electrode used for chronic recording was described by Hoffer et al. (74) and later by Stein et al. (75). It is to date the most successful and most widely used chronic peripheral interface in both animals and humans. An overview of current neuroprosthetic applications based on long-term recording from peripheral nerves is given elsewhere in this chapter. Many of these systems use cuff electrodes as their neural interface, and at the time of this writing, is the only implanted nerve interface being used in humans with spinal cord injury or stroke to provide FNS systems with natural sensory feedback information.

Reshaping Cuff Electrodes. The fixed-diameter, circumferential cuffs or the spiral cuffs have their active recording sites placed around the epineurium, and these electrodes therefore mainly record from the most superficial axons or fascicles. The reshaping cuff electrode attempt to accommodate for that by remodeling the shape of the nerve to access individual fascicles.

Design. Two types of reshaping cuff electrodes were developed by Durand and colleagues at Case Western Reserve University. In the slowly penetrating interfascicular electrode (SPINE) the active sites are placed inside the nerve, however, without penetrating the epineurium (76) (see Fig. 23). This is accomplished by a set of blunt penetrating beams that is slowly pushed into the nerve trunk by a closure tube. The active sites are placed on the side of the beams and may therefore access different fascicles of the nerve trunk. A refinement on this concept, the flat interface nerve electrode (FINE) was later developed (77). This electrode has a fixed shape like the fixed diameter, circumferential cuffs, however, the shape is rectangular instead of round (see Fig. 23). Ideally, the individual fascicles will then make contact with different contact sites along the cuff wall.

Application. The reshaping cuff electrodes were mainly developed as a stimulation platform; however,

Figure 24. A hook electrode consists of two simple wires/hooks that are held in close contact with the nerve surface. The picture shows an example of a custom made hook electrode. (Courtesy of Dr. K. Yoshida, Aalborg University, Denmark.)

both types could potentially be used for recording. Acute studies with the SPINE electrode show that the slowly penetrating beams can safely place active sites within the nerve trunk, and it is possible to selectively activate different fascicles of the nerve (77). One of the main design issues with the FINE electrode has been to choose the right size of the electrode without causing nerve damage. Animal studies have shown that the FINE electrode is suitable for both recording and stimulation in chronic animal implants (78,79).

The Hook Electrode. The hook electrode was among the first extraneural electrodes used in experimental neurophysiology and neuroscience. The hook electrode is not useful for long-term nerve implants, however, it is still widely used in acute animal experiments or as an intraoperative tool for nerve identification, and therefore a brief introduction is given here.

Design. The hook electrode is constructed of usually two or more hook-shaped wires that form the recording/stimulation sites (typical materials used are platinum, stainless steel, or tungsten) (see Fig. 24). The nerve trunk or fascicle is placed so the epineurium makes close contact with the hooks. The hook-wires are soldered to insulated lead-out wires that are used to connect with the recording/stimulation equipment. The lead-out wires are usually threaded inside a tube or glued onto a stiff rod to form a base for holding the hook electrode in place. The hook wires must be stiff enough to support the whole nerve or nerve fascicle without yielding. One of the main advantages of the hook electrode is that it is easily handmade at a very low cost.

Application. The distance between the hooks may be varied to change the electrical recording/stimulation properties, however, the relatively large distance between the active sites means that the electrode has a poor selectivity. To use the hook electrode, the whole nerve must first be made accessible in the body, and surrounding fascia must be dissected away to place the hooks underneath the nerve. To avoid electrical shunting between the hooks caused by the extracellular fluid, a paraffin oil or mineral oil pool is often created around the hook electrode and nerve in acute animal studies. For human experiment, the hook electrode and the

nerve may alternatively be suspended into the air to obtain a similar, insulating effect between the hook wires.

USE OF PERIPHERAL NERVE SIGNALS IN NEUROPROSTHETIC APPLICATIONS

Traumatic or nontraumatic injury to nerves at peripheral, spinal, or cortical level may cause permanent loss of sensory and motor functions. The goal of neuroprosthesis applications is to replace, restore, or augment the lost neural function in order to regain the lost mobility or sensation. Popovic and Sinkjær (80) discussed clinical areas where FES is already important or where it holds great potential if the adequate technology will be developed. In the present section, the state-of-the-art of using information provided by peripheral nerve signals in preclinical evaluated and experimental neuroprosthetic applications will be discussed.

Neuroprostheses systems traditionally work by using functional electrical stimulation (FES) to elicit controlled muscle contraction. The functional electrical stimulation can be applied using an open- (feed forward) or a closed-loop (feedback) controller scheme. The open-loop systems have proven to work, however, since no regulation is provided, excessive stimulation and muscle fatigue are commonly observed. Once the stimulation has been determined in the open-loop system, it is not changed, and it is not possible to detect or account for unexpected events or external disturbances. Several studies have shown that the application of closed-loop control techniques can improve the accuracy and stability of FES activated muscles. However, the closed-loop systems are dependent on feedback on the current state of the part of the body under control. The availability of sensors to provide reliable feedback information is, therefore, essential. An illustration of the basic elements in a closed-loop FES control system is given in Fig. 25.

Artificial sensors placed outside the body have been used widely within closed-loop FES applications to provide the necessary feedback signals [e.g., including goniometers

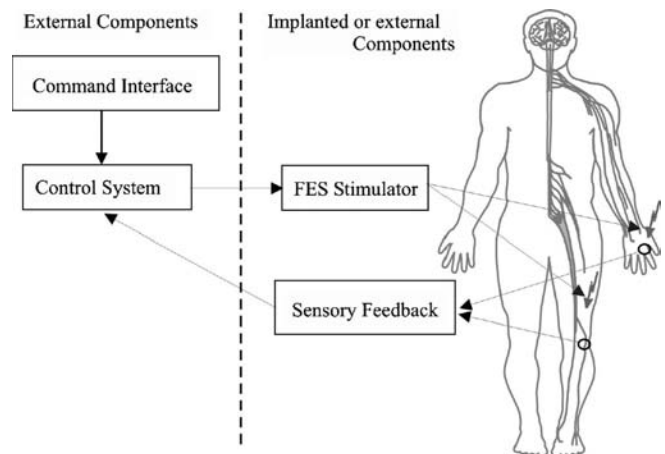

Figure 25. Illustration of the basic elements in a closed-loop neuroprosthesis application. The instrumentation typically includes an external (i.e., outside of the body) command interface and control system and external/implanted interfaces for sensing or activating the biological tissue.

Figure 26. Footdrop correction system, using natural sensory information from the Sural or Peroneal nerve. The nerve signals were processed to determine heel contact with the floor and to decide the timing of the ankle dorsi-flexion stimulation. The stimulation may be applied through a peroneal nerve cuff electrode innervating the Tibialis Anterior muscle or by surface electrodes. (Reproduced with permission from Dr. T. Sinkjær, Dr. M. Haugland, and Dr. M. Hansen.)

and accelerometers (80)]. However, the excess time consumed donning and doffing the artificial sensors, and the poor cosmetic visibility of bulky sensors has proven to be a major disadvantage for end user acceptance (1). Artificial sensors have also been placed inside the body; however, they require power to work and can be a problem to replace in case of failure.

The natural sensors, such as those found in, the skin (cutaneous mechanoreceptors, nociceptors), muscles (proprioceptors), or internal organs (visceral neurons) normally providing the CNS with feedback information on the state of the body. They are presently an attractive alternative to the artificial sensors in the cases where the sensors are still viable below the level of brain or spinal cord injury. Unlike artificial sensors, natural sensors are distributed throughout most of the body, and they do not require power or maintenance. Also, efferent motor signals are of interest to monitor the command signals from the CNS to the motor end organs. In many cases, they can be accessed through the same nerve based electrodes used for FES.

Therefore, the peripheral nerve signals of interest here are any neural tissue that is accessible outside the vertebral canal, including afferent and efferent somatic and autonomic pathways (the peripheral nervous system was defined in section The peripheral nervous system and specific peripheral nerve interfaces are described above).

Preclinical Neuroprosthetic Systems

Cutaneous Afferent Feedback for the Correction of Drop-foot. Foot-drop following upper or lower motor neuron deficits is defined as the inability to dorsiflex the foot during the swing phase of the gait (81). Electrical stimulation of the peroneal nerve has proven to be a potentially useful mean for enhancing foot dorsi-flexion in the swing phase of walking and thereby make the patient walk faster and more securely. The stimulator is often located just

distal to the knee and can be either externally mounted or partly implantable. A key element in the system is the external heel-switch placed under the foot, which provides sensory information on heel-to-ground events necessary to switch on the stimulation at the right time. This system has proved clinically functional in large groups of patients. If the external heel switch is replaced with an implantable sensor, it can provide not only the advantages of foot drop corrections systems without the need for footwear, but also eliminates daily problems of mounting the heel switch or swapping them in different pairs of shoes.

The sural nerve is purely sensory and innervates the skin underneath the foot. It has been shown that whole nerve cuff electrode recordings from this nerve can provide information about foot contact events during walking, including heel-to-ground and toe-off-ground events (82). An example of recorded sural nerve activity during walking is shown in Fig. 26. The sural nerve activity has been processed (i.e., filtered, rectified, and bin-integrated). During walking, the nerve signal modulates, and two large spikes are repeatedly observed that correlate with the transitions between swing-to-stance phase and stance-to-swing phase. One of the most significant problem in correlating the nerve signal activity to the actual heel contact during walking is the noise originating from nearby muscle activity. The inclusion of a decision-assistive method like adaptive logic networks as a part of the postprocessing of the neural signal has been used improved the consistency of detecting reliable events (12,83).

The different elements of the drop foot correction system based on natural sensory feedback are shown in Fig. 26, including the external control unit, the implanted sural nerve cuff electrode and amplifier, and the peroneal nerve cuff electrode and stimulator. The sural nerve cuff electrode is connected to an external amplifier, and the signal output is fed to a microprocessor-controlled stimulator that activates the ankle dorsiflexor muscles.

The use of cutaneous afferent feedback in correction of drop-foot has to date been evaluated in several patients. The first evaluation included a 35-year-old subject with a hemiplegic dropfoot. In this case, the cuff electrode was connected to the control system through percutaneous wires, and an external stimulator was placed over the Tibialis Anterior muscle (84). A later version of the system was tested in a 32-year-old subject, and the external stimulator was here replaced with an implanted cuff electrode around the peroneal nerve, which innervates the tibialis anterior muscle. An implantable system is currently under development and clinical testing by the Danish company Neurodan A/S.

Cutaneous Afferent Feedback for the Restoration of Hand Grasp. The fingers of the human hand contain an estimated 200–300 touch sensing receptors per square centimeters within the skin. It is among the highest densities of sensory receptors in the body (85). The cutaneous receptors and their responses have been studied extensively using microneurography techniques in normal subjects (85–87). The sensors mainly signal information about indentation and stretch of the skin, and the sensors play an important role in the control of precise finger movements and hand grasp while manipulating objects. It was found that slips across the skin were shown to elicit automatic motor reflex responses that increased the grasp force.

A FES system was developed to evaluate the use of cutaneous sensory information in restoration of hand grasp functions. The system has been evaluated in three spinal cord injured subjects (88–92). Results from a 27-year-old tetraplegic male with a complete C5 spinal cord injury (2 years postinjury) are presented in detail here. Before the system was implanted, the patient had no voluntary elbow extension, no wrist function, and no finger function. Furthermore, he had only partial sensation in the thumb, but no sensation in 2nd to 5th fingers. He was implanted with a tripolar nerve cuff electrode on the palmar interdigital nerve (branching of the median nerve). Eight intramuscular stimulation wire electrodes were simultaneously placed in the following muscles: Extensor Pollicis Brevis, Flexor Pollicis Brevis, Adductor Pollicis, and Flexor Digitorum Longus to provide the grip control.

The cuff electrode was implanted around the palmar interdigital nerve, which is a pure cutaneous nerve innervating the radial aspect of the index finger (branching off the median nerve). The cuff electrode recordings were used to detect the occurrence of fast slips (increased neural activity was recorded when objects were slipping through the subject's fingers, and the neural activity showed similar characteristics as the cutaneous sural nerve activity shown in Fig. 26).

The stimulator was controlled by a computer, which also sampled the nerve signals and performed the signal analysis. When stimulation was turned on, the object could be held in a lateral grasp (key grip) by the stimulated thumb. If the object slipped, either because of decreasing muscle force or increasing load, the computer detected this from the processed nerve signal and increased the stimulation intensity with a fixed amount so that the slip was arrested, and the object again held in a firm grip. When extra weight was added, the slipped distance was also comparable to the performance of healthy subjects.

Today this system is developed to an extent where the subject can use it during functional tasks. During an eating session where the subject has a fork in his instrumented hand (grasped between the thumb and index finger), the control system is designed to decrease the stimulation of the finger muscles until the feedback signal from the skin sensors detects a slip between the index finger and the fork. When a slip is detected, the stimulation to the thumb increases automatically proportional to the strength of the sensory feedback, and if no further slips are detected, the controller starts to decrease the stimulation. This continuous tracking of the minimally necessarily needed stimulation means that the hand muscles are only loosely stimulated when the subject decides to rest his arm (which typically happens when they have a conversation with one or more of the persons at a dinner table). The stimulation will automatically increase when they start to eat again by placing the fork in the food. A typically eating session will last 20–30 min. A large fraction of this time is dedicated to “noneating” activities. During such times, the stimulation is at a minimum (keeping the fork in the hand with a loose grasp) and thereby preventing the hand muscles to be fatigued. When the feedback is taken away, the subject will typically leave the stimulation on at high stimulation intensity for the full eating session. This will fatigue the stimulated muscles, and the subject will try to eat their dinner faster, or they will rest their muscles at intervals by manually decreasing the stimulation. It is an effort that requires more attention from the subject than the automatic adjustment of the stimulation intensity.

The natural sensory feedback system was developed at Aalborg University, Denmark, and based on a telemetric system and on the Freehand system (NeuroControl Corp.). The Freehand system consists of a number of epimysial stimulation electrodes to provide muscle activation. More than 200 patients have to date received this system (Fig. 27).

Figure 27. A neural prosthetic system for lateral-key grip restoration after spinal cord injury including sensory feedback. The FreeHand stimulation system (developed at Case Western Reserve University, Ohio) was modified to take advantage of natural sensory feedback signals obtained from a cutaneous, digital nerve in the hand. Experimental Neural Prosthetic Systems

Somatic Afferent Feedback in Control of Joint Movement.

The natural sensors that carry information about movement and orientation of the body in space (proprioception) are primarily located in the muscles, tendons, joints, and ligaments. The sensory signals are essential for the central nervous system in voluntary control of movement. In contrast to the more on-off type of information provided by the natural sensors located in the skin (e.g., heel contract and toe off events as used in correction of drop foot), the muscle spindle afferents are believed to carry information on muscle displacement (length, velocity, and acceleration). The proprioceptive sensors may therefore be useful in FES systems for control of joint movement. A majority of the research within this area has so far focused on restoration of standing and walking after spinal cord injury, however, the same principles explained here may be applied in control of upper extremity joints. Muscle afferent signals have been studied in animal models using intrafascicular (6,93) and whole nerve cuff electrodes (94,95), and these studies have revealed some characteristic features in muscle afferent responses that must be taken into consideration in a future FES system design.

Muscle afferent signals were obtained from passively stretched agonist-antagonist muscle groups around the ankle joint innervated by the tibial and the peroneal nerve branches in an animal model of spinal cord injury (6,94). The muscle afferent signals were recorded during simple flexion-extension rotations of the ankle joint, and it was found that the muscle afferent activity from the two nerves responded in a complementary manner, see Fig. 28. Thus, the muscle afferent activity increased during muscle stretch, but the activity stopped as soon as the movement was reversed, and the muscle was shortened. In the animal models used here, the muscles are not under normal efferent control from the central nervous system, and the intrafusal muscle fibers (where the muscle spindles are located) therefore become slack during muscle shortening, and the muscle spindles stop responding. The muscle afferents can therefore only provide information about muscle length during muscle stretch. In order to obtain a continuous and reliable muscle afferent feedback signal, it is necessary to use information from more muscles or muscle groups acting around a joint.

In spite of the nonlinear nature of the muscle afferent signals, it has shown to be possible to use the signals as feedback in a closed-loop control system. Yoshida and Horch (6) obtained control of ankle extension (ramp-and-hold movement) against a load and ankle flexion-extension (sinusoidal movement) in a cat model. A look-up table was first established by creating a map between the neural activity and the ankle joint angle. The tibial and peroneal nerve activity was simultaneously recorded using intrafascicular electrodes and decoded according to the look-up table.

To better incorporate the nonlinear behavior, more sophisticated information extraction algorithms have been employed to decode the muscle afferent signals, including a Neuro-Fuzzy network (96), and neural networks (97,98). In all cases, continuous information from both an agonist and antagonist muscle group was used as input to the networks.

The next step is to explore if muscle afferent signals on selected peripheral nerves can be recorded in humans and applied to improve FES standing.

Visceral Neural Signals in Control of Bladder Function.

Normal bladder function (storage and emptying of urine) is dependent on mechanoreceptive sensors detecting bladder volume and efferent control that trigger a bladder contraction. Normal bladder function can be affected by a number of pathological diseases or neural injuries, for example when spinal cord injury occurs at the thoracic or cervical level, the neural pathways normally controlling the bladder are affected. Bladder dysfunction can result in an either overactive bladder (small volume capacity and incomplete emptying, referred to as neurogenic detrusor overactivity) or an underactive bladder (high volume capacity), however, the result of both states is incontinence. Neurogenic detrusor overactivity is the most common form of detrusor dysfunction following spinal cord injury. An overfilling of the bladder can also lead to a possible life-threatening condition of autonomic dysreflexia (overactivity of the autonomic nervous system).

Conventional treatments include suppression of reflex contraction by drugs, manual catheterization, or inhibition of the reflex contraction by surgical intervention, which is also referred to as dorsal rhizotomy. Dorsal rhizotomy

Figure 28. Muscle afferent signals recorded from the Tibial and Peroneal nerve branches during passive joint rotation in a rabbit model. The Tibial and Peroneal nerve activity modulated in a push-pull manner (i.e. the nerves responded to muscle stretch of the Gastrocnemius/Soleus and the Tibialis Anterior muscles, respectively). The magnitude of the response modulated with the initial position of the joint (the amount of prestretch in the muscles). (Courtesy of Dr. Jensen, Aalborg University.)

Figure 29. Two examples of recorded neural activity from the sacral roots in an anaesthetized human subject in preparation for surgery for implantation of a FineTech-Brindley Bladder system. The traces show the bladder pressure (top), rectal pressure (middle) and extradural sacral root activity (bottom) over time. (Courtesy of M. Kurstjens.)

increases the bladder capacity, however, reflex erection in male patients is lost, and this is in most cases not an attractive solution. To reestablish continence a closed-loop FES system has been suggested including sensory feedback on bladder volume and/or detrusor activation from bladder nerves.

Work in anaesthetized cats showed correlation between recorded activity from the S2 sacral root and the intravesical pressure associated with fullness of the bladder. Recently, similar information on bladder volume information has also been demonstrated in nerve cuff recordings from the S3 sacral root and the pelvic nerve in anaesthetized pigs (99) and extradural cuff recordings from sacral roots in humans (100) (see Fig. 29). The findings reveal, however, some problems in finding a reliable sensory feedback signal. It proved difficult to detect slow increases in bladder volume (99). Further, recordings from the pelvic nerve or sacral roots, however, are frequently contaminated with activity from other afferents, such as cutaneous and muscle afferents from the pelvic floor, rectum, and anus (100).

A closed-loop FES system for the management of neurogenic detrusor activity would work by using the sensory information from the bladder nerves to inhibit detrusor contractions by stimulating pudendal or penile nerves, or block efferent or afferent pelvic nerve transmission to prevent reflex detrusor contractions. The principle was tested in an anesthetized cat preparation where nerve cuff recordings from the S1 in cats could detect bladder hyper-reflexive like contractions. However, the contractions were detected with a time delay in the order of seconds (using a CUMSUM algorithm), which decreases the feasibility of the system (101).

Visceral Neural Signals in Respiratory Control. Obstructive sleep apnea is characterized by occlusions of upper airways during sleep. Electrical stimulation of the genioglossus muscle directly or via the hypoglossal nerve can

improve the obstructions, however, a signal for detecting the occurrence of the obstructions will be useful in a FES closed-loop application (102).

This principle has been tested in a closed-loop FES system where the response of hypoglossal nerve was recorded during external loading of the pharynx during sleep to simulate upper airway obstructions in a dog model. It was shown that the hypoglossal nerve activity modulated with the pressure both during REM and NREM sleep. Any change in the cyclical rhythm of the recorded activity was used as an indication of the onset of apnea to the controller and triggered the onset of the stimulation of the same hypoglossal nerve to prevent the airway obstruction (103). Stimulation and recording from the same nerve is feasible in this case because the only information needed from the hypoglossal nerve is an indication of the onset of airway obstruction (i.e., no continuous information is needed).

CONCLUSIONS

The goal of the article is to provide the reader with an overview of currently available neural electrodes for long-term interfacing peripheral neural tissue. This is done to evaluate their suitability to monitor the neural traffic in peripheral nerves and their suitability to perform as sensors in neural prosthetic devices.

The role of neural prosthetic systems for increasing the quality of life of disabled individuals is becoming more evident each day. As the demand to develop systems capable of providing expanded functionality increases, so too does the need to develop adequate sensors for control. The use of natural sensors represents an innovation. Future research will show whether nerve-cuff electrodes and other types of peripheral nerve electrodes can be used to reliably extract signals from the large number of other receptors in the body to improve and expand on the use of natural sensors in neural prosthetic systems.

ELECTROPHORESIS

JOHN M. BREWER
University of Georgia
Athens, Georgia

INTRODUCTION

The “electrostatic effect” causes particles with the same sign of charge to repel each other, while two particles of opposite charge attract: Charged particles produce electric fields and a charged particle in an electric field experiences a force. Electrophoretic techniques are based on the movement or flow of ions in a solvent produced by an electric field, causing separation of different ions.

THEORY

An external electric field V produces a force on an ion with a charge Q equal to $VQ(1)$. An ion in a solvent will be accelerated, but movement in the solvent will be slowed by an opposite force that comes from the viscosity of the solvent. For small velocities, the opposite (viscous) force is proportional to the velocity of electrophoresis. We call the proportionality constant the “frictional coefficient”. The forces from the electric field and viscosity are opposed, so the net acceleration becomes zero and the velocity of electrophoresis (v) constant:

$$v = VQ/\text{frictional coefficient}$$

Mobilities of Ions

The velocity an ion reaches for a given applied field is a specific property of that ion. It is called the “mobility” of

Figure 1. (a) Representation of a vertical electrophoresis experiment. (b) The lower drawing represents the stacking phase of disk electrophoresis or isotachopheresis of a single component, ion D. Charge signs are omitted as cationic and anionic isotachopheretic or disk systems exist. (Reprinted from *Clinical Chemistry: Theory, Analysis, Correlation*, 4th ed. Kaplan LA, Pesce AJ, Kazmierczak SC, editors, Electrophoresis, p 204, copyright © 2003, with permission from Elsevier.)

that ion:

$$v/V = \text{mobility of ion} = Q/\text{frictional coefficient}$$

For ions such as proteins that are very large compared with solvent molecules, the frictional coefficient is 6π times the product of the solvent viscosity and the effective radius (size) of the ion (1).

The direction the ion moves is determined by the sign of its charge Q and the direction of the electric field. The electric field is produced by two oppositely charged substances (electrodes) placed at opposite ends of the solution the ion is in, and their polarity (charge) determines the field's direction (Fig. 1) (2).

How fast ions in solution move is also affected by some other factors, but these are still hard to calculate (1,3). In aqueous solvents, ions are "hydrated", bound to a number of water molecules (4,5). A protein has many charged groups, both positive and negative, and those in contact with the solvent also will be hydrated (6) and will in addition have hydrated ions of opposite charge, called

"counterions", nearby. In an electrophoresis apparatus (Fig. 1), the protein will move toward the electrode of opposite charge in an irregular fashion because random diffusional motion adds to the uniform electrophoretic movement. After each change of direction, the smaller ions of opposite charge are out of their equilibrium positions and need time(s) to readjust or move back into position. During the readjustment period(s), the effective voltage that the protein is exposed to is lower than the applied voltage, because the smaller counterions, while out of position, produce a field in the opposite direction.

Positively charged ions (cations) move in the opposite direction to negative ions (anions). They all are hydrated and the movement of the protein or other large ion of interest is slowed by a flow of hydrated ions of opposite charge (counterions) in the opposite direction. This is called an "electrophoretic effect" and, together with the "relaxation" or "asymmetry" effect described before, makes it difficult to use the measured velocities of large ions to calculate their real net charge or effective radius (1,3). Electrophoresis is consequently used largely as an empirical technique.

The mobilities of many small ions are known (7). These values are for fully charged ions. The actual (average) charge of ions like acetate depends on the pH, so the observed or actual (effective) mobility of some ions will also be pH dependent.

$$\text{Effective mobility} = (\text{mobility})(\text{average charge})$$

Proteins or polynucleotides have charged groups that determine their ionic properties. These charged groups in proteins are anionic and cationic, with pK values from 3 to 13, so the effective mobilities of proteins are very pH dependent. For proteins, overall (net) charges vary from positive at low pH to zero (isoelectric) to negative at more alkaline pH values. Substances whose charge can vary from positive to negative are called "amphoteric". Routine electrophoretic separations are done at constant pH values, in a "buffered" solution, to minimize effects of pH on velocity of movement.

Electrical Effects

These techniques are electrical in character. An applied voltage V produces movement of oppositely charged ions in opposite directions. These flows of ions are the current i . Solvents resist movement of ions through them and this resistance is R , so that $V = iR$, just as in a wire or any other electrical device. People using electrophoresis are interested in ion movement, so the reciprocal of the resistance, called the "conductivity" (σ), is used instead: $\sigma V = i$.

Several factors determine the conductivity of a solution. The conductivity is proportional to the concentrations of the ions present (actually to their thermodynamic activities). It is also proportional to their mobilities or, if the pH is a factor, to their effective mobilities. Since all ions contribute,

$$\sigma \propto \sum \sigma_i \propto \sum (\text{concentration})_i (\text{mobility})_i (\text{average charge})_i$$

The conductivity is also proportional to the cross-sectional area through which the ions move, but the area is usually constant.

The current must be constant in any tube or channel through which electrophoresis is occurring. There can be no gaps or accumulations of current. Since the conductivity in different parts of the tube may be different (see below), the voltage along a tube or channel may also differ in different parts of the tube or channel.

The purpose of electrophoresis is to separate ions and this may be measured from the movements of a large number of molecules using band broadening of scattered laser light owing to Doppler effects (8), by following the movement of the interface or "boundary" between a solution of a particular ion and the solvent, or by following the movement of a region or "zone" containing an ion of interest through a solvent (Fig. 1). Currently, most workers follow the position(s) of relatively thin zone(s) of material, since complete separation of a mixture takes less time the thinner the original zone of the mixture is. However, even the thinnest zone contains a leading boundary at the front and a trailing boundary at the back, so the following discussion applies to zone and boundary methods. We assume the ion of interest is a large one, say a protein.

The large ion is usually restricted at first to one part of the tube or channel through which electrophoresis occurs. The solvent in other parts must also contain ions, usually small ones, to carry the current where the large ion is not present. In other words, the large ion is part of the electrical system and so carries part of the current and contributes to the conductivity. It will move in the same direction as small ions with the same charge, called "co-ions". So the large ion is competing with the co-ions to carry the current.

The large ions must replace equivalent amounts (in terms of charge) of co-ions so that an excess of ions of one charge never accumulates anywhere. In other words, total positive charges must always equal total negative charges (electroneutrality principle). Large ions often have lower mobilities than co-ions. The co-ions are diluted by the large ions with a lower mobility. The moving zone with the large ions has then a lower average conductivity.

Since gaps in the current cannot occur, the zone with the large ions must keep up with the co-ions it is partially replacing. To do this, the voltage in the large ion-containing zone must increase to keep the current constant. If a single large ion diffuses across the leading large ion-solvent boundary, it has moved into a region of higher conductivity and lower voltage. Consequently, the single large ion slows down until the large ion zone catches up (2,7).

At the trailing boundary, co-ions with higher mobilities are replacing lower mobility large ions. This increases the conductivity in the region the large ions just left. The voltage right behind the trailing boundary is consequently lower. If a single large ion diffuses back into that region, it will be in a lower voltage and will move more slowly than the large ions in the large ion zone.

The effect of this competition is to cause zones of large ions with mobilities lower than those of the co-ions to be sharp at the leading boundary and diffuse at the trailing boundary. In other words, zone broadening due to diffusion of the large ions is either reduced or increased at the front (leading) and rear (trailing) edges, respectively, of the zone, depending on the relative mobilities of large ions and co-ions.

There may be effects of pH as well. The small co-ions and counterions are often also used to maintain the pH. The competition between large ions and co-ions, by reducing co-ion movement, leads to changes in the ratio of co-ion to counterion where the large ions have moved in or out of a region. The pH is affected by the ratio of small conjugate acid and base ions, either of which may be the co-ion, so movement of the large ion is accompanied by changes in pH. Changes in pH can change the net charge on the large ion, especially if it is a protein, and so change its effective mobility. Changes in the pH where electrophoresis is occurring can add to or reduce the competition effects described above.

Enhancing Resolution

Separations of substances produced by any procedure will be counteracted by the resulting diffusion of the separated substances, so diffusion should be reduced as much as possible. The competition between ions with the same

charge during electrophoresis can add to or counteract diffusion, and this is the basis of "mobility-based" enhanced resolution techniques.

Mobility-Based Methods. Instead of a zone of solution containing large and small ions set between zones of solvent containing the same small ions, we put different small ions on either side of the large ion zone. This is a "discontinuous" solvent system (2,3,7).

Figure 1b shows an upright cylinder whose lower half is filled with co-ion C and counterion B. The upper half of the cylinder has co-ion A and counterion B. An electric field is applied so that the A ions follow the C ions toward one electrode. If the mobility of the A ion and conductivity of the A solution are less than those of the C solution, the boundary between the solutions will move but diffusion across the boundary by either ion will be restricted. Since the current must be the same all along the tube, the lower conductivity A solution must have a higher voltage making the A ions keep up with the C ions. If A ions diffused ahead into the C solution, the A ions would be in a lower voltage region and would slow until the rest of the A solution caught up. If C ions diffused back into the A solution, the higher voltage there would drive them back to the C solution.

Suppose a solution of ions B and D was inserted between the AB and CB solutions. If ion D has a mobility intermediate between those of A and C, it will remain "sandwiched" between the AB and CB solutions and diffusion will be restricted across the AD and DC boundaries. Suppose further that a mixture of ions DEFG... of the same charge as A and C were originally present in the intermediate solution and these had mobilities intermediate to those of A and C. Even if DEFG... were originally mixed together, they would separate and travel, each in separate but adjacent subzones, in order of decreasing mobility going from the C zone to the A zone, all at the same velocity and all with sharply maintained boundaries.

Another effect that occurs in discontinuous systems involves concentrations. If the DEFG... ions were originally very dilute in their original zone, their zone would compress and each ion's subzone would become relatively thin upon starting the electrophoresis. This is because each ion subzone must carry as much current as the A and C zones, and the higher the conductivities of the AB and CB solutions, the thinner the DEFG... subzones will get. If DEFG... are different proteins, which generally have very high molecular weights and relatively low net charges, the subzones will become very thin indeed. The "running" concentrations of DEFG... will become very high.

If the pattern produced by DEFG... as they move down the column is determined or if they are made to elute from the column as they emerge from it, the process is called "isotachopheresis", since DEFG... all move at the same velocity (7). Having DEFG... unseparated from each other makes analysis or preparation difficult, and isotachopheresis is currently relatively little used.

The most frequently employed procedure to separate DEFG... is to increase the effective mobility of the A ion so that it runs through the DEFG... subzones (2,7). These are then in a uniform electric field, that of the AB solution, and so electrophorese independently. While the separating

subzones also begin to diffuse, they were "stacked" in very concentrated, and hence thin subzones. The thinner the subzone is before independent electrophoresis, the thinner it will be at the end of electrophoresis and the better the resolution. This approach is employed in "disk electrophoresis".

The A ion is of lower mobility than the C ion and the pH used lowers its effective mobility further. To increase the effective mobility of the A ion, the original CB solution contains a high concentration of the uncharged conjugate acid or base of the B ion. The ions (and conjugate acid or base) are chosen so that when A replaces C its average net charge increases because of the new or "running" pH, which is controlled by the ratio of B ion to its conjugate acid or base.

It must be emphasized that the running concentrations of the ions and uncharged acids or bases are not arbitrary but are controlled by the physical (electrical) constraints mentioned before and alter if they do not conform initially. The constraints are summarized mathematically in Ref. 7.

The importance of the B ion is emphasized by examination of another electrophoretic technique. Suppose the concentration of the B ion is reduced to zero. Since transport of ions must occur in both directions, reduction of the B ion concentration to zero will reduce migration of A, DEFG..., and C to zero (or nearly zero: in aqueous solvents, there will always be some movement due to ionization of water) (7,9). A, DEFG..., and C will be stacked. Since B must be replaced, because of electrical neutrality, with protons or hydroxyl ions, amphoteric ions such as proteins will be "isoionic". The pH of each zone or subzone is that at which each amphoteric ion has zero net charge. This technique is termed "isoelectric focusing".

To separate DEFG... a mixture of relatively low molecular weight amphoteric substances such as "carrier ampholyte" is added before voltage is applied. These substances have a range of isoelectric points, but the pK values of their acidic and basic groups are close to each other, so they stack to produce a buffered pH gradient (7,10). Indeed, they are prepared and sold on the basis of the pH range they cover.

The proteins "band" or collect at their characteristic isoionic pH values. This state does not last indefinitely, however, since the stacked ampholytes and proteins behave like an isotachopheretic system unless the pH gradient is physically immobilized (7) (see below). Isoelectric focusing is frequently used preparatively, since large amounts of protein may be processed.

Supporting Media-Based Methods. A mechanical problem results from any zone separation procedure. Higher resolution results in thinner separated zones. These are more concentrated, and so are significantly denser than the surrounding solvent, which leads to "convection": the zones fall through the solvent and mix with it. This must be prevented. A preparative isoelectric focusing apparatus uses a density gradient of sucrose or other nonionic substance that contains ions DEFG... and the carrier ampholytes. The separated zones of D, E, and other ions are buoyed by the increasingly dense solvent below them.

Sucrose density gradients have no mechanical strength, so the electrophoresis pathway must be vertical, and in any case the gradient only reduces convection. Generally, a solid or semisolid supporting medium is used. This can be fibrous (paper, cellulose acetate), particulate (cellulose powder, glass beads), or a gel (starch, agar, polyacrylamide). A gel is a network of interacting or tangled fibers or polymers that traps large quantities of solvent in the network. To increase mechanical strength, some polymers can be covalently crosslinked as is routinely done with polyacrylamide supports. Gels usually have a uniform percentage of gel material, but can be prepared with a gradient of gel material or other substances such as urea (10).

Support media should allow as free a passage as possible to electrophoresing ions while restricting convection. Convection (bulk flow) in a capillary is proportional to the fourth power of the capillary radius (1), but the area available for electrophoretic movement is proportional to the square of the radius. Reducing the radius reduces convection much more than the carrying capacity (area) of the capillary.

Capillary tubes can be used without supporting material inside (capillary electrophoresis) (11), but the other materials operate by offering a restricted effective pore size for electrophoretic transport. The effective pore size varies with the medium: 1–2% agar gels have larger average pore sizes than polyacrylamide gels made from 5 to 10% acrylamide solutions.

The importance of the supporting medium is illustrated by an immunoelectrophoretic technique. Electrophoresis is used to separate antigens before antibody diffuses into the separated antigens (immunodiffusion) (12,13). Immunodiffusion requires supports with average pore sizes large enough to allow antibodies, which are large and asymmetric immunoglobins, to diffuse through them, while still stabilizing the zones of precipitate that form. Agar gels, at 1–2% concentrations, are used.

A support medium is in very extensive contact with the solution. Even a capillary tube has a great deal of surface relative to the volume of solution within. Interaction with the support or capillary surface is often not wanted: chemical interactions with the ions being separated or with the other constituents of the solvent interfere with the ion movement. Adsorption of some substances by the fused silica surfaces of capillaries used in electrophoresis can occur (11). The surface must then be coated with inert material. Support media are often chosen for having as little effect on electrophoresis as possible. Such effects are called “electroosmosis”: the solvent flows in an electric field (4). If the medium or capillary inner surface has charged groups, these must have counterions. The charged groups fixed in the matrix of the medium or capillary tube and their counterions are hydrated, but only the counterions can move in an electric field. The counterion movement causes solvent flow next to the capillary wall or support medium.

This case is extreme, but some electroosmosis occurs with any medium. Interaction of any two different substances results in a chemical potential gradient across the interface (4). This is equivalent to an electrical potential difference. Electroosmosis can distort zones of separated

ions, reducing separation, but as capillaries become thinner or average pore sizes smaller, sideways (to electrophoretic movement) diffusion tends to overcome effects of electroosmosis (7).

Electrophoretic procedures are to produce separations, and if interactions of any kind improve separations, they are desirable. Separation of serum proteins by capillary electrophoresis in a commercial apparatus (Beckman-Coulter Paragon CZE 2000) depends partly on electroosmotic flow stemming from charged groups on the silica surface of the capillary.

Electrophoresis in solutions containing ionic detergents can separate uncharged substances. Detergents form clusters in water solutions called “micelles” with hydrophilic surfaces and hydrophobic interiors. Micelles of ionic detergents move in an electric field, and uncharged substances, if they partition into the micelles, will be moved along in proportion to the extent of their partitioning. This is “micellar electrokinetic chromatography” (11).

Electrophoresis in support media that reversibly adsorb substances being separated is called “electrochromatography”. Unlike conventional chromatography, which uses hydrostatic pressure to move solutions of substances to be separated through the medium, electrochromatography uses an electric field.

The interactions with support media used to increase resolution of electrophoretic separations range from indirect to actual adsorption.

Acrylamide derivatives that will act as buffers over a desired pH range are incorporated into polyacrylamide gels and used in isoelectric focusing (7,9,10). These are called Immobilines. They provide stable pH gradients (7) and control movement of amphoteric ions by controlling the pH. They also stabilize zones of protein that form.

Electrophoretic or diffusional movement of large ions is reduced by supports, since they increase the tortuosity of the path the ions must follow. If the average pore size is made comparable to the effective sizes of the ions undergoing electrophoresis, the ions are literally filtered through the medium so that smaller ions would be least retarded and larger ions retarded more. This “molecular sieving” effect can improve the resolution achievable by electrophoretic techniques: the leading edges of zones of large ions are slowed by the gel matrix allowing the rest of the zones to catch up. This makes zones of larger ions thinner and restricts subsequent diffusion.

This effect can also provide information about the physical characteristics of the ions. The effective mobilities of large ions are determined by their net charges and frictional coefficients. The latter is affected by the shape of the large ion: A very asymmetric molecule has a larger effective size than a more compact one (1,3). Two molecules of identical charge and molecular weight can be separated even in the absence of a support if they have sufficiently different shapes. Effective sizes can be determined from electrophoresis on several gels with different average pore sizes. Effective sizes can be used to calculate diffusion constants (1,3), though they are normally used to obtain molecular weights. Large ions of known molecular weights may be electrophoresed on the same gels to calibrate the pore sizes of the gels (12,13) (see below).

If a mixture of large ions of differing shapes and sizes is converted to a mixture with different sizes but the same shape, then they will migrate according to their net charges and molecular weights. If the charges are made a constant function of the molecular weight then the ions will separate according to their molecular weights alone (3,10,12,13). The degree of separation will also be affected by the average pore size of the medium. Proteins that consist entirely or nearly so of amino acids and that have been treated to reduce any disulfide bonds are usually converted to rod-like structures with a nearly constant charge-to-mass ratio by adding the detergent, sodium dodecyl sulfate (SDS). The detergent binds to such proteins in large and highly uniform amounts (3,12,13). The protein-SDS complexes then migrate in order of decreasing polypeptide molecular weight (see below). It is important to recognize that some proteins may not behave "normally" in these respects, for example, if they contain large amounts of carbohydrate. The SDS-PAGE method, as it is called, is currently probably the single most widely used electrophoresis technique in research laboratories.

Polynucleotide fragments have a relatively constant charge-to-mass ratio at physiological pH values, since each nucleotide is of similar molecular weight and has only a single charged group: the phosphate. If they have the same shape, separation of such fragments can be effected on the basis of molecular weight (i.e., number of nucleotides) by electrophoresis (10,13). This is the basis of the technique for determining polynucleotide sequences (see below).

It is possible to separate and measure molecular weights of native (double-stranded) DNA molecules that are larger than the average pore size of the support medium (14). The electric field pulls on all segments of the DNA equally, but eventually, because of random thermal movement, one end is farther along the field direction and the entire molecule is pulled after that end along a path through the gel. If the field is turned off, the stretched molecule contracts or relaxes into a more compact, unstretched condition. If the electric field is turned on again, the process starts over. The rates of these processes are slower with longer DNAs, so, if the rate of change of field direction is appropriate, the DNAs will separate according to size. If not, they will tend to run together. The change in direction of the applied field and the length of time the field is applied in any direction can be adjusted in commercial instruments. The gel used is agarose (agar without the agarosepectin). This is "pulsed-field" gel electrophoresis, and can separate DNA molecules as large as small chromosomes.

Sometimes adsorption strong enough to terminate electrophoretic movement is desired. Substances are separated on a sheet or thin slab of ordinary support medium, then an electric field is applied perpendicular to the face of the sheet and the separated substances are electrophoresed onto a facing sheet of adsorbent material such as nitrocellulose paper. This is "electroblotting" (13,15,16). It concentrates the electroeluted substances on the adsorbent sheet. This makes immunological detection (immunoblotting) or detection by any other method more sensitive (15,16). If the separated substances blotted are DNA, this is "Southern blotting" (17); RNA, "Northern blotting"; protein, "Western blotting" (10,13,15,16). These procedures are to identify

particular proteins or polynucleotides with particular sequences.

Cells in living organisms produce tens of thousands of proteins and polynucleotides, and in very different amounts: for example, the concentrations of serum proteins differ by up to 10^7 -fold, complicating analysis. Increased resolution has been also achieved through use of two-dimensional (2D) electrophoresis. Some 30–60 proteins can be resolved on a column or sheet of polyacrylamide. If electrophoresis is done in two dimensions, with separation on the basis of different properties of the proteins, 900–3600 proteins could be resolved (18,19). The most popular form of 2D electrophoresis involves isoelectric focusing on a gel strip for one dimension, attaching the gel strip to a gel sheet, and performing SDS-gel electrophoresis for the second dimension. Densitometers to scan the gels and software for computerized mapping and indexing of isolated proteins to help analyze the data are available commercially, for example, from BioRad Corp. and Amersham Biosciences Corp. The procedure is laborious and exacting; many factors affect the patterns obtained (19). Use of Immobiline gel strips for the first dimension separation is very important in improving reproducibility (19). The realized or potential information from 2D electrophoresis is so great that it is a very popular technique in research laboratories.

Voltage-Based Methods. Since diffusion is the enemy of separation and increases with the square root of the time (1), it is obviously better to carry out the electrophoresis faster. Since the velocity of electrophoresis increases with the voltage applied, using a higher voltage would improve resolution. However, increasing the voltage also increases the current and this increases electrophoretic heating, called "Joule heating". Joule heating is proportional to the wattage (volts times current) and can cause convective disturbances in solutions, even if a support medium is present. Joule heating is part of the reason electrophoresis is done in solutions with moderate conductivities, equivalent to 0.1 M NaCl or thereabouts (13): Ion concentrations must be high enough to minimize electrostatic interactions between large molecules (1), but high ion concentrations mean high conductivities, which means high current flow at a given voltage and therefore high heat generation. Joule heating is in fact the ultimate limiting factor in any electrophoretic procedure.

Use of thinner supports or capillaries minimizes the effects of heating. Thin (< 1 mm thick) sheets of polyacrylamide allow more efficient heat dissipation (from both sides) and are also useful when comparing samples. They are necessary for 2D electrophoresis (18,19). Thinner supports use less material but require more sensitivity of analysis. Capillaries are even more easily cooled (from all sides) and very high voltages, of the order of several thousand volts, can be used (11). The Beckman Coulter Paragon CZE 2000 has seven capillaries so can accommodate seven samples at once, and serum protein electrophoresis turnaround times are 10 min. Very small sample volumes, often a few nanoliters, are used. On the other hand, electroosmosis can be a major problem and the detection sensitivity is very low: the separated substances

pass a detector, and the capillaries, usually <0.1 mm in diameter, provide a very short optical pathlength. Detection at very short wavelengths such as 214 nm, where extinction coefficients are higher or use of other measuring methods such as fluorescence or mass spectrometry are alternatives that are employed. Still, the ability to use higher voltages for separation, thus improving resolution, has directed much attention to capillary electrophoresis.

EQUIPMENT AND PROCEDURES

The equipment for electrophoresis includes a power supply, the apparatus on which electrophoresis is actually performed, and the reagents through which electromigration occurs.

Power Supply

This is sometimes combined with the apparatus. The power supply provides a dc voltage that produces the electrophoretic movement. Maximum power outputs should be matched with requirements.

Some power supplies may provide for applying a constant voltage, constant power or constant current. The conductivity of a setup changes with time during electrophoresis because of ion movement, so constant voltage is used for ordinary electrophoresis, constant current for isotachopheresis or disc electrophoresis (to make the zone migration velocity constant) and constant wattage for isoelectric focusing (10). Many power supplies also feature timers to prevent running samples too long. Most have an automatic shutdown of power if the apparatus is accidentally opened. Because even low voltages can be dangerous, safety issues must be addressed.

Apparatus

Many types are available, from simple partitioned plastic boxes (e.g., from Beckman-Coulter) to large and elaborate ones (e.g., from Helena). All basically hold the material through which electromigration occurs, horizontally or vertically, either as a plug or cylindrical rod or, most commonly for routine clinical work, as a sheet. Sizes and shapes of electrophoresis chambers are usually determined by the cooling efficiency of the apparatus. Some have special chambers for circulating cold water and some instruments have incorporated cooling units. These may be able to electrophorese a few samples at a time or many.

Horizontal electrophoresis is preferred when the supporting medium cannot stand the mechanical stress of standing upright. Evaporation from the top surface is often a problem; DNA fragments are separated in "submarine" systems, where the support (an agarose gel) is covered in buffer. The supports used when electrophoresis is done vertically are sometimes encased in glass sheets.

The apparatus also provides for the connection between the electrophoresis chamber and the electrodes. Typically, the connection is made through two relatively large volumes of solution, or "reservoirs". These reservoirs minimize the effects of electrolysis. To reduce contamination from extraneous metal ions, the electrodes are normally made of platinum.

Accessories include drying ovens and containers for staining and washing supports, though these may be integrated with the rest of the apparatus.

Reagents

The reagents constitute the supporting medium and provide the ions for electrical conduction throughout much of the apparatus. The ionic substances should be of good purity, but the major requirement is that the ions should not interact strongly with the substances to be separated (like borate with glycoproteins) unless a specific interaction (e.g., SDS) is desired. This means low heavy metal content and avoidance of large polyanions. Generally, buffers and salts with low ionic charges (no greater than phosphate at pH 7 or so) are preferred.

The reagents for supporting media prepared in the laboratory are usually "electrophoresis grade" for the reasons just given; that is, ionic contaminants such as acrylic acid in acrylamide are preferred to be at low levels. Some workers claim that cheaper grades of many reagents are satisfactory. In our experience, the quality of SDS seems to be important, however.

For research work, gel supports are prepared by heating slurries of agar or agarose in buffer or polymerizing acrylamide and derivatives in buffer and pouring them into a support to set. A "comb" with wide teeth is placed in the cooling or polymerizing liquid to form a series of identical rectangular holes or depressions called "wells" in the support. The samples are mixed with sucrose or glycerol (to make them dense enough to fall into the wells) and also with a low molecular weight dye called "tracking dye" (to visibly mark the progress of electrophoresis), then pipetted into the wells before electrophoresis. For routine clinical use, samples of a few microliters of samples not mixed with sucrose or tracking dye are applied to the surface of the support through a template or mask and allowed to soak into the support a few minutes before electrophoresis.

Commercially prepared supports are convenient and tend to be more uniform, so are employed for routine clinical analysis. These include agarose, cellulose acetate and polyacrylamide. They have plastic sheets as backing for strength. Washing or preelectrophoresing these before use is usually unnecessary.

Measurements

This means determining velocity(ies) or location(s) of the substance(s) electrophoresed. In the cases of isotachopheresis or capillary electrophoresis, measurements of absorbance, fluorescence, heat generation, conductivity, and so on are made while the separation is occurring. If the substances are allowed to elute and are collected in separate fractions, analysis may be done at leisure using any appropriate technique.

Usually, the (hopefully) separated substances remain on the supporting medium; however, diffusion continues after electrophoresis and measurements must be made quickly or diffusion slowed or stopped after electrophoresis ends. Fluorescent labeled single-stranded polynucleotides are measured on DNA sequencing gels (polyacrylamide) using a scanning fluorometer. Double-stranded (native)

DNA is detected using dyes that become fluorescent when the dye molecules move between (intercalate) stacked nucleotide bases, which provides great sensitivity and selectivity. Photographs are made of the patterns. Direct measurement of proteins on the support is difficult to do as the support itself often absorbs in the ultraviolet (UV) or scatters. Transparency of cellulose acetate supports can be increased (clearing) by soaking the support in methanol-acetic acid before measuring absorbance. A scanning spectrophotometer must be used. Otherwise, the support is dried or the separated substances, usually proteins, precipitated in the support.

With autoradiography, radioactivity is measured, most often using photographic film (13) after the support is dried. Autoradiography is potentially the most sensitive method of measurement of distributions, since isotopes of very high specific activity can be used.

Precipitation of proteins in the support matrix is usually done by soaking the matrix in 7–10% acetic acid, though trichloroacetic acid is sometimes used. Any SDS must be removed or precipitation does not occur. Adding methanol (30–40%) to the acetic acid and soaking is usually done to remove SDS. The next step is staining using a dye: This is to enhance visibility, for purposes of inspection, photography, or, if a quantitative record is needed (generally the case in routine clinical work), measurement of the absorbance using a scanning spectrophotometer (densitometry). Some commercial clinical electrophoresis apparatuses (e.g., Helena) have automated staining; otherwise, it is done manually.

The support is soaked in a solution of a dye that strongly and specifically adsorbs to the denatured protein. Excess dye is removed by electrophoresis or by diffusion: subsequent soaking in the same solution but without the dye. This leaves a support with colored bands, dots, or stripes where protein can be found.

The important parameters for detection are specificity and sensitivity. One may be interested in staining specifically for phosphoproteins or lipoproteins, for example. Otherwise, the benchmark parameter is sensitivity. Tables showing frequently used stains are given in Refs. 2 and 13. The sensitivity of soluble protein stains increases with the molar extinction coefficient of the dye (20). Substances with very high effective extinction coefficients are more sensitive, such as metal stains (e.g., silver stain) or colloidal stains such as India ink or colloidal gold. Using silver staining, as little protein as 0.1 ng/band can be detected (13).

Sometimes some specific property must be measured, to identify a particular band or spot. With enzymes, the activity is the most specific property available, and two means of identification can be used.

If a substrate or product of the enzyme has a distinctive color, the support is soaked in an assay medium containing the reactant until a color change due to product (or substrate) appears. Naturally, the support and electrophoresis conditions must be such that the activity was not lost beforehand. If substrate or product is of low molecular weight, some way of restricting its diffusion must be used. Enzyme activity-specific stains are called “zymograms” (21).

Alternatively, the support can be cut into successive sections, incubated in assay medium, and absorbance or other changes resulting from enzyme activity measured. Generally, a duplicate support or half of a single support is stained for protein for comparison.

Recovery of material from supports is sometimes desired, for example, for mass spectrometry. The ease of recovery of large molecules such as proteins by diffusion is proportional to the pore size of the supporting medium. Recovery (especially from acrylamide gels) is sometimes done using electrophoresis.

The times required for electrophoresis, including staining and densitometry, are of the order of hours. This has limited clinical applications of electrophoretic techniques, though capillary electrophoresis techniques may change this.

EVALUATION

The result is a pattern or distribution profile given as a function of distance migrated. Often this is expressed as R_f values, relative to the distance migrated by a known ion, usually tracking dye. Electrophoresis of proteins without denaturants (native gel electrophoresis) on several gels of different percentages (pore sizes) is followed by plotting logarithms of their R_f values versus gel concentration, a “Ferguson plot” (12,13). This plot enables separation of the contributions of size and charge: isozymes, for example, have the same size (slopes of the lines) but different charges (ordinate intercepts). In the presence of SDS, protein complexes are dissociated (3,10,12,13). A protein of unknown subunit molecular weight is electrophoresed alongside of a mixture of proteins of known subunit molecular weight in the presence of SDS. The logarithms of the known molecular weights are plotted versus their R_f values, yielding an approximate straight line, and the unknown molecular weight obtained from its R_f value.

However, the pattern is often presented without further analysis. Electrophoresis experiments are often used to assess the purity or “homogeneity” of a preparation of a macromolecule. Electrophoresis is still the single most widely used criterion of purity. It is best if purity is tested under widely different electrophoresis conditions: different pH values, or the presence or absence of denaturants, such as urea or SDS, in the case of proteins.

Isoelectric points can be obtained most readily by isoelectric focusing, which can also be used as a criterion of purity.

A major use of electrophoresis currently is for DNA sequencing, owing to ongoing determinations of entire genomes of organisms. Capillary electrophoresis using linear (uncross-linked) polyacrylamide has replaced use of polyacrylamide sheets as the method of choice for this purpose, since throughput is increased several-fold because of the higher voltages that can be applied. Applied Biosystems has an instrument with 96 capillaries and Amersham Biosciences has models with up to 384 capillaries. Analysis of the profiles is done by the instruments: each fluorescent peak observed is assigned to adenine, cytosine, guanine, or thymine on the basis of the emission

Figure 2. Section of data printout from the Applied Biosystems Prism capillary electrophoresis apparatus. The profile shows signals (fluorescence) given by polynucleotides with a fluorescent nucleotide analogue at the end, obtained as these migrate past the detector. Each peak is produced by a polynucleotide that is one residue (nucleotide) longer than that producing the signal to its left and one residue shorter than the polynucleotide producing the peak to its right. The separation by molecular length is produced by electrophoresis through linear (uncrosslinked) polyacrylamide. Different nucleotide analogues give different emission maxima, so the output identifies these as A, C, G, or T. Note the increasing peak widths due to diffusion. The numbers are the lengths in residues of the polynucleotides. (Courtesy of Dr. John Wunderlich of the Molecular Genetics Instrumentation Facility of the University of Georgia.)

spectra observed as polynucleotides terminated by dideoxynucleotide derivatives (22) with different emission spectra electrophorese past the detector. Data from each capillary are printed separately (Fig. 2).

Routine clinical electrophoresis separations are mostly serum proteins, hemoglobins, or isozymes: creatine kinase, lactic dehydrogenase, and alkaline phosphatase. Then quantitation of the separated proteins is done.

Usually, the proteins are separated on agarose or cellulose acetate sheets, stained, and the resulting pattern scanned using a densitometer. The Beckman-Coulter CZE 2000 instrument with seven capillaries is approved by the FDA for serum protein analysis, and directly measures absorbencies as different proteins move past the detector. In either situation, the electrophoretic patterns from samples (blood serum, urine, or cerebrospinal fluid) obtained from patients are compared with those from samples taken from healthy people (Fig. 3). Higher immunoglobulin levels are seen with a number of conditions such as liver disease and chronic infections for example. The profiles may be analyzed visually, but some densitometers have analytical capabilities. Sometimes fluorescence [usually of reduced nicotinamide adenine denucleotide (NADH) in creatine kinase or lactic dehydrogenase isozyme assays] is scanned instead.

Figure 3. Recordings of absorbance at 214 nm versus time of serum protein electrophoresis on the Beckman-Coulter Paragon CZE 2000. The solid line is the electrophoretogram of a serum protein sample from a person with chronic hepatitis C, relative to a sample from a healthy person (broken line). Characteristic increase in the polyclonal gamma and decreases in albumin and transferrin zones occur. (Courtesy of Beckman-Coulter Inc.)

Reliability

Resolution of proteins whose isoelectric points differ by as little as 0.001 pH unit is claimed for isoelectric focusing using Immobiline gels (13).

The resolving power of electrophoresis on polyacrylamide is sufficiently high that hundreds of polynucleotides, each differing in length from one another by one nucleotide, are separated in DNA sequencing (Fig. 2). Estimates of molecular weights of proteins in SDS-gel electrophoresis is also very widely done. Small differences, of the order of 1000 Da, in molecular weights can be detected (13); absolute molecular weight estimates are less reliable, since the SDS binding depends on the composition of the protein (13). In the author's experience, most protein molecular weights estimated by this technique are not reliable beyond average limits of $\pm 10\%$. It is best to remember that "molecular sieving" techniques in general measure effective sizes, and estimates of molecular weight involves comparisons with proteins of known mass whose shapes and hydrations are assumed to be similar.

While electrophoresis results are generally fairly reproducible from experiment to experiment, it is best to use internal standards whenever appropriate. This is for location and identification of separated substances and for quantitation.

Electrophoresis is widely used, especially in the biological sciences for investigations of macromolecules. It is an excellent analytical method characterized by high resolution and sensitivity and moderately good reproducibility, a method capable of yielding considerable information about

size, shape, composition, and interactions of specific molecules and about distribution of large numbers of molecules at one time.

For clinical purposes, the resolution of isozymes such as lactic dehydrogenase is reliable enough that the technique has been used in critical care diagnoses, that is, life or death decisions.

INTRODUCTION

The Resting Membrane Potential

The cell membrane or sarcolemma, composed of lipid bilayer, is hydrophobic and is highly impermeable to most water-soluble molecules and ions. A potential is developed across the lipid bilayer of the cell membrane due to unequal distribution of charges on the two sides of the membrane, thus the membrane acts as a capacitor. Membrane proteins that span across cell membranes form ion channels allowing transport of small water-soluble ions across the membrane. These channels are highly selective and their selectivity depends on diameter, shape of the ion channel, on the distribution of charged amino acids in its lining (1). The movements of the ions through these channels across the membrane govern its potential.

The transport of the ions across the membrane is either passive or active. The passive mechanism of transport of any ion is governed by its electrochemical gradient, a combination of chemical force exerted by diffusion of ions due to concentration gradient and an electrical force exerted by the electric field developed due the charges accumulated on either side of the membrane (capacitor) (2). Physiologically, cells have a high intracellular potassium concentration, $[K^+]_i$, and a low sodium concentration, $[Na^+]_i$. Conversely, the extracellular medium is high in Na^+ and low in K^+ . In cardiac cells at rest, the membrane is mostly permeable to K^+ ions through K^+ leak channels. As K^+ flows out down its concentration gradient, a negative potential is built up inside the cell. This increases as long as it counterbalances the chemical driving force generated by concentration gradient. This potential at which the net ion flux is zero is called Nernst equilibrium potential of that ion. The equilibrium potential for K^+ is given by its

Nernst equation:

$$E_K = \frac{RT}{zF} \ln \frac{[K^+]_o}{[K^+]_i}$$

where R is the universal gas constant, T is temperature in kelvin, F is Faraday constant, z is the valency of the ion.

Typical resting membrane potentials of excitable cells vary from -90 to -50 mV, depending on the type of the cell. Epithelial cell and erythrocytes have smaller, but still negative membrane potentials. It may tend toward the excitatory threshold for an action potential as in a cardiac pacemaker cell or remain stable with approximately no net ion flux observed in nonpaced cardiac ventricular cells. As the ventricular cell at rest is more permeable to K^+ ions than to any other ion, the resting membrane potential (ca. -84 mV) is close to E_K at 37°C . Due to its permeability to other ions and also due to other transport mechanisms the resting membrane potential does not reach exactly E_K .

The active ionic transport mechanisms maintain the homeostasis of ionic concentrations in both the intra- and extracellular media. These membrane proteins are called carrier (pump) proteins and they utilize energy from hydrolysis of adenosine triphosphate (ATP) to transport ions against their concentration gradient.

EXPERIMENTAL TECHNIQUES TO QUANTIFY IONIC MECHANISMS IN CELLS

The advent of patch clamp technique (3–7) has made it possible to record the current from a single ion channel. The technique involves clamping a patch of the cell membrane and recording either voltage (current-clamp) or current (voltage-clamp or patch-clamp) across the membrane. Using this technique current of order as low as 10^{-12} A can be measured. This could be done using different configurations of patch clamping (7).

1. A freshly made glass pipette with a tip diameter of only a few micrometers is pressed gently on the cell membrane to form a gigohm seal. This is called as cell-attached patch configuration. The pipette solutions form the extracellular solution and the currents across the channel within the patch can be recorded.
2. When gentle suction is applied to the pipette in cell-attached configuration, the membrane ruptures while maintaining the tight seal and the cytoplasm and pipette solution start to mix. After a short time, this mixing is complete and the ionic environment in the cell is similar to the filling solution used in the pipette. This configuration is called whole-cell patch configuration. A recording obtained using this configuration is from whole cell and not from a patch. The advantage of this technique is that the intracellular environment is accessible through the pipette. Current-clamp technique is used in this configuration to measure the action potentials (APs) of excitable cells.

3. Sudden pulling out of the pipette from cell-attached configuration holds the patch that formed the gigohm seal giving rise to the inside-out configuration (inside of the cell membrane is exposed to external bath).
4. Slow pulling out of the pipette from whole cell configuration holds the patch that formed the gigohm seal giving rise to outside-out configuration. Both inside-out and outside-out configurations allow single channel recordings. Both the intracellular and extracellular baths are accessible in these cases.
5. The fifth configuration is obtained by creating artificial channels (permeabilizing membrane) on the cell-attached patch by administering antibiotics, like amphotericin. The voltage and current-clamp recordings obtained in this configuration recordings are similar to whole-cell recordings, the advantage being the intracellular medium is not dialyzed.

VOLTAGE-CLAMP TECHNIQUE

The method of voltage clamping has been the primary experimental tool used to reconstruct models of cellular electrical activity. As the behavior of the ion channels is highly nonlinear under changing action potential, this method enables us to quantify their properties by holding the transmembrane potential (membrane potential) at a particular voltage. The basic principle relies on providing current to balance those currents through the ionic channels that are open and thus the transmembrane voltage is clamped at a chosen constant level (clamp voltage). For example, if the Na^+ channel is studied, the membrane potential is initially held at rest. When this potential is changed instantaneously to a depolarized (more positive) potential, sodium channels open and Na^+ ions tend to move in. The voltage amplifier senses these small changes in voltage and a feedback current of equivalent amount is applied in opposite direction of the ion flow. This measurable current changes for different clamp potentials as the driving force ($V_{\text{Clamp}} - E_{\text{Na}}$), and the gating parameters at that V_{Clamp} changes enabling us to quantify the channel properties. Ion channels conduct ions at a rate sufficiently high that the flux through a single channel can be detected electrically using patch clamp technique. The basic circuit of voltage clamp setup is shown in Fig. 1.

CURRENT-CLAMP TECHNIQUE

The current-clamp technique is used to record action potentials. This technique involves clamping the cell in whole cell configuration and applying a suprathreshold current pulse for a short duration until the Na^+ channels start to activate. The transmembrane change in voltage gives the action potential recording.

A key concept to modeling of excitable cells is the idea of ion channel selectivity of the cell membrane. As the molecular behavior of channels is not known, modeling of

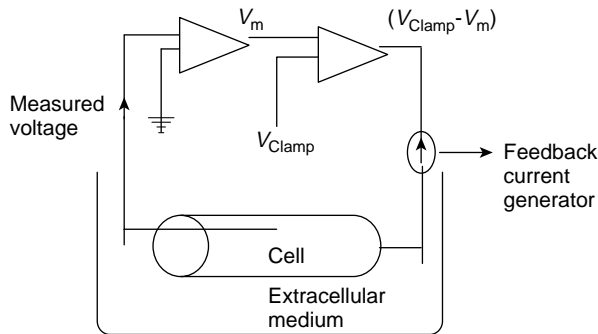

Figure 1. Simplified circuit representation of a voltage-clamp setup (8).

nonlinear empirical models of membrane processes help us to understand the role of various currents in the depolarization and repolarization phases and the phenomena that involve the interaction between these processes.

EXAMPLE OF ACTION POTENTIAL AND UNDERLYING IONIC BASIS: THE CARDIAC ACTION POTENTIAL

Membrane excitability is the fundamental property of the nerve and muscle cells, that is, in response to certain environmental stimuli, generates an all-or-none electrical signal or AP. Many different types of cardiac ion channels and ion pumps altogether form a complex process that results in cardiac AP (9). For example, the normal cardiac action potentials can be classified into two broad categories; those that are self-oscillatory in nature, such as pacemaker cells (sinoatrial and atrioventricular cells) and those that need an external stimulus above a threshold, also called supra threshold, in order to be evoked, such as atrial, Purkinjee fiber, or ventricular cells. An extraordinary diversity in the action potential configurations can be seen in different regions of the heart. The ventricular tissue in particular displays a wide variety of action potential waveforms. These APs include pacemaker potentials in purkinjee cells, and disparate action potential durations (APD) and morphologies in cells from the epicardial, mid-myocardial, and the endocardial layers of the ventricle. The ventricular action potential has been studied more frequently than other representative cardiac membrane potentials because ventricular arrhythmias are believed to constitute the majority of reportedly fatal incidences of cardiac arrhythmias (10).

Phases of Cardiac Action Potential

A typical ventricular action potential in higher mammals such as canine and human consists of four distinct phases (Fig. 1a). Phase 0 corresponds to a rapid depolarization or upstroke of the membrane action potential. Phase 1 is the initial rapid repolarization, and is followed by phase 2, which constitutes the action potential plateau. Phase 3 represents the final repolarization, which allows the ventricular cell to return to its resting state in phase 4. In addition to its morphological features, ventricular APs are commonly measured experimentally to determine its char-

Examples of Simulated Cardiac Ventricular Action Potentials

Figure 2. Examples of typical cardiac action potential waveforms of the dog (11) and rat (12) ventricular cell models. The action potential of the human ventricular cell would be similar to that of the dog (panel a). Please consult Tables 1 and 2 for the underlying ionic currents.

acteristics. These include the resting membrane potential (V_{rest}), the peak overshoot (PO) value that is the maximum positive value achieved during the initial phase 0 depolarization, the maximum upstroke velocity (dV/dt_{max}), which occurs during phase 0, and the APDs measured when the APs have repolarized to 50 and 90% of their final repolarization value, also called APD_{50} and APD_{90} , respectively.

One or more of these characteristics is usually altered in the setting of a pathophysiological condition, and helps to quantify the differences between the normal and the abnormal action potentials.

Contributions of Ion Channels to Cardiac Action Potential

The temporal changes in a typical ventricular action potential configuration, that is, depolarization followed by a repolarization (Fig. 2) are governed by the movement of different ions, such as Na^+ , K^+ , and Ca^{2+} ions across the sarcolemma. These ions are usually transported between the intracellular and the extracellular spaces by means of carrier proteins and channel proteins embedded in the cardiac membrane. These proteins form the passive (ion channel-mediated and carrier-mediated) and active (carrier proteins such as pumps and exchanger) transporters of the cell membrane. The ion channels, the pumps and exchanger are the major ionic currents that form an action potential in mathematical representations. A summary of these currents that are present in a typical cardiac ventricular cell and the role of the currents in action potential generation are summarized in Table 1. The major ionic currents contributing to different phases of the typical action potential are presented in Table 2. The ventricular action potential is the result of a delicate balance of the inward and outward ionic currents and the active transporters (pumps and exchangers).

Table 1. Major Ionic Membrane Mechanisms Underlying a Typical Cardiac Ventricular Action Potential

Membrane Mechanism	Description	Gene (α -subunit)	Role in Action Potential
<i>Inward Ionic Currents</i>			
I_{Na}	Na ⁺ current	SCN5A	Initial depolarization of action potential
I_{CaL}	L-type Ca ²⁺ current	α_{1C} , α_{1D}	Maintains plateau phase of action potential
I_{CaT}	T-type Ca ²⁺ current	α_{1G} , α_{1H}	Present in the late plateau phase
<i>Outward Ionic Currents</i>			
I_t	Ca ²⁺ -independent transient outward K ⁺ current	Kv4.2 Kv4.3 Kv1.4	Responsible for early repolarization
I_{Kr}, I_{Ks}	Rapid and slow delayed K ⁺ rectifier currents	HERG KvLQT1	Aids repolarization during plateau
I_{ss}, I_{Kslow}	Slow inactivating K ⁺ currents	Kv2.1 Kv1.5	Aids late repolarization
I_{K1}	Inward rectifier K ⁺ current	Kir2.1 Kir2.2	Late repolarization, helps establish V_{rest}
<i>Other Ionic Currents</i>			
I_{NaCa}	Na ⁺ -Ca ²⁺ exchanger current	NCX1 NCX2	Late depolarization
I_{NaK}	Na ⁺ -K ⁺ pump current	Na ⁺ -K ⁺ -ATPase (α)	Late repolarization

To restore the intracellular and extracellular ionic concentrations so that homeostasis is maintained, the ions that cross the cell membrane during an action potential are brought back by active mechanisms like Na⁺-K⁺ pump, Ca²⁺ pump and coupled transporters like Na⁺-Ca²⁺ exchanger, Na⁺-H⁺ exchanger. All the active mechanisms utilize hydrolysis of adenosine triphosphate (ATP), the cellular source of energy to achieve this. Of these, Na⁺-K⁺ pump, which brings in 2 K⁺ ions for 3 Na⁺ ions out per ATP consumed, results in a net positive current (I_{NaK}) in outward direction and Na⁺-Ca²⁺ exchanger, which exchanges 3 Na⁺ ions for one Ca²⁺ ion, results in a net positive current (I_{NaCa}) contributing a little to the action potential. In most species, the exchanger current is in its Ca²⁺ influx mode (reverse mode) during depolarization resulting in outward current and is inward during Ca²⁺ efflux mode during repolarization. This is because the equilibrium potential of the current given by ($3E_{Na} - 2E_{Ca}$) is around -40 mV (13). The current contributed by Ca²⁺ pump is negligible as it pumps few ions across membrane. The Na⁺-H⁺ exchanger transports one Na⁺ for H⁺ thereby causing no net flux across the membrane.

By convention, any current inward is considered negative and contributes to depolarization and any current outward is considered positive and contributes to repolarization. An inward current of a cation adds positive charge

to the intracellular content, thereby making the transmembrane potential more positive; that is, depolarizes the membrane away from the resting potential.

MATHEMATICAL MODELING OF CARDIAC CELLS

The Hodgkin-Huxley (HH) paradigm (14) type formalism is approached for numerical reconstruction of ventricular AP. At any particular moment, the movement of any particular ion across the membrane depends on the relative density of the channels, the probability of the channel that is selective to the ion being open, the conductance of the ion, and the net driving force of the ion given by the difference ($V_m - E_{ion}$), where V_m is the transmembrane voltage and E_{ion} is the Nernst potential of the ion (2). Also, it is assumed that ion fluxes are independent of each other, that is, the probability of an ion crossing the membrane does not depend on the probability of a different ion crossing the membrane. Based on this, the cell membrane is modeled as a capacitance in parallel to the resistances that represent the flow of ions through their respective channels along with their driving force. The resistive components are characterized in the original HH model as conductance's (g), the reciprocals of the resistances. The resistive currents can therefore be written

$$I_{ion} = g_{ion} * (V_m - E_{ion})$$

The experiments suggested that these conductances could be voltage and time dependent resulting in a gating mechanism. In HH type models, this gating mechanism is explained by considering the conductance g_{ion} as the product of maximum conductance $g_{ion-max}$ the channel can achieve and gating variables whose value lie between 0 and 1. The behavior of a gating variable x is given by first order differential equation:

$$dx/dt = (x_{\infty} - x)\tau_x$$

Table 2. The Action Potential Phases and the Major Ionic Current Contributors

Phases of Action Potentials	Description	Major Contributing Ionic Currents
Phase 0	Initial depolarization	I_{Na}
Phase 1	Early repolarization	I_t
Phase 2	Plateau phase	I_{CaL} , I_{Kr} , I_{Ks} , I_{CaT}
Phase 3	Late repolarization	I_{K1} , I_{NaK} , I_{NaCa} , I_{ss} , I_{Kslow} , I_{Kr} , I_{Ks} ,
Phase 4	Resting potential	I_{K1}

where x_∞ is the steady-state value the variable reaches at a particular voltage and τ_x is the time constant at that voltage that determines the rate at which steady state is reached. These variables are voltage dependent. All of these parameters are constrained by experimental data. These models represent the lumped behavior of the channels.

Increased understanding of the behavior of ion channels at a single channel level due to improved patch-clamp techniques lead to the development of state specific Markov models. Based on single channel recordings, it is observed that the channel opening or closing is random. Hence, the conductance $g_{\text{ion-max}}$ is multiplied by the total open channel probability of the ion (P_{ion}). These models represent the channel behavior based on their conformational changes and are capable of reproducing single channel behavior (15).

The rate of change of membrane potential to a stimulus current (I_{st}) is given by

$$(dV/dt) = (-1/C_m) * \left(\sum I_i + I_{\text{st}} \right)$$

where C_m is the membrane capacitance, and I_i values are different ionic currents.

THEORETICAL RESEARCH AND EXPERIMENTAL RESEARCH IN MURINE CARDIAC VENTRICULAR CELLS

After the first models of the mammalian ventricular cells by Beeler and Reuter (16) and Drouhard and Roberge (17), sophisticated mathematical models that simulate the cardiac action potentials in ventricular cells from different species such as canine (18,19), guinea pig (20–24), human (25,26), frog (27), and rabbit (28) have been published during the past decade. The model equations have usually based on the Hodgkin–Huxley (14) paradigm, wherein an ionic current is described by a set of nonlinear differential equations, and the parameters within these equations are constrained by experimental data obtained via voltage-clamp experiments in ventricular myocytes. There is a growing recognition that it is important to understand the complex, nonlinear interactions between the ionic milieu of the cardiac cell, that ultimately influence the action potential (29).

The mathematical models have demonstrated to be useful didactic tools in research, and have also quantified the important functional differences in the action potential properties between different species. Additionally, the computational models have also provided valuable, semi-quantitative insights into the diverse ionic mechanisms underlying the normal/abnormal action potential behavior in different animal models. It is not always possible to make precise experimental measurements regarding the contribution of a particular ionic mechanism to an aberrant action potential. The simulation results from these cardiac models have helped in planning for future experimental studies, and also in making predictions in cases where suitable technology is unavailable (or not developed) to make direct experimental measurements (e.g., visualizing the transmural activity within the ventricular wall). These models will play increasingly important roles in

addition to experimental studies in the design and development of future drugs and devices (30). An additional and important feature of these ventricular models has been their ability to simulate intracellular Ca^{2+} transient ($[\text{Ca}^{2+}]_i$). Thus these models incorporate the feedback mechanism between the APD and the intracellular calcium $[\text{Ca}^{2+}]_i$. The APD is known to influence the amplitude of the $[\text{Ca}^{2+}]_i$ in ventricular cells (31), and $[\text{Ca}^{2+}]_i$ in turn influences the action potential waveform by Ca^{2+} -induced Ca^{2+} inactivation of I_{CaL} , and by determining the peak magnitude of I_{NaCa} (13).

The previously developed mathematical models of human, dog, guinea pig, rabbit and frog provide a good basis for the understanding of the ionic mechanisms responsible for the generation of the cardiac action potential. However, there are significant differences in the action potential waveforms and their corresponding properties between different species. The unique nature of the rat cardiac action potential, coupled with the recent available experimental data for the ionic mechanisms involved in the genesis of the action potential in isolated rat myocytes, provided the motivation for us to develop the first detailed mathematical model of the rat ventricular action potential. An adult male rat ventricular myocyte model was constructed (32) and utilized this model to study the ionic basis underlying the action potential heterogeneity in the adult rat left ventricle. Important insights into the role of long lasting Ca^{2+} current (I_{CaL}), the Ca^{2+} -independent transient outward K^+ current (I_t), and the steady-state outward K^+ current (I_{ss}) in determining the electrophysiological differences between epicardial and endocardial cells were obtained. This ventricular cell model has been used to investigate the ionic mechanisms that underlie altered electrophysiological characteristics associated with the short-term model of streptozotocin induced, type-I diabetic rats (33) and spontaneously hypertensive rats (34). Our rat ventricular myocyte model was further utilized to develop models for the mouse apex and septal left ventricular cells (35–37). Thus these model simulations reproduce a variety of experimental results, and provide quantitative insights into the functioning of ionic mechanisms underlying the regional heterogeneity in the adult rat and mouse ventricle.

The ventricular cell models of dog, guinea pig, human, and rabbit described in the previous section have been mainly used to simulate the so-called spike and dome configurations for action potentials (Fig. 2A) commonly observed in ventricular cells from larger mammalian species (38). However, no mathematical model has been published to represent the murine (rat or mouse) cardiac action potential (Fig. 2B) until our rat ventricular cell (12). The murine ventricular action potentials have a much shorter APD (typically the APD at 90% repolarization (APD_{90}) is < 100 ms), and lack a well-defined plateau phase (triangular in shape) (39–41). A comparison of the experimentally recorded ionic currents underlying action potentials in rat–mouse and other mammalian ventricular cells shows that they display markedly different amplitudes and time-dependent behavior. In fact, despite the similarity of action potential waveforms in rat and mouse, the underlying nature of the repolarizing K^+ currents are

different (41–43). Thus the unique action potential characteristics, and the lack of models to quantify these membrane properties provided the motivation to develop the rat and mouse ventricular cell models. The other motivation in this case was the widespread use of the murine cardiovascular system for the investigation of the cellular and molecular physiology of the compromised cardiovascular function (44).

Experimental studies indicate that the patterns of action potential waveforms are somewhat similar in rodents (rat or mouse), although the APD is shorter in mouse, and the complement of the K^+ currents underlying the cardiac repolarization in mouse are also different than those in rat (45,46). The cardiac repolarization in rat is controlled by two distinct depolarization activated K^+ currents, the Ca^{2+} -independent transient outward K^+ current (I_t) and the steady-state outward K^+ current (I_{ss}), (40,47). In mouse ventricular myocytes, an additional current, the 4-AP sensitive (at concentrations less than 100 μM), slowly inactivating, delayed rectifier K^+ current (I_{Kslow}) has been deemed to play an important role (41,48). The properties of the depolarization-activated K^+ currents have now been well characterized in rats (40,49) and mouse (43,48), and appear to be significantly different. It is therefore interesting to investigate in computational modeling whether the reported differences in the properties of the depolarization-activated K^+ currents can account for the dissimilar nature of the action potential configurations observed in rats and mice.

COMPUTATIONAL MODELING OF THE MURINE VENTRICULAR ACTION POTENTIALS

The goal of my computational modeling laboratory has been to unify different experimental data and to develop biophysically detailed models for the rat and mouse ventricular cells and to determine the underlying ionic channels responsible for differences in cardiac action potential variations in rats and mice under normal and diseased conditions. A computational model has been developed for the rat cardiac ventricular cell based on electrophysiology data. Our control model (12) represents the bioelectric activity in the left ventricular cells in adult male rats. The differences in the membrane properties within the left ventricle to simulate the action potential variations of the endocardial and epicardial cells have been formulated. Also, a right ventricular cell model from our control model was built (the left ventricular cell model) to investigate ionic mechanisms in diabetic rats (33). Our right ventricular cell model was also the template for us to develop a mouse ventricular cell model by utilizing experimental data (8,32).

The left (LV) and right (RV) ventricular cell models for the rat consist of a Hodgkin–Huxley type membrane model that is described by the membrane capacitance, various ionic channels; the fast Na^+ current (I_{Na}), long-lasting Ca^{2+} current (I_{CaL}), the 4AP sensitive, Ca^{2+} independent transient outward K^+ current (I_t), steady-state outward K^+ current (I_{ss}), inward rectifier K^+ current (I_{K1}), hyperpolarization activated current (I_f), linear background current

(I_B); the Na^+/Ca^{2+} ion exchanger (I_{NaCa}), and the Na^+/K^+ (I_{NaK}) and Ca^{2+} membrane (I_{CaP}) pumps, that are experimentally observed in rat ventricular cells.

The mouse ventricular cell model was constructed by using the rat right ventricular cell model as the template. The mouse LV apex cell was developed by adding the 4AP sensitive slowly inactivating, delayed rectifier K^+ current (I_{Kslow}) based on the data of Fiset et al. (41) and Zhou et al. (48), and by reformulating I_t and I_{ss} based on experiments performed by Agus et al. (35–37) and Xu et al. (43) in mice. Further, a mouse LV septum cell model was developed by formulating a new current I_{tos} based on the data of (Xu et al. (43)), and by reducing the densities of I_{tof} , I_{Kslow} , and I_{ss} by 70, 23, and 30%, respectively, based on data of Gussak et al. (45).

The important results of our simulation studies are

1. The action potential heterogeneity (Fig. 3) in the adult rat LV is mainly due to the changes in the density and recovery kinetics of I_t and due to the altered density of I_{Na} (12).
2. The RV cell model can be developed from the LV cell model by changing the densities of I_t , I_{ss} , I_{CaL} , and I_{NaK} based on experimental data.
3. The changes in the density and the reactivation kinetics of I_t can account for the action potential prolongation differences in RV myocytes of diabetic (type-I, short term) rats (33) and LV myocytes of spontaneously hypertensive rats (35) (Fig. 4).
4. The presence of I_{Kslow} in mouse is one of the main factors contributing to the faster rate of repolarization seen in mouse compared to rats (Fig. 5) (8).
5. The LV septum cell model had more prolonged action potentials than the apex cells and these simulation results (Fig. 6a) are qualitatively similar to the experimental data of (52) (Fig. 6b).

Simulated Action Potentials of the Epicardial and Endocardial Cardiac Ventricular Cells

Figure 3. Simulated action potentials of the rat left ventricular (LV) epicardial (EPI) (solid line) and endocardial (ENDO) (dashed line) cells (35–37).

Simulated Action Potentials of the Epicardial Cardiac Ventricular Cells for Normal and Spontaneously Hypertensive Rats

Figure 4. Model generated ventricular action potentials of the epicardial cells for the normal rat (N) (solid line) and spontaneously hypertensive (SH) rat (dashed line) (35–37).

- The rat epicardial and endocardial ventricular cell models were more rate-sensitive than the mouse ventricular cell model and these simulation data match the experimental data well.

In conclusion, the mathematical modeling study of murine ventricular myocytes complements our knowledge of the biophysical data with simulation data and provide us with quantitative descriptions to understand the ionic currents underlying the cardiac action potential variations in different species. This kind of computational work will

Figure 6. Simulated and experimentally recorded action potentials of the mouse left ventricular apex (A) (solid line) and the septum (S) (dashed line) cells (35–37).

enhance our understanding of the ionic mechanisms that contribute to the cardiac action potential variation in normal and diseased animals, and will provide us with better treatments for diseases in humans.

DISSEMINATION OF COMPUTATIONAL MODELS

My computational modeling laboratory has developed an interactive cell modeling web site, iCell (<http://ssd1.bme.memphis.edu/icell/>) since 1998. iCell, that integrates research and education, was specifically developed as a simulation-based teaching and learning resource for electrophysiology (35–37,51,52). The main objectives for the development of iCell were (1) to use technology in electrophysiology education, (2) to provide a learning and teaching resource via internet for cellular electrophysiology, (3) to allow the user to understand the cellular physiology mechanisms, membrane transport and variations of action potentials and ion channels by running simulations, and (4) to provide a computer platform independent resource for cellular models to be used for teaching, learning and collaboration. The site consists of JAVA applets representing models of various cardiac cells and neurons, and provides simulation data of their bioelectric transport activities at cellular level. Each JAVA-based model allows the user to go through menu options to change model parameters, run and view simulation results. The site also has a glossary section for the scientific terms. iCell has been used as a teaching and learning tool for seven graduate courses at the Joint Biomedical Engineering Program of University of Memphis and University of Tennessee. This modeling tool was also used as a collaboration site among our colleagues interested in simulations of cell membrane activities. Scientists from the fields of biosciences, engineering, life sciences and medical sciences in 17 countries, Argentina, Belgium, Brazil, Canada, China, England, Germany, Greece, Ireland, Japan, Korea, the Netherlands, New Zealand, Spain, Taiwan, Turkey and the United States, have tested and utilized iCell as a

simulation-based teaching, learning and collaboration environment. The platform-independent software, iCell, provides us with an interactive and user-friendly teaching and learning resource, and also a collaboration environment for electrophysiology to be shared over the Internet. The usage of simulations for teaching and learning will continue advancing simulation-based engineering and sciences for research and development.

The simulations provided by iCell and other resources, such as CellML (<http://www.cellml.org/public/news/index.html>), Virtual Cell (<http://www.nrcam.uchc.edu/>), JSIM (<http://nsr.bioeng.washington.edu/PLN/Software/>), simBio Cell/Biodynamics Simulation Project of Kyoto University (<http://www.biosim.med.kyoto-u.ac.jp/e/index.html>), and E-Cell (<http://ecell.sourceforge.net/>), will continue signifying the important verification and prediction capabilities of the computer models to represent, analyze and complement the physiological data and knowledge. The model development demonstrates that computational models have to be constructed from experimental electrophysiology data, not only to explain and to verify the data that they are based on, but also to predict results for experiments that have not been performed and to guide future experiments.

Overall, computational modeling and simulation results continue to advance our understanding of living systems at the cellular level in cardiac electrophysiology while promoting collaborations and training in interdisciplinary field of bioengineering between scientists in life scientists and engineers. The presentation of computational models in user friendly, interactive and menu driven software are important in bringing collaborators of different disciplines and training scientists and students in cross-disciplinary projects.

IMPACT OF COMPUTATIONAL MODELING IN VENTRICULAR CELLS

The following summarizes impacts of the computational model development of ventricular bioelectric activity and the model-generated data in different disciplines of life sciences. I. *Biophysics and Physiology*: The results of the computational studies expand our knowledge of the living systems at the cellular level in electrophysiology. II. *Clinical Physiology and Medicine*: The insights gained and conclusions derived from the computational studies enhance our understanding of the biocomplexity of the heart, and provide us with better knowledge to be used in the future in treatments for diseases in humans. The cardiac cells' responses to various pathophysiological states with simulation data will also be better understood. III. *Pharmacology*: The differences in ventricular membrane ionic currents, especially outward K^+ currents in different species have very important practical implications. Different drugs are known to affect different ionic currents and to change action potential waveforms in different mammalian heart preparations under various conditions of development, aging and gender. A better understanding of the role of the ionic currents that control repolarization in the ventricular myocytes obtained from various species including rat and mouse, as presented

in this paper, will provide motivation and explanations for species differences in treatment and drug actions, and also promote pharmacological research that may lead to the development of more specific drugs to be used in children and adults.

ACKNOWLEDGMENTS

These computational research projects presented here were funded by the Whitaker Foundation (PI: Dr. S. S. Demir). The author acknowledges the contributions of her former students S. Pandit, S. Padmala, and E. Damaraju to these research projects.

The author thanks her former students, Joe E. McManis, Yiming Liu, Dong Zhang, Srikanth Padmala and Eswar Damaraju for coding JAVA applets in the iCell project, her students Chris Oehmen and Jing Zheng for posting the html pages and Dr. Emre Velipasaoglu, Siddika Demir and Asim Demir for valuable collaborations and discussions. This research was also funded by the Whitaker Foundation (PI, Dr. S. S. Demir).

ELECTRORETINOGRAPHY

GRAHAM E. HOLDER
Moorfields Eye Hospital
London, United Kingdom

INTRODUCTION

The retina, situated at the back of the eye, is highly complex, consisting of different layers and containing many different cell types. It serves to encode images of the outside world into a suitable form for transmission to the brain for interpretation and the process of “seeing”. It is possible to view the retina *in situ* using ophthalmoscopic techniques, and although this may reveal anatomical abnormalities, it may not reveal either the extent or nature of retinal dysfunction. The principal challenge for electroretinography is to provide information regarding retinal function to facilitate patient care.

In essence, a controlled light stimulus is used to stimulate the retina, which responds by generating very small electrical signals that can be recorded, with suitable amplification, using electrodes situated in relation to the eye, usually contacting the cornea. These electrical signals, the electroretinogram (ERG), have defined parameters (timing, shape, size) in normal individuals, and are altered in a predictable manner in disease. In general, the brighter the stimulus, the higher is the amplitude and the shorter the peak time of the ERG. Modification of the adaptive state of the eye (dark adapted or scotopic; light adapted or photopic) facilitate the separation of different cell types and layers within the retina. The objective information provided by electrophysiological examination has a significant effect both on diagnosis and patient management (1).

TECHNIQUES

The main tests of retinal function are the ERG, the massed retinal responses to full-field luminance stimulation, which reflects the function of the photoreceptor and inner nuclear layers of the retina, and the pattern electroretinogram (PERG), which, in addition to being “driven” by the macular photoreceptors, largely arises in relation to retinal ganglion cell function. Knowledge of this latter response can also be particularly useful in improved interpretation of an abnormal cortical visual evoked potential (VEP), but that topic is beyond the remit of this contribution, and the reader is referred elsewhere for a full discussion of the interrelationships between PERG and ERG, and PERG and VEP (2). Brief reference will also be made to the electrooculogram (EOG), which examines the function of the retinal pigment epithelium (RPE) and the interaction between the RPE and the (rod) photoreceptors, and is often used in conjunction with the ERG.

Electrophysiological recordings are affected not only by stimulus and recording parameters, but also by the adaptive state of the eye, and standardization is mandatory for meaningful scientific and clinical communication between laboratories. The International Society for Clinical Electrophysiology of Vision (ISCEV) has published Standards

for EOG (3), ERG (4), PERG (5), and the VEP (6). Readers are strongly encouraged not only to adhere to the recommendations of those documents, but also to consider that the Standards are intended as minimum data sets, and that recording protocols in excess of the Standards may be necessary to accurately establish the diagnosis in some disorders. Typical normal traces appear in Fig. 1.

A brief description of each test follows, with emphasis on response generation. Referencing has been restricted; the reader is referred to standard texts for further details (7,8). The multifocal ERG (mfERG) is a relatively recent addition to the diagnostic armamentarium, and although currently more of a research application than a mainstream clinical tool, this is likely to change in the future as more knowledge is gained of the clinical applications and underlying mechanisms. The ISCEV has published guidelines for mfERG, to which the reader is referred (9).

THE ELECTROOCULOGRAM

The EOG enables assessment of the function of the RPE, and the interaction between the RPE and the retinal photoreceptors. The patient makes fixed 30° lateral eye movements during a period of 20 min progressive dark adaptation, followed by a 12–15 min period of progressive light adaptation. The eye movements are made every 1–2 s for ~10 s each minute. The amplitude of the signal recorded between electrodes positioned at medial and lateral canthi reaches a minimum during dark adaptation, known as the dark trough, and a maximum during light adaptation, the light peak. The development of a normal light peak requires normally functioning photoreceptors in contact with a normally functioning RPE, and reflects progressive depolarization of the basal membrane of the RPE. The EOG is quantified by calculating the size of the light peak in relation to the dark trough as a percentage, the Arden index. A normal EOG light rise is >175% for most laboratories.

THE ELECTRORETINOGRAM

The functional properties of the retinal photoreceptors underpin the principles of ERG recording. The retinal rod system, with ~120,000,000 rod photoreceptors, is sensitive under dim lighting conditions, has coarse spatial and poor temporal resolution. The rods adapt slowly to changes in lighting conditions. They do not enable color vision. They have a peak spectral sensitivity in the region of 500 nm. There are three types of retinal cone. (1) Short wavelength (S-cone), (2) medium (M-cone), and (3) long wavelength (L-cone). In the past, they have been referred to as blue, green, and red, respectively. There are perhaps 7,000,000 M- and L-cones and 800,000 S-cones. The relative proportion of L- versus M-cones varies from individual to individual, but approximates to 50% over a population. They are sensitive under bright lighting conditions; their high spatial resolution enables fine visual acuity; they adapt rapidly to changes in lighting conditions and can follow a fast flicker (L- and M-cones). The overall maximum spectral sensitivity is ~550 nm, in the green-yellow

Figure 1. Typical normal ERG recordings. The rod specific ERG consists of the inner-nuclear layer generated b-wave. With a bright flash the waveform now contains an additional a-wave, the first 10–12 ms of which arise in relation to photoreceptor hyperpolarization. The rod specific and bright flash responses are recorded with full scotopic adaptation. After restoration to photopic adaptation the cone flicker and single flash ERGs are recorded. The former consists of a sinusoidal type waveform, the latter containing clear a- and b-waves. The pattern ERG (PERG) is the response of the macula to a reversing black and white checkerboard. See text for further details.

region of the color spectrum. Normal color vision requires all three cone types, but providing at least two cone types are present (there are some disorders in which that is not the case), at least some color vision is enabled. There are no S-cones in the foveola, the very central part of the macula responsible for very fine acuity.

The ERG is recorded using corneal electrodes and is the mass electrical response of the retina using a brief flash of light as a stimulus. The stimuli are delivered using a Ganzfeld bowl, an integrating sphere that enables uniform whole field illumination (Fig. 2a, b). In addition to flash stimulation, the Ganzfeld also allows a diffuse background for photopic adaptation. Some corneal electrodes are bipolar contact lenses with a built-in reference electrode. If such an electrode is not used, the reference electrodes should be sited at the ipsilateral outer canthi. A standard flash is defined by ISCEV as $1.5\text{--}3.0\text{ cd}\cdot\text{s}\cdot\text{m}^{-2}$. The response to this flash under scotopic conditions, with a fully dilated pupil, is the Standard or mixed response (Fig. 1). It is probably this response that may be regarded as the “typical” ERG, but although there is a cone contribution, the standard response is dominated by rod driven activity. The “maximal” ERGs that appear in this article were recorded to $\sim 11.0\text{ cd}\cdot\text{s}\cdot\text{m}^{-2}$ flash better to view the a-wave. The use of a brighter flash of such intensity is “suggested” in the most recent ISCEV ERG Standard (4). The initial $\sim 10\text{ ms}$ of the a-wave arises in relation to hyperpolarisation of the (rod) photoreceptors and the slope of the a-wave can be

related to the kinetics of phototransduction (10). The larger positive b-wave is generated postreceptorally in the inner-nuclear layer of the retina in relation to depolarization of the ON-bipolar cells (11). The oscillatory potentials, the small wavelets on the ascending limb of the b-wave, are probably generated in relation to amacrine cell activity. When the standard flash is attenuated by 2.5 log units, the stimulus intensity falls below the cone threshold, and a rod-specific b-wave is obtained. At this relatively low luminance there is insufficient photoactivation to record an a-wave (Fig. 1, column A, top).

The ERGs that reflect cone system activity are obtained using a rod-saturating photopic background ($17\text{--}34\text{ cd}\cdot\text{m}^{-2}$) using superimposed single flash and 30 Hz flicker stimulation. The rod system has low temporal resolution and use of a 30 Hz stimulus, combined with a rod-suppressing background, allows a cone-system specific waveform to be recorded. This response is probably the more sensitive measure of cone dysfunction, but is generated at an inner-retinal level (12) and thus does not allow the distinction between cone photoreceptor and cone inner-nuclear layer dysfunction. Although there is a demonstrated contribution from hyperpolarizing (OFF-) bipolar cells to shaping the photopic a-wave (13), this component nonetheless has some contribution from cone photoreceptor function, and some localization within the retina may be obtained with the single flash cone response. The cone b-wave reflects postphototransduction activity, and to a

Figure 2. (a) A conventional Ganzfeld used for ERG recording (front view). (b) The subject in position at the Ganzfeld. (c) Photograph taken using an infrared (IR) camera at the back of the Ganzfeld, which is used to monitor eye position and eye opening during both dark adapted and light adapted conditions. The two gold-foil corneal recording electrodes are well seen. The central forehead ground electrode is easily seen; the outer canthus reference electrodes are just visible. (Courtesy of Chris Hogg.)

Figure 3. A “mini-Ganzfeld” based on light emitting diode technology. The device shown has four independent color channels, blue, green, orange and red, each of which can be used as stimulus or background alone or in combination. (Courtesy of Chris Hogg, CH electronics, Bromley, Kent, UK; www.ch-electronics.net.)

short flash stimulus ON and OFF activity within the photopic system is effectively synchronized.

Separation of the cone ON (depolarizing bipolar cells, DBCs) and OFF (hyperpolarizing bipolar cells, HBCs) responses can be achieved using a long duration stimulus with a photopic background (14,15). The stimulus can be generated either via a shutter system or by using light emitting diodes (Fig. 3). Stimulators based on light emitting diodes (LEDs) offer several advantages over standard stimulators. They are of low cost, have a stable output intensity over time (reducing the need for calibration), enable variable and highly accurate stimulus duration, and have a well-defined narrow band spectral output. Further, being driven by relatively low voltage and current, they are intrinsically safe, and generate low electrical noise. Their use in ERG systems can be expected to increase.

It is also possible to elicit the activity of the S-cone population. In the author’s laboratories this is achieved using blue stimuli superimposed upon a bright orange photopic background, again delivered using a LED based device. The background thus serves to suppress activity from rod and L-/M-cone systems. The response under appropriate recording conditions consists of an early component at ~30 ms arising in relation to L-/M-cone systems (there is overlap of the spectral sensitivities of the different cone systems and a small response arises from L-/M-cones with a bright blue stimulus), followed by a component specific for S-cone function at 45–50 ms (16).

The retinal ganglion cells do not significantly contribute to the clinical (flash) ERG. Also, as a mass response, the ERG is normal when dysfunction is confined to small retinal areas, and, despite the high photoreceptor density, this also applies to macular dysfunction; the full-field ERG is normal if dysfunction is confined to the macula (e.g., Fig. 4, column B).

THE PATTERN ELECTRORETINOGRAM

The response of central retina to a structured isoluminant stimulus can be measured, and is known as the pattern

ERG. The stimulus is usually a reversing black and white checkerboard. The PERG has largely inner retinal origins, but is “driven” by the macular photoreceptors, and PERG measurement thus provides both a measure of central retinal function and, in relation to its origins, of retinal ganglion cell function. It is thus of clinical importance not only in the objective assessment of macular function, but also in the electrophysiological differentiation between optic nerve and macular dysfunction by providing a measure of the retinal response to a similar stimulus to that used to evoke the VEP (see Ref. 2 for a comprehensive review). It is a much smaller signal than the (full-field) ERG and computerized signal averaging is used to extract the PERG signal.

The PERG is recorded using noncontact lens electrodes in contact with the cornea or bulbar conjunctiva to preserve the optics of the eye. Suitable electrodes are the gold foil (17), the DTL (18), and the H–K loop (19). Ipsilateral outer-canthus reference electrodes are essential to avoid contamination from the cortically generated VEP, such as occurs if forehead or ear “reference” electrodes are used (20). Pupillary dilation is not used.

There are two main components of PERG to a reversing checkerboard with a relatively slow reversal rate (<6 reversals s^{-1}). There is a prominent positive component, P50, at ~50 ms followed by a larger negative component, N95, at ~95 ms (21). Clinical measurement of the PERG usually comprises the amplitude of P50, measured from the trough of the early negative N35 component; the peak latency of P50; and the amplitude of N95, measured to trough from the peak of P50 (Fig. 1). Approximately 70% of P50 is likely to be related to retinal ganglion cell function, but the remainder is not related to spiking cell function and may be generated more distally in the retina (22). The exact origins have yet to be ascertained at the time of writing. The N95 is a contrast-related component generated in the retinal ganglion cells.

An analysis time of 150 ms or greater is usually used for recording the PERG, with ~150 averages per trial needed to obtain a reasonable signal-to-noise ratio. As it is a small response, stringent technical controls are important during recording and are fully discussed elsewhere (8). Binocular stimulation and recording is preferred so the better eye can maintain fixation and accommodation, but it is necessary to use monocular recording if there is a history of squint. P50 is sensitive to optical blur, and accurate refraction is needed. At low stimulus frequencies the amplitude of the PERG is related almost linearly to stimulus contrast. A high contrast black and white reversing checkerboard with 0.8° checks in a $10\text{--}16^\circ$ field is recommended by ISCEV.

MULTIFOCAL ERG

The mfERG attempts to provide spatial information regarding cone system function in central retina. The stimulus usually consists of multiple hexagons displayed on a screen (Fig. 5a) each of which flashes on with its own pseudo-random binary sequence (an M-sequence). A cross-correlation of the local flash sequence with the mass

Figure 4. Typical electroretinographic abnormalities in selected diseases compared to those in a normal subject. Column A: Normal subject. Column B: A patient with macular dysfunction; the PERG is undetectable, but full-field ERGs are normal. Column C: “Classical” retinitis pigmentosa; all full-field ERGs are virtually extinguished, but the PERG is normal reflecting sparing of central retinal function. Column D: Rod-cone dystrophy (retinitis pigmentosa); the rod and cone ERGs are markedly abnormal (with the rod ERG being more affected). Note the delayed and reduced cone ERGs, typical abnormalities present when there is generalized cone involvement in the context of photoreceptor degeneration. The abnormal PERG reflects involvement of the macula. Column E: Cone dystrophy; the rod and bright flash ERGs are normal, but the cone single flash and flicker ERGs are delayed and reduced in keeping with generalized cone system dysfunction. The abnormal PERG reflects involvement of the macula. Column F: X-linked congenital stationary night blindness (complete type). The rod specific ERG is undetectable, but the normal a-wave of the bright flash dark adapted ERG confirms the dysfunction to be postphototransduction. There are subtle but significant changes in cone-system derived ERGs (note particularly the broadened trough and reduced amplitude sharply rising peak of the b-wave), and reduction in the PERG.

response derives the responses relating to each individual hexagon thus giving multiple cone system ERG waveforms from a single recording electrode. The mfERG can be of use in disturbances of macular function and to assess the degree of central retinal involvement in generalized retinal disease, but is highly susceptible to poor fixation, and the ability of a patient accurately to maintain good fixation throughout the recording session is a pre-requisite to obtaining clinically meaningful data. Increasing use and development of systems that can control stimulus delivery in relation to eye position can be anticipated. Possibilities include the use of “eye-tracking” devices and direct fundus visualization during stimulation.

CLINICAL APPLICATIONS

EOG

Disorders of rod photoreceptor function can affect the EOG, and the light rise is typically reduced in generalized photoreceptor degenerations such as retinitis pigmentosa (RP,

rod-cone dystrophy), a genetically determined group of disorders. Usually, the reduction in EOG light rise parallels the degree of rod photoreceptor dysfunction, but generalized RPE dysfunction can also manifest a reduced EOG light rise. Indeed, it is the latter property that leads to the main clinical use of the EOG, the diagnosis of Best disease. Best disease, or vitelliform macular dystrophy, is a dominantly inherited macular degeneration related to mutation in the gene *VMD2*. At presentation there are often distinctive vitelliform lesions at the maculae on funduscopy, but other appearances may occur. The diagnostic findings are of a severely reduced or absent EOG light rise accompanied by normal ERGs. Best disease may present in childhood, but a child may find the repetitive eye movements needed for EOG recording difficult or impossible to maintain for the required 30–40 min. Under such circumstances it is appropriate to test both parents; due to the dominant inheritance pattern one of the disorder, one of the parents will have carry the mutant gene and will manifest a reduced EOG. Adult vitelliform macular dystrophy (pattern dystrophy) may sometimes clinically

Figure 5. (a) the typical multifocal ERG stimulus; (b) a normal subject; (c) a macular dystrophy. There is loss of the responses to central hexagons but preservation of more peripheral responses. (d) A retinal dystrophy with sparing of central macular function but loss of the responses in the periphery.

be mistaken for Best disease, but although the EOG light rise may be mildly subnormal, it is not reduced to the same extent as in Best disease. The electrophysiological recordings will usually resolve any clinical dilemma in differential diagnosis.

ERG

Although the rod specific ERG b-wave is a sensitive indicator of retinal rod system dysfunction, the fact that it is generated in the inner-nuclear layer of the retina means that reduction in this response does not allow localization of the defect either to those structures or the upstream rod photoreceptors. It is the a-wave of the responses to brighter flashes that directly reflects activity of the photoreceptors and enables the distinction between photoreceptor dysfunction and a primary disorder of inner-retinal function. Genetically determined photoreceptor degenerations, such as the rod-cone (retinitis pigmentosa, RP) or cone-rod dystrophies, thus give overall ERG reduction (Fig. 4, columns C, D). The cone-derived ERGs in generalized photoreceptor degeneration characteristically show abnormalities of both amplitude and timing, particularly evident in the flicker ERG, but RP may occasionally only affect the rod-derived ERGs in the early stages of disease. Truly restricted disease, such as sector RP, is associated

with amplitude reduction, but no implicit time change, whereas diffuse or generalized disease is usually also associated with an abnormally delayed implicit time. Retinitis pigmentosa is associated with pigmentary migration from RPE into retina consequent upon photoreceptor cell death, but the clinical appearance of the ocular fundus may not reflect the severity or nature of the disorder. Electroretinography not only enables accurate diagnosis, when interpreted in clinical context, but may also provide useful prognostic information. There is no rod system involvement in a pure cone dystrophy; such disorders have normal rod responses, but abnormal cone responses, with the 30 Hz flicker response usually showing both amplitude reduction and delay (Fig. 4, column E).

A waveform in which the bright flash a-wave is spared, but there is selective b-wave reduction, is known as a “negative” or electronegative ERG (e.g., Fig. 4, column F, row 2), and is associated with dysfunction postphototransduction, often postreceptor. For example, in central retinal artery occlusion (CRAO) the finding of a “negative” ERG reflects the duality of the retinal blood supply, with the photoreceptors supplied via choroidal circulation, and the inner-nuclear layer supplied via the central retinal artery. Other causes of negative ERG include X-linked congenital stationary night blindness (CSNB, Fig. 4, column F), X-linked retinoschisis, quinine toxicity, melanoma

associated retinopathy (MAR, an autoimmune mediated disorder that can occur in patients with a history of cutaneous malignant melanoma), Batten disease (one of the ceroid neuronal lipofuscinoses), and occasionally cone-rod dystrophy. Carcinoma associated retinopathy (CAR), unlike MAR, usually give profound global ERG reduction in keeping with dysfunction at the level of the photoreceptor rather than a "negative" ERG. A negative ERG is also a relatively common occurrence in Birdshot chorioretinopathy (BCR), an inflammatory disease, but in that disorder such an appearance may normalize following successful treatment, usually with steroids and/or immunosuppressive agents.

The most common ERG abnormality in BCR, or other forms of inflammatory retinal disease, such as uveitis, is a delayed 30 Hz flicker ERG, but there may be much less marked amplitude change than occurs in photoreceptor degeneration. The ERG abnormalities may occur prior to the development of symptoms, and can normalize following treatment. Electrophysiology can thus play an important role not only in the characterization of the disease, but also in the initiation and monitoring of treatment (23). This relatively recent role of the ERG in the management of inflammatory disease can be expected to receive increasing clinical interest in the future.

PERG

Primary Evaluation of Macular Function. Disorders of macular function result in an abnormality of the P50 component of the PERG, often with preservation of the N95/P50 ratio. It is usually P50 amplitude that is affected; latency changes are only occasionally present, particularly in association with macular oedema or serous detachment at the macula. In clinical practice, the PERG and the (full-field) ERG provide complementary information regarding retinal function; the ERG assesses peripheral retinal function, and the PERG the degree of central retinal involvement. For example, dysfunction confined to the macula will have a normal ERG and an abnormal PERG (Fig. 4, column B), a common combination in macular dystrophies, such as Stargardt-fundus flavimaculatus (S-FFM), whereas generalized retinal dysfunction with macular involvement will have both an abnormal ERG and an abnormal PERG. This facilitates the distinction between macular dystrophy, cone dystrophy, and cone-rod dystrophy in a patient with an abnormal macular appearance and a history suggestive of a genetically determined disorder, important to the prognosis and accurate counseling of the patient. In relation to S-FFM, note that some patients have additional full-field abnormalities that may be of prognostic value (24).

The PERG may be normal even when the ERG is almost extinguished in patients with rod-cone dystrophy but normal central retinal function. Further, the objective assessment of macular function provided by the PERG can sometimes demonstrate early central retinal abnormalities prior to the appearance of symptoms or signs of macular involvement.

Ganglion Cell Dysfunction. The PERG will often be normal in disturbance of optic nerve function. However,

there may be retrograde degeneration to the retinal ganglion cells in optic nerve disease and this may selectively affect the ganglion cell derived N95 component. It is N95 loss that is the common abnormality if the PERG is abnormal in optic nerve disease. That is unlike macular dysfunction, where it is the P50 component that is primarily affected. Shortening of P50 latency may also occur in more severe disease, but, again, is not a feature of macular dysfunction. Primary disorders of retinal ganglion cell, such as Leber hereditary optic neuropathy (LHON) and dominantly inherited optic atrophy (DOA), are associated with N95 component loss, marked at presentation in LHON, but often occurring later in the disease process in DOA. There may be additional P50 amplitude reduction in advanced retinal ganglion cell dysfunction, and the associated shortening of P50 latency then becomes an important diagnostic factor. Further, providing there is sufficient vision remaining in at least one eye to maintain fixation for binocular PERG recording, total extinction of the PERG probably does not occur in optic nerve disease. Even in an eye blind from optic nerve disease (no perception of light), a PERG may still readily be detectable (2).

THE PERG IN RELATION TO VEP INTERPRETATION

Although detailed discussion of the VEP is beyond the scope of this article, a short discussion of the use of the PERG in the improved interpretation of VEP abnormality is warranted. The cortically generated VEP to pattern reversal stimulation is a powerful clinical tool in the detection and assessment of optic nerve dysfunction, and pattern VEP latency delay or loss is frequently associated with optic nerve disease. However, the VEP is generated in the occipital cortex, and a delayed PVEP must never be assumed necessarily to indicate optic nerve dysfunction in a visually symptomatic patient. Similar abnormalities can occur either in macular disease or optic nerve disease. The appearance of the macula may be a poor indicator of function, and remember that a normal macular appearance does not necessarily equate to normal macular function. The different types of abnormality present in the PERG in optic nerve and macular diseases usually allow the differentiation between delayed VEP due to retinal macular disease and that due to optic nerve disease. An abnormal VEP with a normal PERG (or a normal P50 component with an abnormality confined to N95) is consistent with optic nerve/ganglion cell dysfunction, whereas pronounced P50 reduction suggests a disturbance of macular function (e.g., Fig. 4, columns B, D, E, F).

MULTIFOCAL ERG

The multifocal ERG can be used to assess the spatial extent of central retinal cone involvement in disease. Normal traces appear in Fig. 5b. Two clinical examples are shown; Fig. 5c shows a patient with a retinal dystrophy in whom there is sparing of central macular function; Fig. 5d shows a patient with a macular dystrophy with loss of the responses to central hexagons, but preservation of more peripheral responses. As a restricted test of central retinal

cone function, in clinical circumstances the mfERG should always be taken in conjunction with conventional full-field ERG.

CONCLUSIONS AND FUTURE DIRECTIONS

Diagnosis and management of the patient with visual pathway disease is greatly assisted by the objective functional information provided by electrophysiological examination. Separation of the function of different retinal cell types and layers enables characterization both of acquired and inherited retinal disorders, of great importance when counseling families affected by or at risk of a genetically determined disease. The PERG is complementary to the ERG by providing a measure of central retinal function; the mfERG may play a similar role.

ELECTROSURGICAL UNIT (ESU)

JOHN PEARCE
The University of Texas
Austin, Texas

INTRODUCTION

Electrosurgery means the application of radio frequency (RF) current at frequencies between ~ 300 kHz and 5 MHz to achieve a desired surgical result; typically the fusion of tissues or surgical cutting in which the tissue structure is disrupted. In either case, the effect is achieved by heat dissipated in the tissues from the RF current by resistive, or joule, heating. This method has the ability to cut and coagulate tissues simultaneously; and, as a consequence, has made substantial contributions to several branches of clinical medicine since its introduction in the late 1920s.

The tissue effects applied in electrosurgery are typically described as (a) white coagulation, named for its appearance, in which the tissue proteins are degraded at lower temperatures, typically 50–90 °C; (b) black coagulation or carbonization in which tissues are completely dried out (desiccated) and reduced to charred carbonaceous

remnants at higher temperatures; and (c) cutting in which tissue structures are separated by the rapid boiling of small volumes of tissue water. These three results usually occur in some combination depending on the applied current and voltage at the so-called active or surgical electrode.

Electrosurgery accomplishes many surgical jobs better than any other device or technique while drastically reducing the morbidity and mortality associated with surgery. It does this by reducing the time under anesthesia and complications due to operative and postoperative hemorrhage. Many of the delicate techniques in neurosurgery would be impossible without electrosurgery—and it is likely that open heart surgery and much of urologic surgery would likewise not be done.

Historical Background

The application of heat for the treatment of wounds dates back to antiquity. According to Major (1), Neolithic skulls unearthed in France show clear evidence of thermal cauterization. The Edwin Smith papyrus (~3000 BC) (2) describes the use of thermal cautery for ulcers and tumors of the breast. Licht (3) reports that according to Jee (4) the ancient Hindu god Susruta, the highest authority in surgery, said that “caustic is better than the knife, and the cautery is better than either.” Cautery in ancient Hindu medicine included heated metallic bars, boiling liquids, and burning substances.

In cauterization the essential physical mechanism behind the treatment is conduction heat transfer from a hot object placed on the surface to raise the temperature high enough to denature the tissue proteins. Cutting and coagulation by means of electrosurgery is also accomplished by heating tissue to high temperatures, but the essential difference is that the primary mechanism is electrical power dissipation directly in the affected tissues themselves, rather than heat transfer from an external hot object on the tissue surface. It is rather like the difference between heating food in a conventional oven and a microwave oven, in a loose sense. Electrosurgery is sometimes erroneously referred to as electrocautery. Since the physical mechanisms are different it is important to keep these two techniques separate by precise terminology. Electrosurgery is also referred to as surgical diathermy, particularly in Europe. While this term is generally understood, it is a bit of a misnomer since diathermy literally means through-heating, such as might be applied in physical medicine for the relief of pain or in hyperthermia therapy for tumor treatment. Electrosurgical devices in operating rooms are designed and built for surgical use only, and the terminology in this section is standardized on that basis.

Early Experiments with High Frequency Current. The origin of the application of rf current to achieve surgical results is difficult to establish owing to the rapid pace of development in the electrical arts during the late nineteenth and early twentieth centuries. Lee De Forrest, the inventor of the vacuum tube (the audion, 1907 and 1908), filed a patent for a spark gap rf generator to be used for electrosurgery in February of 1907 (it was granted in December of 1907) (5). Also, during the same year, Doyen noted that the

effect of a surgical arc on the tissue was not a function of the length of the arc, and that the temperatures of carbonized tissue were as high as 500–600 °C (6). He also found that final temperatures in the range of 65–70 °C resulted in white coagulation while there was no damage to tissues for temperatures < 60 °C (7).

By far, the most effective promoters of electrosurgery were Cushing and Bovie. W. T. Bovie was a physicist attached to the Harvard Cancer Commission. He had developed two electrosurgical units, one for coagulating and one for cutting. Harvey Cushing, the father of neurosurgery, had been concerned for some time with the problem of uncontrolled hemorrhage and *diabetes insipidus*, the often fatal complications of hypophysectomy, among other concerns (8). In 1926, working with Bovie, he applied high frequency current in cerebral surgery with excellent results. They published their work in 1928, emphasizing the three distinct effects of electrosurgery: desiccation, cutting and coagulation (9).

Early Electrosurgical Generators. Cameron-Miller offered the Cauterodyne in 1926, similar to the later model of 1930 that featured both vacuum tube cutting and spark gap coagulation. It came in a burl wood case for \$200. It is not known if the original 1926 device included tube cutting. The device designed and manufactured by W. T. Bovie was of higher fundamental frequency than the other early devices. The Bovie device used a 2.3 MHz vacuum tube oscillator for pure cutting (i.e., Cut 1) and a 500 kHz fundamental frequency spark gap oscillator for fulguration and desiccation (Cut 2–4 and Coag). The overall size, circuit and configuration of the Bovie device remained essentially constant through the 1970s. Bovie's name is so closely associated with electrosurgery that it is frequently referred to as the Bovie knife in spite of the extensive work which preceded his device and the numerous devices of different manufacture available then and now. In essence, the available electrosurgical generators between ~1930 and the 1960s were of the similar design to that used by Bovie, and consisted of a spark gap generator for coagulating and a vacuum tube generator for cutting.

The introduction of solid-state electrosurgical generators in the early 1970s by Valleylab and EMS heralded the modern era of isolated outputs, complex waveforms, more extensive safety features and hand-activated controls. Interestingly, hand-activated controls are actually a recent rediscovery and improvement on those used by Kelly and Ward (10) and those available on the Cauterodyne device. In some ways, higher technology devices of all designs are made inevitable by the recent proliferation of delicate measurement instrumentation that is also attached to a patient in a typical surgical procedure.

Clinical Applications

The topics chosen in this introductory survey are by no means comprehensive. Those readers interested in specific surgical techniques should consult the texts by Kelly and Ward (10) and Mitchell et al. (11) for general, gynecologic, urologic and neurosurgical procedures; Otto (12) for minor

electrosurgical procedures; Harris (13), Malone (14), and Oringer (15,16) for dental electrosurgery; and Epstein (17) and Burdick (18), for dermatologic procedures.

When high frequency currents are used for cutting and coagulating, the tissue at the surgical site experiences controlled damage due either to disruptive mechanical forces or distributed thermal damage. Cutting is accomplished by disrupting or ablating the tissue in immediate apposition to the scalpel electrode. Continuous sine waveforms (e.g., those obtained from vacuum tube or transistor oscillators) have proven most effective for cutting. Coagulating is accomplished by denaturation of tissue proteins due to thermal damage. Interrupted waveforms, such as exponentially damped sinusoids (obtained from spark gap or other relaxation-type oscillators) are effective for coagulation techniques requiring fulguration, or intense sparking (*fulgur* is Latin for lightning). However, when no sparks are generated, coagulation is created by tissue heating alone, and the specific waveform is immaterial: only its effective heating power, or root-mean-square (rms) voltage or current determine the extent of the effect. Suffice it to say that the difference between cutting and coagulation is due to combined differences in heat-transfer mechanisms and spatial distribution of mechanical forces. In general, the tissue damage from cutting current is confined to a very small region under the scalpel electrode and is quite shallow in depth. Cells adjacent to the scalpel are vaporized and cells only a few cellular layers deep are essentially undamaged. Though dependent on surgical technique, generally only the arterioles and smaller vessels are sealed when a cut is made using pure sine wave currents. Coagulation currents are used to close larger vessels opened by the incision, to fuse tissue volumes by denaturing the proteins (chiefly the collagen) and to destroy regions of tissue. The tissue damage when coagulating is deeper than when cutting. In the majority of applications for coagulating current, the damage in the tissue is cumulative thermal damage rather than tissue disruption or ablation.

Cutting is a monopolar procedure, although some experiments have been performed with bipolar cutting. That is, the scalpel electrode represents essentially a point current source and the surgical current is collected at a remote site by a large area dispersive, or return electrode. Coagulation may be accomplished using either monopolar or bipolar electrodes. In bipolar applications, both the current source and current sink electrodes are located at the surgical site. A typical bipolar electrode might consist of forceps with the opposing tongs connected the two active terminals of the generator. In both cutting and coagulating processes, whether monopolar or bipolar electrodes are used, a layer of charred tissue often condenses on the cool electrode that must periodically be removed (19).

The histologic effects of cutting current are varied and apparently depend on technique. Knecht et al. (20) found that the healing process in an electrosurgical incision was a bit slower than for incisions made by a cold scalpel. In their study, the wound strength of an electrosurgical cut was less than that of a cold scalpel cut until ~ 21 days after surgery. After 21 days, no difference in wound strength was measurable. Ward found that an electrosurgical cut

generally formed slightly more scar tissue on healing than a cold scalpel cut if the closure of the two wounds was identical (21). The cellular layers within ~ 0.1 mm of the scalpel electrode showed electrodesiccation effects when sine wave cutting was used (21). In a later series of studies on tissues of the oral cavity, Oringer observed that when the cutting current was carefully controlled, the damage was confined to the cut cellular layer, and the layer of cells adjacent to the cut was undamaged (14,15). The cell destruction was apparently self-limiting to the extent that no damage to the cytoplasm or cell nucleus of the cut layer was visible in light or electron micrographs (14). Oringer (16) describes the margin of an excised squamous cell carcinoma that had been removed with electrosurgery. Under the electron microscope at a magnification of 47,400 the margin was seen to contain several clear examples of cells sheared in half with no damage to the remainder. Oringer, and others, observed faster healing with less scar tissue in the electrosurgical incision. The variety of results obtained is likely due to differences in waveform, surgical technique, tissue characteristics and scalpel electrodes used in the studies.

When combined sine wave and interrupted (coagulating) waveforms are used, or when spark gap sources are used for cutting, a coagulum layer extends deeper into the tissues under the desiccated layer (21). Coagulation techniques include (1) fulguration (also called spray coagulation or black coagulation) in which the tissue is carbonized by arc strikes, (2) desiccation, in which the cells are dehydrated resulting in considerable shrinking, and (3) white coagulation, in which the tissue is more slowly cooked to a coagulum. In fulguration techniques, the active electrode is held a few millimeters from the surface of the tissue and arcs randomly strike from the electrode to the tissue. The cell structure is destroyed at a very high temperature resulting in charring of the tissue. In desiccation, the water is evaporated from the cell relatively slowly leaving a white dry flake of powder, the cells appear shrunken and drawn out with elongated nuclei. The overall cellular anatomical characteristics are preserved (21). Desiccation techniques normally take longer to accomplish than fulguration for the same volume of tissue. In white coagulation, the electrode is in intimate contact with the tissue. No arcs strike so the electrode voltage is low by comparison. The total electrode current may be high, but the tissue current density (current per unit area) at all points on the electrode is moderate and the duration of the activation is therefore relatively long. The cellular effects are varied, ranging from a tough coagulum when connective tissue predominates to granular debris easily removed by a curet when the majority of the tissue is epithelial (21). Often the goal of coagulation is to shrink and fuse or thermally damage tissue collagen.

Minor Surgery. Minor surgery may be described as surgery applied to tissues on exterior surfaces of the body under local anesthetic, which includes dermatology. Other external surfaces, which include oral, vaginal and cervical tissues, are also routinely treated as minor surgery cases on an outpatient basis or in the office. Typical minor surgery procedures include the removal of warts, moles

Figure 1. Electrodes typically used for general electro-surgery.

and vascular nevi, the surgical reduction of sebaceous cysts, epilation, cervical conization, relief of chronic nasal obstruction, and the removal of polyps and tumors. The techniques used in minor surgery are very similar to those of general surgery, although the cutting electrodes come in a wider variety of shapes and sizes.

Figure 1 illustrates some of the electrodes used (19). The standard scalpel blade electrode used for incision is elliptical in cross-section with a cutting edge which is of small radius (not sharp) in order to yield the very high current densities required for tissue ablation. The scalpel electrode is sometimes angled for special techniques. Scalpel electrodes are usually used for incisions, but may also be used for coagulation. The flat side of the blade can be applied to a tissue mass to obtain coagulation. The tip of the electrode may be suspended above the tissue for fulguration. Other electrode shapes accumulate less carbonized tissue residue than the scalpel, and are often preferred for coagulation. The needle, standard coagulation and ball electrodes are used either for desiccation or fulguration. The ball electrode may be used with coagulating current to treat persistent nose bleed that does not respond to other methods.

Bipolar forceps and the turbinate electrode are used in bipolar procedures. The forceps electrode has one electrical connection on each side of the forceps, and is used, for example, to grasp a seeping vessel; current between the forceps electrodes then seals off the vessel end by fusing the vessel walls together. The turbinate electrodes are used to

obtain submucous coagulation (desiccation) in the nasal turbinates for relief of chronic vasomotor rhinitis: swelling of the soft tissue in the nasal cavity caused by, for example, allergies or irritants.

Neurosurgery and General Surgery. Blood is toxic to neural tissue. Consequently, blood loss during neurosurgery is to be avoided at all costs. At its inception, electro-surgery presented the first technique that accomplished cutting with negligible blood loss. This was this feature of electro-surgery that so strongly attracted Cushing. Many of the now commonplace neurosurgical procedures would be impossible without some method for obtaining hemostasis while cutting.

White coagulation is generally used in neurosurgery since it does not cause charring. White coagulation takes a relatively long time to obtain compared to fulguration or cutting. Holding the scalpel electrode to a location for long activation times allows deep penetration of the high temperature zone. This effect is used to advantage in rf lesion generation for selective disabling of neural tissue. Bipolar applicators restrict the current to a smaller region and are used extensively for microneurosurgical techniques, since they are more precise and safer. Many of the techniques are properly classed as microsurgery. Often the tissue being cut or coagulated is stabilized with a suction probe while current is applied. The suction probe is usually nonconductive glass or plastic; however, on occasion a metal

suction probe is used with monopolar coagulation to localize the current to the immediate area (11). Incisions of the cerebral cortex are usually made with monopolar needle electrodes. Surface tumors are removed by applying a suction probe to the tumor and excising it at the base with a cutting loop.

Dental Electrosurgery. The tissues of the oral cavity are particularly highly vascularized. Also, the mouth and alimentary canal contain high concentrations of bacteria. Since the ability to ingest food is critical to survival these tissues are among the fastest healing of the body. Electrosurgery plays an important role in oral surgery in that it drastically reduces bleeding that would obscure the operative field and the undesirable postoperative effects of pain, edema and swelling in the submaxillary triangle (15). It can be quite difficult to accurately resect redundant tissue masses by cold scalpel techniques in the oral cavity. Electrosurgery allows accurate resection with minimal elapsed time and complications, an important feature when fitting prosthodontic devices. Electrosurgery reduces the hazard of transient bacteremia and secondary infection (14), and the danger of surgical or mechanical metastasis of malignant tumor emboli during biopsy (15). In short, all of the advantages obtained in other types of surgery are experienced in dental surgery as well as some additional beneficial aspects.

The active electrodes used in dental electrosurgery are for the most part similar to those shown in Fig. 2 (19). Several shapes specific to dental procedures are: the open hook electrodes in Fig. 2a are used along with other needle

Figure 2. Electrodes typically used for dental electrosurgery. (a) Open hooks and needles, straight and angulated to reach difficult locations. (b) Straight and angulated cutting loops.

electrodes to create subgingival troughs, those in Fig. 2b are used with ball electrodes, and loop electrodes for seating orthodontic appliances and denture prostheses and exposing roots. Other interesting applications include the removal of premalignant neoplastic lesions from the surface of the mucosa using a planing loop and the removal of tissue masses from the tongue. Carefully applied electrosurgery can be used to advantage on teeth as well as the soft tissues of the oral cavity.

Urologic Surgery. Electrosurgery is used extensively in urologic procedures. Urologic procedures, specifically transurethral resections of the prostate, utilize by far the highest currents at high voltage for the longest durations and largest number of activations per procedure of any electrosurgical technique. Other urologic applications of electrosurgery include: the resection of bladder tumors, polyp removal by means of a snare electrode or desiccating needle, kidney resection to remove a stone-bearing pocket, and enlarging the urethral orifice in order to pass stones. These other procedures utilize power levels similar to those of general surgery.

A transurethral resection is intended to increase the caliber of a urethra that has been partially closed by an enlarged prostate gland. This procedure is one of the earliest applications of electrosurgery in urology, having been described in considerable detail by Kelly and Ward in 1932 (21). During transurethral resection, the urethra is irrigated with a nonconductive sterile solution, either dextrose or glycerine, while a cutting loop is advanced to remove the encroaching tissue. Surgical cutting accomplished in a liquid medium requires higher currents since the liquid carries heat away and disperses the current (even though it is nonconductive) more than a gaseous environment would. A typical resectoscope used in this procedure is shown diagrammatically in Fig. 3. A long outer metal sheath, which is plastic coated, contains a cutting loop that can be extended from the sheath, a fiber optic cable bundle for viewing the cutting action, an illumination source (either a bulb at the end or an illumination fiber optic bundle), and spaces for influx and efflux of irrigating fluid. The cutting loop (of thin diameter to yield the high current densities required) is moved in and out of the sheath by the surgeon as required to accomplish the resection.

Gynecologic Surgery. One of the common gynecologic applications of electrosurgery is cervical conization. Other common gynecologic applications of electrosurgery include the removal of tumors, cysts, and polyps. The use of electrosurgery in laparoscopic tubal ligations will be treated in some detail since it is also a very common procedure. The laparoscopic tubal ligation is a minimally invasive sterilization procedure typically accomplished by advancing an electrode through a small incision in order to coagulate the Fallopian tube. The position of the uterus is fixed by a cannula inserted through the cervix under the surgeon's control. The abdominal cavity is insufflated with CO₂ gas in order to separate the tissue structures. The coagulating electrode is then advanced through a small incision in the abdominal wall to the Fallopian tube by the surgeon,

Figure 3. Resectoscope typical for transurethral resections of the prostate (TURP).

observing through an endoscope (laparoscope), which has been inserted through a separate small incision. The isolated Fallopian tube is then coagulated at high current but relatively low voltage.

Both monopolar and bipolar electrosurgical electrodes have been used for this procedure; however, monopolar tubal ligation methods are to be avoided as there have been many instances of bowel wall perforations and other complications following monopolar tubal ligation procedures owing to surgical current flow in the bowel wall. Bipolar techniques confine the current to a small region of tissue and the risk of bowel perforation is minimal in comparison. A bowel wall perforation can still result due to heat transfer from the coagulated tissue, so the coagulating forceps and Fallopian tube must be held away from the bowel wall and allowed to cool before being released. Note that a surrounding CO_2 gas environment will increase the time required for tissue cooling.

FUNDAMENTAL ENGINEERING PRINCIPLES OF ELECTROSURGERY

RF Generators for Electrosurgery

In general, the RF frequencies used for electrosurgery fall between 350 kHz and 4 MHz, depending on manufacturer and intended use. The available output power ranges from ~ 30 –300 W. Peak open circuit output voltages vary from < 200 V to 10 kV. Higher open circuit voltages are used to strike longer arcs for fulguration, while the lower voltages are used for bipolar coagulation. Most devices are capable of generating several different waveforms, said to be appropriate for differing surgical procedures.

Vacuum Tube and Spark Gap Oscillators. The original rf generators used in electrosurgery, diathermy, radiotelegraphy, and radar circuits were spark gap oscillators (Fig. 4). The exponentially damped sine waveform (Fig. 4b) results from a breakdown of the spark gap (SG in Fig. 4a) that initializes the oscillations. The waveform is often called a Oudin waveform, though it is typical of all spark gap units, Oudin output circuit or not. The RFC is a RF choke to prevent the rf signal from coupling to the power line. Later generator designs utilized vacuum tube oscillator circuits that were typically Tuned-Plate, Tuned-Grid Oscillators (22), as shown in Fig. 5a (Birtcher Electrosectilis), or Hartley oscillators, Fig. 5b (Bovie AG). The output of vacuum tube electrosurgical units is available as either partially rectified [meaning that the RF oscillator is active only on one of the half-cycles of the mains power (i.e., one vacuum tube)] or fully rectified [meaning that the RF

oscillator is active on both half-cycles of the mains power (Fig. 5c)]. In both circuits of Fig. 5 each vacuum tube, V1 and V2, oscillates on opposite half cycles of the mains power, period T . Electrosurgery generator designs varied little from the standard units built by Bovie and Cameron-Miller in the 1920s until ~ 1970 when solid-state generators became available. Solid-state generators made possible much more sophisticated waveforms and safety devices in a smaller overall package. Though not specific to solid-state technology, isolated outputs became common when solid-state electrosurgery units were introduced. Until ~ 1995 all electrosurgery generators acted essentially as voltage sources with a typical output resistance in the

Figure 4. Spark gap oscillator rf generator. (a) Spark gap oscillator circuit. SG = spark gap, which acts as a switch, RFC = radio frequency choke, L and C determine the fundamental rf frequency, f_0 and R the damping (R = the patient). (b) Oudin waveform with amplitude determined by the supply voltage peak, V_s . (c) Frequency spectrum of the output Oudin waveform has energy centered at $\pm\omega_0$, the fundamental RF oscillation frequency with energy concentrated at harmonics of the repeat frequency to both high and low frequencies.

neighborhood of 300–500 Ω. Recent generator designs incorporate embedded microprocessors and have constant power delivery modes. Interestingly, both Bovie and Cameron-Miller electrosurgical devices are available in the present day, though the designs are considerably different.

Solid-State Generators. Solid-state electrosurgical generators generally operate on a different design principle than the vacuum tube devices. Rather than combine the oscillator and power amplifier into one stage, solid-state generators utilize wave synthesis networks that drive a power amplifier output stage. This approach has the advantage that quite complex waveforms may be employed

for cutting and coagulating; although to date the waveforms used vary little, if at all, from those of vacuum tube and spark gap oscillators. Many solid-state generators (chiefly those with bipolar transistors in the output amplifier) do not have as high open circuit output voltages as vacuum tube and spark gap devices. It sometimes appears to the user of those devices that there is less power available for cutting and coagulating since the lower open circuit voltages will not strike arcs as far away from the tissue. This turns out to be a limitation of concern in the high voltage procedures, namely in TURPs, but not in high current procedures, such as laparoscopic tubal ligations. In general, solid-state generators that use bipolar transistors in the high voltage output amplifier stage are vulnerable to transistor failure. The more recently introduced solid-state generators (after ~1985) employ high voltage VMOS or HEXFET field effect transistors (23) in the output stage to give higher open circuit voltages and/or to reduce the stress on the bipolar output transistors.

A general block diagram of a typical solid-state electrosurgical generator is shown in Fig. 6 (24). The fundamental frequency, most often ~500 kHz, is generated by a master oscillator circuit, typically an astable multivibrator. The primary oscillator acts as the clock or timing reference for the rest of the generator. The unmodified master oscillator signal is amplified and used for cutting. An interrupted waveform is formed by gating the continuous oscillator output through an external timing circuit, as shown in the figure. The repeat frequency of the timer is typically on the order of 20 kHz (24), much higher than that of spark gap oscillators. The duty cycle of a waveform is the ratio of duration of the output burst to the time between initiation of bursts. Duty cycles for solid state coagulating waveforms vary, but a duty cycle of 10–20% would be considered typical. This is in sharp contrast to the spark gap devices that have duty cycles often < 1%. The higher duty cycle of solid-state units compensates in part for their lower peak output voltages so the actual maximum available power is similar in both families of devices.

Constant power output is obtained by measuring the output voltage and current and adjusting the drive signal to compensate for changes in the equivalent load impedance (25), as in Fig. 7a. The sampling rate for this adjustment is on the order of hundreds of hertz (~200 Hz for the device depicted). In Fig. 7b, the performance of the example system is compared to a standard voltage source generator

Figure 6. Block diagram for typical solid state ESU. Footswitch (and hand switch) controls simplified by omitting the interlock circuitry that prevents simultaneous activation. Master oscillator sets fundamental RF frequency, f_0 . Interrupted waveform repeat frequency, f_{rep} . Provisions for blending cut and coag modes often provided. with fixed output impedance 300 Ω and maximum output power of 250 W at 300 Ω load impedance. The differences at high load impedances typical of electrosurgical cutting (up to ~ 2 k Ω) are easily seen in the figure.

Safety Appliances. Since the electrosurgical unit (ESU) represents a high power source in the operating room, the potential for adverse tissue effects and accidental results must be managed. One of the more common types of accident has historically been one or more skin burns at the dispersive, or return, electrode site (during monopolar procedures). Often these have resulted from the return electrode losing its attachment to the skin. Earlier ESU designs incorporated a so-called circuit sentry, or its equivalent, which ensured that the return electrode cable made contact with the return electrode by means of monitoring current continuity through the cable and electrode connection at some low frequency. This ensured that the electrode was connected to the ESU, but did not ensure that it was connected to the patient.

Modern ESU devices monitor the patient return electrode to ensure its continued connection to the skin. In these devices, the patient return electrode is divided approximately into halves and a small current (typically on the order of 5 mA or less) at high frequency but below the surgical frequency (typically in the neighborhood of 100 kHz) is applied between the electrode halves, the connection being through the skin, only, as in Fig. 8 (25). The impedance between them is monitored, and if it exceeds maximum or minimum limits, or a set fraction of

the baseline value (typically 40% or so over the baseline) an alarm sounds and the generator is deactivated. The patient return monitor system resets the baseline impedance if it falls below the initial value.

The high frequency of operation of electrosurgery units also contributes to the hazards associated with its use. At very high frequencies, current may flow in two different ways. First, in good conductors, such as skin and other wet tissues, the current flows by conduction and Ohm's law applies. Second, in insulating dielectric substances, such as air, surgical rubber or plastic, the current flows as so-called displacement current. The value of the displacement current density is linearly related to the frequency, so for the same materials, voltages and geometric arrangement of conductors, higher frequencies conduct more displacement current in dielectric substances than do lower frequencies. A consequence of this relationship is that at electrosurgical frequencies and voltages the capacitance between the wire conductor in a scalpel electrode and tissue over which the wire passes may have low impedance if the insulation is thin. Scalpel electrode wires are covered with thick insulation of high dielectric constant in order to prevent tissue damage at high scalpel electrode voltages. If the wire is inadequately designed or the insulation is damaged, the displacement current in the wire insulation may be dense enough to cause damage to the underlying tissue.

Electrosurgical unit outputs may be isolated, referred to ground, or grounded terminals (Fig. 9). Grounded patient return leads (Fig. 9a) have a hard wired connection to the ESU chassis ground wire. Referred to ground means that

Figure 8. Patient return monitor circuit ensures that the return electrode remains attached to the patient. Split return electrode conforms to patient contours; both halves of return electrode carry surgical rf current. Insulator prevents lower frequency interrogation current from finding a shorter pathway. Current pathway is through the patient's skin, ensuring contact.

there is a fixed impedance, typically a capacitor, between the patient return lead and ground (Fig. 9b). The capacitance is chosen to represent a low impedance at the ESU rf frequency and a high impedance at power mains frequency and frequencies associated with stimulation of electrically excitable tissues. Isolated outputs (Fig. 9c) have high impedance to earth ground at both output terminals, usually by means of an output transformer; these are almost uniformly used for bipolar modes, and are common in monopolar modes as well. No isolation system is ideal,

however, and all rf currents should be thought of as ground seeking in some sense. In an isolated system, either patient lead can become a source of RF current.

A less obvious consequence of the high frequency is that every object in the room (the surgeon, the patient, the operating table and associated fixtures, the electrosurgical generator, other instrumentation) all have a small but finite parasitic or distributed capacitance to earth. This makes all of the RF currents in the operating room ground seeking, to some extent. Even the best isolated generator will have some ground leakage current at RF, and this value may be much more than the mains frequency leakage current (depending on the design of the output circuitry). Certainly, all of the grounded output generators can have significant differences between the active cable current and the return or dispersive electrode cable current. The difference current flows in all of the parallel pathways, conductive and/or capacitive. If any of these pathways carry too much current in too small an area, a thermal burn could develop. To the extent reasonable, direct conductive pathways through clamps, foot stirrups, and other metallic fixtures should be eliminated. This can be accomplished by using devices that have insulating covers over the pieces likely to contact the tissue, or insulated couplings, connectors or other barriers at some location between the tissue and the clamp which connects the device to the surgical table. Additional safety can be obtained by using monitors and other instruments that have RF isolation built into their electrode leads. These precautions and others will greatly reduce the hazards associated with alternative current pathways. There are International Electrotechnical Commission standards that cover the requirements for electrosurgical applicators, generator output connections, and isolation schemes (26,27). It is important to note that safe operation of electrosurgical devices can be obtained by more than one design strategy. The ESU, patient, and surroundings should be thought of as a system, in order to ensure a safe environment.

Representative Surgical Procedures

The output voltages and currents that are required of an electrosurgical generator depend on the particular procedure for which it is to be used. Fulguration requires high voltages to initiate the arcs, but not large currents, so a generator of high output impedance works quite well. Spray coagulation uses higher currents at the high voltages, the difference between spray coagulation and fulguration being one of degree rather than principle. White coagulation requires relatively high current at low voltage

since no arc is formed at the scalpel electrode. The highest power, that is voltages and currents together, is required for transurethral resections of the prostate (TURP) procedures. The cutting characteristics of the various generator designs make them more or less optimal for certain procedures. Given the variety of designs available and variations in surgical technique among the users, it is no surprise to find that generator selection often boils down to personal preference.

The two modes used in electrosurgical procedures, bipolar, and monopolar, have quite different current field distributions. The bipolar mode is very effective in coagulating small vessels and tissue masses. Bipolar techniques are especially useful in microsurgical procedures. In bipolar electrosurgery, a two-wire coagulating electrode is clamped around a tissue lump or vessel and electrosurgical current is applied between the electrodes until the desired surgical effect is obtained. In monopolar electrosurgery, there are two separate electrodes, an active or cutting electrode and a large area dispersive or ground or return electrode located at some convenient remote site. Current is concentrated at the active electrode to accomplish the surgery while the dispersive or return electrode is designed to distribute the current in order to prevent tissue damage. The majority of applications of electrosurgery utilize monopolar methods, since that is the traditional technique and is most effective for cutting and excision. There are, however, many situations in which bipolar methods are preferred.

The power needed for a particular cutting or coagulating action depends on whether or not an arc is established at the scalpel electrode, on the volume of tissue, and on the type of electrosurgical action desired. Bipolar actions,

which are typified by forceps electrodes grasping a volume of tissue to be coagulated, engage only a very small volume of tissue, since the current field is confined to be near the forceps, and usually white coagulation is desired. Consequently, the current is moderate to high and the voltage is low: tens to hundreds of milliamps (rms) at 40–100 V (rms), typically. In bipolar activations the current is determined primarily by the size of forceps electrodes used, and to a lesser extent by the volume of tissue. The volume of tissue more directly affects the time required to obtain adequate coagulation.

Monopolar actions, which may be for cutting or coagulation, are more variable and difficult to classify. In a study reported in 1973 in *Health Devices* (28), the voltages, currents, resistances, powers, and durations of activation during various monopolar electrosurgical procedures were measured. The resistance measured in this study was the total resistance between the active electrode cable and the dispersive electrode cable. Two types of procedure have significantly different electrical statistics compared to all other surgical cases: laparoscopic tubal ligations and transurethral resections of the prostate. The data in Table 1 have been grouped into general surgery (hernia repair, laparotomies, cholecystectomies, craniotomies etc.), laparoscopic tubal ligations, and TURPs. The table has been assembled from data collected at several different hospitals during procedures performed by different surgeons. For each separate surgical case, the minimum, average and maximum of each variable was recorded. The data in the table represent the means and standard deviations of the recorded minimum, average and maximum value calculated over the cases as originally presented in Ref. 19. While the total

^aData collected by ECRI and reported in *Health Devices*(28). Data given include the means of each variable and its associated standard deviation in parentheses. The raw data were given as the minimum, average and maximum value during a particular procedure. The mean is the mean of the recorded minimum, average, or maximum value over all procedures in the study. This table originally appeared in Ref. 19.

number of cases studied under each category is not large, the data do give an overall indication of the range expected in surgical cases.

On the average, laparoscopic tubal ligations required the fewest activations (the range was 5–29), and TURPs by far the most activations (the range was 70–469). The resistances presented by the series combination of the scalpel electrode and tissue were similar for all procedures at 410 Ω for laparoscopic tubal ligations (range 130–1080 Ω), 580 Ω for TURPs (range 340–1800 Ω) and 1070 Ω for general surgery (range 180–2650 Ω). Higher equivalent resistances correlate with arc formation during the cutting process, so the values associated with general surgery might reasonably be expected to be higher.

Ablation, Coagulation and Tissue Fusion

The electrosurgical unit is designed to create irreversible thermal alteration of tissues; that is, controlled thermal damage. The objective is to heat target tissues to temperatures for times sufficient to yield the desired result. All of the physical effects of rf current are the result of elevated temperatures. The key observation is that the degree of alteration depends on both the temperature and the time of exposure. This section describes tissue effects resulting from the rf current from lower to higher temperature ranges.

Kinetic models of thermal damage processes based on an Arrhenius formulation have been used for many years to describe and quantify thermal damage (29):

$$\Omega(\tau) = \int_0^\tau Ae^{-[E/RT]} dt \tag{1}$$

The dimensionless parameter, Ω is an indicator of the relative severity of the thermal damage. Thermal damage is a unimolecular reaction in which tissue proteins change irreversibly from their native ordered state to an altered damage state. In the kinetic model, A is a measure of the molecular collision frequency (s^{-1}), E is an energy barrier the molecules surmount in order to transform from native state to denatured state ($J \cdot mol^{-1}$), R is the universal gas constant ($J \cdot mol^{-1} \cdot K$), T is the absolute temperature (K), and t is the time (s). The damage process coefficients, A and

E , must be experimentally determined. This model assumes that only a single first-order process is active: The model can be used on multiple-process damage accumulation if each process is thermodynamically independent with its own set of process coefficients. A damage process may be described by its critical temperature, T_{crit} , defined as the temperature at which $d\Omega/dt = 1.0$.

The physical significance of Ω is that it is the logarithm of the ratio of the initial concentration of undamaged material, $C(0)$, to the remaining undamaged material at the conclusion, $C(\tau)$:

$$\Omega(\tau) = \ln \left\{ \frac{C(0)}{C(\tau)} \right\} \tag{2}$$

However, typical damage end points have been qualitative tissue indicators such as edema formation or hyalinization of collagen (i.e., amorphous collagen as opposed to the normal regular fibrous array). One exception that has proved useful is the birefringent properties of some tissues, primarily muscle and collagenous structures. Birefringent tissue acts similarly to a quarter wave transformer in that polarized light has its polarization rotated as it passes through a regular array. Consequently, when observed through an analyzer filter rotated 90° with respect to the polarizer, birefringent tissue appears bright and nonbirefringent tissue dark (Fig. 10). In muscle, the birefringent properties are due to the regularity and spacing of the actin-myosin array. In collagenous connective tissues, it is the array of collagen fibers that determines birefringence. In both cases, elevated temperatures destroy the regularity of the array and birefringence is lost. In numerical models the transient temperature history of each point may be used along with equations 1 and 2 to predict the extent of thermal damage for comparison to histologic sections.

Ablation. Electrosurgical (RF) current, lasers, ultrasound, and microwaves have been used to obtain coagulative necrosis in myocardium *In vivo* for the elimination of ectopic contractile foci. The first meaning for ablation is to remove, as by surgery. The second meaning, to wear away, melt or vaporize is more familiar in the engineering sense (as in ablative heat transfer). In cardiac ablation, the goal

Figure 10. Principle of tissue birefringence. (a) Birefringent tissue is able to rotate the polarization (large arrow) of polarized light. (b) Thermally damaged tissue loses this property.

is to deactivate badly behaved cardiac muscle (reentrant pathways). Though no actual mass defects are created in the tissue structure, the process is termed “ablation” in the sense that the affected tissue is removed from the inventory of electrophysiologically active cardiac muscle. Results are evaluated in clinical use by monitoring electrophysiologic activity during treatment. Additional feedback may be applied to improve the repeatability of results.

Figure 11 illustrates the loss of birefringence at elevated temperatures in cardiac muscle. Figure 11a shows a circular disk active electrode applied to the epicardial surface

(b)

(c)

of excised myocardium. The ground plane is applied to the endocardial surface. Figure 11b is a light microscopic (LM) view of the histologic section at an original magnification of $10\times$ stained with hematoxylin and eosin. Figure 11c is the corresponding Transmission Polarizing Microscopy (TPM) view of the same section. The views are taken from the region shown in dashes at the outer edge of the disk electrode. While the boundary of thermal damage can just be identified by a skilled observer in the LM image (Fig. 11b), a clear line of demarcation is visible in the TPM image (Fig. 11c). For heating times in the range of 1–2 min useful estimates of the kinetic coefficients are $E = 1.45 \times 10^5$ ($\text{J}\cdot\text{mol}^{-1}$) and $A = 12.8 \times 10^{21}$ (s^{-1}). These coefficients give erroneous predictions for heating times outside of this range, however.

Birefringence loss identifies irreversible major structural damage in the cardiac myocyte. It is certainly arguable that electrophysiologic function is probably lost at lower temperatures than the $50+^\circ\text{C}$ required to achieve the result shown in the figure. However, clinically, the 50°C isotherm seems to correspond with the desired result (30), and also with the birefringence loss boundary for heating times in this range (31).

Tissue Fusion and Vessel Sealing. Irreversible thermal alteration of collagen is apparently the dominant process in coagulation and successful tissue fusion (32–34). Electron microscopic (EM) studies suggest that the end-to-end fusion process in blood vessels is dominated by random reentwinement of thermally dissociated adventitial collagen fibrils (Type I) during the end stage heating and early cooling phases (34). Successful vessel seals depend on the fusion of intimal surface tissues and the support provided by thermal alteration of medial and adventitial tissues.

Collagen is a ubiquitous tissue structural protein consisting of three left-hand α -helices wound in a rope-like molecular form (Fig. 12) with a periodicity of ~ 68 nm (35). In this figure a small segment of a typical 300 nm long molecule is shown. The 300 nm molecules spontaneously organize into quarter-staggered microfibrils 20–40 nm in diameter and these coalesce into larger diameter collagen fibers *In situ*. There are at least 13 different types of collagen fibers that form the structural scaffolding for all tissues, the most common are Types I, II, and III collagen. Collagen *In situ* is birefringent. One useful measure of irreversible thermal alteration in collagen is that when heated for sufficient time to temperatures in excess of $\sim 60^\circ\text{C}$ the regularity of the fiber array is disrupted and collagen loses its birefringent property (see Fig. 13). When viewed through the analyzer, native state collagen shows up as a bright field due to its birefringent properties. Thermally damaged collagen loses this property and is dark in the field. The kinetic coefficients for collagen birefringence loss in rat skin are (36): $A = 1.606 \times 10^{45}$ (s^{-1}) and $E = 3.06 \times 10^5$ ($\text{J}\cdot\text{mol}^{-1}$). The birefringence-loss damage process in collagen has a critical temperature of 80°C . These coefficients have proven useful over a wide range of heating times from milliseconds to hours.

Collagen shrinks in length as well as losing its organized regular rope-like arrangement of fibers. A model for

Figure 12. Sketch of periodic structure of the basic collagen molecule.

collagen shrinkage obtained by Chen et al. (37,38) is a bit different in style from the first-order kinetic model. They measured shrinkage in rat *chordae tendonae* over several orders of magnitude in time for temperatures between 65 and 90 °C and under different applied stresses. They were able to collapse all of their measured data into a single curve, sketched approximately in Fig. 14. In their experiments an initial “slow” shrinkage process (for equivalent exposure time $< \tau_1$) is followed by a rapid shrinkage rate ($\tau_1 < t < \tau_2$) and a final slow shrinkage process. The practical maximum for shrinkage in length, ξ (%), is 60%. Longer equivalent exposures result in gellification of the collagen and complete loss of structural properties. After initial shrinkage, the collagen partially relaxes during cooling, indicated by the shrinkage decay region in Fig. 14. The curve fit functions utilize a nondimensional time axis, t/τ_2 , where the fit parameters are expressed in the form of the logarithm of the time ratio:

$$\nu = \ln \left\{ \frac{t}{\tau_2} \right\} \quad (3)$$

The shrinkage is obtained by interpolation between the two slow region curves (through the fast region):

$$\xi = (1 - f(\nu))[a_0 + a_1\nu] + f(\nu)[b_0 + b_1\nu] \quad (4)$$

where $a_0 = 1.80 \pm 2.25$; $a_1 = 0.983 \pm 0.937$; $b_0 = 42.4 \pm 2.94$; and $b_1 = 3.17 \pm 0.47$ (all in %). The best-fit interpolation function, $f(\nu)$, is given by

$$f(\nu) = \frac{e^{\alpha(\nu - \nu_m)}}{1 + e^{\alpha(\nu - \nu_m)}} \quad (5)$$

where $\alpha = 2.48 \pm 0.438$, and $\nu_m = \ln\{\tau_1/\tau_2\} = -0.77 \pm 0.26$. Finally, at any temperature τ_2 is given by

$$\tau_2 = e^{[\alpha + \beta P + M/T]} \quad (6)$$

where $\alpha = -152.35$; $\beta = 0.0109$ (kPa $^{-1}$); P = applied stress (kPa); and $M = 53,256$ (K).

The functional form of τ_2 contains the kinetic nature of the process, but is in the form of an exposure time rather than a rate of formation, as was used in Eq. 2, and so the coefficient, M , is positive. To use the collagen shrinkage model, the shrinkage is referred to an equivalent τ_2 . That is, at each point in space and time an equivalent value for the increment in t/τ_2 is calculated and accumulated until shrinkage is calculated.

A representative clinical application of collagen shrinkage is the correction of hyperopia using rf current, termed Conductive Keratoplasty. In this procedure a small needle electrode is inserted into the cornea to a depth of just over one-half of the thickness (see Fig. 15a). A teflon shoulder controls the depth of insertion. The speculum used to retract the eyelids comprises the return electrode in this procedure (Fig. 15b). The RF lesions are placed at 45° increments on circumferences with diameters of 6, 7, or 8 mm—8, 16, or 24 lesions depending on the degree of curvature correction (i.e., diopter change) required (Fig. 15c). Pulsed RF current heats and shrinks the corneal collagen to decrease the circumference and thus the radius of curvature of the cornea. Figure 16 is a histologic cross-section of a typical lesion seen a few minutes after its creation. Figure 16a is a light microscopic section (hematoxylin and eosin stain) and Fig. 16b is the corresponding transmission polarizing microscopy section showing the loss of collagenous birefringence near the electrode path. The effect of shrinkage on the collagen fibers is clearly visible as the normal fibrous wave is stretched in the vicinity of the electrode site (Fig. 16b).

A representative example of tissue fusion processes is the sealing of blood vessels by fusion of the intimal surfaces. In this application, forceps electrodes grasp the vessel and a bipolar rf current is used to heat and fuse the tissue (Fig. 17). An example experimental result is shown in Fig. 18, where a successful seal was obtained *In vivo* in a femoral artery. In that experiment a thermocouple was advanced through the vessel to the site of the electrodes, accounting for the hole in the cross-section.

Sealing and fusion of vessels by electrosurgical current is strongly influenced by the inhomogeneous architecture of the tissue constituents, particularly in the large arteries. Inhomogeneities in electrical properties of the constituents, specifically smooth muscle, collagen and elastin, lead to sharp spatial gradients in volumetric power deposition that result in uneven heating. The mechanical properties of the various tissue constituents are also of considerable importance. Vascular collagen and elastin distribution varies from vessel to vessel, species to species in the same vessel, and point to point in the same vessel of the same species.

Cutting Processes

The essential mechanism of cutting is the vaporization of water. Water is by far the most thermodynamically active tissue constituent. Its phase transition temperature near 100°C (depending on local pressure) is low enough that vaporization in tissue exerts tremendous forces on the structure and underlying scaffolding. The ratio of liquid to vapor density at atmospheric pressure is such that the volume is multiplied by a factor of ~ 1300 when liquid water vaporizes. Expansion of captured water is capable of disrupting tissue structure and creating an incision. The goal in electrosurgical cutting is to vaporize the water in a very small tissue volume so quickly that the tissue structure bursts before there is sufficient time for heat transfer to thermally damage (coagulate) surrounding tissues (39). The same strategy is used in laser cutting.

Cutting electrodes have high rates of curvature to obtain the high electric fields necessary to accomplish cutting. The electrodes are not generally sharp, in a tactile sense, but the edge electrical boundary conditions are such that extremely strong electric fields result. With the possible exception of needle electrodes, the scalpel electrodes of Figs. 1 and 2 are not capable of mechanically damaging tissues. The intense electric fields vaporize tissue water

ahead of the electrode, and the tissue structure parts due to internal tension to allow the electrode to pass essentially without tissue contact. Certainly, if the surgeon advances the electrode too quickly there is a dragging sensation due to perceptible friction, and much more radiating thermal damage around the incision site.

Good cutting technique requires matching the generator output characteristics (primarily the source impedance, but also to some extent the fundamental frequency), open circuit voltage setting, electrode shape and cutting speed to optimize the surgical result. Continuous sine waves are more effective for cutting than interrupted waveforms since the time between vaporization episodes is so much shorter that radiating heat transfer is virtually eliminated. Well-hydrated compartmentalized tissues, like skeletal muscle or gingiva, cut more cleanly than drier tissues, such as skin. Higher fundamental frequencies seem to give cleaner cuts than lower frequencies, but the reason for this is not known.

ADVANCED PRINCIPLES OF ELECTROSURGERY

Hazards of Use and Remedies

Any energy source, including electrosurgery, has hazards associated with its use. The goal of the user is to achieve safe use of the device by minimizing the risk. While it is not possible to completely eliminate hazards, it is possible by

careful technique to reduce them to acceptable levels. Several of the common hazards associated with electrosurgery are alternate site burns, explosions, stimulation of excitable tissues, and interference with monitoring devices and pacemakers. The RF currents are designed to thermally damage tissues, so the possibility of alternate site burns (at sites other than the surgical site) is always present. Explosions of combustible gases were, and still are, a hazard of electrosurgery. Combustible gases include at least two relatively little-used anesthetic agents (ether and cyclopropane) and bowel gas, which has both hydrogen and methane, as a result of bacterial metabolism. Arcs and/or sparks are routinely generated when cutting tissue so there is always an ignition source for a combustible mixture. While the fundamental frequency of electrosurgery is above the threshold for stimulation, arcs or sparks generate low frequency components that can stimulate electrically excitable tissues, that is, muscle and nerve. Radiated rf in the operating room and rf currents in the tissues posed few problems in early days, unless a faulty ground or other machine fault led to a burn at some alternate site. In the present day, electrosurgery raises considerable havoc with instrumentation amplifiers, pacemakers, and other electronic measurement

devices. Because so many potentially current-carrying objects and devices are now routinely attached to the patient, the attendant hazards have increased.

The remarkable feature of electrosurgical accidents is that, although they are rare (one estimate puts the probability at $\sim 0.0013\%$, or 200 out of 15 million procedures using electrosurgery, on an annual basis) they are usually a profound and traumatic event for the patient and the surgical team, and often cause for expensive litigation. The non-surgeon might reasonably wonder, in the light of the problems, why electrosurgery is used. The answer is that the tremendous advantages achieved by the use of electrosurgery (the remarkable reduction in morbidity and mortality and the low cost compared to competing technologies) make it a very effective technology for use in clinical medicine. It is important to note that hazards attend any energy source (and electrosurgery is one among several in the operating room) and they can be reduced and managed, but not eliminated. Clever application of appropriate technology can make considerable contributions in this area by reducing device interactions.

Alternate Site Burns

Electrosurgical units in general have very high open circuit output voltages that may appear at the scalpel electrode when it is not in contact with the tissue. When current is flowing the scalpel voltage is much reduced. Standard vacuum tube electrosurgery units may have open circuit voltages approaching 10,000 V peak-to-peak. This high open circuit output voltage is very effective in the initiation of fulguration techniques and in the spray coagulation of large tissue segments, which makes these units popular for certain procedures, especially in urologic surgery. However, the high voltages at the scalpel electrode also can initiate arcs to other objects, and must be handled with caution. This can be an especially difficult problem in minimally invasive surgery through an endoscope since the surgeon's field of view may be limited. The solid-state electrosurgery units usually have lower maximum output voltages (somewhere in the range of 1000–5000 V peak-to-peak depending on design) the exception being recent designs based on HEXFET or VMOS technology, which approach the open circuit voltage of vacuum tube devices.

All electrosurgery units have output voltages that are potentially hazardous.

It is prudent to inspect all surgical cables periodically for damage to the insulation: especially those that are routinely steam sterilized. While in use, it is not a good idea to wrap the active cable around a towel clamp to stabilize it while accomplishing cutting or coagulation: The leakage current to the towel clamp will be concentrated at the tips of the towel clamp and may cause a burn. One should not energize the electrosurgical unit when the scalpel is not being used for cutting or coagulating. This is because when not using electrosurgery, the full open circuit voltage is applied between the active and return electrode cables, and one runs the risk of inadvertent tissue damage. Care should be taken to ensure that an unused scalpel electrode is not placed in a wet environment during surgery. The leakage current of any scalpel electrode may be increased by dampness. Additionally, some of the hand control designs can be activated by moisture at the handle. In one recent case, a hand control scalpel was placed on the drape in between activations. The scalpel was in a valley in the drape sheet in which irrigating fluid collected. The pooled fluid activated the electrosurgery machine and a fairly severe steam or hot water burn resulted on the patient's skin.

The high voltages and frequencies typical of electrosurgery make it essential to use apparatus with insulation of good integrity. It should also be kept in mind that the electric fields extend for some distance around cables in use at high voltage. An effort should be made not to have active and return electrode cables running parallel to each other for any distance in order to reduce the capacitive coupling between them, unless the apparatus is specifically designed to be used this way, as in bipolar device cables.

There is an additional problem in monopolar endoscopic surgery that must be addressed. It arises when a metal laparoscope with an operating channel is isolated from a voltage reference plane, as depicted in Fig. 19. In this case, the insulating skin anchor isolates the metal laparoscope (or metallic trocar sleeve) so that its potential is determined by parasitic capacitances between the metallic elements. The resulting circuit creates a capacitive voltage divider, diagrammed in Fig. 20. The two parasitic capacitances are unavoidable. The voltage divide ratio for this

Figure 19. Diagram of isolated laparoscope with active operating channel.

Figure 20. Equivalent capacitive voltage divider circuit for isolated laparoscope with active operating channel.

equivalent circuit is

$$V_L = \frac{C_1}{C_1 + C_2} \quad (7)$$

The parameter C_1 is always quite a bit larger than C_2 , and the surface potential on the laparoscope, V_L , may be as much as 80–90% of the surgical voltage. This induced voltage is capable of generating sparks to the surrounding tissues out of the field of view of the surgeon. Several cases of distributed severe burns have resulted from situations similar to this. There are two remedies. First, the operating laparoscope may be grounded. This does not eliminate the C_1 capacitance, so there will be capacitively coupled currents between the scalpel electrode and the laparoscope. However, the laparoscope will be at zero potential. The second approach involves monitoring the scalpel electrode and return electrode currents. If they are substantially different then a hazard situation exists. There is at least one commercial device designed to do this.

Explosions. The original explosion hazard in the operating room arose from the use of explosive anesthetic agents, such as ether and cyclopropane. Combustible mixtures of these gases can be ignited by any arc discharge of sufficient energy—by static discharges between personnel and grounded objects, by arcs due to power switch openings in mains-powered devices, and by electrosurgical arcs at the cutting site. A few early instances of explosions and ensuing fires in operating rooms stimulated the establishment of requirements for operating room construction and use to lessen this hazard. In particular, operating rooms in the United States were required to have semiconducting flooring that was to be checked periodically for conductivity; operating room personnel were required to wear conductive shoe covers that would drain off accumulated static charge to the conductive flooring; and explosion-proof switches and plugs were required below the five foot level where the relatively heavy combustible gases might collect. Also, surgical table coverings and fixtures are connected to ground through moderate impedance in order to prevent static accumulation. These requirements greatly reduced the explosion risk in the operating room, but lead to some rather amusing *non sequiturs*. For example, it makes little sense to attach an explosion-proof foot switch to an electrosurgical generator (particularly to a spark gap oscillator) since arcing is inherent to the use of electrosurgery. Of course, since the wall plugs for mains power were required to be explosion proof, the power line plug on the generator was also often explosion proof. Because of the inordinate expense of explosion proof construction and the

rare use of combustible gases, the majority of new operating room construction is designed to satisfy the requirements for oxygen use only and specifically designated not for use of explosive gases.

There are, however, other explosion–combustion sources. Two constituents of bowel gas are combustible, hydrogen and methane, and there is almost always sufficient swallowed air to comprise an explosive mixture. Approximately 33% of the adult population are significant methane producers due to the indigenous gut flora and fauna responsible for certain aspects of digestion. One preventive measure that has been used is insufflation of the bowel with carbon dioxide, or some other inert gas, during electrosurgery. A large volume of CO_2 will dilute and displace the combustible mixture, reducing the chance of explosion.

Additionally, care must be taken in pure oxygen environments not to ignite organic materials. Body hair has been ignited in a pure oxygen environment by an electrosurgical arc. In surgery on the larynx, both electrosurgery and CO_2 lasers have ignited plastic endotracheal tubes and surgical gloves in the oxygen-rich environment.

Stimulation of Electrically Excitable Tissues. The stimulation of motor nerves is a well-known phenomenon accompanying electrosurgery. Stimulation of the abdominal muscles is often observed, and the obturator nerve bundle (connecting the spinal column to the leg) is also quite often stimulated. Obturator nerve stimulation is inherent to transurethral resections, and the resulting movement is always undesirable. Part of the stimulation problem arises from the low frequency components of the surgical arc, and part from the confinement of current. For example, the obturator nerve is clustered with the major blood vessels supplying the leg (iliac/femoral artery and vein) and emerges from the pelvis under the inguinal ligament into the upper thigh area. The pelvic bone structures are essentially nonconductive and impede current flow. The nerve–artery–vein cluster represents a relatively high conductivity pathway of small cross-section between the abdomen and the upper thigh, a typical location for the return electrode. As such, the surgical current in TURP procedures is somewhat concentrated in that tissue cluster, and stimulation is often observed. In the case of general abdominal surgery, the majority of surgical current flows in the surface tissue structures, reducing the likelihood of obturator stimulation. In the case of transurethral resections, the current source is deep in the floor of the abdomen, and the surface tissues carry a smaller fraction of the total surgical current. The very high currents in TURPs and the frequent use of spark gap oscillators means that an abundant supply of intense low and high frequency signals is contained in the surgical current. It is a personal observation that motor unit stimulation is closely correlated with relatively intense arc strikes while accomplishing cutting or coagulating. This is to be expected from the frequency spectrum of the surgical signals.

There are, in addition, several reported instances of ventricular fibrillation induced by electrosurgery (40–43). The low frequency arc components and high intensity high frequency signals are capable of stimulating

excitable tissues, with ventricular fibrillation as a possible outcome.

Interference with Instrumentation. The cutting current generated by standard oscillators, such as the vacuum tube and solid-state devices, has a well defined, narrow bandwidth. When an arc is struck at the surgical site, extensive signal energy is added at the high frequency end and at the low frequency end of the spectrum. Signals from spark gap oscillators have these components whether or not an arc is established at the tissue. Over the range of physiological frequencies the arc components are of very low amplitude compared to the generator fundamental frequency; but since the surgical currents and voltages are very high, the arc components may be many times larger than physiological signals such as the ECG. This creates a considerable problem for all measuring instruments including demand, or noncompetitive, pacemakers. There are many reported instances of inhibition of demand pacemakers by electrosurgery (44–47).

The population most at risk for pacemaker inhibition is patients undergoing either open heart surgery or transurethral resections of the prostate. Open heart operations put the electrosurgical scalpel electrode in close proximity to the pacemaker electrodes. The TURPs use the highest currents and voltages, and the interference signals are potentially large at the pacemaker electrodes. There is some indication that a higher incidence of prostate problems is associated with long-term pacemaker implantation, so it is to be expected that this problem will continue. The present use of shielded pacemakers virtually eliminates microwave sensitivity, but not electrosurgical effects.

All pacemakers may be damaged to failure by electrosurgery signals, and some caution should be observed when performing electrosurgery in the presence of pacemakers. Bipolar electrosurgery is much less likely than monopolar to cause interference with pacemakers because the surgical current field is confined and the voltages are low. There are many techniques for which bipolar electrosurgery is unacceptable, however, so monopolar methods must be used. In those cases, care should be exercised to encourage the surgical current field to avoid the right ventricle. To the extent that is practical, elevate the pacing electrode site (either the right ventricular wall or the external surface) away from the conductive fluids and tissues when cutting near the heart. Place the dispersive electrode on the left side of the body (this will only help a little bit). Anticipate some form of pacemaker malfunction.

Representative Electric Field Distributions

The effect of rf current on tissues is to heat them according to the first law of thermodynamics:

$$\rho_t c_t \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + q_{\text{gen}} + q_m + w_t c_b (T_a - T) - h_{\text{fg}} \frac{\partial m}{\partial t} \quad (8)$$

where ρ = density ($\text{kg}\cdot\text{m}^{-3}$), c = specific heat ($\text{J}\cdot\text{kg}^{-1}\cdot\text{K}^{-1}$), T = temperature (K), t = time (s), k = thermal conductivity ($\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$), q_{gen} = externally applied rf power ($\text{W}\cdot\text{m}^{-3}$), q_m = metabolic heat ($\text{W}\cdot\text{m}^{-3}$), w = perfusion

Figure 21. Geometry for infinite flat plate electrode calculation.

($\text{kg}_b\cdot\text{kg}_t^{-1}\cdot\text{s}^{-1}$), h_{fg} = vaporization enthalpy ($\text{J}\cdot\text{kg}^{-1}$) and dm/dt is the mass rate of vaporization ($\text{kg}\cdot\text{s}^{-1}$). Each term in the relation has units of ($\text{W}\cdot\text{m}^{-3}$) and the t subscript refers to tissue, while the b subscript refers to blood properties. This form does not include vaporization processes typical in cutting. Typically, both metabolic heat and perfusion heat transfer are negligible in electrosurgery. It is important to note that all of the tissue properties are dependent on the water content. As tissue dries out the density, electrical, and thermal conductivity decrease. As temperature rises the electrical conductivity increases $\sim 1\text{--}2\%$ / $^\circ\text{C}$, until drying at higher temperatures causes a decrease.

At electrosurgical frequencies the quasistatic assumption applies (simplifying calculations) and heat dissipation is dominated by joule, or resistive, heating ($\text{W}\cdot\text{m}^{-3}$):

$$q_{\text{gen}} = \mathbf{E} \cdot \mathbf{J} = \sigma |\mathbf{E}|^2 = \frac{|\mathbf{J}|^2}{\sigma} \quad (9)$$

where \mathbf{E} = electric field vector ($\text{V}\cdot\text{m}^{-1}$), \mathbf{J} = current density vector ($\text{A}\cdot\text{m}^{-2}$), and σ = electrical conductivity ($\text{S}\cdot\text{m}^{-1}$). This section reviews several representative electric field distributions.

Simple Field Geometries: Analytical Solutions. The simplest case is that of the electric field between parallel plates (Fig. 21). For a uniform medium between the plates the electric field is uniform (i.e., V increases linearly from V_2 to V_1) and is equal to the voltage difference divided by the distance between the plates: $(V_1 - V_2)/d = \Delta V/d$. It points from the higher potential (V_1) to the lower potential (V_2). In this case the heating term, q_{gen} , is also simple: $q_{\text{gen}} = \sigma \Delta V^2/d^2$. For an operating voltage difference of 50 V(rms) and plate separation distance of 2 cm, the electric field is 2500 ($\text{V}\cdot\text{m}^{-1}$), and if the electrical conductivity is 0.3 ($\text{S}\cdot\text{m}^{-1}$) the power density would be $1.88 \text{ W}\cdot\text{cm}^{-3}$.

Another simple analytical solution is for the case of coaxial cylinders (Fig. 22). In this geometry the potential increases as the natural log of the radius from V_2 to V_1 , and the electric field (pointing in the radial direction) is given by

$$\mathbf{E} = \frac{I_L}{2\pi\sigma r} \mathbf{a}_r \quad (10)$$

where I_L = the current per unit length of coaxial structure (i.e., length into the page, $\text{A}\cdot\text{m}^{-1}$). For this geometry the rf power generation decreases as $1/r^2$:

$$q_{\text{gen}} = \mathbf{E} \cdot \mathbf{J} = \sigma \left[\frac{I_L}{2\pi\sigma} \right]^2 \frac{1}{r^2} \quad (11)$$

Figure 22. Geometry for coaxial cylinder electrode example. The outer cylinder typically comprises the return electrode, $V_2 = 0$.

For a center cylinder electrode 2 mm in diameter and outer cylinder 2 cm in diameter and tissue electrical conductivity $0.3 \text{ (S}\cdot\text{m}^{-1}\text{)}$, the overall conductance per unit length would be $G = 0.816 \text{ (S}\cdot\text{m}^{-1}\text{)}$ — that is, $G = 2\sigma / (\ln\{b/a\})$. At a voltage difference of 50 V(rms), the current per unit length would be $I_L = 40.9 \text{ (A}\cdot\text{m}^{-1}\text{)}$ and maximum electric field $21.7 \text{ (kV}\cdot\text{m}^{-1}\text{)}$ at $r = 1 \text{ mm}$. The maximum volume power density would be $142 \text{ W}\cdot\text{cm}^{-3}$ at $r = 1 \text{ mm}$ in this example.

These examples are useful in understanding simple surgical fields. The uniform electric field case is not very different from that obtained near the center of a bipolar forceps electrode used to coagulate a tissue volume. The coaxial case is close to the electric field around a needle electrode as long as one is not too close to the tip. In both cases the analytical field expressions are simple because the boundaries are parallel to Cartesian and cylindrical coordinates, respectively. Also, the boundaries are chiefly isopotential, or Dirichlet, boundaries.

Disk Electrode Field. The electric field around a disk electrode applied to a large volume of tissue is a much more complex geometry (Fig. 23). This geometry was solved analytically by Wiley and Webster (48) for the $V = 0$ reference electrode located at $r = +\infty$ and $z = -\infty$. The electrode is an isopotential surface ($\partial V / \partial r = 0$) and the air is insulating (zero flux, $\partial V / \partial z = 0$); and at the edge of the disk ($r = a$) the field must satisfy two mutually exclusive boundary conditions. The consequence is that the electric field and current density both increase without bound at

Figure 23. Solution geometry for disk electrode applied to infinite medium. Return electrode, $V = 0$, located at $r = \infty$ and $z = -\infty$.

Figure 24. Normalized surface current density under the electrode from $r = 0 - 0.95a$.

the electrode edge, $r = a$ (48):

$$J_z(r, 0) = \frac{J_0}{2[1 - (r/a)^2]^{1/2}} \quad (12)$$

where $J_0 = I / \pi r^2$, the average current density. Figure 24 plots the normalized surface current ($J_0 = 1$) density versus normalized radius under the electrode. For radii less than $\sim 0.89a$ the current density is less than the average value. This is at first glance an alarming result: It is not obvious why burns do not result at the edge of every electrode. There are three mitigating factors. First, the singularity at $r = a$ is an integrable singularity—meaning that one may integrate $J_z(r, 0)$ from $r = 0$ to $r = a$ and get a finite result (i.e., integral $\{J_z dA\} = I$, the total current). Second, actual electrodes do not have mathematically sharp edges, but rather are filleted. Third, heat transfer dissipates the temperature rise at the edge and even though q_{gen} increases without bound (in a microscopic sense) the temperature rise at the edge reaches a finite maximum—still much higher than that at the center of the electrode, however.

The electric fields near a disk electrode, such as that used to ablate myocardium (Fig. 11) is very similar to the analytical solution. Figure 25 is the result of a quasi static Finite Element Method (FEM) calculation for the geometry used to create Fig. 11. The assumed electrode potential is 50 V(rms), and the isopotential lines (25a) are not significantly different in shape from those of the analytical solution (48). The electric field (current density lines) lines (Fig. 25b) are very crowded at the edge of the electrode, as expected from the above discussion. The result is that the volume power density, q_{gen} , (Fig. 25c) is higher by a factor of 1000 or more (see the $12 \text{ W}\cdot\text{cm}^{-3}$ contour) than about one electrode radius away (cf. to the $0.062 \text{ W}\cdot\text{cm}^{-3}$ contour).

Needle Electrode Field. Needle electrodes are often used to desiccate or coagulate small lesions. They are also used to shrink corneal collagen to change its curvature, as was discussed above (in the section Ablation, Coagulation and Tissue Fusion). The electric field around the tip of such an electrode is extremely high compared to the average value.

Figure 25. Circular disk electrode FEM model results. Muscle conductivity $90.3 \text{ S}\cdot\text{m}^{-1}$. (a) Potential field, $V(r,z)$. (b) Electric field streamlines. (c) Volume power density with contours at 0.062 , 0.86 , and $12 \text{ W}\cdot\text{cm}^{-3}$.

For comparison, the electric field and corresponding volume power density field were calculated around a needle electrode in cornea: Cornea electrical conductivity, at $1.125 \text{ S}\cdot\text{m}^{-1}$, is quite a bit higher than the $0.3 \text{ S}\cdot\text{m}^{-1}$ assumed for muscle in previous calculations. An electrical conductivity of $1.5 \text{ S}\cdot\text{m}^{-1}$ was assumed for the aqueous humor, accounting for the discontinuity in the constant power density contours at the interface. The results are shown in Fig. 26 for an assumed electrode potential of 50 V(rms) .

Note that the volume power densities are extremely high compared to the disk electrode calculation due to the small dimensions of the needle electrode. Power densities of $100 \text{ kW}\cdot\text{cm}^{-3}$ have adiabatic (no heat transfer) heating rates near $27,000 \text{ }^\circ\text{C}\cdot\text{s}^{-1}$ and will vaporize significant amounts of water in microseconds. In practice, the applied voltage is in the neighborhood of $50\text{--}80 \text{ V (rms)}$, however, pulsed rf is used with pulse times in the neighborhood of $15 \text{ }\mu\text{s}$. Vaporization begins during the first rf pulses in a very small volume around the electrode tip. Subsequent drying near the tip causes the dominant heat-

ing field to advance from the tip toward the surface while the overall impedance decreases due to an average increase in temperature around the electrode. At the higher voltage settings the heating may be sufficient to cause the impedance to increase near the end of rf activation due to drying in the cornea (49).

Bipolar Forceps Electrode Field. The bipolar forceps electrodes typically used in vessel sealing are essentially flat plate electrodes. The electric field between them is nearly uniform, with some small electrode edge effect. Figure 27 is a representative FEM calculation assuming an applied potential of 50 V(rms) and electrode separation of 2 mm . Here the power densities are in the neighborhood of $150\text{--}200 \text{ W}\cdot\text{cm}^{-3}$. The calculations have again assumed a uniform electrical conductivity of $0.3 \text{ S}\cdot\text{m}^{-1}$ while the actual value is a complex combination of collagen ($\sigma = 0.26\text{--}0.42 \text{ S}\cdot\text{m}^{-1}$ depending on orientation), elastin ($\sigma = 0.67\text{--}1.0 \text{ S}\cdot\text{m}^{-1}$ depending on orientation) and smooth muscle ($\sigma = 0.3 \text{ S}\cdot\text{m}^{-1}$).

Figure 26. Needle electrode in cornea, FEM model results. Cornea conductivity $1.125 \text{ S}\cdot\text{m}^{-1}$, aqueous humor $1.5 \text{ S}\cdot\text{m}^{-1}$. (a) Potential field $V(r,z)$ for 50 V (rms) electrode potential. (b) Electric field streamlines. (c) Volume power density with contours at 115 , 3.2 , and $0.098 \text{ kW}\cdot\text{cm}^{-3}$.

Figure 27. Bipolar forceps applied to a vessel, FEM model results. (a) Potential field, $V(x,y)$ for 50 V(rms) electrode potential. (b) Electric field streamlines. (c) Volume power density, q_{gen} , with contours at 85, 193, and 443 ($\text{W}\cdot\text{cm}^{-3}$). (d) Typical result: canine femoral artery temperature 89 °C for 2 s (thermocouple in center of artery; original magnification 40 \times , Mallory's trichrome stain).

SUMMARY

Radio frequency current has been used for many years to reduce time under anesthesia and improve the clinical result. The ability to simultaneously cut tissue and coagulate blood vessels greatly reduces morbidity and mortality, and enables a large number of procedures that are otherwise not possible, especially in neurosurgery. Electrosurgery is one of several energy sources making substantial contributions in surgery, sources that include: lasers, microwaves, ultrasound, micromechanical disruption, and cryogenics. The major advantage of electrosurgery over the other modes originates from its ability to shape the treated tissue volume by design of the applicator electrode geometry alone. Consequently, a single electrosurgical generator is capable of a wide range of applications from various forms of coagulation and tissue fusion to cutting, either through an endoscope or in open procedures, either microsurgery or, as it were, macrosurgery. Since the

electrodes are in contact with tissue, apposition pressure may be applied to improve the fusion probability. Electrode contact also gives the surgeon tactile feedback not characteristic of many of the other energy sources.

Useful predictions of clinical outcomes may be made with quasistatic electric field models coupled to transient thermal models including kinetic formulations of damage accumulation. Numerical model work can be used (1) to study trends due to uncertainty in tissue properties or changes in electrode voltage, current, power, or time of application; (2) to reveal discontinuities in the electric field due to boundary, conditions; and (3) to study the relative importance of each of the governing physical phenomena individually. When trends in the model match experimental results, one knows that all of the relevant physical phenomena have been included and the surgical process is well understood.

As with any such source of energy there are hazards in the use of electrosurgery. The hazards may be minimized, but not eliminated. Nevertheless, the advantages of use far outweigh the disadvantages, particularly in several very important procedures. The best safeguard is an informed and vigilant user population.

ENDOSCOPES

BRETT A. HOOPER
Areté Associates
Arlington, Virginia

INTRODUCTION

The word endoscope is derived from two Greek words, endo meaning "inside" and scope meaning "to view". The term endoscopy is defined as, "using an instrument (endoscope) to visually examine the interior of a hollow organ or cavity of the body." In this second edition of the *Encyclopedia of Medical Devices and Instrumentation*, we will revisit the excellent background provided in the first edition, and then move on from the conventional "view" of endoscopes and endoscopy to a more global "view" of how light can be delivered inside the body and the myriad light-tissue interactions that can be used for both diagnostic and therapeutic procedures using endoscopes. We will update the medical uses of endoscopy presented in the first edition, and then look at the medical specialties that have new capabilities in endoscopy since the first edition; cardiology and neurosurgery. This will be by no means an exhaustive list, but instead a sampling of the many capabilities now available using endoscopes. We will also present new delivery devices (fibers, waveguides, etc.) that have been introduced since the optical fiber to allow a broader range of wavelengths and more applications that deliver light inside the body.

HISTORY

Pre-1800s

Endoscopy had its beginnings in antiquity with the inspection of bodily openings using the speculum, a spoon-shaped instrument for spreading open the mouth, anus, and vagina. Another instrument of fundamental importance to endoscopy is the catheter, as it has been used to evacuate overfilled bladders for more than 3000 years. Catheters and a rectoscope were used by Hippocrates II (460–377 BC), where inspection of the oral cavity and of the pharynx was routine, including operations on tonsils, uvula, and nasal polyps. This trend continued for the better part of two millennia.

1800–1900

In 1804, Phillip Bozzini came upon the scene with the *Lichtleiter*, and attempts were made to view into the living body through the endoscope's narrow opening (1). It took almost 100 years to achieve this goal. These prototype endoscopes consisted of hollow tubes through which light of a candle, and even sunlight, was projected in order to visualize the inside of a bodily opening. The *Lichtleiter*, the light conductor, consists of two parts: (1) the light container with the optical part; and (2) the mechanical part, which consists of the viewing tubes fitted to accommodate the anatomical accesses of the organs to be examined. The apparatus is shaped like a vase, is ~35 cm tall, made of hollow lead, and covered with paper and leather. On its front is a large, round opening divided into two parts by a vertical partition. In one half, a wax candle is placed and held by springs such that the flame is always in the same position. Concave mirrors are placed behind the candle and reflect the candle light through the one-half of the tube onto the object to be examined. The image of the object is then reflected back through the other half of the tube to the eye of the observer. Depending on the width of the cavity to be examined, different specula were used. These specula consisted of leaves that could be spread open by use of a screw device in order to expand the channels. An example is shown in Fig. 1.

Figure 1. Phillip Bozzini's *Lichtleiter* endoscope.

In 1828, the physicist C. H. Pfaff mentioned that platinum wires could be made incandescent through electric current. The glowing platinum wire has a desirable side effect; its white-hot heat illuminates the cavity of a surgical field so brightly that it provided the first internal light source. In 1845, the Viennese dentist Moritz Heider was the first to combine the illumination and tissue heating capabilities of the platinum wires when he cauterized a dental pulp with this method. However, the simultaneous heat that is produced by the wire is so intense that it was difficult to attach to the tip of small endoscopes. The term endoscopy was first used in the medical literature in 1865 by two French physicians, Segals and Desmoreaux. In 1873, Kussmaul, successfully passed a hollow tube into the stomach of a sword-swallower. Observation was limited because these long stiff hollow tubes were poorly lit by sun, candlelight, and mirrors. It took the advent of X rays to prove the swallowing of a sword was not a trick (2). Later that year, Gustave Trouvé, an instrument maker from Paris, introduced the polyscope at the World Exhibition in Vienna. His polyscope took many forms; rectoscope, gastroscope, laryngoscope, and cystoscope for looking into the rectum, stomach, larynx, and urinary tract, respectively. Trouvé was responsible for the idea of using electric current successfully for endoscopic illumination by placing the light source at the tip of the instrument, and the first to accomplish internal illumination. He was also the first to utilize a double prism for two observers by splitting the field with a Lutz prism by 90°, and incorporated a Galilean lens system, which magnified 2.5-fold, but did not enlarge the visual field. In 1876, Maximilian Nitze started his work on the urethroscope, and by the fall of 1877 he had instruments for illumination of the urethra, bladder, and larynx that used the platinum wire illumination method. Nitze also reported the first cystoscopy of the urinary bladder in 1877. As early as 1879, Nitze had his instrument patented for bladder, urethra, stomach, and esophagus in both Europe and the United States. The use of fiber optics was foreshadowed by Dr. Roth and Professor Reuss of Vienna in 1888 when they used bent glass rods to illuminate body cavities. With the invention of the light bulb by Thomas Edison, small light sources could be attached to the tip of the endoscopes without the need for cooling. The mignon lamp with a relatively small battery to operate it, led the next resurgence in endoscopy.

1900–Present

It was not until the early 1900s, however, that endoscopy became more than a curiosity. With the advancement of more sophisticated equipment and the discoveries of electrically related technologies, illumination capabilities were greatly improved. New and better quality lenses, prisms, and mirrors dramatically enhanced the potential applications of endoscopy and opened up new avenues of application. During this period, Elnor is credited in 1910 with the first report of a technically advanced gastroscope (3) to view the stomach, and only 2 years later, Sussmann reported the first partially flexible gastroscope, which utilized screw systems and levers to contort the scope's shaft (4). The diagnostic merit of endoscopy was beginning to be

realized, as an atlas of endoscopic pathologies was being developed (5). Methods for saving images of the scene under investigation ranged from the early metal halide photographic process to 35 mm film cameras. Cameras were attached on view ports to allow simultaneous documentation of the view that the endoscopist had. Only within the last few decades has the use of digital photography been applied to the field of endoscopy, with an enhancement in diagnostic potential because of digital signal processing capabilities. In spite of the technical advances, problems with heat produced at the tip, blind spots in the field of view, and organ perforation limited the widespread use of endoscopes.

The most significant technological development began in the 1950s with the introduction of fiber optics. These thin glass or plastic optical fibers (on the order of 1 mm) allowed for “cold light” illumination at the tip, controlled flexibility to remove blind spots, and with quality image transmission opened up photographic capabilities, thus improving previous limitations. The use of fiber optics also allowed for the incorporation of ancillary channels for the passage of air, water, suction, and implementation of biopsy forceps or instruments for therapeutic procedures. Obviously, the most significant capabilities fiber optics has brought to endoscopes are their small size, flexibility, and ability to deliver laser light. Lasers are now used in both diagnostic and therapeutic procedures. In fact, the overwhelming advantage of using laser light is that it can act as both a diagnostic and therapeutic light source, and often in the same endoscope. Let us now look briefly at the theory behind efficient propagation of light in an optical fiber.

LIGHT DELIVERY WITH OPTICAL FIBERS

Efficient light delivery is made possible in solid-core optical fibers by use of total internal reflection. Total internal reflection (TIR) is achieved at the interface between two media when the incident medium has a refractive index larger than the transmitting medium, $n_i > n_t$, and the angle of incidence is greater than the critical angle. The critical angle is defined as the angle of incidence i where the transmitted angle t goes to 90° , and with no transmittance there is total internal reflection. For a given interface where n_i and n_t are known, the critical angle can be calculated from Snell's law as (6)

$$\theta_{\text{critical}} = \sin^{-1}(n_t \sin \theta_t / n_i) \quad (1)$$

For the optical fiber, TIR is achieved by designing the core refractive index n_i to be greater than the cladding refractive index n_t , and by focusing the input light so that it propagates along the axis of the fiber thereby maintaining a large angle with respect to the interface between core and cladding (see Fig. 2). Apart from choosing a fiber material that has close to lossless transmission at the wavelength of choice, one needs to focus the light beam so that the diameter of the fiber core is at least three times the radius of the input light beam and the cone of convergent focused light of angle 2θ is less than the acceptance cone of the fiber core. The acceptance half-angle of the fiber is related to the

Figure 2. Light coupling into an optical fiber with core refractive index n_i and cladding refractive index n_t , and the associated incident angles (θ and θ_i), refracted angles, and their ray trajectories. The numerical aperture (NA) is a measure of the acceptance angle θ of a fiber.

NA and the refractive indexes by

$$\text{NA} = n_0 \sin \theta = (n_i^2 - n_t^2)^{1/2} \quad (2)$$

Numerical apertures for solid-core fibers range from 0.2 to 1 for fibers in air, where $n_0 = 1.0$, and are a measure of the light gathering capability of a fiber. An NA of 1 indicates that essentially all light incident at the fiber, even light near a 90° angle of incidence, can be launched into the fiber. In practicality, the NA approaches 1 and focusing and transverse mode distribution then play an important role in efficient light coupling. This is the case for unclad single-crystal sapphire fibers where the NA approaches one. For hollow-core waveguides (HWGs) the same rules apply for efficient coupling, that is, core diameter at least three times the radius of the input light beam and the convergence angle of the focused light θ less than the acceptance angle of the waveguide. Waveguiding is accomplished by coating the inside of the HWG with a metallic or dielectric coating depending on the desired wavelength. Fibers are available in diameters from several micrometers, for single-mode transmission, to ~ 1 mm, for multimode fibers. A propagating mode in a fiber is a defined path in which the light travels. Light propagates on a single path in a single-mode fiber or on many paths in a multimode fiber. The mode depends on geometry, the refractive index profile of the fiber, and the wavelength of the light. In the next section, we will look at the many different kinds of “optical fibers” that have become available since the previous edition and the myriad wavelengths that are now available for diagnostic and therapeutic procedures through endoscopes.

NEW “OPTICAL FIBER” DEVICES

There are now available to the endoscopist an array of different light delivery devices that can be incorporated into an endoscope. Conventional silica glass fibers transmit wavelengths from the visible (400 nm) to the mid-infrared (IR) ($2.5 \mu\text{m}$). New solid-core fibers are available for the transmission of IR wavelengths; these include germanium-oxide glass, fluoride glass, sapphire (out to $5 \mu\text{m}$), and silver halide fibers (out to $30 \mu\text{m}$) (7–9). In addition to the conventional solid-core optical fiber, there are now fibers available that have a hollow core and fibers that are intentionally “holey”, that is to say they have a solid core with an array of periodic holes that run the length of the fiber. The hollow waveguides come in two flavors, but each efficiently transmits IR wavelengths.

The first hollow waveguide is a small silica tube that is metal coated on the inside and efficiently transmits IR light

from ~ 2 to $10\ \mu\text{m}$. These HWGs can be optimized for transmission of $2.94\ \mu\text{m}$ Er:YAG laser light or $10.6\ \mu\text{m}$ CO_2 laser light, and can therefore handle high laser power for therapeutic procedures (Polymicro Technologies, LLC). The second HWG is known as a photonic bandgap fiber (PBG) and is made from a multilayer thin-film process, rolled in a tube, and then heat drawn into the shape of a fiber. These PBG fibers are designed to transmit IR wavelengths, but only over a narrow band of $1\text{--}2\ \mu\text{m}$, for example, $9\text{--}11\ \mu\text{m}$ for delivery of CO_2 laser light (Omniguide Communications, Inc.). The “holey” fibers are silica fibers that have been very carefully etched to create holes in a periodic pattern about the center of the core that span the length of the fiber. The pattern of these holes is chosen to propagate light very efficiently at a particular band of wavelengths, hence these fibers can be designed for a particular application; to-date largely in the visible and near-IR.

With each of these new fibers there are trade-offs in flexibility, transmission bandwidth, and ability to handle high power laser light. There are also differing fiber needs for diagnostic and therapeutic application. Diagnostic imaging fibers, for example, require a large NA for high light gathering capability. Comparatively, a therapeutic fiber endoscope may require a small NA to confine the delivery of the high power laser light to a specific region. This can also be achieved by use of evanescent waves launched at the interface between a high refractive-index optic and the tissue. Evanescent waves are different from the freely propagating light that typically exits fibers in that it is a surface wave. This surface wave only penetrates into the tissue on the order of the wavelength of the light. For typical wavelengths in the visible and IR, this amounts to light penetration depths on the order of microns, appropriate for very precise delivery of light into tissue. Both diagnostic and therapeutic applications have been demonstrated by coupling a high refractive-index conic tip (sapphire and zinc sulfide) to a HWG (see Fig. 3) (10). The

diagnostic capability allows Fourier transform infrared (FTIR) spectroscopy to be performed on living (*In vivo*) tissue, where, for example, fatty tissues can be distinguished from normal intimal aorta tissue. Through the same HWG catheter, tissue ablation of atherosclerotic plaque has proven the therapeutic capabilities. These diagnostic and therapeutic applications can potentially take advantage of evanescent waves, HWGs, and mid-infrared FT spectroscopy in the $2\text{--}10\ \mu\text{m}$ wavelength range (10).

A hybrid optical fiber consisting of a germanium trunk fiber and a low OH silica tip has shown the ability to transmit up to $180\ \text{mJ}$ of Er:YAG power for applications requiring contact tissue ablation through a flexible endoscope (11). This pulse energy is more than sufficient for ablation of a variety of hard and soft tissues.

Next, we will look at the potential influence these new light delivery systems may have in endoscopy.

MEDICAL APPLICATIONS USING ENDOSCOPY

Endoscopy has had a major impact on the fields of medicine and surgery. It is largely responsible for the field of minimally invasive surgery. The ability to send diagnostic and therapeutic light into the body via minimally invasive procedures has reduced patient discomfort, pain, and length of hospital stay; and in some cases has dramatically changed the length of stay after a procedure from weeks to days. Optical fibers have had a profound effect on endoscopy, and in doing so, dramatically changed medicine and surgery. These small, flexible light pipes allowed physicians to direct light into the body where it was not thought possible, and even to direct laser light to perform microsurgies in regions previously too delicate or intricate to access.

In this section, we will examine the state of endoscopy in arthroscopy, bronchoscopy, cardiology, cystoscopy, fetoscopy,

Figure 3. An example of a HWG endoscope. Both diagnostic and therapeutic applications have been demonstrated by coupling a high refractive-index conic tip (sapphire and zinc sulfide) to a HWG. In this geometry with two waveguides, diagnostic spectrometer light can be coupled into the tip in contact with tissue via one waveguide and sent back to a detector via the other waveguide.

Figure 4. Arthroscope and internal components used to view the interior of knee joint space.

gastrointestinal endoscopy, laparoscopy, neurosurgery, and otolaryngology.

Arthroscopy

Arthroscopy had its birth in 1918 when Takagi modified a pediatric cystoscope and viewed the interior of the knee of a cadaver (12). Today its use is widespread in orthopedic surgery with major emphasis on the knee joint. Arthroscopy has had a major impact on the way knee surgery is performed and with positive outcomes. The surgery is minimally invasive often with only two small incisions; one for an endoscope to visualize the interior of the knee, and another to pass microsurgical instruments for treatment. Presently, endoscopes have the ability to view off-axis at a range of angles from 0 to 180°, with varying field-of-view (see Fig. 4). The larger the field-of-view the more distorted the image, as in a fish-eye lens. A 45° off-axis endoscope, for example, with a 90° field-of-view can be rotated to visualize the entire forward-looking hemisphere.

The most common procedure is arthrotomy, which is simply the surgical exploration of a joint. Possible indications include inspection of the interior of the knee or to perform a synovial biopsy. Synovia are clear viscous fluids that lubricate the linings of joints and the sheaths of tendons. Other indications include drainage of a hematoma or abscess, removal of a loose body or repair of a damaged structure, such as a meniscus or a torn anterior cruciate ligament, and the excision of an inflamed synovium (13,14).

Future directions in orthopedic surgery will see endoscopes put to use in smaller joints as endoscopes miniaturize and become more flexible. The ultimate limit on the diameter of these devices will likely be 10s of micrometers, as single-mode fibers are typically 5–10 μm in diameter. These dimensions will allow for endoscopy in virtually every joint in the body, including very small, delicate joints. Work in the shoulder and metacarpal-phalanges (hand-finger) joints is already increasing because of these new small flexible fiber optic endoscopes.

Bronchoscopy

Bronchoscopy is used to visualize the bronchial tree and lungs. Since its inception in the early 1900s bronchoscopy has been performed with rigid bronchoscopes, with much wider application and acceptance following the introduction of flexible fiber optics in 1968. An advantage of the equipment available is its portability, allowing procedures to be done at a patient's bedside, if necessary. With the introduction of fiber optics, in 1966, the first fiber optic bronchoscope was constructed, based on specifications and characteristics that were proposed by Ikeda. He demonstrated the instrument's use and application and named it the bronchofiberscope. Development over the last several decades has seen the use of fiberoptic endoscopes in the application of fiberoptic airway endoscopy in anesthesia and critical care. These endoscopes have improved the safe management of the airway and conduct of tracheal and bronchial intubation. Fiber optic endoscopy has been particularly helpful in the conduct of tracheal and bronchial intubation in the pediatric population.

Bronchoscopy is an integral part in diagnosis and treatment of pulmonary disease (15,16). Bronchoscopic biopsy of lung masses has a diagnostic yield of 70–95%, saving the patient the higher risk associated with a thoracotomy. Pulmonary infection is a major cause of morbidity and mortality, especially in immuno-compromised patients, and bronchoscopy allows quick access to secretions and tissue for diagnosis. Those patients with airway and/or mucous plugs can quickly be relieved of them using the bronchoscope. Another diagnostic use of the bronchoscope is pulmonary alveolar lavage, where sterile saline is instilled into the lung then aspirated out and the cells in the lavage fluid inspected for evidence of sarcoidosis, allergic alveolitis, for example. Lavage is also of therapeutic value in pulmonary alveolar proteinosis.

Bronchoscopy is usually well tolerated by the patient with complications much less than 1% for even minor complications. Laser use has also allowed for significant relief of symptoms in cancer patients.

Cardiology

Early developments in minimally invasive cardiac surgery included the cardiac catheter (1929), the intra-aortic balloon pump (1961), and balloon angioplasty (1968). Endoscopy in cardiology has largely focused on using intravascular catheters to inspect the inside of blood vessels and more recently the inside of the heart itself. Catheters are thin flexible tubes inserted into a part of the body to inject or drain away fluid, or to keep a passage open. Catheters are similar to endoscopes, and they also have many diagnostic and surgical applications.

For diagnostic purposes, angiography uses X rays in concert with radio-opaque dyes (fluoroscopy) to look for blockages in vessels, usually the coronary arteries that supply oxygenated blood to the heart. A catheter is introduced into the femoral artery and sent up the aorta and into the coronary arteries to assess blood flow to the heart. The catheter releases the dye and real-time X-ray fluoroscopy tracks the dye as it is pumped through the coronary artery. Angiography in concert with intravascular

Figure 5. Image of a blood vessel with a stent using IVUS. (Courtesy of LightLab Imaging.)

ultrasound (IVUS) is the currently accepted diagnostic in cardiology (17–21). IVUS emits acoustic energy out the tip of a catheter and listens for echoes to image the inside of coronary arteries (see Fig. 5). An IVUS image is a cross-sectional view of the blood vessel, and complements the X-ray fluoroscopy image. The IVUS has been used to assess atherosclerotic plaques in coronary arteries and has been very successful at guiding the placement of stents. Stents are expandable metal mesh cages in the shape of cylinders that act as scaffolding to open obstructions in vessels caused by atherosclerosis.

Another technique showing promise in endovascular imaging uses light. The light-driven technology, optical coherence tomography (OCT), is successful at detecting fatty plaques, including those that are vulnerable to rupture. Figure 6 compares OCT images of coronary artery to

Figure 6. Images of coronary artery comparing OCT with conventional histology. (Courtesy of LightLab Imaging.)

conventional histology (LightLab Imaging, Inc.). Visible are the necrotic core of an atherosclerotic plaque and the thin cap at the intimal surface of the vessel. Near-IR light has been used diagnostically for differentiating between oxygenated and deoxygenated blood in myocardium (22–24). The NIR light in the 2–2.5 μm wavelength range has also been used to characterize myocardial tissue (25). In this wavelength range, the absorption due to water is declining through a local minimum, while there are absorption peaks in fat at 2.3 and 2.4 μm that show distinct spectral signatures. It has also been suggested that IR light might be used to identify atherosclerotic plaques (26–29), including plaques that are at high risk of rupture or thrombosis (30). Arai et al. showed that fibrofatty plaques have characteristic absorbances at mid-IR wavelengths of 3.4 and 5.75 μm that are significantly greater than normal aorta tissue (29). Peaks at these wavelengths, and potentially other subtleties in the absorption spectra [derived from multivariate statistical analysis (MSA)], can be targeted for developing a diagnostic profile similar to that described by Lewis and co-workers for IR and Raman spectroscopic imaging (31,32). These mid-IR frequencies may also be optimized for selective therapy via precise laser surgery (10,33,34).

Surgical laser techniques have become routine over the past two decades in a number of medical specialties such as ophthalmology and dermatology. However, in cardiology initial enthusiasm for fiber optic catheter ablation of atherosclerotic plaque (laser angioplasty) waned in the face of unpredictable vascular perforations, restenosis, and thrombosis (35,36). Therapeutically, IR light has found application in transmural revascularization (TMR) through several partial myocardial perforations (37). Ideally, lasers can ablate tissue with exquisite precision and nearly no damage to the surrounding tissue. This precision requires extremely shallow optical penetration, such that only a microscopic zone near the tissue surface is affected. This has been accomplished by using short laser pulses at wavelengths that are strongly absorbed by proteins (193 nm in the UV) (38) or water (3 μm in the IR) (39).

Therapeutic techniques using catheters recently have targeted the atherosclerotic plaque that is deposited in the vessel wall as we age. The deposition of atherosclerotic plaque in coronary arteries is important for two reasons; the arteries are small (1–3 mm), and they supply blood to the heart muscle itself, so any reduction or blockage of oxygen-supplying blood to the heart shows up symptomatically as angina or worse, a heart attack. Catheters equipped with lasers and inflatable balloons have been used to open these blockages by ablating the plaque or compressing the plaque back into the vessel wall, respectively. Problems with balloon angioplasty have been vessel wall perforation, thrombosis (blood clot formation), and restenosis (reobstruction of the vessel due to an immune response). Recently, balloon angioplasty was augmented by the use of stents, as mentioned above. These expandable cages are opened via a balloon catheter in the vessel lumen and act as a mechanical scaffold to hold the plaque obstruction in place on the vessel wall. Stenting, however, still suffered from restenosis, because of the mechanical injury induced by the stent. Stents coated with small amounts of

Figure 7. Cystoscope and accessories used for viewing the urinary tract in the medical specialty urology.

drugs (drug-eluting stents) have met with some success, in that they are able to retard the regrowth of intimal hyperplasia responsible for the restenosis.

Cystoscopy

Endoscopy is an integral part of the practice of urology. There are many procedures that look inside the urinary tract using a cystoscope, with typical access through the ureter (see Fig. 7). Common cystoscopy procedures include ureteral catheterization, fulguration and or resection of bladder tumor(s), direct vision internal urethrotomy, insertion of stent, removal of bladder stone, and kidney stone fragmentation (40,41).

A wide variety of therapeutic accessories are available for endoscopic treatment, including snares and baskets for stone removal, and electrohydraulic lithotripsy and laser delivery for fragmenting large stones (42,43). These procedures are minimally invasive and, therefore, can be accomplished with a much lower rate of morbidity and mortality than would be achieved in an open surgical procedure.

Laser incision of urethral, bladder neck, and urethral strictures and fragmentation of kidney stones is being investigated using flexible endoscopes made from germanium fibers to transport Er:YAG laser light. Bladder neck strictures are defined as a narrowing or stenosis of the bladder neck that may result in recalcitrant scarring and urinary incontinence. A significant number of patients undergoing surgery for benign or malignant prostate cancer suffer from bladder neck strictures, and there is no simple and effective minimally invasive treatment. The Er:YAG laser can ablate soft tissue $\sim 20\text{--}30$ times better than a Ho:YAG laser ($2.12\ \mu\text{m}$), which is the laser of choice in urology. The absorption coefficient is many orders of magnitude different for these two lasers, $\sim 10,000\ \text{cm}^{-1}$ for Er:YAG versus $400\ \text{cm}^{-1}$ for the Ho:YAG. This translates to a $1/e$ depth of optical penetration of 1 versus $25\ \mu\text{m}$ for these two lasers. Water is the dominant absorptive chromophore in the tissue in this mid-IR region of the spectrum. Hence, the Er:YAG is better suited to procedures where precision is required in laser ablation of soft tissue.

Fetoscopy

Fetoscopy allows for the direct visualization of a fetus in the womb. It also allows for the collection of fetal blood samples and fetal skin sampling, for diagnosis of certain hemoglobinopathies and congenital skin diseases, respectively (44–46).

The instrument is a small-diameter (1–2 mm) needle-scope with typical entry through the abdominal wall under local anesthesia and guided by ultrasound. Optimal viewing is from 18 to 22-weeks gestation when the amniotic fluid clarity is greatest. Once the instrument is introduced, a small-gauge needle is typically used to obtain blood samples or small biopsy forceps can be used for skin biopsy.

Complete fetal visualization is not usually achieved. The procedure has some risk with fetal loss $\sim 10\%$ and prematurity another 10% . The future of this procedure is not clear, as it is not currently in general use, despite the safe and relatively simple prenatal diagnosis it offers. It has been replaced in many circumstances by ultrasound for the fetal visualization aspect, but is still valuable for blood and skin sampling.

Gastrointestinal Endoscopy

The techniques of fiberoptic gastrointestinal (GI) endoscopy were developed in the 1960s, but surgeons were slow to embrace the techniques. These procedures were developed by gastroenterologists who became skilled practitioners and teachers of the art (see Fig. 8). Gradually, GI surgeons adopted these procedures, and in 1980 the American Board of Surgery mandated that endoscopic training be a part of the curriculum in general surgical training. Endoscopy has since become an integral part of surgical education and practice (47). The GI endoscopy is used in the esophagus, stomach, small bowel and liver, biliary, colon, and in pediatric endoscopy. There are numerous accessories available for the GI endoscope. They include biopsy forceps, graspers, cautery tools, and wire snares (see Figs. 9 and 10).

Figure 8. Upper intestinal panendoscope for the adult patient.

Figure 9. An end view of the distal tip of a panendoscope illustrating the accessory channels and illumination ports.

In the esophagus, endoscopy is used in the dilation of benign esophageal strictures, balloon dilatation of Achalasia, management of foreign bodies and bezoars of the upper GI tract, and endoscopic laser therapy of GI neoplasms (48–50). Endoscopy of benign esophageal strictures is a common procedure performed by gastroenterologists to treat esophageal narrowing and relieve dysphagia. Achalasia is a motility disorder of the esophagus characterized by symptoms of progressive dysphagia for both solids and liquids with (1) aperistalsis in the body of the esophagus, (2) high lower esophageal sphincter (LES) pressure, and (3) failure of the LES to relax. Examples of foreign bodies are coins, meat impaction, frequently in the elderly population, sharp and pointed objects, such as, a toothpick, a chicken or fish bone, needles, and hatpins. Bezoars are a hard mass of material often found in the stomach and are divided into three main types: phytobezoars, trichobezoars, and miscellaneous. These bezoars can be managed by endoscopy dependent on size and location, typically by capture and removal rather than endoscopic fragmentation. Since the 1970s, the incidence of esophageal adenocarcinoma has increased more rapidly than any other form of cancer and now represents the majority of esophageal neoplasms in the West (51). Esophagectomy is considered the gold standard for the treatment of high grade dysplasia in Barrett's esophagus (BE) and for noninvasive adenocarcinoma (ACA) of the distal esophagus (52). Barrett's esopha-

Figure 10. A polyp wire snare device with retraction handle.

gus is the replacement of native squamous mucosa by specialized intestinal metaplasia and is known to be the major risk factor for the development of adenocarcinoma. A recent study of 45 patients supports the use of endoscopic surveillance in patients who have undergone "curative" esophagectomy for Barrett's dysplasia or localized cancer (53–55). OCT imaging has recently shown the ability to image Barrett's esophagus through a small fiber endoscope. The GI neoplasm treatment is also particularly amenable using neodymium-YAG laser palliative treatment of malignancies of the esophagus and gastroesophageal junction as first described by Fleischer in 1982.

For the stomach, endoscopic therapy for benign strictures of the gastric outlet is but one procedure. These strictures of the gastric outlet are similar to the esophageal stricture mentioned above. They are most frequently caused by peptic ulcer disease in the region of the pylorus, although chronic ingestion of nonsteroidal anti-inflammatory drugs is a frequent cause as well. Other endoscopic procedures in the stomach include sclerotherapy of esophageal varices (abnormally swollen or knotted vessels, especially veins), percutaneous endoscopic gastrostomy and jejunostomy, injection therapy for upper GI hemorrhage, and thermal coagulation therapy for upper GI bleeding.

In the small bowel and liver, enteroscopy is an endoscopic procedure to directly inspect the small bowel mucosa and take biopsies by enteroscopy from selected sites in the jejunum and proximal ileum. Until the recent development of the enteroscope, these parts of the small bowel were not possible to endoscopically evaluate. Enteroscopy is in its technological infancy. It presently allows for access to the most proximal aspects of the small bowel to obtain tissue at bleeding lesions. However, it cannot be utilized to adequately visualize the entire mucosa.

Endoscopy in the biliary system is used to perform sphincterotomies, papillotomies and stent insertions, to manage large bile duct stones and malignant biliary strictures, biliary and pancreatic manometry, and endoscopic retrograde cholangiopancreatography. The use of endoscopes all but changed the surgical technique for gallbladder removal and moved its outcome from a major inpatient surgery to a minimally invasive surgery with only small incisions for the endoscope.

In the colon, nonoperative and interventional management of hemorrhoids is performed with endoscopes. Other procedures include dilatation of colonic strictures, approaches to the difficult polyp and difficult colonic intubation, and clinical approaches of anorectal manometry. Additionally, colonoscopy is used for investigating irritable bowel syndrome, Crohn's disease, and ulcerative colitis (47,56).

Pediatric endoscopy has been used to perform gastroscopy, colonoscopy, and endoscopic retrograde cholangiopancreatography. Advances have largely involved the application of techniques used in adults to the pediatric patient; this was made possible with the introduction of smaller fiberoptic endoscopes.

And finally general endoscopy has been used as a surveillance program for premalignant lesions, to assess outpatient endoscopy, and endosonography and echo probes.

Laparoscopy

Laparoscopy or peritoneoscopy is an important diagnostic procedure that allows direct visualization of the surface of many intra-abdominal organs, as well as allowing the performance of guided biopsies and minimally invasive therapy. Landmarks in laparoscopic surgery include the first laparoscopic appendectomy (1983) and the first laparoscopic cholecystectomy (1987). The first laparoscope was an ordinary proctoscope with illumination coming from an electric headlight worn by the endoscopist. Since then, with the advent of newer technologies, a fiber optic cable was added to the rigid telescope making flexible laparoscopes available. Today, despite the advent of various noninvasive scanning technologies, laparoscopy is still clinically useful for visualizing and biopsying intra-abdominal tumors, particularly those that involve the liver, peritoneum, and pelvic organs (57,58).

The laparoscopic procedure begins with the introduction of a trocar into the abdomen at the inferior umbilical crease for insufflation of carbon dioxide gas. A trocar is a sharply pointed steel rod sheathed with a tight-fitting cylindrical tube (cannula), used together to drain or extract fluid from a body cavity. The whole instrument is inserted then the trocar is removed, leaving the cannula in place. The gas acts as a cushion to permit the safe entry of sharp instruments into the peritoneal cavity and enable a better view. Common procedures include laparoscopic cholecystectomy and laparoscopic appendectomy, laparoscopic removal of the gallbladder and appendix, respectively. Laparoscopic cholecystectomy has all but replaced the conventional surgery for removal of the gallbladder. What used to involve opening the abdominal cavity for gallbladder removal and a 5–7 day stay at the hospital, has been transformed to a minimally invasive procedure with only a few days in the hospital. Lastly, laparoscopic sterilization and abortion are also performed with endoscopes.

Neuroendoscopy

Fiber optics is particularly well suited for the field of neuroendoscopy for both diagnostic and therapeutic procedures in the inner brain, because of size, flexibility, visualization, and laser delivery. We briefly review a case study that highlights some of the advantages of fiber optic endoscopes for minimally invasive surgery in the inner brain.

A recent case report on laser-assisted endoscopic third ventriculostomy (ETV) for obstructive hydrocephalus shows the use of diagnostic and therapeutic endoscopy in neurosurgery (59). Under stereotactic and endoscopic guidance, multiple perforations in the ventricular floor using a 1.32 μm neodymium–yttrium–aluminum–garnet (Nd:YAG) or an aluminum–gallium–arsenide (AlGaAs) 0.805 μm diode laser and removal of intervening coagulated tissue ensued with a 4–6 mm opening between third ventricle and basilar cisterns. These perforations allow for the cerebrospinal fluid (CSF) to be diverted so that a permanent communication can be made between the third cerebral ventricle and arachnoid cisterns of the cranial base. In a series of 40 consecutive cases, 79% of the patients had a favorable outcome. This compares well with a recent

series summarizing > 100 patients and long-term follow-up with success rates ranging from 50 to 84%.

When the 1.32 μm Nd:YAG laser is used, the high absorption in water requires that the fiber be placed in contact with the ventricular floor. Conversely, the high power diode laser's dispersion-dominant properties can lead to damage to neural structures around the ventricular cavity. Therefore, the 0.805 μm diode laser was used in a contact mode, but only after carbonization of the fiber tip so that thermal increase of the fiber tip allowing ventricular floor perforation was due to absorption of the laser energy by the carbon layer only and not by direct laser–tissue interaction. The 1.32 μm Nd:YAG laser was found to have higher efficiency for coagulation and perforation than the 0.805 μm diode laser, and would appear to be the better choice for neuroendoscopic use in this procedure. The endoscope allows for visualization and treatment of a very difficult part of the brain to access, and the use of lasers in endoscopes is advantageous in cases of distorted anatomy and microstructures and may reduce technical failures.

In another case of endoscopic-delivered laser light for therapeutic purpose, an IR free-electron laser (FEL) was used to ablate (cut) a suspected meningioma brain tumor at Vanderbilt's Keck FEL Center (60). A HWG catheter was used to deliver 6.45 μm IR FEL light to a benign neural tumor in the first human surgery to use a FEL. The 6.45 μm FEL light is a candidate for soft tissue surgery because of its ability to ablate (cut) soft tissue with a minimum of thermal damage to the surrounding tissue; on the order of micrometers of damage. This is obviously very important for surgery in the brain where viable, eloquent tissue may be in contact with the tumorous tissue that is being removed.

The FEL is a research center device that generates laser light over a vast portion of the electromagnetic spectrum; to date FELs have generated laser light from the UV (190 nm) to millimeter (61). The FEL is beneficial in identifying wavelengths, particularly in the IR where there are no other laser sources, for selective laser-tissue interaction.

Otolaryngology

Early use of endoscopes for ear, nose, and throat often focused on the interior of the ear. The benefit of endoscopes for diagnosis and therapy had been recognized early on with the advent of the laser and fiber optics (62–65). Recent investigations at the University of Ulm on the use of an Er:YAG laser with a germanium-oxide fiber delivery system has focused on tympanoplasty and stapedotomy (middle ear surgery) (66). The Er:YAG laser was found to be optimum for operating on the eardrum along the ossicles as far as the footplate without carbonization, and with sharp-edged, 0.2-mm-diameter canals “drilled” through the bone. Using this technique, children with mucotympanon could have their eardrums reopened in the doctor's office without the need for drain tubes.

An endoscope suitable for quantitatively examining the larynx (vocal chords) uses a green laser and a double reflecting mirror (67). The device can be clipped onto the shaft of a commercial rigid laryngoscope. The double reflecting mirror sends out two beams parallel to one

another that allows for quantitative morphometry of laryngeal structures such as, vocal cords, glottis, lesions, and polyps.

The miniaturization and flexibility of fiber optics has allowed endoscopes to be applied in the small and delicate organ of the ear with much success. A case in point for the unique capabilities that the fiber optic endoscope has that can be applied to many fields of medicine in a very productive manner.

Future Directions

One pressing issue for “reusable” endoscopes is the ability to guarantee a clean, sterile device for more than one procedure. With the advent of the World Wide Web (WWW), many web sites are available to gain information on endoscopes, as well as the procedures they are used in. The U.S. Food and Drug Administration (FDA) has a site at their Center for Devices and Radiological Health (CDRH) that monitors medical devices and their performance in approved procedures. The FDA has also created guidelines for cleaning these devices.

The results of an FDA-sponsored survey, Future Trends in Medical Device Technology: Results of an Expert Survey in 1998, expressed a strong view that endoscopy and minimally invasive procedures would experience significant new developments during the next 5 and 10 year periods leading to new clinical products (68). The 15 participants included physicians, engineers, healthcare policy-makers and payers, manufacturers, futurists and technology analysts. In interviews and group discussions, survey participants expressed an expectation of continuing advancements in endoscopic procedures including fiber optic laser surgery and optical diagnosis, and a range of

miniaturized devices. Clinically, most participants expected an emphasis on minimally invasive cardiovascular surgery and minimally invasive neurosurgery; two new fields we introduced in this edition. Also predicted were continuing advances in noninvasive medical imaging, including a trend to image-guided procedures. Most profound expectations were for developments in functional and multimodality imaging. Finally, participants observed that longer term trends might ultimately lead to noninvasive technologies. These technologies would direct electromagnetic or ultrasonic energy, not material devices, transdermally to internal body structures and organs for therapeutic interventions.

Perhaps a stepping-stone on this path is the PillCam (Given Imaging), a swallowable 11×26 -mm capsule with cameras on both ends and a flashing light source, used to image the entire GI tract from the esophagus to the colon. The PillCam capsule has a field of view of 140° , and enables detection of objects as small as 0.1 mm in the esophagus and 0.5 mm in the small bowel. Figure 11 shows the PillCams used for small bowel (SB) and esophagus (ESO) procedures and samples of the images obtained. Shown are examples of active bleeding, Crohn’s disease, and tumor in the small bowel; and normal Z-line, esophagitis, and suspected Barrett’s in the esophagus. Patient exam time is 20 min for an esophageal procedure and 8 h for a small bowel procedure. As the PillCam passes through the GI tract images are acquired at 2 Hz and the information is transmitted via an array of sensors secured to the patient’s chest and abdomen and passed to a data recorder worn around the patient’s waist. The PillCam generates $\sim 57,000$ images in a normal 8 h procedure, while the patient is allowed to carry on their normal activity. An obvious enhancement of patient comfort.

Figure 11. The PillCam from Given Imaging and sample images from the small bowel and esophagus. Shown are examples of active bleeding, Crohn’s disease, and tumor in the small bowel; and normal Z-line, esophagitis, and suspected Barrett’s in the esophagus. The PillCam is a swallowable 11×26 mm capsule with cameras on both ends and a flashing light source, used to image the entire GI tract from the esophagus to the colon.

Figure 12. The da Vinci Surgical System consists of (a) a surgeon console, patient-side cart, instruments, and image processing equipment. The surgeon operates while seated at a console viewing a 3D image of the surgical field. The surgeon's fingers (b) grasp master controls below the display that translate the surgeon's hand, wrist, and finger movements into precise, real-time movements of the surgical instruments (c) inside the patient. The patient-side cart provides the robotic arms, with two or three instrument arms and one endoscope arm, that execute the surgeon's commands. The laparoscopic arms pivot at the 1 cm operating ports eliminating the use of the patient's body wall for leverage and minimizing tissue damage. The instruments are designed with seven degrees of motion that mimic the dexterity of the human hand and wrist. Operating images are enhanced, refined, and optimized for 3D viewing through the (d) 3D endoscopic camera system. (Courtesy of Intuitive Surgical, Inc.)

AESOP (formerly Computer Motion and now Intuitive Surgical) was the first robot, FDA approved in 1994, to maneuver a tiny endoscopic video camera inside a patient according to voice commands provided by the surgeon. This advance marked a major development in closed chest and port-access bypass techniques allowing surgeons direct and precise control of their operative field of view. In 1999, one-third of all minimally invasive procedures used AESOP to control endoscopes.

The da Vinci Surgical System (Intuitive Surgical) provides surgeons the flexibility of traditional open surgery while operating through tiny ports by integrating robotic technology with surgeon skill. The da Vinci consists of a surgeon console, a patient-side cart, instruments and image processing equipment (see Fig. 12). The surgeon operates while seated at a console viewing a 3D image of the surgical field. The surgeon's fingers grasp the master controls below the display with hands and wrists naturally positioned relative to their eyes, and the surgeon's hand, wrist, and finger movements are translated into precise, real-time movements of endoscopic surgical instruments inside the patient. The patient-side cart provides up to four robotic arms, three instrument arms, and one endoscope arm that execute the surgeon's commands. The laparoscopic arms pivot at the 1 cm operating ports and are designed with seven degrees of motion that mimic the dexterity of the human hand and wrist. Operating images are enhanced, refined, and optimized using image synchronizers, high intensity illuminators, and camera control units to provide enhanced 3D images of the operative field via a dual-lens three-chip digital camera endoscope. The FDA has cleared da Vinci for use in general laparoscopic surgery, thoracoscopic (chest) surgery, laparoscopic radical

prostatectomies, and thoracoscopically assisted cardiectomy procedures. Additionally, the da Vinci System is also presently involved in a cardiac clinical trial in the United States for totally endoscopic coronary artery bypass graft surgery. This technology will likely find application in vascular, orthopedic, spinal, neurologic, and other surgical disciplines that will certainly enhance minimally invasive surgery.

Minimally invasive technologies that enhance the present state of endoscopy will continue. The expectation that microelectromechanical systems (MEMS) technology will add a plethora of miniaturized devices to the armament of the endoscopist is well founded, as it is an extension of the impact that fiber optics had on the field of endoscopy. The MEMS will likely add the ability to have light source and detector at the tip of the endoscope, instead of piping the light into and out of the endoscope. Many other functions including "lab on a chip" MEMS technology may allow for tissue biopsies to be performed *in situ*. This miniaturization will likely lead to more capabilities for endoscopes, as well as, the ability to access previous inaccessible venues in the body. Endoscopy is poised to continue its substantial contribution to minimally invasive procedures in medicine and surgery. This will pave the way for the likely future of noninvasive procedures in surgery and medicine.

INTRODUCTION

History of Tissue Engineering

In 1988, researchers gathered at the Granlibakken Resort in Lake Tahoe, CA under the sponsorship of the National Science Foundation (NSF) to develop the fundamental principles of tissue engineering as an emerging technology. Based on an earlier proposal by Dr. Y.C. Fung to develop an Engineering Research Center focused on the engineering of living tissues, NSF held several meetings that led to the decision to designate tissue engineering as a new emerging field. A formal definition was finally agreed upon at the Granlibakken workshop. Based on this meeting, tissue engineering is defined as “the application of the principles and methods of engineering and the life sciences toward the fundamental understanding of structure–function relationships in normal and pathological mammalian tissues and the development of biological substitutes to restore, maintain, and improve function” (1). This was further refined in 1992 by Eugene Bell who developed a list of more specific goals:

1. Providing cellular prostheses or replacement parts for the human body.
2. Providing formed acellular replacement parts capable of inducing regeneration.
3. Providing tissue or organ-like model systems populated with cells for basic research and for many applied uses such as the study of disease states using aberrant cells.
4. Providing vehicles for delivering engineered cells to the organism.
5. Surfacing nonbiological devices (2).

These discussions eventually culminated in the pioneering review article by Langer and Vacanti in 1993 (3). The general strategies to create engineered tissue would include the isolation of cells or cell substitutes, the use of tissue-inducing substances, and development of three-dimensional (3D) matrices on which to grow tissue.

Much of tissue engineering owes its beginnings to reconstructive surgery and internal medicine. In the sixteenth century, Gaspare Tagliacozzi developed a method for nasal reconstruction using flaps of skin taken from the arm and grafted onto the injury site (4). With the scientific development of the germ theory of disease and the sterile techniques that were introduced, modern surgery became established as a means to treat patients with internal injuries. In the late nineteenth century, surgeons used veins and arteries as conduits to enhance the nerve regeneration (5). World War I saw improvements in reconstructive surgery as doctors were able to hone their skills due to the number of soldiers injured in battle. Reconstructive surgery had its limitations in terms of the availability of biological material. By the 1940s, much progress had been made in understanding the function of the immune system by accepting tissue from a donor. This eventually led to the first successful organ transplant (kidney) in 1954. The next 50 years, would see tremendous advances in organ transplants as well as in immunosuppressive drug therapy.

An alternative to organ transplant has been the development of artificial devices to mimic biological function. The mid-nineteenth century also saw the rise in the use of prosthetic limbs that would initiate the use of artificial devices to replace biological functions. Artificial limbs were used as far back as the Dark Ages to assist knights heading off to battle. The intervening centuries saw improvements over such devices through the use of stronger, lighter materials, and a better understanding of biomechanics (6). Besides limbs, artificial devices have also been invented to replace the function of certain internal organs. The dialysis machine was created in the 1940s to assist patients with acute renal failure. In 2001, an implantable artificial heart was first used in a human. While many advances have been made in artificial devices, some of the drawbacks include the breakdown of the artificial materials, a lack of interaction with the human body, and the inability to self-renew.

The modern era of tissue engineers seeks to overcome the limitations of reconstructive surgery, organ transplants, and prosthetic devices by creating functional, completely biocompatible tissues and organs. Since the late 1980s, the field of tissue engineering has grown exponentially and continues to draw scientists from diverse fields, from the biological and medical sciences to engineering and materials science.

THEORY

Tissue engineering adds to the modern health care system by providing the tools to assist in the repair of tissue and organs damaged by injury and disease. An exact replica of the tissue could potentially be grown in the lab and later inserted into the patient. Alternatively, precursors may be placed in the body with the expectation that it will develop into fully formed functional tissue. Also, devices may be implanted into the body to encourage the regeneration of already existing tissue in the body.

Engineered tissue is created by combining relevant cells and chemical factors within a 3D matrix that serves as a

Figure 1. Basic components of engineered tissue.

scaffold (Fig. 1). Sterile cell culture techniques allow for the expansion of cells *in vitro* to obtain sufficient quantities for use in engineered tissue. Cells can originate from the patient, another donor, or even animal tissue. As our understanding of biochemical cues during development expands, tissue formation can be better controlled through the delivery of pertinent growth factors or through the interaction of complex multiple cell cultures. Scaffold materials may be biological (collagen, extra cellular matrix) or synthetic. Synthetic materials can be designed to mimic the extra cellular matrix and may be infused with chemical factors to support tissue regeneration. Since the discovery and availability of synthetic polymers in the 1940s, scientific advances have made these materials biodegradable and biocompatible.

Cellular Processes

During the formation of tissue, either during development or in the lab, cells undertake many different processes. In order to maintain the integrity of the tissue, the cells must adhere to others as well as to the surrounding matrix material. Certain cells must migrate through the 3D space in order to properly position themselves within the tissue. Once in position, they must also continue to multiply to provide adequate tissue growth. Vascularization and innervation of the tissue is required to complete integration of the engineered tissue with its surroundings. Tissue derived from donor material also has immune concerns.

Development. Engineered tissue is best created by mimicking the processes that occur during development (7). Following fertilization, the zygote divides until the blastocyst is formed. The early embryonic tissue is comprised of two cell phenotypes: epithelial cells and migratory mesenchymal cells. The transformation between these cells is regulated by growth factors, the extra cellular matrix, and intracellular signaling. As the embryo develops, these cells will become diversified as they commit to various tissue forms. These cells will eventually differentiate into the various cell types found in the body.

Morphogenesis describes the cascade of events that leads to the spatial pattern formation of the developing

embryo. Regeneration of tissue mimics this process. Specific chemical factors, called morphogens, provide information on the pattern via diffusion. The combination of various morphogens due to diffusion leads to complex pattern formation. One well-studied example is the development of bone. Several bone morphogenic factors have been isolated and observed to affect the bone and cartilage morphogenesis and formation. Also, BMPs have been implicated in the development of tissue as diverse as skin, eye, heart, and kidney. These morphogens have the potential to assist in the engineering of bone tissue.

Adhesion. Tissue is held together by the adhesion processes between different cells and the cells and extracellular matrix. The cell–cell interactions consist of tight, anchoring, and communication junctions. Tight junctions are composed of transmembrane proteins that form connections between cells. More contact points will decrease the permeability between the cells so that the tissue can become essentially impermeable. This is typically found with epithelial cells, as in the intestinal, reproductive, and respiratory tract, where the barrier that is formed is essential to function.

Anchoring junctions are loosely held connections that take advantage of the cytoskeleton. With adherens junctions, actin filaments of the cytoskeleton are connected and linked to integrins on the cell exterior. These integrins form focal contacts that interact with cadherins found on the surface of other cells. The focal contacts can also interact with extracellular domains. With the involvement of the cytoskeleton, these junctions can also affect cell function by providing a mechanism to signal changes in cell growth, survival, morphology, migration, and differentiation.

Desmosomes are similar to adherens junctions, but they involve intermediate filament protein, such as vimentin, desmin, and keratin. These junctions connect with other cells via cadherins. A similar junction called the hemidesmosome behaves in the same manner, but connects with basal lamina proteins via integrin.

Communication junctions are those that provide direct communication between cells. These are large proteins that form pore structure that connects the two cells. These large pores (connexons) allow the transport of molecules between cells. These junctions are commonly found between neurons for rapid signal conduction.

In order to connect with other cells or the extracellular matrix, the junction proteins must interact with some receptor molecule. Integrins will bind with the amino acid sequence arginine-glycine-aspartic acid (RGD). This sequence is found in several proteins, such as collagen and fibronectin and these peptides can be incorporated onto other surfaces in order to improve cell adhesion. Cadherin–cadherin binding is mediated via Ca^{2+} . Without the presence of Ca^{2+} , the connection is subject to proteolysis. The Ig-like receptors contain motifs found in immunoglobulins. These receptors can interact with neural cell adhesion molecule (N-CAM) and are present during development. Finally, selectins are specific receptor types that are expressed during the inflammatory response. The lectin domain found in oligosaccharides on neutrophils allows

these cells to interact with endothelial cells along the surface of blood vessels.

Migration. During embryogenesis, diffusible factors and ECM composition are important factors in the pattern formation of tissue development. The migration of cells is necessary for the formation of tissue not just for development, but also during regeneration. Cell migration is also observed in other body functions. Angiogenesis, or blood vessel formation, involves the migration of endothelial cells into new tissues. For immune responses, B and T cells patrol the body ready to attack invaders. Tumor invasion and, more importantly, metastasis relies on the migration of cancer cells into other parts of the body. Controlling migration can help to control the spread of cancer.

Signals from various factors can lead to the release of cells from their contact with other cells or with the extracellular matrix. Once released, different mechanisms can affect the migration pattern of the cell depending on the cell type. Cells may move in random directions. The movement can be modeled by Brownian motion. In this case, motion is due to collisions with other particles. This motion is characterized by the time between collisions, the mean free path (average distance before hitting another particle) and the average speed. The characteristics are dependent on the density of the particles.

Of more relevance is the issue of directed migration. Direct migration depends on some sort of gradient. In response to some kind of stimulus, cells may move toward or away from the source of the stimulus. The stimulus may affect speed, direction, or both. Chemotaxis is the general term describing the response of cells to a chemical gradient. The strength of the effect is dependent on the absolute concentration as well as the steepness of the gradient.

Growth. Mitosis is a tightly controlled process to regulate cell growth and depends on signals from the cell's environment. During mitosis, the deoxyribonucleic acid (DNA) is replicated and copies are separated as the cells divide into two exact copies. This process repeats itself depending on the extracellular signaling and the properties of the cell itself. Certain cells, such as pancreatic beta cells, are locked in the cell cycle and mitosis is arrested. In order to overcome this barrier, stem cells can be used to generate new differentiated cells. Also, cells may be converted into a precursor cell form that can undergo proliferation before switching back to the differentiated form.

Cell growth relies on the availability of essential nutrients. As the need for nutrients increases during cells proliferation, the availability becomes reduced barring some mechanism for distributing the nutrients to the growing tissue. Distribution of nutrients occurs naturally in the human body in the form of the network of blood vessels. The lack of such a vasculature for engineered tissue limits the effective size that tissue can grow.

Vascularization. For most engineered tissue to become integrated into the human body, it must become vascularized by the body's own blood vessel network. The body provides a natural mechanism for neovascularization by the process of wound healing. When tissue has been

damaged, a cascade of events is initiated to block the bleeding wound and encourage healing. Platelets, fibrin, and fibronectin first form a mesh plug. Mast cells release chemotactic agents to recruit other cells as part of the inflammatory response. Keratinocytes migrate to the site of the injury and begin to proliferate. Vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are released to encourage blood vessel formation. Once the new tissue has been vascularized, remodeling of the tissue occurs to complete the healing process.

For engineered tissue, two options are used to ensure vascularization and promote tissue growth and integration. The engineered tissue can be designed to contain a vascular network *in vitro* that would then be connected to the body's own network when it is implanted. This presents a significant engineering challenge in trying to create several different types of engineered tissue in one construct simultaneously. An alternative method is to engineer the tissue to recruit blood vessels from the body's existing framework. This has been accomplished through the controlled release of VEGF from the biodegradable support matrix of the engineered tissue (8).

Innervation. To become fully integrated into the body, certain tissues and organs must also reconnect with the body's own nervous system. Several organs of the body form connections with the sympathetic nervous system. These connections are important to regulation of the organ. Skeletal muscle tissue makes sensory and motor connections via the peripheral nervous system. In any case, the cells of these engineered tissues need to make synaptic connection with the axons of the relevant neurons. Because the new tissue is being engineered to replace that which has been lost to injury or disease, the neural framework may not be available for integration. If it is present, the neurons may be encouraged to regenerate toward the tissue and form new connections. Another complex, but theoretically possible, option may be to engineer the tissue with neural connections that can be later integrated into the existing nervous system. Also, artificial devices may be integrated into the system to provide the appropriate control of the tissue function.

Immune Concerns. As with organ transplants, engineered tissue also has concerns of rejection by the immune system. The major histocompatibility complex I (MHC I) present on the cells of the engineered tissue are recognized by the T cells of the immune system as a foreign body. This would eventually lead to cell lysis. The primary means of preventing rejection, though, is the use of immune suppressant drug therapy. While this may be acceptable, for a patient receiving a life saving organ transplant, it is not for those receiving engineered tissue. Certain tissues, such as cartilage, may not interact with the immune system. Metabolic tissues that only interact chemically can be physically separated from the environment. Some engineered tissues may contain cells that are only temporary until the body's own cells can take over. In these cases, immune suppressant drug may be a viable option. For most other tissues, methods are being developed for side stepping the immune system.

Because the cells of the immune system are formed within the bone marrow, one method is to transplant the bone marrow from the cell and tissue donor along with the organ. The donated bone marrow can form a chimera with the patient's existing bone marrow to allow the adaptation of the immune system to the new tissue (9).

At the molecular level, the antigen of the foreign cell can be blocked or completely eliminated. In order to block the antigen, a fragment of antibody to the antigen can be added to the tissue to mask the foreign cells from the patient's own immune system (10). This effect is temporary as the fragments will eventually separate from the antigen. Another drawback is that it may not counter all the mechanisms of immune response. The antigen can also be removed by placing an inactive form of the antigen gene into the cells (11). A gene can also be added to the cells to produce a protein that will inhibit rejection (12). Finally, oligonucleotides can be added to hybridize with either ribonucleic acid (RNA) or DNA in order to inhibit the transcription or translation of the antigen molecule (13).

Microencapsulation is a means of physically separating the cells from the environment. For this method, cells are surrounded by a porous synthetic material. As long as the membrane coating remains intact, the cells are isolated from the immune system. The pore size can be adjusted to allow chemical interaction with the environment while preventing cellular interaction. The encapsulation should allow nutrients to permeate through the membrane and reach the cells. This was first used in clinical studies for the encapsulation of xenogenic pancreatic islets (14).

Cell Types. While the response of the immune system is of great importance to the success of the engineered implant, the source of cells and their application will determine the best method for immunomodulation. Cells may come from the patients themselves (autologous), from a human donor (allogeneic), or from another species (xenogeneic). Each type has its own advantages and disadvantages.

Autologous cells are derived from the patient, expanded in culture, and then placed back into the patient. These cells are completely biocompatible with the patient and this eliminates the need for any immune modulation. Genzyme, for example, has developed a successful protocol for the repairing articular cartilage. One drawback to using autologous cells is that it requires a period of time to expand the cells. This would not be acceptable for patients needing an immediate tissue replacement. As a result, the engineered tissue does not have off-the-shelf availability. Depending on the tissue and the amount of damage, the amount of cells that may be harvested from the patient may be insufficient to form tissue.

Allogeneic cells can help to overcome some of the drawbacks to autologous cells because the cells come from donor sources that may be pooled together. This can provide off-the-shelf availability, but at the expense of immune rejection. The cells can be engineered to become immune acceptable or immunosuppressive drug therapy may be used. These cells are also well suited for tissues that do not interact with the patient's vasculature system or may only be used until the native tissue regenerate.

Advanced Tissue Science developed a skin replacement tissue (Dermagraft) with cells derived from circumcision surgeries.

Xenogeneic cells are derived from nonhuman species. An animal source can provide an unlimited amount of cells, but they provoke an acute immune response within minutes of implantation into the body. One useful application of such cells is the encapsulation of pancreatic islets (14,15). The membrane can be adjusted to allow the islets to regulate blood sugar and insulin levels while protecting the cells from the immune system. Another drawback to xenogeneic cells is the threat of transmission of animal viruses and well as endogenous retroviruses that may interact with the patient.

Cells that have been isolated may be modified to alter their characteristics before being incorporated into engineered tissue. Primary cells that are subcultured eventually become cell lines. These cell lines may be finite or continuous. The cells may also be normal or transformed compared to the primary cell from which it is derived. Transformation is associated with genetic instabilities that may lead to a change in the phenotype. These changes may impart different growth characteristics for the cell, such as immortalization, anchorage independence, and overall growth rate. The genetic material may be altered to effect gene expression. Changes in protein expression may effect the secretion of chemical factors or even the formation of extracellular matrix. In the worst case, cells may become cancerous and prove to be detrimental to the patient. Examples of stable, well-characterized cell lines used in tissue engineering include HEK-293 for nerve growth factor secretion (16), and 3T3-L1 for adipose tissue formation (17).

Primary cells as well as cell lines can be artificially transformed by introducing new genes by the process of transfection. In this process, a new gene is carried by some vector, such as a liposome or virus, to the host cells. The gene is transferred into the cells and delivered into the nucleus where it can be transcribed. This method allows the creation of cells with desirable characteristics for engineered tissue. Such cells may secrete growth factor that will enhance tissue formation. Examples of engineered tissue utilizing transfected cells include insertion of hBMP-4 gene in bone marrow stromal cells for bone tissue engineering (18) and aquaporin gene transfection in the LLC-PK1 cell line for a bioartificial renal device (19), secretion of neuronal growth factors from fibroblasts to enhance axonal regeneration (20).

Regardless of the source, primary cells have limitations depending on their age and genetic makeup. Adult cells may only have a limited number of cell divisions before they reach senescence or even become cancerous. Transformed cell lines may allow for continuous growth, but without proper control can become a problem for the patient. These cells are typically used to enhance regeneration of existing tissue, but do not become integrated into the body. Because of these issues, a universal cell that can develop into multiple tissue types has an infinite capacity to proliferate without loss of function, and if immune acceptable would be ideal for engineered tissue. Stem cells come closest to meeting these criteria.

Figure 2. Stem cell potency. Relationship of stem cells to various stages of development. Cells and tissue derived from stem cells are shown in italics.

Stem Cells. The potency of stem cells is defined by their ability to differentiate into one or more cell genotypes (see Fig. 2). Unipotent stem cells give rise to only one cell type (*ex. Spermogonia*). Multipotent stem cells are more functional and can differentiate into multiple cell types. Embryonic stem cells are considered pluripotent in that they can form all the cell types found in an embryo and adult. The fertilized egg develops into an embryo as well as the amniotic sac and is considered totipotent. Embryonic stem cells hold the most promise for engineering tissue, but more work must be done on the basic principles of stem and progenitor cell biology as well as on the control of differentiation.

Multipotent stem cells obtained from embryonic or adult sources are considered the optimal choice for tissue engineering applications because of their ability to form multiple tissue type. Hematopoietic stem cells (HSCs) are the most well characterized of stem cells. While isolated from bone marrow, HSCs can differentiate to form skeletal muscle, cardiac muscle, hepatocytes, endothelial cells, and epithelial cells. Multipotent stem cells can be found in several other tissues, such as brain, heart, pancreas, retina, liver, and lung, and skin.

To take full advantage of the functionality of stem cells, more work needs to be done to elucidate the mechanisms for differentiation. Once established, stem cells can be encouraged to differentiate into the required cell type.

The mechanism may rely on an environmental cue as to whether they are physical contact, chemical, or chemotactic in nature. The ability of stem cell to proliferate, integrate, and differentiate also depends on the methods of identifying, isolating, and expanding. Protocols for stem cell culture need to be developed and optimized to ensure the cells achieve their full potential.

Since some stem cells are harder to obtain than others, getting stem cells to transdifferentiate from one form to another would allow for further flexibility. Evidence suggests that bone marrow stromal cells may convert to neural stem cells (21) and neural stem cells to hematopoietic stem cells (22). Recent evidence, though, points to the fusion of stem cells with other cells instead of true transdifferentiation (23).

Another source for stem cells is from embryos discarded from *in vitro* fertilization clinics. Human embryonic stem cells have an even greater capacity to form tissues than the multipotent stem cells. These cells have been isolated from humans and protocols for long-term cultures have successfully been developed (24). The use of embryonic stem cells has raised many ethical concerns because of the destruction of the fetus from which they are derived. This has led to legislation tightly regulating their use. To avoid these concerns, several proposals have been suggested to obtain embryonic stem cells without compromising the potential for life (25).

Stem cells have been used successfully for tissue engineering applications. Stem cells have been seeded on scaffolds to form cartilage, small intestine, and bone (26). Neural stem cells have also been used for repair of spinal cord injuries (27). Embryonic stem cells have also been seeded onto scaffolds where the native vasculature integrated into the engineered tissue (28).

Instead of preseeding cells on scaffolds, stems cells may also be injected directly to the site of injury to promote tissue regeneration. Clinical studies in nonhuman primates have shown that neural stem cells can enhance repair of spinal cord injuries (29). Stem cells have also been used to regenerate damaged cardiac muscle tissue (30). Embryonic stem cells may also be used to regenerate pancreatic beta cells in order to alleviate diabetes (31). Mesenchymal stem cells also show some promise for the repair of articular cartilage for those suffering from osteoarthritis (32).

Scaffolds

Primary cells will form monolayer cultures when dissociated from tissue. In order to encourage the cells to form engineered tissue, they must be placed in a 3D matrix that acts as a support scaffold. Ideally, these scaffolds should be compatible with the cells as well as being biodegrade. The scaffold should have a high porosity to ensure the diffusion of nutrients and other chemical factors as well as provide room for cell migration and proliferation. The material should have a higher surface area to ensure adequate room for cell attachment. The matrix should maintain its structural integrity until tissue integration has been completed. For certain applications, the final construct may need to be formed into a specific 3D shape (see Fig. 3).

Figure 3. Example of a scaffold for engineered tissue. This scaffold is designed for nerve regeneration. The cylindrical conduit was manufactured by using the solvent casting method (see below) with particle leaching. Poly(vinyl alcohol) rods were coated with a suspension of salt crystals in a poly(lactic acid) (PLA)–chloroform solution. Dissolution of the rods permitted the formation of the large central pore through which nerve tissue could regenerate. A porosity of 85% was obtained by controlling the volume fraction of salt crystals.

For tissue engineering, scaffolds may come in different forms. An acellular matrix can be used to recruit cells from the host tissue (33). With this form, the immune response is not a concern though inflammation may occur. For most applications, cells must be seeded onto the scaffold to ensure successful tissue formation. Cells can be seeded onto collagen gels that mimic the naturally occurring extracellular matrix (34,35). Cells can also be encouraged to self-assemble in culture. These systems are ideal for tissue that forms simple shapes, such as sheets and cylinders (36,37). Biodegradable polymers provide a flexible means of creating scaffolds with properties desirable for tissue formation.

Natural Polymers. Macromolecules found with the extracellular matrix provide chemical and structural support for living tissue. Because of their function in tissue formation, these natural polymers provide an excellent scaffold for engineering new tissue. These natural polymers have some limitations in their application. The mechanical properties and degradation rates cannot be controlled as well as synthetic polymers (38). Also, material derived from donors may elicit an immune response (39). Many of these limitations can be overcome by chemical modification of the materials as well as creating composite materials of natural polymers or natural–synthetic polymers.

Collagen is a large family of proteins that make up much of the extracellular matrix. At least 19 different types have been isolated. Fibrillar collagen is comprised of several collagen types that combine to form extended structures that assist in maintaining tissue integrity. The relative amounts of collagen are characteristic of the tissue type. Collagen has been used for cartilage (40), nerve regeneration (41), gallbladder engineering (42), corneal tissue (43),

and skin (44). It can be cross-linked to enhance mechanical properties (45). Magnetically aligned collagen fibers can also be used to enhance nerve regeneration (46).

Matrigel is comprised of proteins found in the basal lamina. The basal lamina, or basement membrane, is a specialized area of the extracellular matrix found at epithelial–stromal boundaries. It is composed of collagen, laminin, nidogen, and perlecan, (a heparin sulfate proteoglycan). It has been used for spinal cord repair (47) vascular network formation (48), and cardiac tissue (49).

Alginates are synthesized naturally by brown seaweeds as well as some bacteria. They are comprised of units of mannuronic and guluronic acid. The proportion and repeat unit sequence is dependent on the organism of origin. Alginates will form a gel in the presence of calcium ions. Alginates have been used for cartilage (50), cardiac tissue (51), and liver engineering (52).

Fibrin is formed from the polymerization of fibrinogen that occurs during the wound healing process. The process is controlled by the presence of thrombin. Fibrin has been used for cardiovascular repair (53), bone (54), cartilage (55), and skin (56). Like collagen, the fibrin chains can be cross-linked to alter the characteristics of the matrix (57).

Chitosan is derived from chitin, a polysaccharide that comprises the exoskeleton of crustaceans. The amide group on chitin is replaced by an amine group. Since chitosan is not protein based, it does not elicit an immune response. Chitosan has been used for the engineering of cartilage (58) and bone (59). It has also been combined with other materials to create novel composite matrices (60,61).

Besides isolating single components as scaffolding material, intact decellularized tissue can also be used. In this method, tissue is obtained from a donor and the cells are destroyed chemically using compounds, such as sodium dodecyl sulfate. This method is currently used to engineer blood vessels (62) and heart valves (63). Decellularized tissue may also be applied to the engineering of other types of tissues, such as utilizing porcine skin for urinary tract reconstruction (64).

Synthetic Polymers. While natural polymers are an excellent choice for scaffolds because of their biocompatibility, synthetic polymers offer more flexibility. Composites with natural polymers can also be made to take advantage of their properties as well. Biodegradable polymers also have the additional benefit of decomposing into nontoxic metabolites that can be removed from the body as waste. The molecules can be modified to obtain mechanical properties and appropriate degradation rates that are well suited to the specific application.

The most common polymers in use are PLA and poly(glycolic acid) (PGA). These are the first two polymers to obtain approval by the Food and Drug Administration (FDA) for use in medical implants. During degradation, the polymer is hydrolyzed to form lactic and glycolic acids. Since PLA is more hydrophobic than PGA, it has a slower degradation rate. As such, the degradation rate of the polymers can be easily adjusted by changing the ratio of lactic acid to glycolic acid within copolymers of PLA and PGA, poly(lactic-*co*-glycolic acid) (PLGA). The degradation

rate is also affected by the overall molecular weight and extent of crystallinity of the polymer. During degradation, the polymer swells with water. The nonspecific interactions between the water and polymer lead to hydrolysis at random locations along the polymer chain. This leads to bulk degradation of the matrix that can be detrimental to the release profile of drugs. The hydrophobicity of PLA also makes the matrix less amenable for cell adhesion. Adsorption of proteins, such as laminin (65), to the matrix surface encourages cell adhesion. Amines can also be incorporated into the polymer chain to control protein and cell attachment (66), because many types of tissue have been engineered using PLA, PGA, as well as combinations of their stereoisomers and copolymers (see Ref. 67 for a review).

The limitations due to bulk degradation can be overcome using matrices based on polyanhydrides. These polymers degrade only at the surface. When used for drug delivery, the release profiles can be affected just by altering the shape of the matrix. For tissue engineering, these polymers provide a mechanism for renewing the surface to allow new areas for cells to grow. As the surface degrades, cells will slough off providing a fresh surface for cell growth. One example of such a polymer, recently approved by the FDA for use in the treatment of glioblastoma multiforme, is derived from bis(*p*-carboxyphenoxy propane) and sebacic acid.

While PGA, PLA, and their copolymers provide much flexibility for developing scaffolds that have particular degradation properties, they are fairly brittle. This makes them unsuitable for use in certain engineered tissues, such as tendon and ligament, where mechanical stresses may be present. Polycaprolactone (PCL) is also a polyester, but its longer monomer unit provides greater elasticity. The polymer and degradation product is nontoxic, which has led to its FDA approval for use as a long-term contraceptive implant (68). Other elastomeric polymers are poly-4-hydroxybutyrate and polyhydroxyalkanoate, which have been used in various engineered tissues (69).

Certain polyesters have been developed to degrade into biocompatible products that make them suitable for drug delivery and tissue engineering applications. Poly(propylene fumarate) (PPF), for example, will degrade into fumaric acid, a natural component of the Krebs's cycle, and 1,2-propandiol, a common drug diluent. Mechanical properties can be improved through the use of chemical cross-linkers or certain ceramic composites (70). A tyrosine-based polycarbonate is another polyester that has been used in bone engineering (71). This osteoconductive polymer has excellent structural properties and has been shown to promote bone growth (72).

Like polyanhydrides, poly(ortho esters) can be designed for surface degradation. Their use in drug delivery (73) also make them suitable candidates for tissue engineering. Some poly(ortho esters) may degrade into acidic by-products that can autocatalyze the degradation process, which may be useful for systems where fast degradation of the scaffold is desired.

In contrast to most hydrocarbon-based polymers, poly(phosphazenes) consist of a phosphorous and nitrogen chain. These polymers undergo hydrolysis to form

phosphate and ammonium salts. Ethyl glycinate substituted poly(phosphazenes) have shown promise for osteoblast attachment (74).

Polyurethanes have long been used for medical implants because of their good biocompatibility and mechanical properties. They have been used in long-term implants, such as cardiac pacemakers and vascular grafts. Though not degradable, these polymers can be cross-linked with degradable compounds to create scaffolds for engineered tissue (75). The main disadvantage is the toxicity of the degradation byproducts especially for cross-linkers based on diisocyanates.

Poly(amino acids) have good potential as a scaffold material because they are biocompatible and release amino acids as their degradation product. Poly-L-lysine is a common example that is adsorbed to surfaces in order to improve cell adhesion. Enzymatic degradation makes the breakdown of the polymer difficult to control. These polymers also have high reactivity and moisture sensitivity. Along with being expensive to produce, these materials have limited use for engineered tissue. An alternative is to create a pseudo-poly(amino acid), where the amino group in the polymer backbone is replaced with another nonamide linkage. This can improve the stability and mechanical properties of the polymer (76).

Hydrogels. Hydrogels are a subcategory of biomaterials defined by their ability to retain water within their polymeric matrix. Because of the high water content, hydrogels have mechanical properties similar to that of soft tissue. This may limit the application of hydrogels to certain tissues, but the environment closely simulates the environment of native tissue. Hydrogels are created by the cross-linking of water soluble polymers while in an aqueous environment. The cross-linking can be initiated chemically or via exposure to light of a particular wavelength. Natural polymers, such as fibrin and collagen, can be used to create hydrogels. For synthetic hydrogels, polyethylene glycol is a popular choice because of its biocompatibility, hydrophilicity and customizable transport properties (77).

Cells can also be entrapped within the matrix during the gelling process that permits a more uniform distribution. Cell entrapped in hydrogels include chondrocytes (78), fibroblasts (79), and smooth muscle (80). Photoinitiated cross-linking can be used to create cell-matrix composites *in situ* (81). In such systems, cells still maintain their viability (82). This process can be used to create a cell-polymer matrix that fits exactly into the shape of the tissue defect.

Scaffold Fabrication. Once a biomaterial has been chosen that has the properties crucial to the particular tissue to be engineered, it must be fabricated into an appropriate matrix in which the cells can survive and form the tissue. Several factors, such as porosity and pore structure, surface area, structural strength, and shape, are relevant to the design of a suitable scaffold. In general, a high porosity is important to the formation of tissue because it provides space for the cells to grow, as well as allows nutrients to diffuse into the matrix and promote cell survival (3). For certain situations, though, the porosity

should be optimized to ensure that growth factors important to tissue regeneration are retained within the matrix (83).

The strength of the scaffold is important to ensure that the scaffold will protect the regenerating tissue until it becomes integrated into the body. Also, some engineered tissue, such as bone and cartilage, may require a strong scaffold in order to retain integrity while functioning under physiological loading conditions. The structural strength is dependent on the mechanical properties of the polymer as well as the processing of the scaffold. A high surface area will ensure adequate contact for the cell adhesion. Depending on the polymer, the surface may have to be modified to improve adhesion. Depending on the application, the scaffold may need to be processed to form a particular 3D shape. For example, cylinders can be used as vascular grafts and for nerve regeneration.

Several processing techniques are available for the fabrication of scaffolds (Table 1). These techniques allow for the control of porosity and pore structure as well as the contact area for cell adhesion. In fiber bonding, a polymer is dissolved in a suitable solvent and fibers from another polymer are suspended within the solution (84). The solvent is then removed by vacuum drying. Heat is slowly applied to the composite material to cause the fibers to bond to one another. The other polymer is again dissolved leaving behind the bonded fiber matrix. To ensure success in this process, solvents must be chosen that do not dissolve the fibers and the fibers must have a melt temperature lower than that of the matrix polymer.

A similar method, called particle leaching, involves the incorporation of particles suspended within the polymer solution (85). As with fiber bonding, the particles are locked within the polymer matrix after vacuum drying is done to remove the solvent. In this method, though, the particles

Table 1. Summary of Various Scaffold Fabrication Methods

Fabrication Method	Characteristics
Solvent casting	No thermal degradation Residual solvent may harm cells
Fiber bonding	High porosity Thermal degradation Limited solvent-polymer combination
Particle leaching	Porosity easy to control Entrapment of particle with matrix Brittle foams
Gas foaming	No organic solvents Noncontinuous pores
Freeze drying	Small pore sizes Low temperature
Phase separation	For entrapment of small bioactive molecules Low temperature
Extrusion	Long fibers Thermal degradation
Membrane lamination	Three dimensional shapes
3D printing	Slow processing Control of shapes
<i>In situ</i> polymerization	Limited polymer-cell combinations Injectable, shape to fit defect

are removed via dissolution leaving behind a porous matrix. Typically, salt or sugar crystals, which are soluble in water, are suspended within a relatively hydrophobic polymer. The porosity can be controlled by altering the amount of particles suspended in the matrix. If the amount of particles is too low, they may become trapped within the polymer and remain undissolved. The foams that are formed tend to be brittle and also may require prewetting with ethanol to promote fluid infiltration. Instead of suspending the particles in a solution, they can be placed into a polymer melt that is subsequently cooled and the particles later dissolved away. A major drawback to this process is the thermal degradation of the polymer that can greatly affect its mechanical properties.

With gas foaming, carbon dioxide is added to the solid polymer at a very high pressure so that it infiltrates the matrix (86). When the pressure is rapidly dropped, the gas will expand within the polymer creating a porous foam. This method eliminates the need for an organic solvent whose presence may be detrimental to cell survival and tissue formation. One disadvantage is that the pores may not connect. This can be overcome by using this method in combination with particulate leaching.

Freeze drying can also be used to create porous polymer matrices (87). A polymer dissolved in an organic solvent can be mixed with water to form an emulsion. The emulsion is then quenched in liquid nitrogen and the water is removed by freeze drying. This method can create a matrix with 90% porosity and very high surface area, but the pore size may be too small.

Bioactive molecules may be added to the polymer matrix so that their release can enhance tissue formation. In many cases, though, the bioactive molecule may be incompatible with the organic solvent or thermal conditions used in the processing of the polymer matrix. Phase separation may be used to overcome this problem (88). In this method, the bioactive molecule is dispersed within the polymer solution and the solution is cooled until two liquid phases are formed. The two immiscible liquids are quickly frozen and the solvent is removed by sublimation. Removal of the solvent-rich phase leads to the highly porous structure while the bioactive molecule remains trapped within the solid polymer phase. The cold temperatures used in this process ensure that the bioactive molecule is not adversely affected. This method works well with small molecules, but can be difficult with large proteins.

For certain structural applications, such as bone, the mechanical strength of the polymer matrix is important to the success of the engineered tissue. In these cases, the matrix should have a high compressive strength to help the tissue maintain its integrity until the formation of the engineered tissue. To improve the mechanical properties of the polymer, hydroxyapatite fibers may be included to reinforce the polymer matrix (89).

Specific 3D shapes may be required for certain engineered tissue. Simple shapes like rods and cylinders can be formed via thermal extrusion (90). Particulates can be added to create porous structures as with the particulate leaching methods described earlier (91). The extrusion process may also lead to thermal degradation of the polymer matrix. Membranes formed by other techniques may

be cut into particular patterns and stacked to form specific 3D shapes (92). The membranes can be bonded through the use of a suitable solvent. The 3D printing is a method akin to rapid prototyping that can also be used to form specific shapes (93). In this method, a polymer powder is spread into an even layer, and solvent is sprayed in a specific pattern to bind the powder together. Another powder layer is added and the solvent is sprayed on to bind the powder to the previous layer. The process is repeated until the entire structure has been formed. Using this method, features as small as 300 μm can be formed.

When specific shapes are not required, *in situ* polymerization can be used to deliver cells and matrix molecules to the site of the tissue defect. This process can be used to create a cell-polymer matrix to precisely fill the site of the defect. Poly(propylene fumarate) has been used as bone cement (94). Hydrogels containing chondrocytes have been used for cartilage engineering (95).

To ensure proper cell adhesion and growth, the surface of the polymer must be suitable for cell attachment. The wettability and surface free energy greatly influence the extent of cell adhesion. A more hydrophilic surface is necessary to ensure cells will attach to the surface. This must be balanced with the cells needed to interact with surrounding cells in order to form tissue. Surface eroding polymers, such as polyanhydrides, can also renew their surface providing additional area for cell adhesion, which helps to promote cell growth. The surface of the polymer may need to be modified. Amphipathic molecules may be adsorbed to the surface. For example, the polar side chains of poly-L-lysine provide a suitable surface for cell attachment. Extracellular matrix molecules, such as laminin, fibronectin, and collagen, can also be adsorbed to the surface. These molecules contain the amino acid sequence (RGD), which binds to integrins present on the cell surface. The RGD along with IKVAV and YIGSR (found on laminin) can also be covalently bonded to the polymer to create sites for cell adhesion.

The surface of the scaffold can also be modified using microfabrication techniques, these methods can be used to alter the surface chemistry for improved cell adhesion or to create micron scale structural features to affect cell function (96). Besides altering the surface chemistry, microfabrication techniques can also be used to create microscale morphological features on the surface. Microscale features can affect the attachment, motility, and proliferation of fibroblasts in culture (97). The texture of the surface can also influence cardiac myocytes at the molecular level, such as protein localization and gene expression (98). Grooved surfaces can also be used to physically align cells and direct nerve regeneration (99).

Photolithography is a technique commonly used in the production of computer chips. With this method, a special type of photopolymer called a photoresist is coated onto the surface of the scaffold material. Separately, metal is coated onto a glass substrate and laser etched to form a mask in the pattern of interest. The mask is placed over the photoresist and ultraviolet (UV) light is shown through to polymerize the photoresist into the pattern of interest. A solvent is used to remove the unpolymerized photoresist and expose the scaffold. The surface can now be modified

by several methods. Compounds, such as collagen and laminin, can be adsorbed to the surface. Small molecules, such as the RGD tripeptide, can be covalently bonded to the surface. The surface can also be exposed to oxygen plasma to make the area more hydrophilic. Once modified, the remaining photoresist can be removed using another solvent. The success of this method depends on the choice of appropriate solvents and photoresist to use in conjunction with the scaffold and surface modifiers. The major drawback of this technique is that it can only be applied to planar surfaces and relies on the use of expensive specialized equipment. Lithography can also be used to create elastomeric stamps. These stamps can be used to place molecules onto the substrate in a defined pattern. The stamp can be used repeatedly, which helps to reduce the cost compared to traditional photolithography.

Reactive ion etching builds on the premise of photolithography to create microstructural features on the surface (see Fig. 4). Using glass or quartz for the substrate, metal can be deposited onto the patterned photoresist. When the photoresist is removed, the surface is exposed to ion plasma that etches into the substrate leaving deep grooves in the surface. The substrate can now be used as a mold. The polymer matrix can be dissolved and cast onto the mold and dried. When the matrix is lifted from the mold, it will contain the micropatterned structure. As with photolithography the matrix can only be planar. Despite this disadvantage, this method has been used to improve nerve regeneration in bioartificial nerve grafts (100).

Surface of the biodegradable matrix can be etched directly using the process of laser ablation. In this method, a laser beam is used to etch grooves into the substrate. The laser is pulsed rapidly to allow the dispersion of thermal energy and thus reduce the degradation of the polymer matrix.

Another method for depositing molecules in specific patterns is through the use of microfluidics. In this method, a microscale channel system is placed on top of the substrate. Various solutions are passed through the channel and molecules are allowed to interact with the substrate surface. The channel system is removed leaving behind the patterned substrate.

Figure 4. Microfabrication of polymer surface using a combination of reactive ion etching and compression molding. Grooves are 10 μm wide and 3 μm deep.

Signals

Once cells have been seeded onto a biodegradable matrix, signals must be provided to ensure the cells will continue to grow and form fully functional tissue (see Fig. 5). These signals must mimic the environment in which tissue naturally regenerates or develops. Signals may come from contact with the extracellular matrix or other cells. Diffusible factors may be delivered to the cells spatially and transiently. Mechanical and electrical stimuli may also promote tissue formation for certain cell types. Cues may also be provided based on the spatial arrangement of the cells.

Extracellular Matrix. When forming tissue, cells will interact with various proteins that make up the ECM. The ECM is comprised of collagens, proteoglycans, hyaluronic acid, fibronectin, vitronectin, and laminin. Integrins that are found on the surface of cells can interact with short amino acid sequences located on various ECM proteins. For example, cells will adhere to the arginine-glycine-aspartic acid-serine sequence (RGDS) found in fibronectin (101). Integrins are transmembrane proteins that also interact with cytoskeletal proteins like actin. In response to changes in the ECM, they modulate signals to the cells that result in a change in cell function. Certain amino acid sequences have also been implicated in the interactions between integrins and the ECM for specific cell types. These include REDV for endothelial cell adhesion (102), IKVAV for neurite outgrowth (103), and LRE for synaptic development (104).

Figure 5. Examples of signals used to control tissue formation. (a) Cell–matrix interaction (RGD–integrin binding). (b) Cell–cell interaction (desmosome). (c) Diffusible factors (chemotaxis). (d) Mechanical forces (shear). (e) Spatial organization.

The primary purpose of the ECM is to anchor the cells so that tissue can form. The connection can ensure that polarized cells are oriented in the correct direction. When cells die, the ECM may retain its integrity until new cells can grow and form tissue. The composition of the ECM varies among tissues. The differences help to define the boundaries between tissue types as well as promote a microenvironment that is best suited for that particular tissue. Soluble regulatory factors may also be stored within the ECM. Disruption of ECM, and thus the tissue, lead to the release of these regulatory factors in order to affect cell function. The ECM can affect functions, such as cell growth, differentiation, and apoptosis. During development, the ECM plays a role in the repatterning of the epithelial-mesenchymal transformation. The physical connect between the cells and the ECM also helps with the modulation of signals due to mechanical stresses.

Diffusible Factors. During development or tissue regeneration, soluble diffusible factor help to control various cell functions, such as proliferation, adhesion, migration, and differentiation. Examples include the various families of growth factors and morphogenic proteins as well as nutrient to ensure cell survival. These factors may be expressed by the cell itself (autocrine) or it may come from a nearby cell (paracrine) or a remote site (endocrine). These factors can elicit changes in the cell cycle, promote differentiation, encourage cell motility and regulate the synthesis of DNA and protein.

During normal development or regeneration, these factors are secreted from various cells and delivered to the target tissue. In order to mimic this effect in engineered tissue, various methods may be used. Prior to implantation, the engineered tissue may be subject to a medium that is supplemented with factor to promote tissue growth. The scaffold for the engineered tissue may have soluble factors incorporated into the matrix. As the substrate degrades, the factors are released in a controlled manner. Molecules may also be immobilized onto the surface of the scaffold in order to alter cell function. Immobilized growth factors can still impart their effect on the cell without being internalized by endocytosis. This provides a mechanism to potentiate the effect of the growth factor.

For controlled release, the scaffold has a dual purpose to provide structural support for the engineered tissue as well as deliver signaling factors at the appropriate time and dose. Other particles that provide controlled release, such as microspheres, may also be incorporated into the engineered tissue. Using a combination of chemical factors with different release profiles can mimic the developmental processes.

Spatial Organization. The spatial arrangement of the cells in culture can have a direct impact on their function. Three-dimensional scaffolds provide support, but also encourage cells to display the appropriate phenotype for tissue formation. Hepatocytes are prone to loss of phenotype when cultured as a monolayer (105). Chondrocytes exhibit fibroblast behavior in monolayers compared to 3D systems. The 3D cultures secrete a great amount of type II collagen that is essential for cartilage formation (106).

The shape of the scaffold is an important consideration for the regeneration of certain tissue types. Nerve tissue engineering uses tubular conduits to help guide the regenerating axons. A luminal diameter that is 2.5 times the diameter of the nerve bundle is optimal for axon extension (107).

Mechanical Modulation. When grown in static cultures, cells tend to settle and form monolayers. This can lead to a loss of phenotype that would be detrimental to tissue formation. To prevent this disaggregation, cells can be cultured in microgravity (108). Microgravity is achieved through the use of specialized bioreactor systems that keeps the cell-scaffold matrix suspended within the media. The net mechanical forces on the tissue are essentially zero.

Mechanical stress may need to be imparted on the engineered tissue in order to ensure the proper development. Shear stresses can encourage the alignment of fibrillar extracellular matrix proteins, such as collagen. This effect will encourage the cell to align with the matrix (109). Alignment of collagen can also be achieved through the use of magnetic forces (46). Pulsatile shear stresses can also effect the orientation of endothelial cells in engineered blood vessels (110). This cyclic stress lead to the orientation of the cells along the circumference of the blood vessel as compared to cells aligned in the axial direction for constant shear loading.

Physical loading of tissue can also impact the mechanical properties of tissues. Signals are modulated via the interaction between the cells and the ECM. Cyclic loading can improve the tensile strength of tissues, such as arteries, heart valves, ligament, muscle, and bone (111). Hydrostatic pressure can also effect the formation of tissue. Cyclic pressure can alter the metabolic function of chondrocytes to produce greater amounts of type II collagen for cartilage formation (112).

Electrical Signals. Besides chemical and mechanical signals, cells will also respond to electrical stimuli, such as electric fields and direct current. Electric fields describe the amount of force exhibited by a charged particle. These forces can have an impact on materials that can be induced to carry a charge, such as cells, or individual ionic molecules. Electric fields can be used to move polarizable materials (dielectrophoresis) or encourage the motion of ions (iontophoresis). Application of direct current (dc) can also be used to mimic the conduction of electrical signals. The effect depends on the tissue type and its conductivity as well as the type of current (alternating or direct), the frequency and magnitude of voltage, and the uniformity of the electric field.

Because the neuromuscular system relies on electrical signaling for its functions, such stimulation can affect tissue formation. Muscle will atrophy when not exposed to an electrical stimulus. Providing an electrical stimulus to muscles until new neural connection can be made will greatly improve the likelihood of success for the nerve regenerative process. Neurons themselves may also respond to electrical stimuli by altering the effect of biochemical cure on growth cone dynamics (113). Myocytes will

develop into functional heart tissue under electrical stimulation (114). Muscle progenitor cells also show improved contractility when exposed to electrical stimulation (115).

Other tissues that do not typically exhibit electrical behavior may still respond to such stimuli. Corneal epithelium has been found to emit dc electrical fields with injured tissues. These cells will migrate toward the cathode in the presence of artificial electrical fields (116). Direct and alternating current (ac) electrical fields can also be used to reduce wound area and wound volume comparatively (117,118).

Cell-to-Cell Interactions. Cells can communicate directly with each other through physical contact via tight junctions, gap junctions, cadherins, and desmosomes or through chemical interactions using soluble factors. Such contact is important for architectural support and for inducing a favorable phenotype. In complex tissue containing multiple cell types, one cell type can act as a physical support for other cells. For example, smooth muscle cells help to support various tubular tissues, such as bladder ducts and blood vessels. Other cells may provide molecular signals to control the metabolic processes in other cells. Schwann cells secrete growth factors that stimulate neurons to regenerate. Without this chemical support, some cells may cease to proliferate and eventually die.

Bioreactor Technology

Once the appropriate cell source, scaffold, and signaling molecules have been selected, the engineered tissue construct may require a specialized bioreactor in which to grow. The bioreactor can provide the vehicle for supplying chemical factors, as well as place mechanical stresses on the tissue if necessary. Liquid media optimized for tissue growth supplies nutrients to the growing tissue and waste products are removed.

A perfusion bioreactor describes the general type of system where cells are retained. The cell-scaffold construct is held in place and media is continuously fed into the bioreactor. The tissue may be physically pinned in place or fixed due to a balance of gravitational and shear forces. Spinner flasks provide mixing through the use of stirrers (119). The engineered tissue is pinned in place while the stirrer keeps the fluid well mixed. The mixing ensured that adequate nutrients are delivered to the cells and wastes are quickly removed to prevent toxic buildup.

Several tissues may require mechanical stimuli in order to achieve full functionality. Novel bioreactor systems have been developed to provide these stresses. Pulsatile shear forces have been used to create engineered arteries with burst strengths comparable to native vessels (110). Placing chondrocytes under cyclic hydrodynamic pressure can enhance the formation of articular cartilage (120). Mechanical cyclic stretching can also improve the strength of engineered ligaments (121).

Tissue Properties

Biomechanics. Engineered tissue should have the same mechanical properties of native tissue in order to achieve full functionality. This issue is especially important with

tissue, such as bone and cartilage. Mechanical properties can also influence the tissue architecture by altering the structure of the extracellular matrix. The cytoskeleton interactions with the extracellular matrix can also be affected by the mechanical properties of the tissue. This can alter cell growth, movement, and metabolic function.

Certain tissues also interact with the nervous system based on mechanical signals. The alveoli and passageways in lungs respond to inhalation (122). Stretch receptors in the urinary bladder can detect when the organ must be emptied. Sensory receptors in the skin can detect touch. Engineered tissue must account for physical interaction with other tissue as well as the outside environment.

The influence of biomechanics can be seen at multiple spatial dimension. At the lowest level, biomechanics is influenced by the forces of individual molecules. The individual proteins of the extracellular matrix determine its mechanical properties. The formation and dissolution of chemical bonds can also alter the strength of the tissue. At the cellular level, the plasma membrane and cytoskeleton influence the physical properties of the cell. Cells can also interact with their environment via mechanotransduction pathways. The adhesion, aggregation, and migration of cells will affect the overall tissue and its mechanical properties. At the tissue level, cells interact with the extracellular matrix to create a material with specific physical properties that are essential to its function. An example of this hierarchy can be seen in tendon tissue (123). Individual collagen molecules are bundled together to form microfibrils and fibrils. These fibrils combine with fibroblasts to create fascicles that in turn comprise the tendon tissue.

The mechanical properties of structural tissue can be defined by the relationship between stress and strain. As a certain level of stress is placed on the tissue, it will deform. This deformation relative to the initial length defines the strain. In many cases, stress is proportional to strain. The constant of proportionality is called the Young's modulus. For some tissue-like bone, the Young's modulus may vary from location to location (124).

Tissue exhibits characteristics of viscoelastic behavior. As with most biological materials, tissue is slow to deform in response to stress. This slow deformation is known as creep. When stress is quickly placed on tissue and the tissue deforms, the amount of force needed to maintain the deformation decreases over time. This phenomenon is known as stress relaxation. This viscoelastic behavior may be due to the presence of interstitial fluid or the movement of collagen fiber as with cartilage. Subtissue components, like lamellae in bone, may slip relative to one another. Also, some tissue may undergo internal friction due to repeated motions as is seen in tendons and ligaments.

Besides normal forces due to stress, shear forces can also influence the physical properties of tissue. Shear forces are present in tissue where fluid flow is involved. For example, blood flow will influence the properties of endothelial cells in veins and arteries. Compressive forces cause the flow of interstitial fluid in cartilage.

Structural tissue must be engineered to respond to the shear and normal forces it will encounter when placed into the body. In some cases, such as bone, the material placed

into the site of injury must meet the mechanical requirements of the surrounding tissue. If not, the engineered tissue will become damaged thus reducing the chances of recovery.

Biocompatibility. Ideally, the cells and scaffolds that are used in engineered tissue would not provoke an immune or inflammatory response. Unless cells are obtained from the patients themselves, the possibility of rejection remains. The possibility of rejection is dependent on the access that the immune system has with the implanted engineered tissue. For tissue that lacks an established vasculature, for example, cartilage and epidermis, the immune response is limited. Also, certain engineered tissues may utilize cells for a short period of time until the patient's own cells recover. For example, nerve regeneration may be promoted through the use of donor Schwann cells that may become unnecessary once the nerve has recovered. Barring these special cases, methods must be developed to protect the tissue from the immune system.

As with organ transplants, the primary method of controlling the immune response to engineered tissue is through the use of immunosuppressant therapy. These drugs are required for the life of the patient. To avoid side effects and the long-term implications of having a suppressed immune system, methods must be developed to mask the cells. Bone marrow from the donor can be transplanted with the engineered tissue to create a chimera. The combined bone marrow can reduce the likelihood of rejection.

At the molecular level, surface antigens can be altered to prevent rejection. Fragments of antibodies that do not elicit cytotoxic T cell attack may be used to make the antigen from the patient's own immune system. This is only temporary and may not prevent all immune mechanisms. Gene ablation can be used to create cells where the antigen coding gene has been inactivated. Alternatively, a gene may be added that is used to synthesize a protein that inhibits rejection. The DNA or RNA that codes for the antigen can be blocked with oligonucleotides that hybridize to prevent transcription or translation.

For cells whose function is primarily metabolic, the cells can be encapsulated to isolate them from the immune system. Encapsulation is accomplished by surrounding the cells with an artificial membrane. The pores in the membrane must be small enough to prevent interaction with the immune system, but large enough to allow nutrients and therapeutic proteins to pass through. The membrane must also be able to withstand any mechanical stress that may disrupt the membrane and allow interaction with the immune system.

Besides the immune system, the implantation of engineered tissue will, to some extent, elicit an inflammatory response. The response initiates a cascade of chemical reactions that alters the gene expression of circulating blood cells (granulocytes, platelets, monocytes, and lymphocytes), resident inflammatory cells (e.g., macrophages, mast cells) and endothelial cells. In conjunction with the cellular activation, many compounds (e.g., growth factors, cytokines, chemokines) are released. The overall

effect is characterized by increased blood flow to the tissue that increases temperature and causes redness, swelling, and pain. This creates an environment that isolates the inflamed tissue from the body and promotes wound healing.

During the wound healing, damaged tissue is cleared by the circulating blood cells. A fibrin and fibronectin meshwork is created to act as a substrate for migrating and proliferating cells. Granular tissue containing fibroblasts, myofibroblasts, monocytes, lymphocytes, and endothelial cells forms at the site of the injury. The endothelial cells lead to the formation of new blood vessels (angiogenesis). The tissue undergoes remodeling as tissue regenerates to replace what had been lost. At the end of the process, fibroblast, myofibroblast, and endothelial cells will undergo programmed cells to reduce scarring and return the tissue to its original form.

Engineered tissue and biomaterials implanted in the body can be affected by the inflammatory and wound healing processes. During the granulation process, fibroblasts may migrate to the implant and encase it. This may isolate the engineered tissue from the surrounding tissue and prevent the integration of the engineered tissue with the native tissue. The additional layer of cells will reduce the diffusion of nutrients to the implant. Also, vascularization may be reduced further, hampering regeneration. Though, the layer of fibroblasts may be problematic, the complete lack of fibroblasts may also indicate some level of toxicity from the implant. The ideal implant will enhance the wound healing process while ensuring the engineered tissue does not become isolated.

Cryopreservation

To engineer tissue that can be delivered on demand, methods must be developed for long-term storage. Cryopreservation can be used not only for the storage of the final tissue product, but also for the cellular components. When new cells are isolated for use in engineered tissue, they may be preserved for later expansion to prevent senescence or DNA mutation. The original tissue from which cells are derived may also be stored for later use. The isolated cells can be preserved while a sample is screened for infectious agents as well as the ability to form functional tissue. Cells must be banked in accordance with FDA regulations to ensure their genetic stability. During the production stage, the engineered tissue may be preserved at various steps for later quality control testing. The engineered tissue can be stored at hospitals to ensure availability.

The protocol for cryopreservation depends on the cooling rate as well as the addition of compounds to reduce cell damage. If the cooling rate is too low, osmosis will drive water from the cell leading to severe dehydration. A high cooling rate will promote intracellular ice formation. The expansion of the ice forming inside the cell may lead to damage of the plasma membrane. Additives may be used to prevent cell damage caused by the increased ionic concentration in the unfrozen part of the tissue. Additives may be permeating [dimethyl sulfoxide (dmss) and ethylene glycol] or nonpermeating [poly(vinyl pyrrolidone) and starch]. The use of permeating additives would necessitate additional

steps to remove the additive in preparation of the engineered tissue for implantation. One drawback to nonpermeating additives is that the osmotic stress due to high extracellular concentrations may lead to dehydration of the cells. The viability of the cells that have been preserved will depend not just on the method, but also on the cell concentrations and the type of cell.

Regulations

During the 1990s, the FDA recognized the need to develop regulations for products derived from tissue engineering principles. Engineered tissue is renamed by the FDA as tissue engineered medical products (TEMPs), which would include products used to replace damage tissue. Organs for transplantation and blood were excluded from this designation. Examples include artificial skin, bone graft, vascular grafts, nerve grafts and metabolic assist devices.

The primary concerns of TEMPs were disease transmission, controls of product manufacturing to ensure product integrity, clinical safety and efficacy, promotional claims, and monitoring the industry. The characteristics that determine the level risk include the cells source, the viability of cells and tissue, homologous function, manipulation of the implant chemically or genetically, systemic versus local effects, the long-term storage of the device, and the combination of the cells with other cells or drugs.

The first rule (63 FR 26744 Establishment Registration and listing of manufacturers of Human Cellular and Tissue-based Products) proposed the registration of the various established companies involved in the manufacturing of TEMPs in order to provide better communication between the FDA and industry. The second rule (Suitability Determination for Donors of Human Cellular and Tissue-Based Products, Final Rule 5/24/04 changes to 21 CFR 210, 211, 820) is designed to make changes to the regulations for Good Manufacturing Practices to require industry to test cells and tissue in order to prevent the transmission of disease and the unwitting use of contaminated tissue. The third rule (Current Good Tissue Practice for Manufacturers of Human Cellular and Tissue-based Products; Inspection and Enforcement, final rule 5/25/05 changes to 21 CFR 820) defines the methods, facilities, and controls used in the manufacturing of TEMPs.

EXAMPLES OF ENGINEERED TISSUE

Engineered tissue implants are designed from a combination of cells, a biodegradable scaffold, and chemical signal. Once a need has been established for an implant, the system must be designed to be compatible with the patient. The implant relies on an adequate source of cells that can form functional tissue. Alternatively, the implant may be designed to recruit cells from the patient. Since the human body is not a static system, the engineered tissue must be able to interact with the patients existing tissue. Cells must continue to survive. The structure of the scaffold must maintain its integrity until the tissue is fully integrated. The tissue structure should be achieved very quickly and be fully accepted by the host. The implant should foster cell migration into and out of the new tissue.

The implant should seamlessly integrate with surrounding tissue.

Tissue can be categorized into three main types: structural, metabolic, or combination. Structural tissue provides physical strength and a stable structure. The strength is determined by the extracellular matrix supported by the cells. Examples of structural tissue include bone, ligament, and vascular grafts. Metabolic-type tissues are defined as having functions based on the secretion or absorption of chemicals. These can be subdivided into tissues that respond to some stimulus (pancreas) and those that function independent of stimuli (liver). Combined tissue exhibit characteristics of both structural and metabolic tissue (skin).

Metabolic

Pancreas. The pancreas controls the blood sugar level through the regulation of insulin. The loss of this function leads to diabetes mellitus and requires daily injection of insulin. Over the long term, diabetes can damage other tissue such as eyes, kidneys, and nerve. Islets of Langerhans comprise only 1–2% of pancreatic tissue, but are the cells that regulate insulin levels. The islets are comprised of different cell types that lack the capacity to expand. As a result, islets must come from donor material.

The number of organ donors cannot supply sufficient islets to fill the demand of diabetes patients. Xenografts offer a viable alternative. Pig pancreatic tissue is currently used for insulin production and so is considered a good candidate for islet transplantation. To prevent an acute immune response, the islets must be encapsulated. Glucose and insulin along with other small molecules would diffuse across the membrane to allow chemical interaction while preventing antibodies from initiating an immune response.

Pancreatic islets have been encapsulated in various polymers. A biodegradable hydrogel-based coating has been developed for timed degradation of the capsule (125). The polymer can be modified to degrade at the same time that the islets reach the end of their functional life. The cells would then be removed by the immune system. Additional islets can be injected into the patient as necessary. A bioartificial device incorporating microencapsulated pancreatic islets can be connected to the vasculature to allow chemical interaction between the islets and the blood stream (126).

An alternative to the bioartificial pancreas is to inject islets directly into the existing pancreatic tissue. Islets have successfully been transplanted into diabetic patients (127). For this method to be successful, the islets must be completely biocompatible with the patient. Progenitor cells have been isolated from pancreatic tissue that exhibits the capacity to differentiate into cells similar to beta cells (128). Evidence indicates that adult stem cells may also develop into pancreatic cells without showing any indication of transdifferentiation (129). More work, though, needs to be done to create a universally acceptable stem cell derived pancreatic islet.

Liver. The primary cause of liver damage is cirrhosis due to alcohol consumption and hepatitis. This damage will

prevent the proper metabolism of nutrients as well as toxic substance that must be removed from the body. When damage is severe enough, the only treatment available is an organ transplant, but due to the shortage of liver donors, many patients die waiting. Partial liver transplants use a single donor liver that is divided and transplanted into multiple patients. This technique demonstrates the ability of implanted tissue to assist the native liver (130). Individual cultured hepatocytes may also be transplanted to assist in liver function (131). Cells are placed in organs with a high level of vascularization (liver, pancreas, spleen). This enhances the chemical interaction between the hepatocytes and the blood stream. Like islets, the hepatocytes may also be microencapsulated to eliminate the need for immune suppressant therapy.

Until an organ becomes available, a patient can be sustained through the use of a liver assist device. Several different liver assist devices have been developed (132). In these systems, hepatocytes are placed within a bioartificial device and allowed to contact blood for plasma. The cells are retained behind some form of membrane and small molecules are allowed to diffuse through and become metabolized. The technology behind liver assist devices may eventually lead to the development of a whole engineered organ.

Future research is geared toward creating an engineered organ. Techniques will need to be developed to ensure a high level of vascularization through the engineered organ. Another method is to create a totally implantable liver assist device to act as a permanent liver replacement. The system will need to be engineered to be self-contained and small enough to fit into the abdomen of the patient.

Structural Tissue

Bone. The main purpose of bone is to provide structural support for the human body. Bone also helps to protect the internal organs of the body. It provides attachment sites for muscles to allow locomotion.

The primary cells found in bone are osteoclasts, osteoblasts, and osteocytes. Osteoblasts are responsible for the deposition of bone matrix while osteoclasts erode it. The cell dynamics permits the continuous turnover of bone matrix material that helps the tissue quickly respond to damage. Osteocytes can respond to mechanical stimuli and also promote blood–calcium homeostasis. The bone matrix is comprised of 65–70% hydroxyapatite. The remainder is composed of organic molecules, such as collagen 1, fibronectin, and various glycoproteins, sialoproteins and, proteoglycans (133).

Autologous bone grafts are the primary method for bone repair. This method has been very successful, but is restricted by the amount of tissue that can be obtained from the patient. Allogenic tissue may be used, but its rate of graft incorporation is much lower. Also, rejection of the tissue may be problematic and may introduce pathogens. Metals and ceramics offer an alternative to the grafts, but cannot become fully integrated into the existing tissue. This may lead to fatigue failure at the metal–bone interface or breakup of the ceramic material.

For engineered bone tissue, the graft combines scaffold with bone cells and compounds that promote osteoinduction. The most common scaffold is based on natural or synthetic hydroxyapatite (134). These materials have major drawbacks in terms of their brittleness and rapid dissolution rate. Many synthetic and natural polymers have been considered for use as a scaffold (133). Osteoblasts are the primary cell component of engineered tissue because of their ability to synthesize bone matrix. These cells may be isolated from the patient or donor source. Another option is to isolate mesenchymal stem cells from the bone marrow. The cells have been shown to differentiate into the various bone cells when exposed to dexamethasone (135). The primary growth factors that have been found to affect bone tissue formation are bone morphogenetic proteins (BMPs), transforming growth factor beta (TGF-), fibroblast growth factors (FGFs), insulin growth factor I and II (IGF I/II), and platelet derived growth factor (PDGF). The VEGF may also be incorporated into the matrix to promote vascularization of the bone tissue.

The bioreactors used for bone tissue engineering have mostly been confined to spinner flask and rotating wall vessels. The rotating wall vessels help to promote cell interactions, but the microgravity imposed by the bioreactor may actually lead to bone loss (136).

Currently, most engineered bone tissue utilizes a combination of mesenchymal stem cells with a highly porous biodegradable matrix (133). Alternatively, multipotent cells isolated from the periosteum seeded on PLGA scaffolds created bone tissue that was well integrated with the native tissue (137). Transfecting bone progenitor cells with BMP-2 can also enhance their ability to create new tissue (138).

Because of the large number of growth factor that can influence bone formation, more work must be done to understand the underlying mechanisms of how these growth factors influence the various bone cell types. New materials with surface modifications are also being evaluated for their ability to control cell differentiation and migration. Rapid prototyping is also emerging as a processing technique to create scaffolds with control spatial arrangement, porosity, and bulk shape (139).

Cartilage. Cartilage is divided into two types: fibrous and articular. Fibrocartilage is used to provide shape, but flexibility to body parts, such as the ear and nose, while articular cartilage is found in joints where bone meets bone. Damage to articular cartilage can lead to painful arthritis and loss of motion. Traditional surgical repair techniques involve removal of damaged cartilage and reshaping the tissue to prevent further damage. Grafts from autologous tissue have not been successful in repair tissue. One reason for the difficulty in repair is the lack of a vasculature. The wound healing process available to other tissue types will not effect cartilage regeneration.

Genzyme has developed a procedure that involves the use of autologous cells that are expanded in culture and reintroduced into the site of injury. This method has had a fairly high success rate and can be used for defects up to 15 cm². Larger defects require the use of a scaffold to hold the engineered tissue in place. Photoinitiators can be

combined with chondrocytes and other growth factors to engineer tissue *in vivo* (140). Ultraviolet light is then used to initiate polymerization. This method is ideal for irregularly shaped defects and is less invasive. The hydrogel structure of the cross-linked polymer is also ideal for cartilage growth because the chondrocytes have a spherical morphology like that of native cells.

One of the main characteristics of cartilage that gives it strength is the trizonal arrangement of collagen fiber. This characteristic is difficult to mimic *in vitro*. Polyethylene oxide based photopolymers have successfully been used to encapsulate chondrocytes into discrete layers (141). Chondrocytes also respond to mechanical stresses that will affect its production of extracellular matrix. Cyclic hydrostatic pressure that mimics the forces present in knee joints can increase the synthesis of type II collagen (112). Type II collagen is an important protein in the extracellular matrix of articular cartilage. Fibrocartilage ECM consists primarily of type I cartilage.

Cell culture technology has allowed for the rapid expansion of autologous chondrocytes. Problems associated with immune rejection can be avoided, but two surgeries are required to create the engineered cartilage. Inroads have been to engineer cartilage that is structurally equivalent to native tissue. With proper control of differentiation, stem cells may be injected directly into the injured site to form new cartilage. Advances in immunomodulation technology may render stem cells resistant to the immune system that will eliminate the need for acquiring autologous cells. Also, injectable biomaterials may eventually be created that can be spatially arranged *in situ* to mimic the trizonal arrangement of collagen.

Blood Vessels. Blood vessels play a major role in delivering nutrient and removing wastes from all parts of the body. Disruptions to the flow of blood can lead to tissue loss downstream from the site of injury. In response to transection of the blood vessel, a cascade of events leads to the clotting of the blood and wound repair. Beside physical damage to the blood vessel, atherosclerosis can lead to partial or complete blockage of the blood vessel. Within the heart, this can lead to myocardial infarction and even death unless bypass surgery is performed. Artificial grafts are used to bypass the flow of blood around the site of the blockage. This method has only been successful for grafts >6 mm (142). Small diameter grafts are being engineered to fill this gap (143). The major problem with grafting is restenosis, which can lead to failure.

The artery consists of three layers: intimal, medial, and adventitia. The intimal layer is comprised of the endothelial cells that line the inside of the blood vessel. For engineered arteries, these cells are typically obtained from donor material. Advances still need to be made in stem cell research to create new endothelial cells. The smooth muscle cells of the medial layer control the flow of blood via constriction or dilation of the artery. The adventitia layer is made up of fibroblasts and extra cellular matrix. While this layer is commonly left out of engineered arteries, its presence provides additional mechanical strength (37).

For the scaffold, PLA, PGA and their copolymers as well as poly-4-hydroxybutyrate are most commonly used. Engi-

neered arteries have also been created without the use of synthetic materials (37). In these cases, donor arteries have their cells removed. The remaining matrix structure is reseeded with endothelial cells on the inner-lumen and smooth muscle cells on the exterior. Once the cell-scaffold implant has been created, a mechanical stimulus can be used to confer increased strength. Specialized bioreactors that provide cyclic shear flow that mimic the pulsatile flow of blood have been developed for engineering arteries (144).

The ideal engineered artery would have the mechanical strength to withstand the pulsatile shear stresses and blood pressure, would be biocompatible, and would integrate seamlessly with the existing blood vessel. Since autologous vessels may not be practical for patients suffering from atherosclerosis, an acellular implant would be better suited. Acellular implants have displayed excellent results in animal models (145). These systems have a greater capacity to remodel their structure to better mesh with the native tissue. Cells are recruited from the existing tissue. Better understanding of the remodeling mechanism in humans would help to improve these implants.

Combined

Skin. Skin is considered to be the largest organ of the body. Its primary function is to protect the body from the environment. It helps to regulate fluid content and body temperature. Skin acts as the first line of defense for immune surveillance. Sensory receptor found in the skin help the body examine the environment. When injured, skin has the capacity to self-repair. The common form of injury to skin is a burn. Ulcerations may also form due to venal stasis, diabetes, and pressure sores. Skin continuity may be disrupted due to accidental physical trauma or the removal of skin cancers. Though the skin has the capacity to regenerate, engineered skin may be required to provide physical protection and metabolic regulation until the native tissue covers the wound.

Skin is comprised of two layers: the dermis and epidermis. The epidermis is the outer layer comprised of keratinocytes. This layer protects the dermis layer and helps to regulate heat and water loss. The dermis contains the vasculature, nerve bundles, and lymphatic systems that connect the skin to the rest of the body.

The traditional method to large area skin repair was to obtain skin from intact portions of the body and spread it around to increase the rate of regeneration. This was problematic for patients with severe injuries. Also, the area for harvesting may become damaged as well. An alternative was to use donor cadaver tissue that usually provoked an immune response. To overcome these obstacles, skin may be engineered to be biocompatible with the patient and help to promote the body's ability to self-repair.

Engineered skin should contain a belated structure that allows for rapid vascularization and innervation from the body. The dermis layer should promote rapid wound repair. The epidermal layer should have the capacity to protect the body from the environment. The system should become fully integrated into the wound (146).

Initially, engineered skin was designed to act as a wound dressing and not become integrated with the native

tissue. Alloderm, from Life Cell Technologies and approved in 1992, was an acellular dermal matrix derived from cadaver tissue. Integra was approved in 1996 and consisted of a silicone sheet coated with collagen and glycoaminoglycans. The silicone sheet helped to prevent fluid loss, but needed to be removed when the tissue eventually healed. Autologous cultured skin substitutes have been used in combination with Integra for engraftment into burn wounds of pediatric patients. The elastic quality of this engineer skin allowed the new tissue to grow with the patient (147). In 1998, Organogenesis received FDA approval for the first tissue engineer product (Apligraf). The product utilized a collagen gel sheet seeded with fibroblast. Dermagraft (Advanced Tissue Sciences) was the first skin substitute to utilize biodegradable polyglactin. The fiber mesh was coated with fibroblasts that secrete growth promoting factors. More advanced cultured skin substitutes, next generation engineered skin, should have a full thickness bilayered structure that can become integrated into the wound for faster recovery.

For full thickness engineered skin to become integrated into the patient's own tissue, the dermis layer must promote immediate vascularization. Without a supply of nutrients to the tissue, the epidermal layer would begin to die and slough off (148). The inclusion of fibroblasts and endothelial cells in the dermis layer promoted the formation of a capillary bed that improved neovascularization (149).

Engineered skin can also be used for other functions besides wound repair. Stem cells that are normally present in the epidermis may be transfected and included in engineered skin to produce therapeutic proteins for patient suffering from chronic disorders (150). Engineered skin may contain hair follicle cells to create tissue for hair implants (151). Future engineered skin should include melanocytes to match the skin to the patient's native tones as well as sweat glands to regulate sweating and sensory receptors that integrate with the existing nervous system.

Nerves. Nerve tissue engineering presents a unique problem not encountered with other tissue. Nerve tissue is comprised of neurons and satellite cells. In the peripheral nervous system, the satellite cells are Schwann cells. These cells secrete growth factors to stimulate nerve regeneration when they lose contact with neurons. In contact with neurons, Schwann cells ensheath or myelinate the axon in order to enhance the conduction of the electrical signal. The central nervous system (brain and spinal column) contains oligodendrocytes that ensheath axons and astrocytes forming the blood-brain barrier. Instead of promoting regeneration, oligodendrocytes are actually inhibitory. Damage to these neurons can lead to the loss of sensory and motor function, paralysis, and even death.

When a nerve becomes severed, the proximal segment of the axon closest to the cell body will extend and enter the degenerated distal portion and continue growing until new synaptic connections are made. If connections are not made in a timely manner, the neuron may lose function and die making the loss of function permanent. The traditional method of nerve repair is to surgically reconnect the two severed ends. When the damage is too extensive to reconnect the tissue, donor tissue from a less critical nerve is

used to bridge the gap. As an alternative, an engineered bioartificial nerve graft can be used to bridge the gap to eliminate the need for the donor material. Several nerve grafts have been developed that utilize different scaffolds materials, various cells, and combinations of growth factor in order to enhance nerve regeneration (152). Clinical trials for peripheral nerve repair have shown success using poly(tetrafluoroethylene) to regenerate nerve tissue with gaps up to 4 cm long (153). The FDA has also approved a PGA conduit (Neurotube, Neuroregen LLC, Bel Air, MD) and a collagen-based nerve tube (NeuraGen, Integra Neurosciences, Plainsboro, NJ) for peripheral nerve repair. For the material that is chosen, the physical parameters of the conduit, such as porosity, can be optimized to ensure adequate nutrient reach the regenerating tissue while retaining growth factor with the implant (83).

Various chemical matrices, such as ECM components, can be added to the conduit to further enhance nerve regeneration (152). While the inclusion of these factors may provide incremental improvements in the overall design, they have not surpassed traditional surgical techniques to regenerate nerves (154). In the 1940s, Weiss, a pioneer in artificial nerve graft research, claimed that the ideal substrate for nerve regeneration is degenerated nerve (155). Degenerated nerve contains the matrix molecules and cellular components that have been naturally optimized to promote nerve regeneration.

Non-neuronal cells may be added to the artificial nerve graft in order to create an environment that mimics the natural nerve regeneration process. Schwann cells can be used to enhance the regeneration of both peripheral and central nerve tissue (156). Though they are not found in the central system, Schwann cells can overcome the inhibitory effect of the oligodendrocytes. Alternatively, fibroblasts transfected to produce nerve growth factor and seeded into an artificial nerve graft have been used to regenerate nerve tissue (157). Neural stem cells used in conjunction with a structured polymer scaffold have led to functional recovery from spinal cord injuries in rat models (27).

The next generation of nerve grafts should regenerate nerve tissue over much longer distances than currently achieved. Grafts containing a matrix comparable to degenerated nerve should make this possible. Microfabrication techniques also show promise for control of the growth of axons at the cellular level (100). Eventually, techniques must be developed to transplant new neural tissue into the existing system. This will become necessary for the innervation of engineered tissue and organs that relay on communication with the nervous system. Additional research is needed to understand the impact of additional neural contact on the overall system. These techniques may make possible a cure for paralysis where nerve tissue has degenerated beyond repair.

FUTURE PROSPECTS

The advances made in tissue engineering since the 1980s are set to transform the standard methods for medical care. The previous section is just a small sampling of the tissues currently under investigation. Just about every tissue in

the body is currently being studied for repair using engineered tissue or cell therapy. Though much has been accomplished, more work still needs to be done.

Stem cells have shown great promise as a universal cell for developing engineered tissue implants. Research adult stem cells, such as mesenchymal and hematopoietic cells, hints at their capacity to act as a pluripotent cell type. Additional work may reveal more cell types that these can differentiate into. Strict regulations may hinder investigation of embryonic stem cells, but additional research in cultivation methods can alleviate ethical concerns. More work still needs to be done to control the differentiation of these cells to prevent the formation of teratomas.

The variety of tissue types being engineered makes development of a single universal scaffold difficult. The mechanical characteristics of individual tissues require scaffolds with specialized properties. Although a few polymers have been accepted by the FDA, more will need to be evaluated to ensure enough options are available for the engineered tissue. New biomaterials should also be investigated to ensure a wide variety of options. For a given class of biomaterials, though, the polymer should be customizable to ensure the appropriate mechanical and degradation properties. Also, the material should be capable of manipulation to enhance adhesion and control tissue formation.

As stem cells increase in importance, more signaling factors to control differentiation will be needed. Such control should not be limited to diffusible factors, but should also include surface bound molecules that can mimic the cell-cell contact interactions that occur during development. Such molecules may be bound to the surface using microfabrication techniques to encourage differentiation of the stem cells into spatially arranged multiple cell types. With advances in gene transfer and other immunomodulation techniques, stem cells may be rendered fully biocompatible with the patient regardless of the donor source.

Several specific examples of engineered tissues were presented earlier. Each tissue type has its own issues that must be overcome for the engineered tissue to be successful. In general, though, many tissues must interact with the existing vascular and nervous systems. As engineered tissue turns to engineered organs, protocols must be developed to ensure adequate nutrient will reach the cells. Vascular endothelial growth factor provides a means of recruiting blood vessels to the new tissue, but would not be useful in growing whole organs *in vitro*. Bioreactors will need to be designed to accommodate multiple tissue types, including endothelial cells for neovasculature formation. As the mechanisms for stem cell differentiation become better understood, the possibility of growing entire organs may become a reality.

Another general concern for engineered tissues is the connection with the existing nervous system. Muscle and skin interact with the peripheral nervous system. Several internal organs interact with the brain via the autonomic nervous system. For such organs and tissue to be fully integrated and functional, methods must be developed to attract existing neurons. In some cases, nerve tissue may not be present so the engineered tissue may need to include a neural component that can be integrated with the nervous system.

Engineered tissue will ultimately be used to repair practically any tissue in the body. With the almost infinite combinations of biomaterials, growth factors and cells, the only limit to creating new tissue is one's imagination.

ENVIRONMENTAL CONTROL

DENIS ANSON
College Misericordia
Dallas, Pennsylvania

INTRODUCTION

Electronic aids to daily living (EADLs) are devices that can be used to control electrical devices in the client's environment (1). Before 1998 (2), these devices were generally known by the shorter term, "Environmental Control Unit" (ECU). Technically, this term should be reserved for furnace thermostats and similar controls. The more generic EADL applies to control of lighting and temperature, but also applies to control of radios, televisions, telephones, and other electrical and electronic devices in the environment of the client (3,4). See Fig. 1.

These systems all contain some method for the user to provide input to the EADL, some means of determining the current state of the device to be controlled (although this is often visual inspection of the device itself, since EADLs are

Figure 1. Components of an EADL system.

generally thought of as being applied to the immediate environment), and a means of exerting control over the targeted device. The degree and generalization of control differs among various EADL systems. These systems may provide a means of switching power to the target device, of controlling the features of an external device, or may subsume an external device to provide enhanced control internally.

POWER SWITCHING

The simplest EADLs only provide switching of the electrical supply for devices in a room. Although not typically considered as EADLs, the switch-adapted toys provided to severely disabled children would, formally, be included in this category of EADLs. To adapt a conventional battery powered toy, the therapist inserts a "battery interrupter" to allow an external switch to control the flow of power from the batteries to the workings of the toy. Power switching EADLs operate in precisely the same manner. A switch is placed in series with the device to be controlled, so that the inaccessible power switch of the device can be left in the "ON" position, and the device can be activated by a more accessible external switch. To provide control over appliances and lights in the immediate environment, primitive EADL systems consisted of little more than a set of electrical switches and outlets in a box that connected to devices within a room via extension cords. Control 1(5), for example, allowed the connection of eight devices to the receptacles of the control unit. Such devices are limited in their utility and safety, since extension cords pose safety hazards to people in the environment through risks of falls (tripping over the extension cords) and fires (overheated or worn cords). Because of the limitations posed by extension cords, EADL technology was driven to use remote switching technologies (Fig. 2).

Second generation EADL systems used various remote control technologies to activate power to electrical devices in the environment. These strategies include the use of ultrasonic pulses [e.g., TASH Ultra 4 (6)] (Fig. 4) infrared (IR) light [e.g., Infrared Remote Control (7)], and electrical signals propagated through the electrical circuitry of the home [e.g., X-10 (8) Fig. 3]. All of these switching

Figure 2. Electralink power switching module.

technologies remain in use, and some are used for much more elaborate control systems. Here we are only considering power switching, however (Fig. 4).

The most prevalent power-switching EADL control system is that produced by the X-10 Corporation. The X-10 system uses electrical signals sent over the wiring of a home to control power modules that are plugged into wall sockets in series with the device to be controlled. (In a series connection, the power module is plugged into the wall, and the remotely controlled device is plugged into the power module.) The X-10 supports up to 16 channels of control, with up to 16 modules on each, for a total of up to 256 devices controlled by a single system. The signals used to control X-10 modules will not travel through the home's power transformer so, in single family dwellings, there is no risk of interfering with devices in a neighbor's home. This is not necessarily true, however, in an apartment setting, where it is possible for two X-10 users to inadvertently control each other's devices. The general set-up of early X-10 devices was to control up to 16 devices on an available channel so that such interference would not occur. In some apartments, the power within a single unit may be on different "phases" of the power supplied to the building. (These phases are required to provide 220-V power for some appliances.) If this is the case, the X-10

Figure 3. X-10 switching modules.

signals from a controller plugged into one phase will not cross to the second phase of the electrical wiring. A special "phase cross-over" is available from X-10 to overcome this problem. The X-10 modules, in addition to switching power on and off, can be used, via special lighting modules, to dim and brighten room lighting. These modules work only with incandescent lighting, but add a degree of control beyond simple switching. For permanent installations, the wall switches and receptacles of the home may be replaced with X-10 controlled units. Because X-10 modules do not prevent local control, these receptacles and switches will work like standard units, with the added advantage of remote control.

When they were introduced in the late 1970s, X-10 modules revolutionized the field of EADLs. Prior to X-10, remote switching was a difficult and expensive endeavor, restricted largely to applications for people with disabilities and to industrial applications. The X-10 system, however, was intended as a convenience for able-bodied people who did not want to walk across a room to turn on a light. Because the target audience was able to perform the task without remote switching, the technology had to be inexpensive enough that it was easier to pay the cost than get out of a chair. The X-10 made it possible for an able-bodied

Figure 4. Tash Ultra-4 power switching modules.

person to remotely control electrical devices for under \$100, where most disability-related devices cost several thousand dollars.

Interestingly, the almost universal adoption of X-10 protocols by disability related EADLs did not result in sudden price drops in the disability field. In cases where simple power switching provided adequate control, many clinicians continue to adapt mass-market devices for individuals with disabilities. While this may not be a good use of clinician time, it does allow those with limited funding to gain a degree of control over their environments.

FEATURE CONTROL

As electronic systems became more pervasive in the home, simply switching of lights and coffee pots failed to meet the needs of individuals with disabilities who wanted to control the immediate environment. With wall current control, a person with a disability might be able to turn a light or television on and off, but would have no control beyond that. A person with a disability might want to be able to surf cable channels as much as an able-bodied person with a television remote control (9). When advertisements are blaring from the speakers, a person with a disability might want to be able to turn down the sound, or tune to another radio station. Because the ability to control a radio from across the room became a sales advantage when marketing to sedentary, able-bodied adults, nearly all home electronic devices are now delivered with a remote control, generally using IR signals. Most of these remote controls are not usable by a person with a disability, however, due to the small buttons and labels that require fine motor control and good sensory discrimination (Fig. 5).

The EADL systems designed to provide access to the home environment of a person with a disability must provide more than on/off control of home electronics. They must also provide control of the features of home electronic devices. Because of this need, EADL systems frequently have hybrid capabilities. They will incorporate a means of directly switching power to remote devices, often using

X-10 technology. This allows control of devices such as lights, fans, and coffee pots, as well as electrical door openers and other specialty devices (10). They will also typically incorporate some form of IR remote control, which will allow them to mimic the signals of standard remote control devices. This control will be provided either by programming in the standard sequences for all commercially available VCRs, televisions, and satellite decoders, or through teaching systems, where the EADL learns the codes beamed at it by the conventional remote. Preprogrammed control codes allow a simple set-up process to enable the EADL to control various devices, but only those devices whose codes existed prior to the manufacture of the EADL. The advantage of the learning approach is that it can learn any codes, even those that have not yet been invented. The disadvantage is that the controls must be taught, requiring more set-up and configuration time for the user and caregivers. In addition, there are cases where the internal IR switching speed of the EADL differs enough from that of the device to be controlled that some signals cannot be reproduced reliably.

Infrared remote control, as adopted by most entertainment systems controllers, is limited to approximate line of sight control. Unless the controller is aimed in the general direction of the device to be controlled (most have wide dispersion patterns), the signals will not be received. This means that an EADL cannot directly control, via IR, any device not located in the same room. However, IR repeaters, such as the X-10 Powermid (11) can overcome this limitation by using radio signals to send the control signals received in one room to a transmitter in the room of the device to be controlled. With a collection of repeaters, a person would be able to control any infrared device in the home from anywhere else in the home.

One problem that is shared by EADL users and able-bodied consumers is the proliferation of remote control devices. Many homes now are plagued with a remote control for the television, the cable-satellite receiver, the DVD player/VHS recorder (either one or two devices), the home stereo/multimedia center, and other devices, all in the same room. Universal remote controls allow switching from controlling one device to another, but are often cumbersome to control. Some hope is on the horizon for improved control of home audiovisual devices with less difficulty. In November of 1999, a consortium of eight home electronics manufacturers released a set of guidelines for home electronics called HAVi (12). The HAVi specification will allow compliant home electronics to communicate so that any HAVi remote control can operate the features of all of the HAVi devices sharing the standard. A single remote control can control all of the audiovisual devices in the home, through a single interface. Such standards are effective to the extent that they are actually implemented. As of the summer of 2004, the HAVi site lists six products, from two manufacturers, that actually use the HAVi standard.

The Infrared Data Association (13) (IrDA) is performing similar specifications work focusing purely on IR controls. The IrDA standard will allow an IR remote control to operate features of computers, home audiovisual equipment, and appliances equipped with IR controls through a

Figure 5. Imperium 200H provides infrared remote control of entertainment systems, power switching, and hospital bed control.

single standard protocol. In addition to allowing a single remote control to control a wide range of devices, IrDA standards will allow other IrDA devices, such as PDAs, personal computers, and augmentative communications systems to control home electronics. Having a single standard for home electronics will simplify the design of EADL systems for people with disabilities.

A more recent standard, V2 (14), offers a much greater level of control. If fully implemented, V2 would allow a single EADL device to control the all of the features of all electronic devices in its vicinity, from the volume of the radio through the setting of the thermostat in the hall, to the "Push to Walk" button on the cross-walk. Using a V2 EADL, a person with a disability could move from environment to environment, and be able to control the V2 enabled devices in any location.

One interesting aspect of feature control by EADLs is the relationship between EADLs and computers. Some EADL systems, such as the Quartet Simplicity (15), include features to allow the user to control a personal computer through the EADL. In general, this is little more than a passthrough of the control system of the EADL to a computer access system. Other EADLs, such as the PROXi (16), are designed to accept control inputs from a personal computer. The goal in both cases is to use the same input method to control a personal computer as to control the EADL. In general, the control demands of an EADL system are much less stringent than those for a computer. An input method that is adequate for EADL control may be very tedious for general computer controls. On the other hand, system that allows fluid control of a computer will not be strained by the need to also control an EADL. The

"proper" source of control will probably have to be decided on a case-by-case basis.

One of the most important features of the environment to be controlled by an EADL is not generally thought of as an electronic device. In a study of EADL users conducted in Finland (17), users reported that the feature that provided the most gain in independence was the ability to open doors independently. While doors are not electronic devices, powered door openers may be, and can be controlled through the EADL.

SUBSUMED DEVICES

Finally, modern EADLs frequently incorporate some common devices that are more easily replicated than controlled remotely. Some devices, such as the telephone, are so pervasive that an EADL system can assume that a telephone will be required. Incorporating telephone electronics into the EADL is actually less expensive, due to telephone standardization, than inventing special systems to control a conventional telephone. Other systems designed for individuals with disabilities are so difficult to control remotely that the EADL must include the entire control system. Hospital bed controls, for example, have no provisions for remote control, but should be usable by a person with a disability. Hence, some EADLs include hospital bed controls internally, so that a person who is in the bed can control its features (Fig. 6).

A telephone conversation may be considered as having several components. The user must "pick up" to connect to the telephone system (able-bodied individuals do this by

Figure 6. Relax II scanning EADL with IR remote control and X-10 switching.

picking up the handset). If the user is responding to an incoming call, the act of picking up initiates the connection. If the user is “originating” a call, the act of picking up will be followed by “dialing”, which describes the person to whom the user wishes to speak. When a connection is made (both parties have picked up), a conversation may ensue. At the end of the conversation, the call is “terminated” by breaking the connection.

Many EADL systems include a built-in speakerphone, which will allow the user to originate and answer telephone calls using the electronics of the EADL as the telephone. Because of the existing standards, these systems are generally analogue, single-line telephones, electronically similar to those found in the typical home. Many business settings now use multiline sets, which are not compatible with home telephones. Other settings use digital interchanges, which are also not compatible with conventional telephones. Finally, there is a move currently to use “Voice Over Internet Protocol” (VOIP) to bypass telephone billing and use the internet to carry telephone conversations. Because of this, the telephone built in to a standard EADL may not meet the needs of a disabled client in an office or other setting. Before recommending an EADL as an access solution for a client, therapists should check that the EADL communication system is compatible with the telecommunications systems in that location.

Because the target consumer for an EADL will have severe restrictions in mobility, the manufacturers of many of these systems consider that a significant portion of the customer’s day will be spent in bed, and so include some sort of control system for standard hospital beds. These systems commonly allow the user to adjust head and foot height independently, extending the time the individual can be independent of assistance for positioning. As with telephone systems, different brands of hospital bed use different styles of control. It is essential that the clinician match the controls provided by the EADL with the inputs required by the bed to be controlled.

CONTROLLING EADLs

For an EADL to provide improved function to the individual with a disability, it must provide a control interface that is more usable than that of the devices it controls. The common strategies for control found in EADLs are scanning and voice command.

Scanning Control

While scanning control is not particularly useful for computer control (17), it may be quite satisfactory for control of an EADL. When controlling a computer, the user must select between hundreds of options, and perform thousands of selections per day. When controlling the environment, the user may select among dozens of options, but will probably not be making more than a hundred selections during the day. While the frequent waits for the desired action to be offered in a computer scanning input system can have a crippling effect on productivity, the difference between turning on a light *now* versus a *few*

seconds from now is of little consequence. Because of this, many EADL systems provide a scanning control system as the primary means of controlling the immediate environment.

As with computer scanning, EADL scanning may be arranged in a hierarchical pattern. At the topmost level, the system may scan between lights, telephone, bed, entertainment, and appliances. When “lights” are selected, the system might scan between the various lights that are under EADL control. When a single light is selected, the system may scan between “Off”, “Dimmer”, “Brighter”, and “On”. As the number of devices to be controlled increases, the number of selections required to control a particular feature will increase, but the overall complexity of the device need not.

Voice Command

Like scanning, voice command may be significantly more functional in controlling an EADL than a computer. If the user is willing to learn specific voice commands for control that are selected to be highly differentiable, a voice command EADL system can be highly reliable. As the potential vocabulary increases, the likelihood of misrecognitions increases and the quality of control goes down.

As with all voice-command systems, background noise can impair the accuracy of recognition. An EADL may easily recognize the commands to turn on a radio in a quiet room, for example, but may be unable to recognize the command to turn off the radio when it is playing in the background. This problem will be exacerbated if the voice commands are to be received by a remote microphone, and when the user is not looking directly at the microphone. On the other hand, the use of a headset microphone can improve control accuracy, but at the cost of encumbering the user.

In addition to microphone type and quality, voice quality can affect the reliability of the system. For individuals with high level spinal cord injuries or other neurological deficits, voice quality can change significantly during the course of a day. A command that is easily recognized in the morning when the person is well rested may be ignored later in the day, after the user has fatigued. At this later time, the user’s tolerance for frustration is also likely to be lessened. The combined effect of vocal changes and frustration may result in the user abandoning the device if an alternative control is not provided. While voice command of EADLs has a “magical” quality of control, for the person whose disability affects vocal quality or endurance, it can be a sporadic and limiting magic.

Other Control Strategies

For those systems that are controlled by a computer, any access method that can be used to control the computer can provide control over the environment as well. This includes mouse emulators and expanded keyboards as well as scanning and voice input. A recent study (18) has also demonstrated the utility of switch-encoding as a means of controlling the environment for children as young as 4, or, by extension, for individuals with significant cognitive limitations. In this strategy, the user closes one or two switches in coded patterns (similar to Morse code) to

operate the features of devices in the environment. The devices can be labeled with the control patterns for those users who cannot remember the controls, or during the training phase.

The technology now exists, though it has not been applied to EADL systems, to combine head and eye tracking technologies so that a person with a disability could control devices in the environment by simply looking at them. Head-tracking technology could determine, from the user's location, what objects were in the field of view. Eye tracking could determine the distance and fine direction of the intended object. A "heads-up" display might show the features of the device available for control, and provide the control interface. With such a system, a user wearing a headset might be able to turn on a light simply by looking at it and blinking. This type of control strategy, combined with the V2 control protocol, would allow a person with a disability truly "magical" control of the environment.

THE FUTURE OF EADLs

Recognizing that the EADL provides a bridge between the individual with a disability and the environment in which they live, EADL development is likely to occur in two directions. The interface between the individual and the EADL will be enhanced to provide better input to the EADL, and remote controls will become more pervasive so that more of the world can be controlled by the EADL.

The user's ability to control the EADL is a function of the ability of the person to emit controlled behavior. Scanning requires the presence or absence of an action, and ignores any grading. As assistive technologists develop sensing technologies to identify gradients of movement or neural activity, the number of selections that can be made directly increases. For example, current EADLs may be controlled by eye-blink for severely disabled individuals. But in the future, EADLs could use eye-tracking technology to allow a person to look at the device in the environment to be controlled, and then blink to activate it. Electroencephalography might, eventually, allow the control of devices in the environment by simply *thinking at* them (19,20).

The continued development of remote control technologies will, in the future, allow EADLs to control more of the environment that is currently available. Currently, EADLs can switch power to any device that plugs into the wall or that uses batteries. Feature control, however, is very limited. Cross-walk controls, elevators, and ATM machines do not have the means of remote control today, and are often beyond the reach of a person with a significant disability. Microwave ranges, ovens, and air conditioners also have feature controls that might be, but are not, remotely controllable. If interoperability standards like V2 are accepted, the controls that are provided for sedentary, able-bodied users may provide control for the EADLs of the future. It is generally recognized that the inclusion of remote control for EADL access is not cost-effective, but if the cost of providing remote control for able-bodied users becomes low enough, such options might be made available, which will allow EADLs of the future to control them as well.

EQUIPMENT ACQUISITION

ROBERT STIEFEL
 University of Maryland
 Baltimore, Maryland

INTRODUCTION

Equipment acquisition is the process by which a hospital introduces new technology into its operations. The process involves determining the hospital's needs and goals with respect to new technology and equipment, how best to meet those needs, and instituting the decisions. The process involves virtually every clinical and support department of the hospital. This is consistent with the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (1) medical equipment management standards which require hospitals to have a process for medical equipment acquisition.

Unfortunately, in many hospitals it is a ritual, the control and details of which are jealously guarded. In fact, the needs of the hospital's operation would be much better served if all departments knew how the process worked. If the rules of the process were known and based upon the stated goals and priorities of the institution, then the people who must attempt to justify requests for new equipment would be able to do their jobs better, and with subsequently better results. If a new technology can improve the hospital's finances and/or clinical or support functions, then the methods by which this can be used to justify requests should be clearly explained. If the hospital's reimbursement structure is such that the introduction of new technology is difficult, but the improvement of current functions is more easily funded, then this should be explained.

In short, there should be a policy and procedure for the method by which the hospital acquires new equipment. It should define what the hospital means by a capital expenditure, reflect the hospital's overall goals and objectives, clearly state how to prepare a justification, and explain, at least in general terms, how a decision is to be made about the funding of a proposal.

The scope of this article is limited to the justification, selection, and implementation of new medical technology and equipment (Table 1). It is not intended to provide cookbook methods to be followed exactly, but instead to explain principles that can be applied to different hospitals and their differing needs. This seems to be particularly appropriate because needs vary not only between hospitals, but also with time.

JUSTIFICATION PROCESS

The justification process lays the groundwork for the acquisition of medical equipment. The better the justification, the more dependable the results will be. If the rules of the justification process are carefully planned, and just as carefully followed, the equipment acquisition function of the hospital will be respected and adhered to by other components of the hospital system. It is via the justification process that the hospital's needs are recognized, proposals

are created to meet these needs, and sufficient funds are budgeted to fulfill the most acceptable proposals.

Needs assessment is the first step in the justification process. The requirement for new equipment can be based upon a variety of disparate requirements. There can be a need for new technology or expansion of an existing service. Need for equipment can be based upon cost effectiveness of new technology, safety, maintenance costs, or simply a need to replace old equipment. The justification for acquiring equipment based upon any of these reasons must be supported by facts.

The age of equipment by itself is not sufficient justification for replacing equipment. If the age of equipment exceeds accepted guidelines, and maintenance costs, for example, are also exceeding accepted guidelines, then the replacement of equipment is adequately justified. What this points out, however, is that there must be guidelines for replacement of equipment based upon both age and maintenance costs.

A general guideline is that when equipment is over 7 years old, it is time to start considering its replacement. The age when equipment should be considered for replacement can also be based on its depreciation life, which varies depending on the type of device. Wear and tear, along with the advancement of the state of the art in equipment design, will start catching up with the equipment at about this time. When total maintenance costs exceed approximately one and one-half times replacement cost or when an individual repair will cost more than one-half the replacement cost, it is probably more appropriate to consider replacing the equipment. Age and/or maintenance costs by themselves do not necessarily require equipment replacement. There can be mitigating circumstances, such as the fact that the older equipment might be impossible to replace. If an item is one of a standardized group, or part of a larger system, it might be unrealistic to consider replacing the entire group or system.

Safety considerations should be relatively easy to document. If the performance of equipment puts it out of

compliance with accepted standards, the standards and the performance of the equipment can be documented. Again, however, judgment can mitigate these standards. If a piece predates current safety or performance standards, it is perfectly acceptable to continue using it if clinical and engineering personnel believe it still performs safely and as intended. This judgment should also be documented.

Cost effectiveness is, by itself, adequate justification for equipment acquisition. If it can be shown that within 3–5 years, the acquisition of new equipment will save more than the cost of the acquisition, it will be money well spent. The justification must be done very carefully, however, to recognize all costs that will be incurred by the acquisition of new equipment, and any additional operating costs.

If an existing clinical service is covering its costs and it can be shown that there is a need to expand the service, the equipment necessary to support the expansion can be cost justified. Again, the justification must be done carefully to ascertain that there are sufficient trained people, or people who can be trained to use the equipment, as well as a sufficient population of patients requiring the service.

The acquisition of new technology requires the most difficult and demanding justification. The technology itself must be assessed. Determine whether the technology is viable, provides a needed service, and will be accepted. There must be clinical professionals capable of utilizing the technology or in a position to be trained to do so. Cost justification of new technology is equally difficult. Very careful thought will have to be given to identifying all costs and revenues. The cost of the equipment, the cost of the supplies necessary to operate it, and the cost of the personnel to operate it must all be determined.

In addition, the space requirements and special installation requirements, such as electrical power, computer networking, air conditioning, plumbing, or medical gases, will all have to be determined. Maintenance costs will have to be identified and provisions made to cover them. It must be determined that there is an adequate population base that will provide patients to take advantage of the new technology. State and local approval (certificate of need) may also have to be met. The entire process is very time consuming, and should be carefully planned to meet the scheduling of the hospital.

Once needs have been justified, primarily by the people intending to apply the new equipment, it will be necessary to create a formal proposal. The formal proposal should be prepared by a select group of people (medical, nursing, purchasing, administration, and clinical engineering) most closely associated with the management and use of the equipment. Physicians are concerned with the function performed by the equipment, nursing with the equipment's operations, and clinical engineering with the design, safety and performance, and dependability of the equipment. Administration and purchasing are involved with managing costs. Information technology staff may need to be involved if equipment is networked, or facilities staff if there are special installation requirements.

The proposal must provide a precise definition of the clinical needs, the intended usage of the equipment, any restrictions of a clinical nature, and a thorough financial plan. The financial planning, in particular, should include

accepted planning techniques. For example, life-cycle cost analysis is perhaps the most thorough method for determining the financial viability of a new project. (Life-cycle analysis is the method of calculating the total cost of a project by including the initial capital cost, the operating costs for the expected lifetime of the equipment, and the time cost of money.)

At this stage, it is appropriate to consider a variety of physical or environmental factors that affect or are affected by the proposed new equipment. The equipment will require space for installation, use, and maintenance. Its power requirements might call for a special electrical source, medical gases or vacuum, or a water supply and drain. Its size might prevent it from passing through doors. The equipment might require special air-handling consideration if it generates heat or must be operated in a temperature- and/or humidity-controlled environment. Its weight might preclude transport in elevators or require modification of floors, or its sensitivity to vibration might require a special installation. If the equipment is either susceptible to or generates electrical or magnetic fields, special shielding may be required. There might be special standards that restrict the selection or installation of the type of equipment.

After the staff intending to use and manage the equipment have completed their proposal, it will be necessary to present this to the committee responsible for budgeting new equipment or new projects. This "capital equipment budget committee" will typically be chaired by an individual from the hospital's budget office and should include representatives from central administration, nursing, and clinical engineering. It is their responsibility to review proposals for completeness and accuracy as well as feasibility with respect to the hospital's long-range plans and patient population. Their judgment to approve or disapprove will be the necessary step before providing funds.

SELECTION PROCESS

Once the acquisition of new equipment has been justified, planned, and budgeted, the next step is to select the equipment that will actually be purchased. Again, this is a formal process, with sequential steps that are necessary to achieve the most appropriate equipment selection. There are commercial software products available that help hospitals establish priorities, develop proposals, and select capital equipment (e.g., Strata Decision Technology).

For most equipment, a standing capital equipment committee can oversee the selection and acquisition process. This committee should at least include representatives from clinical engineering, finance, and purchasing. It might also include representatives from nursing and information technology.

For major equipment or new technology, a selection committee should be formed specifically for each acquisition. Such a committee should include physician, nursing, and administrative personnel from the area for which the equipment is intended, and a representative from clinical engineering. Since the representative from clinical engineering will serve on virtually all of these ad hoc selection committees, this person's experience would make him/her

the best choice for chairperson. Realistically, however, it might be more politically expedient to allow one of the representatives from the area to chair the committee.

The first step involves a literature review. A library search should be conducted, and the clinical engineering department’s professional subscriptions reviewed, for example, *Health Devices* and *Biomedical Instrumentation and Technology*. Look for applicable standards from AAMI or the American National Standards Institute (ANSI). Obtain product literature from the manufacturers being considered. Research the information maintained by the FDA Center for Devices and Radiological Health (CDRH) at <http://www.fda.gov/cdrh>. The FDA-CDRH Manufacturer and User Facility Device Experience Database (MAUDE) contains reports of adverse events involving medical devices, and their “Safety Alerts, Public Health Advisories, and Notices” page contains safety-related information on medical devices.

A list of proposed vendors to be contacted can be created by consulting the *Health Devices Sourcebook* (ECRI) (2). These vendors should be contacted and their literature on the type of equipment being evaluated requested. Part of the evaluation includes evaluating the manufacturers and vendors. Commencing with this initial contact, notes should be kept on the responsiveness and usefulness of the representatives contacted.

A request for proposal (RFP) should be written on the basis of the needs determined during the justification process and the information acquired from the literature review. When the selection criteria are straightforward, the RFP and the request for quotation (RFQ) can be combined. For more complex selections, such as equipment systems or new technology, the RFP and RFQ should be separate processes.

The RFP should be carefully written, well organized, and thoroughly detailed. It should contain useful background information about the institution and the specific user area. Applicable documents, such as drawings, should be either included or explicitly made available for review by the vendors. The equipment requirements should include a statement regarding the major objectives to be fulfilled by the equipment. The description of the specific requirements must include *what* is to be done, but should avoid as much as possible restrictions on *how* it is to be done. It is likely that, given reasonable latitude in addressing the equipment requirements, manufacturers can make useful suggestions based upon their experience and the unique characteristics of their equipment.

The RFP should contain a description of the acceptance testing that will be conducted before payment is approved. It should also contain a request for a variety of ancillary information: available operator and service documentation; training materials and programs; warranties; and maintenance options and facilities. There should also be a request for the names of at least three users of comparable equipment, located as close as possible to the hospital so that site visits can be conveniently arranged. The RFP should be reviewed by the entire in-house evaluation committee.

A cover letter should accompany the RFP to explain the general instructions for submitting proposals: who to call for answers to questions, deadline for submission, format,

and so on. When appropriate, there can also be such information as to how the proposals will be evaluated, how much latitude the vendors have in making their proposals, and the conditions under which proposals can be rejected. It is not necessary to send the RFP to all known vendors of the type of equipment being evaluated. If there is any reason why it would be undesirable to purchase from particular vendors, for example, poor reputation in the area or unsatisfactory dealings in the past, it would be best to eliminate them from consideration before the RFP process.

The response of the vendors to the RFP will allow the selection committee to narrow the field to equipment that is likely to meet the defined needs. The full evaluation committee should review the proposals. There will have been a deadline for submission of proposals, but it might not be appropriate to strictly enforce it. It is more important to consider the long-term advantages to the hospital and not to discount an otherwise acceptable proposal for being a few days late. The proposals should be reviewed for completeness. Has all of the requested information been provided? Are there any misinterpretations? Are there exceptions? The vendors should be contacted and additional information requested or clarifications discussed as necessary. It will now also be possible to determine the type of acquisition required, that is, whether the equipment can be purchased from a single vendor, whether it will have to be purchased from more than one vendor and assembled, or whether the equipment will require some special development effort to meet the clinical needs.

Evaluate the quality of each proposal. A simple form can be used to record the results. The form should include the elements of the review. Score the responses according to the relative importance of each element, and whether there was a complete, partial, or no response (Table 2). Include comments to explain the reason for each score. Based upon a review of the proposals submitted, the evaluation

committee should agree on which vendors and equipment to consider further (i.e., the proposals that offer equipment that meets the established criteria).

The next step will be to request equipment for an in-house evaluation. The equipment requested for testing should be the exact type that would be ordered. If preproduction prototypes or engineering models are accepted for evaluation, it should be realized that there are likely to be changes in the operation and performance of the final product. The dependability of prototype equipment cannot be judged. In short, the evaluation will not be complete, and, to some extent, the ability to judge the equipment or compare it with other equipment will be hampered.

The most important aspect of the entire equipment acquisition process, especially for equipment types not already in use, is the in-house, comparative evaluation. This evaluation has two phases: engineering and clinical. The equipment requested for comparative evaluation has been selected from the proposals submitted. The field should be narrowed to include only vendors and equipment worthy of serious consideration. Therefore, it will be worthwhile to commit significant effort to this evaluation.

The engineering phase of the evaluation will need test procedures, test equipment, and forms for documenting the

results. The clinical phase will need representative areas, users, protocols, a schedule for training as well as use, and a method for collecting results: an interview, a review meeting, or a questionnaire. All of these details should be settled before the arrival of the equipment. For example, it might be determined that sequential testing would be preferable to simultaneous testing. Neither the hospital nor the vendor would want to store equipment while waiting for its evaluation.

The first step in testing equipment is the engineering evaluation, done in the laboratory. The tests include safety and performance aspects. Mechanical safety criteria include consideration of the ruggedness or structural integrity of the equipment as well as the potential for causing injury to patients or personnel. Electrical safety tests are conducted per the requirements in the AAMI/ANSI *Electrical Safety Standard* and NFPA electrical standards as appropriate. Performance testing is done as described by any published standards, according to the manufacturer's own service literature, and per the needs determined in the justification process. The results of the engineering tests should be summarized in a chart to facilitate comparison (Table 3). Differences and especially flaws should be highlighted.

In addition to the straightforward safety and performance tests, a number of characteristics should be evaluated based upon engineering judgment. The physical construction should be judged, especially if there are constraints imposed by the intended application or installation. A study of the construction and assembly can also allow a judgment regarding reliability. This judgment should be based upon the quality of hardware and components, the method of heat dissipation (fans suggest an exceptional requirement for heat dissipation and require periodic cleaning), the method of construction (the more wiring and connectors, the more likelihood of related failure), and whether the design has had to be modified by such means as alterations on circuit boards or “piggybacked” components.

The maintainability of the equipment is reflected both in the methods of assembly and in the maintenance instructions in the operator and service manuals. The manuals should explain how and how often preventive maintenance or inspection or calibration should be performed. Finally, a clinical engineer should be able to judge human engineering factors. For example, ease of use, how logical and self-explanatory is the front panel, self-test features, and the chances or likelihood of misuse all affect the safety and efficacy of the equipment.

Design a form to record the engineering evaluation results. The form will vary in the specific features and tests that are included, according to the type of equipment that is being evaluated, but the basic format will remain

the same. Include comments to explain the reason for the score of each item. Table 3 is an example of an engineering evaluation form.

The physicians, nurses, and clinical engineers on the evaluation committee should contact their counterparts at the institutions named as users of their equipment by the vendors. Site visits can be particularly useful in cases where the equipment or technology being considered is new to the hospital. The committee can see the application firsthand, and talk to the actual users face to face. Record and score the results of interviews (Table 4).

Clinical testing is performed after engineering testing. Equipment must satisfactorily pass the engineering testing to be included in the clinical testing; there is no point in wasting people’s time or taking a chance on injuring a patient. Clinical testing should not be taken lightly; it is usually more important than the technical testing. The clinical testing is done only on equipment that has survived all of the previous tests and by the people who will actually be using it.

The clinical testing should be designed so that the equipment is used for the intended application. The equipment included in the clinical testing should be production equipment unless special arrangements are likely to be made with the manufacturer. Users should be trained just as they would be for the actual equipment to be purchased. In fact, the quality of the training should be included in the evaluation. Users should also be given questionnaires or be interviewed after the equipment has been used (Table 5).

Table 5. Clinical Testing Questionnaire

One further consideration to be judged by the full evaluation committee is that of standardization. There are numerous valid reasons for standardizing on equipment. Repairs are easier to accomplish because of technicians' familiarity with the equipment. Repair parts are easier and less expensive to keep in inventory. Standardization allows exchange of equipment between clinical areas to help meet varying demands. Training is also more easily provided.

There are also valid drawbacks, however. Standardization makes the hospital dependent upon a limited number of vendors. It can interfere with user acceptance if users feel they have little or no say in the selection process. It can also delay the introduction of new technology. It is important that the evaluation committee consider the relative importance of the pros and cons of standardization in each case.

Assessment of the equipment should result in a ranking of the equipment that has successfully completed the engineering and clinical testing. The advantages and disadvantages of each item should be determined and ranked in order of importance. Alternatively, the criteria can be listed in order of importance. If possible, the list should be divided between criteria that are mandatory and those that are desirable. Then a judgment on whether the equipment does or does not satisfy the criteria can be made. From this charting, it is likely that clear preferences will become obvious.

Ideally, there will be two or more finalists who are close to equal in overall performance at this point. These finalists should be sent a request for quotation (RFQ). The responses to the RFQ will allow a cost comparison. A life-cycle cost analysis can be accomplished with the aid of the hospital's financial officer. This will give a more accurate depiction of the total cost of the equipment for its useful lifetime. While it is beyond the scope of this article to describe life-cycle cost

analysis, it takes into account the initial costs (capital cost of equipment plus installation), operating costs over the anticipated life of the equipment (supplies, service, fees), and the time cost of money (or present value). It may or may not take personnel costs into account, since these will likely be the same or similar for different models. To calculate a percent score for purposes of evaluation, divide the cost of the least expensive equipment by the cost of the equipment being evaluated, and multiply by 100.

With the completion of the evaluation, a comparison of the results should lead to a final selection. This should be as objective as possible. If additional information is needed, there should be no hesitation in contacting vendors. In fact, it may be useful to have a final presentation by the vendors. Develop a point system for the individual elements of the proposal reviews, engineering evaluations, user interviews, clinical testing, and cost comparison. Weight these elements according to their relative importance (Table 6).

Once the hospital has made its final choice of vendor and equipment, it is not necessary to end negotiations. Negotiations should be conducted before a vendor knows that they are the preferred provider. Before a vendor is certain of an order, they are much more likely to make concessions. Requests for extra features, such as spare equipment, spare parts, special tools, and test equipment, may be included in the final quote. Trade-in of old equipment and compromises on special features or warranties, for example, can help reduce the cost of equipment. Consider negotiating hardware and software upgrades for a specified period.

For large orders (e.g., dozens of infusion pumps), or for installations (e.g., monitoring systems), request that the vendor unpack, set up, inspect, distribute or install, and document (using the hospital's system) the equipment at no additional cost. In most cases, the hospital will want

the vendor to provide user training. This training should meet the hospital's specified needs (e.g., all users, all shifts, train the trainer, videotapes or computer programs, etc.). The hospital may also need service training for its clinical engineering department. The hospital can negotiate not only the service school tuition, but also room, board, and travel. The negotiated quote should be reviewed by the end-users, clinical engineering, finance, purchasing, and a contracts lawyer.

IMPLEMENTATION PROCESS

The successful conclusion of the equipment acquisition process cannot be realized until the equipment is satisfactorily put into use. As with all the previous steps in the equipment acquisition process, the implementation process requires planning and monitoring.

The purchase order with which the equipment is ordered is a legal document: a contract. As such, it can protect the rights of the hospital. Therefore, it is important to include not only the equipment being ordered, but also all agreed-upon terms and conditions. These terms and conditions should include delivery schedules, the work to be performed by the vendor, warranty conditions, service agreements, operator and service manuals, acceptance criteria and testing, and operator and service training.

Before the equipment is delivered, arrangements should be made for installation, for personnel to transport the equipment, for storage, and for personnel to test the equipment. If any of these are to be the responsibility of the vendor, they should be included in the purchase order. If the hospital has to perform any modifications or fabrications, all necessary parts and preparations should be in place.

Acceptance testing should be done upon the completion of installation. The test procedures for acceptance testing should come from the initial specifications and from the manufacturer's data sheets and service manuals. Acceptance testing should be thorough, because this is the ideal time to obtain satisfaction from the manufacturer. It is also appropriate to initiate the documentation per the standard system of the hospital at this time. The invoice for the equipment should not be approved until the equipment has been satisfactorily tested.

After the equipment is in place and working properly, training should be scheduled. The manufacturer or their representative, or the selected hospital personnel, should have the training program completely prepared. If ongoing training will be necessary over the lifetime of the equipment, in-service instructors should be involved in the initial training as well. The clinical engineering personnel responsible for inspection and maintenance should also receive operator and service training.

An often overlooked, but useful, adjunct to the implementation process is follow-up on the installation. Users should be polled for the acceptance of the equipment and their perception of its usefulness. Engineering personnel should review the dependability of the equipment from their service records. All of the people involved in the equipment acquisition process should learn from every acquisition, and what they have learned should be reviewed during this follow-up.

CONCLUSION

Table 1 can be used as a list of tasks that should be accomplished (or at least considered) in the equipment acquisition process. A schedule and checklist can be generated from this list.

The equipment acquisition should be fully documented, ideally by a write-up of the entire process. Table 1 can be used to create an outline for the final report. The results of the equipment acquisition process should be shared with manufacturers and other interested parties. It should always be the intention of the hospital personnel to improve the situation with respect to the manufacturer. Perhaps the most dependable way for medical equipment manufacturers to learn what is important to hospitals is to review what hospitals have said about the evaluation of new equipment during their acquisition process.

INTRODUCTION

Preventive maintenance (PM) is one of the many functions of a clinical engineering department. The other functions include incoming inspection/testing, prepurchase evaluation, coordination of outside equipment service, hazard and recall notification, equipment installation, equipment repair and upgrade, purchase request review, equipment replacement planning, device incident review, and regulatory compliance maintenance. The primary objective of a PM program for biomedical equipment is to prevent failure, which is achieved through (1) detecting the degradation of any non-durable parts of the device and restoring them to like-new condition; (2) identifying any significant degradation of the performance of the device and restoring it to its proper functional level; and (3) detecting and repairing any partial degradation that might create a direct threat to the safety of the patient or operator.

The term preventive maintenance has its origins with mechanical equipment that has parts that are subject to wear and need to be restored or replaced sometime during the useful lifetime of the device. PM refers to the work performed on equipment on a periodic basis and should be distinguished from "repair" work that is performed in response to a complaint from the equipment user that the device has failed completely or is not working properly. The term "corrective maintenance" is often used instead of the term "repair."

Today, medical equipment uses electronic components that fail in an unpredictable manner, and their failure cannot be anticipated through measurements and checks performed during a PM (1). Also, equipment failures that are attributable to incorrect set up or improper use of the device or the use of wrong or defective disposable accessory cannot be prevented by doing PM (2). It has been argued that current medical devices are virtually error-free in terms of engineering performance. Device reliability is an intrinsic function of the design of the device and cannot be improved by PM. In modern equipment, the need for performance and safety testing is greatly reduced because of the design and self-testing capability of the equipment (3,4). For example, the Philips HeartStart FR2+ defibrillator performs many maintenance activities itself. These activities include daily and weekly self-tests to verify readiness for use and more elaborate monthly self-tests that verify the shock waveform delivery system, battery capacity, and internal circuitry. The manufacturer also states that the FR2+ requires no calibration or verification of energy delivery. If the unit detects a problem during one of the periodic self-tests, the unit beeps and displays a flashing red or a solid red warning signal on the status indicator (5).

The term "scheduled (planned) maintenance" was introduced in 1999 by a joint AAMI/Industry Task Force on

Servicing and Remarketing while developing a document for submission to the FDA entitled "Joint Medical Device Industry Proposed Alternative to the Regulation of Servicers, Refurbishers, and Remarketers" (6). However, many still use the traditional term preventive maintenance rather than this new, more carefully defined term. According to the document developed by the AAMI/Industry Task Force, the term scheduled (planned) maintenance "consists of some or all of the following activities: cleaning; decontamination; preventive maintenance; calibration; performance verification; and safety testing." Among these activities, the three key activities are (1) preventive maintenance (PM); (2) performance verification (PV) or calibration; and (3) safety testing (ST).

These three terms are defined by the AAMI/Industry Task Force as follows. "Preventive maintenance is the inspection, cleaning, lubricating, adjustment or replacement of a device's nondurable parts. Nondurable parts are those components of the device that have been identified either by the device manufacturer or by general industry experience as needing periodic attention, or being subject to functional deterioration and having a useful lifetime less than that of the complete device. Examples include filters, batteries, cables, bearings, gaskets and flexible tubing." PM performed on a medical device is similar to the oil, filter, and spark plug changes for automobiles.

"Performance Verification is testing conducted to verify that the device functions properly and meets the performance specifications; such testing is normally conducted during the device's initial acceptance testing." This testing is important for detecting performance deterioration that could cause a patient injury. For example, if the output of the device (such as temperature, volume, or some form of energy) is not within specifications, it could result in an adverse patient outcome (7). If the performance deterioration can be detected by visual inspection or by a simple user test, then periodic performance verification becomes less critical. The data obtained during maintenance will also assist in determining the level and intensity of performance verification.

"Safety testing is testing conducted to verify that the device meets the safety specifications, such testing is normally conducted during the device's initial acceptance testing."

HISTORICAL BACKGROUND

The concept of a facility-wide medical equipment management program first emerged in the early 1970s. At that time, there was little management of a facility's medical equipment on a centralized basis. Examples of the lack of proper management that affected the quality of care are described in detail in the literature (8) and include poor frequency response of ECG monitors, heavy accumulation of dirt inside equipment, delay in equipment repair, little attention to the replacement of parts that wear over time, and the consequential high cost of repairs.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has played an important role in

promoting equipment maintenance programs in hospitals in the United States. Almost all hospitals in the United States are accredited by the JCAHO and are required to comply with their standards.

Poor or nonexistent equipment maintenance programs (8) coupled with the “great electrical safety scare” of the early 1970s (9) created the impetus that has popularized electrical safety programs in hospitals. Since then, equipment maintenance and electrical safety testing has been an important part of clinical and biomedical engineering programs in hospitals. The JCAHO standards in the mid-1970s required that all electrically powered equipment be tested for leakage current four times a year (10).

In 1983, the Medicare reimbursement program for hospitals changed to a much tighter fixed-cost approach based on so-called Diagnostic Related Groups (DRGs). In 1979, JCAHO increased the maximum testing interval for patient care equipment to six months. This change was made in response to pressure from hospitals to reduce the cost of complying with their standards. It has been reported that there was no other rationale for changing the testing intervals (10).

In 2001, JCAHO removed the annual PM requirement for medical equipment (11). The reason cited for the change was that the safety and reliability of medical equipment had improved significantly during the prior decade. It was also stated that some equipment could benefit from maintenance strategies other than the traditional “interval-based” PM. Other PM strategies suggested included predictive maintenance, metered maintenance (e.g., hours of usage for ventilators), and data-driven PM intervals.

INVENTORY

A critical component of an effective PM program is an accurate inventory, which has been a key requirement in the JCAHO equipment standards since they were introduced in the early 1970s. The 2005 JCAHO standard (EC.6.20) requires a current, accurate, and separate inventory of medical equipment regardless of ownership (12). The inventory should include all medical equipment used in the hospital (owned, leased, rented, physician-owned, patient-owned, etc.). A complete and accurate inventory is also helpful for other equipment management functions including tracking of manufacturer’s recalls, documenting the cost of maintenance, replacement planning, and tracking model-specific and device-specific issues. The equipment list should not be limited to those devices that are included in the PM program (13).

INCLUSION CRITERIA

In 1989, JCAHO recognized that not all medical devices are equally critical with respect to patient safety and introduced the concept of risk-based inclusion criteria for the equipment management program. Fennigkoh and Smith developed a method for implementing a risk-based equipment management program by attributing numerical values to three variables; “equipment function,” “physical risks associated with clinical application,” and “mainte-

nance requirements” (14). They compounded these values into a single variable; the equipment management (EM) number. The EM was calculated as follows: EM = Function rating + Risk rating + Required Maintenance rating. The three variables were not weighted equally. Equipment function constituted 50% of the EM number whereas risk and maintenance each constituted 25%. The authors acknowledge the somewhat arbitrary nature of weighting the equipment function rating at 50% of the EM number; however, they viewed this variable as the device’s most significant attribute. The authors also arbitrarily set a level for the EM number at greater than or equal to 12 to determine whether the device will be included in the EM program. Devices included in the EM program are assigned a unique control number. Devices with an EM number less than 12 were excluded from the EM program and are not assigned a control number.

Although risk-based calculators using the original Fennigkoh and Smith model are still widely used, criticism of this method exists on the basis that this particular risk-based approach is arbitrary. The factors used in the calculation, their weighting, the calculated value above which one decides to include the device in the management program, and what PM interval to use are criticized as all being somewhat subjective or arbitrary (13).

SELECTING THE PM INTERVAL

Selecting an appropriate PM interval is a very important element of an effective maintenance program. Several organizations have offered guidelines, requirements, and standards for the selection of an appropriate PM interval for the various devices. This list includes accreditation organizations (e.g., JCAHO), state authorities (e.g., California Code of Regulations, Title 22), device manufacturers, and national safety organizations (e.g., NFPA). JCAHO is the primary authority that most people look to for minimum requirements for the PM intervals for medical devices. However, the JCAHO 2005 Standards [EC.6.10 (4) and EC.6.20 (5)] put responsibility back on the hospital to define PM intervals for devices based on manufacturer recommendations, risk levels, and hospital experience. JCAHO also requires that an appropriate maintenance strategy be selected for all of the devices in the inventory (12).

According to one source (7) two approaches exist to determining the proper PM interval. One is fixed and the other is evidence-based. Other sources present some contradictory views on how to select a PM interval for a device. Some (13,15) argue that PMs should not necessarily follow the manufacturer’s recommended intervals but should be adjusted according to the actual PM failure rate. Ridgway and Dinsmore (16,17) argue that if a device is involved in an incident where a patient or staff member is injured, a maintainer who has not followed the manufacturer’s recommendations will be deemed to have some legal liability for the injury, irrespective of how the device contributed to the injury. Dinsmore further argues that the manufacturer recommendations should be followed

Table 1. Conflicting Recommendations for the PM Intervals of Some Devices

Device Type	ASHE PM Interval (months)	ECRI PM Interval (months)
Defibrillator	3	6
Apnea monitor	6	12
Pulse oximeter	6	12

because the manufacturer developed the device and proved its safety to the FDA. He states that if no recommendations exist from the manufacturer, then it is up to the clinical engineering department to decide on the maintenance regimen. National organizations such as the American Society of Hospital Engineering (18) and ECRI (2) have published recommendations on PM intervals for a wide range of devices. The recommendations by ASHE were published in 1996 and ECRI in 1995. However, conflicting recommendations exist for certain devices in the list (see Table 1).

The ANSI/AAMI standard EQ56 (19) "Recommended Practice for a Medical Equipment Management Program" does not attempt to make specific recommendations for PM intervals for devices. And, in many cases, PM interval recommendations from the manufacturers are not readily available. Those that have been made available are often vague with little or no rationale provided. In some cases, their recommendations simply state that testing should be conducted periodically "per hospital procedures" or "per JCAHO requirements."

Intervals for the electrical safety testing of patient care equipment are discussed in the latest edition of NFPA 99-2005, Health Care Facilities, Section 8.5.2.1.2.2. Although this document is a voluntary consensus standard and not a regulation, many private and government agencies reference and enforce NFPA standards. The following electrical safety testing intervals are recommended. The actual interval is determined by the device's normal location or area in which the device is used. For general care areas, the recommended interval is 12 months; for critical care areas and wet locations, the recommended interval is 6 months. The standard does allow facilities to use either longer or shorter intervals if they have a documented justification from previous safety testing records or evidence of unusually light or heavy use (20).

In a similar fashion, the evidence-based method allows adjustment of the interval up or down depending on the documented finding of prior testing (7). This method is based on the concepts of reliability-centered maintenance (21). Ridgway proposes an evidence-based method using a PM optimization program that is based on periodic analyses of the results of the PM inspections. His approach takes into consideration the severity of the problems found during the PMs. It classifies the problems found into one of the four PM problem severity levels, level 1 through 4. This method incorporates the concepts found in Failure Modes and Effects Analysis (FMEA)—a discipline that has been recently embraced by the JCAHO. It requires the classification of the problems discovered during the PM testing

into four levels of criticality. Level 1 problems are potentially life-threatening, whereas the other levels are progressively less severe. Examples of level 1 problems include defibrillator output energy being significantly out of specification or an infusion pump significantly under- or over-infusing. For a more detailed explanation of this method, see Ref. (22). Others (23,24) have used maintenance data in a similar way to rationalize longer maintenance intervals.

It should be noted that some regulations, codes, or guidelines and some manufacturer's recommendations may advance more stringent requirements than other standards for the same type of device or an interval that the facility has used successfully in the past. In these instances, the facility needs to balance the risks of non-compliance, which may include injury to the patient, liability, and penalties for the organization, against the cost of compliance. Many factors exist that need to be evaluated before modifying the generally recommended intervals, including equipment maintenance history and experience, component wear, manufacturer recommendations, device condition, and the level of technology used in the device (2).

Note also that the manufacturer's recommendations for their newer models of medical devices are generally less stringent than those for their older models. In many instances, the recommended PM intervals are greater than 12 months.

PM PROCEDURES

Selecting an appropriate PM procedure is another important element of an effective maintenance program. Both ECRI (2) and ASHE (18) have published PM procedures for a broad range of devices. It should be noted that the manufacturers usually provide more detailed PM procedures for their specific devices than those published by ECRI and ASHE. It is recommended that manufacturers' recommendations that appear to be too complex be evaluated to see if they can be simplified (2). See Fig. 1 for a sample PM procedure for an infusion pump.

EVALUATION OF A PM PROGRAM

The facility's PM completion or completed on-time rates are parameters that have been favored by both facility managers and external accreditation agencies (7). However, the value of PM completion rate as an indicator of program quality has been debated for many years (25). Until 2003, to pass the maintenance portion of the medical equipment program, the JCAHO required a consistent 95% PM completion rate. The shortcoming of this standard is that the 5% incomplete PMs could, and sometimes did, include critical devices such as life-support equipment. To address this undesirable loophole, the JCAHO, in 2004, discontinued the 95% requirement. The 2005 standard EC.6.20 now segregates medical equipment into two categories: life-support and nonlife-support devices. Life-support equipment is defined by JCAHO as those devices that are intended to sustain life and whose failure to perform their primary function is expected to result in death. Examples include ventilators, anesthesia

For: **INFUSION PUMP**PM Procedure No. **IP001**Interval: **xx months**Estimated annual m-hrs: **x.0**

Check the **AC** box if **Action Completed** and the **AMR** box if **Adjustment or Minor Repair** was required to bring the device into conformance with the performance or safety specifications. In this case provide a **note*** on the nature of the problem found, in sufficient detail to identify the **level of potential severity** of the problem.

AC/AMR **Preventive Maintenance**

- SM1. Inspect/clean the chassis/housing especially any moving parts including any user-accessible areas under covers (if applicable). Examine all cable connections. Replace any damaged parts, as required.
- SM2. Confirm that all markings and labeling are legible. Clean or replace, as required.
- SM3. Replace or recondition the battery, as required.

AC/AMR **Performance Verification**

- PV1. Verify that the flow rate or drip rate is within specification. Perform self-test, if applicable.
- PV2. Verify that all alarms (including occlusion and maximum pressure) and interlocks operate correctly.
- PV3. Verify that the battery charging system is operating within specification.
- PV4. Verify the functional performance of all controls, switches, latches, clamps, soft touch keys, etc.
- PV5. Verify the functional performance of all indicators and displays, in all modes.
- PV6. Verify that the time/date indication is correct, if applicable.

AC/AMR **Safety Testing**

- ST1. Check that the physical condition of the power cord and plug, including the strain relief, is OK.
- ST2. Check the ground wire resistance. (< 0.5 ohm).
- ST3. Check chassis leakage to ground. (< 300 micro amps).

* **Notes:**

Figure 1. Sample PM procedure for an infusion pump.

machines, and heart–lung bypass machines (12). ECRI suggests that the following additional devices be included in the life-support category: anesthesia ventilators, external pacemakers, intra-aortic balloon pumps, and ventricular assist devices (26). The completion of PMs for life-support equipment is scored more stringently than the completion rate performance for nonlife-support equipment. It is theoretically possible that if the PM of a single life-support device is missed, an adverse, noncompliance “finding” could be generated by the survey team. However, it has been reported that the surveyors will probably be more focused on investigating gaps in the process that led to the missed PM (27).

The 2005 JCAHO standards do not contain an explicit PM completion requirement. However, many organizations appear to have set the goal for on-time PM completion rate for life-support equipment at 100% and the goal for the nonlife-support equipment at better than 90%. An important aspect of PM completion is calculating the on-time PM completion rate. The JCAHO does not state how the PM completion rate should be calculated. Hospitals are free to specify in their management plan that they have allowed themselves either 1 or 2 months of extra time to complete the scheduled maintenance. It is important for those devices that have maintenance intervals of three months or less, or are identified as life-support equipment, that the PMs be completed within the month they are scheduled for PM. Sometimes, additional time may be needed for devices that are unavailable because they are continuously in use. In this case, the appropriate department and the safety/environment of care committee should be informed about the delay.

The real issue to be addressed is the effectiveness of the program. However, “effectiveness” of a PM program is difficult to measure. If the purpose of the restoration of any nondurable parts is to reduce device failures, then the effectiveness of this element can be measured by the resulting reduction in the device failure rate. In principle, repair rates and incident analyses can provide a relationship between PM and equipment failures (7).

Two challenges associated with achieving an acceptable PM completion rate exist. The first is to find the missing equipment listed on the monthly PM schedule. Multiple documented attempts should be made to locate any devices that are not found, which should be followed with a written communication to the clinical users seeking their assistance in locating the device. It is important to get a written acknowledgment from the users that they have attempted to locate the devices in question. This acknowledgment will help when explaining to the surveyors that efforts were made to locate the device. However, if the devices cannot be located after this extended search it must be assumed that they are no longer in use in the facility. The question now is, are they still on site but deliberately or accidentally hidden away? Or have they really been removed from the facility? Until these questions can be answered, no satisfactory way to deal with accounting for the failure to complete the overdue PM exists. One strategy to reduce the potential administrative paperwork is to classify the missing equipment as “unable to locate.” This action (classifying the devices as unable to locate) should be commu-

nicated to the appropriate departments including the user departments, the safety/environment of care committee, materials management, and security. Consistent loss or unable to locate device(s) should be viewed negatively by the facility and should serve as an indicator that the facility needs to re-evaluate its security plan. The users should be reminded not to use the missing device(s) if they reappear. These device(s) should be readily identifiable with the “out-of-date” PM sticker. The service provider should be notified so that they can give the re-emerging device(s) an incoming inspection and restart its PM sequence.

The second challenge is to gain access to equipment that is continually in use for patient care. It is difficult to complete the PM if the device is in constant use for monitoring or treatment of patients. Examples of devices that often fall into this category include ventilators, patient monitors, and certain types of laboratory or imaging equipment. Ideally, to alleviate this problem, a back-up unit should be available to substitute while maintenance is performed on the primary unit. This spare unit can also serve as a back-up for emergency failures as well. A good working relationship with the users is very helpful in these circumstances.

DOCUMENTATION

Documentation of maintenance work is another important element of an effective maintenance program. The 2005 JCAHO standards require the hospital to document performance, safety testing, and maintenance of medical equipment (12).

Complete scheduled maintenance and repair documentation is required when a device is involved in an incident, or when the reliability of the device is questioned, and also to determine the cost of maintenance. Most accrediting and regulatory organizations accept a system of exception reporting, which is recording only the results of steps failed during performance verification as part of scheduled maintenance or after repair (18). It has been generally accepted that it is reasonable to record only what went wrong during the PM procedure (13). Having extensive documentation is considered a safe practice. ECRI supports the use of exception reporting and recommends that before deciding on using exception reporting the hospital take into account that exception reporting, with its lack of affirmative detail, may be less than convincing evidence in the event of a liability suit (2).

Two ways to document scheduled (planned) maintenance exist. One is to record the maintenance by hand on a standard form or preprinted PM procedure and file the records manually. The other is to use a computerized maintenance management system (CMMS). Computerized records should help in reducing the time and space required for maintaining manual documentation. Even with CMMS, the department may need to have a way to store or transpose manual service reports from other service providers. Other technologies like laptops and personal data assistants (PDAs) can further assist in implementing the maintenance program. A comprehensive review of CMMSs, that are currently in use can be found in

the literature (28). The CMMS helps the clinical engineering staff to manage the medical equipment program effectively. The core of the CMMS consists of equipment inventory, repair and maintenance record, work order subsystem, parts management subsystem, reporting capabilities, and utilities. A CMMS can be classified broadly as internally developed (typically using commercial off-the-shelf personal computer hardware and database software) and commercially available applications (desktop and web-based) (29).

STAFFING REQUIREMENTS

The number of full-time equivalents (FTEs) required to do scheduled maintenance varies based on the experience of the staff, the inventory mix, and the inventory inclusion criteria. See Ref. 30 for the method to determine the number of FTEs required for maintenance. Based on a clinical engineering practice survey, an average of one FTE is required to support 590 medical devices (31). The generally cited relationship between the support required for scheduled maintenance and repair for a typical inventory mix of biomedical devices is 750–1250 devices per FTE. Cost of the maintenance program includes salaries, benefits, overtime and on-call pay, cost of test equipment and tools, and training and education expenses. Salaries for the clinical engineering staff can be obtained from the annual survey published by the *Journal of Clinical Engineering* and the *24 × 7* magazine.

PM STICKERS

PM stickers or tags are placed on a device to indicate that maintenance has been completed and the device has been found safe to use. They also convey to the user a warning not to use the device when the sticker is out-of-date. Color-coded stickers (see Fig. 2) or tags are not required by the JCAHO, but they can be very helpful in identifying devices that need maintenance (2,32).

ENVIRONMENTAL ROUNDS

Conducting environmental rounds is another important aspect of the medical equipment maintenance program. The intent of these rounds is to discover situations, which are, or could lead to, an equipment-related hazard or safety problem. The clinical engineering staff should conduct

regular inspections of all clinical areas that are considered to be “medical equipment-intensive” areas (e.g., ICU, CCU, NICU, ER, and surgery). The interval between these equipment-related environmental safety rounds should be adjusted according to the frequency with which hazards are found. Other areas that are considered less equipment-intensive such as medical/surgical and other patient care floors, laboratory areas, and outpatient clinics should also be surveyed for electrical safety hazards but less frequently. The equipment items in these areas are usually line-powered items that do not have nondurable parts requiring periodic attention and they usually do not require periodic calibration or performance checking. These items need periodic visual inspections to ensure that they are still electrically safe (i.e., that no obvious defects exist such as a damaged power cord or evidence of physical damage that might electrify the case or controls). The search should be focused on the physical integrity of the equipment, particularly the power cord and the associated connectors and other equipment defects such as dim displays, torn membrane switches, taped lead wires, and so on. Items with power cords that are exposed to possible abuse from foot traffic or the wheels of other equipment should receive closer attention than those items with less exposed cords. Damaged wall outlets should be noted, as should the use of extension cords or similar “jury-rigged” arrangements. Other indicators that should be noted and investigated further are equipment enclosures (cases) that are obviously distorted or damaged from being dropped. In addition to these potential electrical safety hazards, other targets of this survey are devices with past-due PM stickers or with no sticker at all. When a safety hazard is identified, or a past due or unstickered item is found, appropriate corrective actions should be taken immediately and documented as required (33).

ESOPHAGEAL MANOMETRY

VIC VELANOVICH
Henry Ford Hospital
Detroit, Michigan

INTRODUCTION

The purpose of the esophagus is to act as a conduit for food from the mouth to the stomach. This is an active process that is initially a conscious act with chewing and swallowing, then becomes unconscious when the bolus of food enters the esophagus. As part of this process, the esophageal musculature acts to propagate the food bolus to the stomach and to prevent reflux of gastric contents to the esophagus to protect the esophagus itself. There are several disease processes of the esophagus for which the assessment the esophageal musculature function would contribute to the diagnosis and management. This assessment is done indirectly through the measurement of intraesophageal pressures. This pressure measurement is accomplished with esophageal manometry (1).

ESOPHAGEAL ANATOMY AND PHYSIOLOGY

The esophagus is, in essence, a muscular tube that connects the mouth to the stomach. The esophagus anatomically starts in the neck, traverses the thorax, and enters into the abdomen to join the stomach. It is ~20–25 cm in length, with the start of the esophagus being the upper esophageal sphincter and the end being the gastroesophageal junction. The upper esophageal sphincter is primarily made up of the cricopharyngeus muscle attached to the cricoid cartilage anteriorly. The musculature of the upper esophagus is made of striated muscle, and this transitions to smooth muscle in the lower esophagus. The esophagus is made up of three primarily layers: the inner-mucosa, the middle-submucosa, and the outer-muscle layer. The muscle layer is made up of an inner-circular muscle layer and an outer-longitudinal layer. At the inferior end of the esophagus is the lower esophageal sphincter. This is not a true anatomical sphincter, but rather a physiological high pressure zone that is the cumulation of thickening of the distal 5 cm of the esophageal musculature, the interaction of the esophagus with the diaphragmatic hiatus, and at 2 cm of intraabdominal esophagus. The lower esophageal sphincter should not be confused with the gastroesophageal junction, which is the entrance of the esophagus to the stomach, nor with the Z line, which is the transition of the esophageal squamous mucosa to the glandular gastric mucosa.

The lower esophageal sphincter is tonically contracted during rest to prevent reflux of gastric contents into the esophagus. It relaxes with a swallow. Swallowing is divided into an oral stage, pharyngeal stage, and esophageal stage. The oral and pharyngeal stage prepare food by chewing, the tongue pushing the food bolus to the pharynx, the soft palate is pulled upward, the vocal cords are closed and the epiglottis covers the larynx, the upper esophageal sphincter relaxes, and the contraction of the pharyngeal

muscles initiate the primary peristaltic wave. The esophageal stage consists of a peristaltic wave that pushes the food bolus to the stomach. There are primary peristaltic waves, which are initiated by the pharynx with a swallow. Secondary peristaltic waves are initiated within the esophagus due to distention of the esophagus with food. As the bolus reaches the lower esophagus, the lower esophageal sphincter relaxes.

INDICATIONS FOR ESOPHAGEAL MANOMETRY

Indications for esophageal manometry include the following five problems. (1) Dysphagia, to assess for an esophageal motility disorder, such as achalasia or nutcracker esophagus. It is important that mechanical causes of dysphagia, such as cancer, have been excluded. (2) Gastroesophageal reflux disease, not for primary diagnosis, but for possible surgical planning. (3) Noncardiac chest pain, which may be of esophageal origin. (4) Exclusion of generalized gastrointestinal disease (e.g., scleroderma or chronic idiopathic pseudoobstruction), and exclusion of an esophageal etiology for anorexia nervosa. (5) Determination of lower esophageal sphincter location for proper placement of an esophageal pH probe (2).

EQUIPMENT

The basic equipment used for manometry is the manometry catheter, infusion system (for water perfused systems), transducers, Polygraf or A/D converter, and computer with appropriate software (Fig. 1).

Esophageal manometry catheters come in two basic types: water perfused and solid state. The water perfused catheter contains several hollow tubes. Each tube has one side opening at a specific site on the catheter. The openings are at various points around the circumference of the catheter. There is a 4 cm catheter with side holes placed 5 cm apart, and a 8 cm catheter with 4 lumens placed 1 cm apart in the most distal end of the catheter, then 5 cm apart for the next proximal 4 lumens. The radial spacing helps to accurately measure upper and lower esophageal sphincter pressures that are asymmetrical. The water perfused catheters require an infusion system. The manometric pump uses regulated compressed nitrogen gas to deliver distilled water through the channels of the catheter. The pressurized water from each channel is connected to a single opening in the catheter within the patient's esophagus. The pressure changes are transmitted to the transducer, and these pressure changes are recorded and charted by a computer with the appropriate software.

The solid-state catheter has internal microtransducers. These directly measure intraesophageal pressures and contractions. Some advantages are that the sensors respond faster, do not require that the patient lie down, and record pressures circumferentially. An additional advantage is that as these catheters do not require fluid containers, potential pitfalls with fluid disinfection are avoided. Some drawbacks are that they are delicate, more expensive to purchase and repair, and are prone to baseline drift. As with the water-perfused system, the

Figure 1. The esophageal manometry console with computer. (Courtesy of Medtronic Corp., Minneapolis, MN.)

solid-state system requires that the catheter be connected to a computer console for recording and storing pressure data.

Additional items are needed. These include a manometer calibration tube for calibrating the solid-state catheter, a viscous lidocaine, a lubricating jelly, tissues, tape, an emesis basin, a syringe, a cup of water, a penlight, and tongue blades.

CONDUCT OF THE TESTING

Prior to the procedure, the pressure channels require calibration and connection to the computer console. The patient sits upright and one of the nares is anesthetized. Lubricating jelly is applied to the catheter and inserted through one of the nares into the pharynx. The patient is asked to swallow and the catheter advanced into the esophagus to the stomach. The catheter is advanced for ~65 cm to insure all the sensor ports are within the stomach. If using water-perfused catheters, the patient is moved to the supine position. If using solid-state catheters, the patient is kept in the semi-Fowler position, which is the head and torso of the patient at a 45° angle bent at the waist.

The esophageal motility study consists of (1) the lower esophageal sphincter study, (2) esophageal body study, and (3) the upper esophageal sphincter study. Before beginning the study, insure that all sensor ports are within the stomach by having the patient take a deep breath and

watching the motility recording. It should show a smooth tracing with a pressure increase during inspiration. An alternative method of determining that all side holes are within the stomach is to apply gentle pressure to the epigastrium to confirm that there is a simultaneous increase in the recorded pressure. When all channels are within the stomach, a gastric baseline is set to establish a reference for pressure changes.

The lower esophageal sphincter study measures sphincter pressure, length, location, and relaxation. This is done using either the “station pull-through” or “slow continuous pull through” methods. With the station pull-through technique, the catheter is slowly withdrawn through the sphincter at 1 cm increments while looking for changes in pressure. When the first channel enters the sphincter, pressure will increase from baseline by at least 2 mmHg (0.266 kPa). This identifies the lower border of the sphincter. As the catheter is continued to be pulled back, the “respiratory inversion point” is reached. This is the transition from the intraabdominal to the intrathoracic esophagus. With inspiration, the catheter will record positive pressures within the abdomen, but negative pressures within the thorax. Inferior to the respiratory inversion point is the lower esophageal sphincter high pressure zone. This is the physiologic landmark used to perform pressure measurements and relaxation studies. When the distal channel passes through the upper border of the lower esophageal sphincter, the pressure should decrease from baseline. The length traveled from the lower to the upper

Figure 2. Lower esophageal sphincter profile as determined by esophageal manometry. (Courtesy of Medtronic Corp., Minneapolis, MN.)

border of the sphincter measures the sphincter length. The slow continuous pull-through method is done while the catheter is pulled back continuously, while pressures are being recorded. The catheter is pulled back 1 cm every 10 s. These methods lead to identifying the distal and proximal borders of the sphincter, overall sphincter length, abdominal sphincter length, and resting sphincter pressure (Fig. 2). Sphincter relaxation involves observing the response of the lower esophageal sphincter to swallowing (Fig. 3). This is done by asking the patient to swallow 5 mL of water with the catheter positioned in the high

Figure 3. Manometric tracings of lower esophageal sphincter relaxation. (Courtesy of Medtronic Corp., Minneapolis, MN.)

Figure 4. Manometric tracings of esophageal body peristalsis. (Courtesy of Medtronic Corp., Minneapolis, MN.)

pressure zone. The pressures are recorded with the swallow. Accurate determination of lower esophageal relaxation requires a Dent sleeve. Although this can be measured using side holes, artifact can be created.

The study of the esophageal body determines the muscular activity of the esophagus during swallowing. There are four components of the study: (1) peristalsis, (2) amplitude of contractions, (3) duration of contraction, and (4) contraction morphology (Fig. 4). These measurements are made with the distal pressure sensor positioned 3 cm superior to the upper border of the lower esophageal sphincter. The patient takes 10 wet swallows with 5 mL of room temperature water. Esophageal body amplitude is the force with which the esophageal musculature contracts. The amplitude is measured from baseline to the peak of the contraction wave. Duration is the length of time that the esophageal muscle remains contracted. It is measured from the point at which the major upstroke of the contraction begins to the point at which it ends. Velocity is a measurement of the time it takes for a contraction to migrate down the esophagus (unit of measure is cm s^{-1}). These measurements are used to determine esophageal body motility function.

The study of the upper esophageal sphincter includes (1) resting pressure, (2) relaxation, and (3) cricopharyngeal coordination (Fig. 5). The study is done by withdrawing the catheter in 1 cm increments until the upper esophageal sphincter is reached. This is determined when the pressure measured rises above the esophageal baseline. The catheter

is positioned so that the first sensor is just superior to the sphincter and the second sensor is at the proximal border of the sphincter. The remaining channels are in the body of the esophagus. The patient is given 5 mL of water for wet swallows. The catheter is withdrawn during this process. However, it should be emphasized that the upper esophageal sphincter is quite asymmetric; therefore, pressure readings are meaningless unless the exact position of the side holes are known.

This concludes the study and the catheter is removed from the patient.

INTERPRETATION OF THE TEST

Esophageal motility disorders are categorized into primary, secondary, and nonspecific (3). Primary esophageal disorders are those in which the dysfunction is limited only to the esophagus. Examples of these include the hypotensive lower esophageal sphincter associated with gastroesophageal reflux disease, achalasia, diffuse esophageal spasm, hypertensive lower esophageal sphincter, and nutcracker esophagus. Secondary esophageal motility disorders are those in which the swallowing occurs as a result of a generalized disease. Examples of these include collagen-vascular disorders (e.g., scleroderma), endocrine and metabolic disorders (diabetes mellitus), neuromuscular diseases (myasthenia gravis, multiple sclerosis, and Parkinson's disease), chronic idiopathic intestinal pseudo-obstruction,

Figure 5. Manometric tracings of the upper esophageal sphincter. (Courtesy of Medtronic Corp., Minneapolis, MN.)

and Chagas' disease. Nonspecific esophageal motility disorders are those that are associated with the patient's symptoms, but the pattern of manometric dysmotility does not fit into the primary or secondary categories. Another category that is becoming better recognized and characterized is ineffective esophageal motility, which occurs when esophageal motility appears normal, but does not result in effective propagation of the food bolus down the esophagus.

INTRODUCTION

Our knowledge about the brain has increased dramatically in the last decades due to the incorporation of new and extraordinary techniques. In particular, fast computers enable more realistic and complex simulations and boosted the emergence of computational neuroscience. With modern acquisition systems we can record simultaneously up to few hundred neurons and deal with issues like population coding and neural synchrony. Imaging techniques such as magnetic resonance imaging (MRI) allow an incredible visualization of the locus of different brain functions. On the other extreme of the spectrum, molecular neurobiology has been striking the field with extraordinary achievements. In contrast to the progress and excitement generated by these fields of neuroscience, electroencephalography (EEG) and evoked potentials (EPs) have clearly decreased in popularity. What can we learn from scalp electrodes recordings, when one can use sophisticated devices like MRI, or record from dozens of intracranial electrodes? Still a lot.

There are mainly three advantages of the EEG: (1) it is relatively inexpensive; (2) it is noninvasive, and therefore it can be used in humans, (3) it has a very high temporal resolution, thus enabling the study of the dynamics of brain processes. These features make the EEG a very accessible and useful tool. It is particularly interesting for the analysis of high level brain processes that arise from the activity of large cell assemblies and may be poorly reflected by single neuron properties. Moreover, such processes can be well localized in time and even be reflected in time varying patterns (e.g., brain oscillations) that are faster than the time resolution of imaging techniques. The caveat of non-invasive EEGs is the fact that they reflect the average activity of sources far from the recording sites, and therefore do not have an optimal spatial resolution. Moreover, they are largely contaminated by noise and artifacts.

Although the way of recording EEG and EP signals did not change as much as multiunit recordings or imaging techniques, there have been significant advances in the methodology for analyzing the data. In fact, due to their high complexity, low signal/noise ratio, nonlinearity, and nonstationarity, they have been an ultimate challenge for most methods of signal analysis. The development and implementation of new algorithms that are specifically designed for such complex signals allow us to get information beyond the one accessible with previous approaches. These methods open a new gateway to the study of high level cognitive processes in humans with noninvasive techniques and at no great expense. Here, we review some of the most

common paradigms to elicit evoked potentials and describe basic and more advanced methods of analysis with special emphasis on the information that can be gained from their use. Although we focus on EEG recordings, these ideas also apply to magnetoencephalographic (MEG) recordings.

RECORDING

The electroencephalogram measures the average electrical activity of the brain at different sites of the head. Typical recordings are done at the scalp with high conductance electrodes placed at specific locations according to the so-called 10–20 system (1). The activity of each electrode can be referenced to a common passive electrode (or to a pair of linked electrodes placed at the earlobes)—monopolar recordings—or can be recorded differentially between pairs of contiguous electrodes—bipolar recordings—. In the latter case, there are several ways of choosing the electrode pairs. Furthermore, there are specific montages of bipolar recordings designed to visualize the propagation of activity across different directions (1). Intracranial recordings are common in animal studies and are very rare in humans. Intracranial electrodes are mainly implanted in epileptic patients refractory to medication in order to localize the epileptic focus, and then evaluate the feasibility of a surgical resection.

Figure 1 shows the 10–20 electrode distribution (a) and a typical monopolar recording of a normal subject with eyes

Figure 1. (a) Electrode montage of the 10–20 system and (b) an exemplary EEG recording with this montage. All electrodes are referenced to a linked earlobes reference (A1 and A2). F = frontal, C = central, P = parietal, T = temporal, and O = occipital. Note the presence of blinking artifacts (marked with an arrow) and of posterior alpha oscillations (marked with an oval).

open (b). Note the high amplitude deflections in the anterior recordings due to blinking artifacts. In fact, one of the main problems in EEG analysis is the very low signal/noise ratio. Note also the presence of ongoing oscillations in the posterior sites. These oscillations are ~ 10 Hz and are known as the alpha rhythm. The EEG brain oscillations of different frequencies and localizations have been correlated with functions, stages and pathologies of the brain (2–4).

In many scientific fields, especially in physics, one very useful way to learn about a system is by studying its reactions to perturbations. In brain research, it is also a common strategy to see how single neurons or large neuronal assemblies, as measured by the EEG, react to different types of stimuli. Evoked potentials are the changes in the ongoing EEG activity due to stimulation. They are time locked to the stimulus and they have a characteristic pattern of response that is more or less reproducible under similar experimental conditions. They are characterized by their polarity and latency, for example, P100 meaning a positive deflection (P for positive) occurring 100 ms after stimulation. The recording of evoked potentials is done in the same way as the EEGs. The stimulus delivery system sends triggers to identify the stimuli onsets and offsets.

GENERATION OF EVOKED POTENTIALS

Evoked potentials are usually considered as the time-locked and synchronized activity of a group of neurons that add to the background EEG. A different approach explains the evoked responses as a reorganization of the ongoing EEG (3,5). According to this view, evoked potentials can be generated by a selective and time-locked enhancement of a particular frequency band or by a phase resetting of ongoing frequencies. In particular, the study of the EPs in the frequency domain attracted the attention of several researchers (see section on Event-Related Oscillations). A few of these works focus on correlations between prestimulus EEG and the evoked responses (4).

SENSORY EVOKED POTENTIALS

There are mainly three modalities of stimulation: visual, auditory, and somatosensory. Visual evoked potentials are usually evoked by light flashes or visual patterns such as a checkerboard or a patch. Figure 2 shows the grand average visual evoked potentials of 10 subjects. Scalp electrodes were placed according to the 10–20 system, with linked earlobes reference. The stimuli were a color reversal of the (black/white) checks in a checkerboard pattern (sidelength of the checks: 50'). There is a positive deflection at ~ 100 ms after stimulus presentation (P100) followed by a negative rebound at 200 ms (N200). These peaks are best defined at the occipital electrodes, which are the closest to the primary visual area. The P100 is also observed in the central and frontal electrodes, but not as well defined and appearing later than in the posterior sites. The P100–N200 complex can be seen as part of an ~ 10 Hz event-related oscillation as it will be described in the following sections. Visual EPs can be used clinically to identify lesions in the

Figure 2. Grand average visual evoked potential. There is mainly one positive response at 100 ms after stimulation (P100) followed by a negative one at 200 ms (N200). These responses are best localized in the posterior electrodes.

visual pathway, such as the ones caused by optic neuritis and multiple sclerosis (6–9).

Auditory evoked potentials are usually elicited by tones or clicks. According to their latency they are further subdivided into early, middle, and late latency EPs. Early EPs comprise: (1) the electrocochleogram, which reflects responses in the first 2.5 ms from the cochlea and the auditory nerve, and (2) brain stem auditory evoked potentials (BSAEP), which reflect responses from the brain stem in the first 12 ms after stimulation and are recorded from the vertex. The BSAEP are seen at the scalp due to volume conduction. Early auditory EPs are mainly used clinically to study the integrity of the auditory pathway (10–12). They are also useful for detecting hearing impairments in children and in subjects that cannot cooperate in behavioral audiometry studies. Moreover, the presence of early auditory EPs may be a sign of recovery from coma.

Middle latency auditory EPs are a series of positive and negative waves occurring between 12 and 50 ms after stimulation. Clinical applications of these EPs are very limited due to the fact that the location of their sources is still controversial (10,11). Late auditory EPs occur between 50 and 250 ms after stimulation and consist of four main peaks labeled P50, N100, P150, and N200 according to their polarity and latency. They are of cortical origin and have a maximum amplitude at vertex locations. Auditory stimulation can also elicit potentials with latencies of > 200 ms. These are, however, responses to the context of the

stimulus rather than to its physical characteristics and will be further described in the next section.

Somatosensory EPs are obtained by applying short lasting currents to sensory and motor peripheral nerves and are mainly used to identify lesions in the somatosensory pathway (13). In particular, they are used for the diagnosis of diseases affecting the white matter like multiple sclerosis, for noninvasive studies of spinal cord traumas and for peripheral nerve disorders (13). They are also used for monitoring the spinal cord during surgery, giving an early warning of a potential neurological damage in anesthetized patients (13).

Evoked potentials can be further classified as exogenous and endogenous. Exogenous EPs are elicited by the physical characteristics of the external stimulus, such as intensity, duration, frequency, and so on. In contrast, endogenous EPs are elicited by internal brain processes and respond to the significance of the stimulus. Endogenous EPs can be used to study cognitive processes as discussed in the next section.

EVOKED POTENTIALS AND COGNITION

Usually, the term evoked potentials refers to EEG responses to sensory stimulation. Sequences of stimuli can be organized in paradigms and subjects can be asked to perform different tasks. Event-related potentials (ERPs) constitute a broader category of responses that are elicited by “events”, such as the recognition of a “target” stimulus or the lack of a stimulus in a sequence.

Oddball Paradigm and P300

The most common method to elicit ERPs is by using the oddball paradigm. Two different stimuli are distributed pseudorandomly in a sequence; one of them appearing frequently (standard stimulus), the other one being a target stimulus appearing less often and unexpectedly. Standard and target stimuli can be tones of different frequencies, figures of different colors, shapes, and so on. Subjects are usually asked to count the number of target appearances in a session, or to press a button whenever a target stimulus appears.

Figure 3 shows grand-average (10 subjects) visual evoked potentials elicited with an oddball paradigm. Figure 3 a shows the average responses to the frequent (non target) stimuli and (b) shows one to the targets. The experiment was the same as the one described in Fig. 2, but in this case target stimuli were pseudorandomly distributed within the frequent ones. Frequent stimuli (75%) were color reversals of the checks, as in the previous experiment, and target stimuli (25%) were also color reversals but with a small displacement of the checkerboard pattern (see Ref. (14) for details). Subjects had to pay attention to the appearance of the target stimuli.

The responses to the nontarget stimuli are qualitatively similar to the responses to visual EPs (without a task) shown in Fig. 2. As in the case of pattern visual EPs, the P100–N200 complex can be observed upon nontarget and target stimulation. These peaks are mainly related with primary sensory processing due to the fact that they do not depend on the task, they have a relatively short latency

Figure 3. Grand-average pattern visual evoked potentials with an oddball paradigm. (a) Average responses for the nontarget stimuli and (b) average responses for the target stimuli. Note the appearance of a positive deflection at ~ 400 ms after stimulation (P300) only upon the target stimuli.

(100 ms) and they are best defined in the primary visual area (occipital lobe). Note, however, that these components can also modulate their amplitude in tasks with different attention loads (15,16). Target stimulation led to a marked positive component, the P300, occurring between 400 and 500 ms. The P300 is larger in the central and posterior locations.

While the localization of the P300 in the scalp is well known, the localization of the sources of the P300 in the brain are still controversial (for a review see Ref. (17)). Since the P300 is task dependent and since it has a relatively long latency, it is traditionally related to cognitive processes such as signal matching, recognition, decision making, attention and memory updating (6,18,19). There have been many works using the P300 to study cognitive processes [for reviews see Refs. (18–20)]. In various pathologies cognition is impaired and this is reflected in abnormal P300 responses, as shown in depression, schizophrenia, dementia and others [for reviews see (18,21)].

The P300 can be also elicited by a passive oddball paradigm (i.e., an oddball sequence without any task). In this case, a P300 like response appears upon target stimulation, reflecting the novelty of the stimulus rather than the execution of a certain task. This response has been named P3a. It is earlier than the classic P300 (also named P3b), it is largest in frontal and central areas and it habituates quickly (22,23).

Mismatch Negativity

Mismatch negativity (MMN) is a negative potential elicited by auditory stimulation. It appears along with any change in some repetitive pattern and peaks between 100 and 200 ms after stimulation (24). It is generally elicited by the passive (i.e., no task) auditory oddball paradigm and it is visualized by subtracting the frequent stimuli from the deviant one. The MMN is generated in the auditory cortex. It is known to reflect auditory memory (i.e., the memory trace of preceding stimuli) and can be elicited even in the absence of attention (25). It provides an index of sound discrimination and has therefore being used to study dyslexia (25). Since MMN reflects a pre-attentive state, it can be also elicited during sleep (26). Moreover, it has been proposed as an index for coma prognosis (27,28).

Omitted Evoked Potentials

Omitted evoked potentials (OEPs) are similar in nature to the P300 and MMN, but they are evoked by the omission of a stimulus in a sequence (29–31). The nice feature of these potentials is that they are elicited without external stimulation, thus being purely endogenous components. Omitted evoked potentials mainly reflect expectancy (32) and are modulated by attention (31,33). The main problem in recording OEPs is the lack of a stimulus trigger. This results in large latency variations from trial to trial, and therefore OEPs may not be visible after ensemble averaging. Note that trained musicians were shown to have less variability in the latency of the OEP responses (latency jitter) in comparison to non-musicians due to their better time-accuracy (34).

Contingent Negative Variation

Contingent negative variation (CNV) is a slowly rising negative shift appearing before stimulus onset during periods of expectancy and response preparation (35). It is usually elicited by tasks resembling conditioned learning experiments. A first stimulus gives a preparatory signal for a motor response to be carried out at the time of a second stimulus. The CNV reflects the contingency or association between the two stimuli. It has been useful for the study of aging and different psychopathologies, such as depression and schizophrenia (for reviews see Refs. (36,37)). Similar in nature to the CNVs are the “Bereitschaft” or “Readiness” potentials (38), which are negative potential shifts preceding voluntary movements [for a review see Ref. (36)].

N400

Of particular interest are ERPs showing signs of language processing. Kutas and Hillyard (39,40) described a negative deflection between 300 and 500 ms after stimulation (N400), correlated with the appearance of semantically anomalous words in otherwise meaningful sentences. It reflects “semantic memory”; that is, the predictability of a word based on the semantic content of the preceding sentence (16).

Error Related Negativity

The error related negativity (ERN) is a negative component that appears after negative feedback (41,42). It can be elicited with a wide variety of reaction time tasks and it peaks within 100 ms of an error response. It reaches its maximum over frontal and central areas and convergent evidence from source localization analyses and imaging studies point toward a generation in the anterior cingulate cortex (41).

BASIC ANALYSIS

Figure 4a shows 16 single-trial visual ERPs from the left occipital electrode of a typical subject. These are responses to target stimuli using the oddball paradigm described in the previous section. Note that it is very difficult to distinguish the single-trial ERPs due to their low amplitude and due to their similarity to spontaneous fluctuations in the EEG. The usual way to improve the visualization of the ERPs is by averaging the responses of several trials. Since evoked potentials are locked to the stimulus onset, their contribution will add, whereas one of the ongoing EEG will cancel. Figure 4b shows the average evoked potential. Here it is possible to identify the P100, N200, and P300 responses described in the previous section.

The main quantification of the average ERPs is by means of their amplitudes and latencies. Most research using ERPs compare statistically the distribution of peak amplitudes and latencies of a certain group (e.g., subjects in some particular state or doing some task) with a matched control group. Such comparisons also can be used clinically and, in general, pathological cases show peaks with long latencies and small amplitudes (2,6).

Figure 4. (a) Sixteen single-trial responses of a typical subject and (b) the average response. The triangle marks the time of stimulation. Note that the evoked responses are clearly seen after averaging, but are hardly identified in the single trials.

Another important aspect of ERPs is their topography. In fact, the abnormal localization of evoked responses can have clinical relevance. The usual way to visualize the topography of the EPs is via contour plots (43–47). These are obtained from the interpolation of the EP amplitudes at fixed times. There are several issues to consider when analyzing topographic plots: (1) the way the 3D head is projected into two dimensions, (2) the choice of the reference, (3) the type of interpolation used, and (4) the number of electrodes and their separation (46). These choices can indeed bias the topographic maps obtained.

SOURCE LOCALIZATION

In the previous section, we briefly discussed the use of topographic representations of the EEG and EPs. Besides the merit of the topographic representation given by these maps, the final goal is to get a hint on the sources of the activity seen at the scalp. In other words, given a certain

distribution of voltages at the scalp one would like to estimate the location and magnitude of their sources of generation. This is known as the inverse problem and it has no unique solution. The generating sources are usually assumed to be dipoles, each one having six parameters to be estimated, three for its position and three for its magnitude. Clearly, the complexity of the calculation increases rapidly with the number of dipoles and, in practice, no more than two or three dipoles are considered. Dipole sources are usually estimated using spherical head models. These models consider the fact that the electromagnetic signal has to cross layers of different impedances, such as the dura mater and the skull. A drawback of spherical head models is the fact that different subjects have different head shapes. This led to the introduction of realistic head models, which are obtained by modeling the head shape using MRI scans and computer simulations. Besides all these issues, there are already some impressive results in the literature [see Refs. (49,86)] and references cited therein describing the use and applications of the LORETA

software; Ref. (50) and an extensive list of publications using the BESA software at <http://www.besa.de>). Since a reasonable estimation of the EEG and EP sources critically depends on the number of electrodes, dipole location has been quite popular for the analysis of magnetoencephalograms, which have more recording sites.

EVENT-RELATED OSCILLATIONS

Evoked responses appear as single peaks or as oscillations generated by the synchronous activation of a large network. The presence of oscillatory activity induced by different type of stimuli has been largely reported in animal studies. Bullock (51) gives an excellent review of the subject going from earlier studies by Adrian (52) to more recent results in the 1990s (some of the later studies are included in Ref. (53)). Examples are event-related oscillations of 15–25 Hz in the retina of fishes in response to flashes (54), gamma oscillations in the olfactory bulb of cats and rabbits after odor presentation (55,56) and beta oscillations in the olfactory system of insects (57,58). Moreover, it has been proposed that these brain oscillations play a role in information processing (55). This idea became very popular after the report of gamma activity correlated to the binding of perceptual information in anesthetized cats (59).

Event-related oscillations in animals are quite robust and in many cases visible by the naked eye. In humans, this activity is more noisy and localized in time. Consequently, more sophisticated time–frequency representations, like the one given by the wavelet transform, are needed in order to precisely localize event-related oscillations both in time and frequency. We finish this section with a cautionary note about event-related oscillations, particularly important for human studies. Since oscillations are usually not clear in the raw data, digital filters are used in order to visualize them. However, one should be aware that digital filters can introduce “ringing effects” and single peaks in the original signal can look like oscillations after filtering. In Fig. 5, we exemplify this effect by showing a delta function (a) filtered with a broad and a narrow band elliptic filter (b,c, respectively). Note that the original delta function can be mistaken for an oscillation after filtering, especially with the narrow band filter [see also Ref. (51)].

WAVELET TRANSFORM AND EVENT-RELATED OSCILLATIONS

Signals are usually represented either in the time or in the frequency domain. The best time representation is given by the signal itself and the best frequency representation is given by its Fourier transform (FT). With the FT it is possible to estimate the power spectrum of the signal, which quantifies the amount of activity for each frequency. The power spectrum has been the most successful method for the analysis of EEGs (2), but it lacks time resolution. Since event-related oscillations appear in a short time range, a simultaneous representation in time and frequency is more appropriate.

The Wavelet transform (WT) gives a time–frequency representation that has two main advantages: (1) optimal

Figure 5. A delta function (a) after broad (b) and narrow (c) band pass filtering. Note that single peaks can look like oscillations due to filtering.

resolution in the time and frequency domains; (2) no requirement of stationarity. It is defined as the correlation between the signal $x(t)$ and the wavelet functions $\psi_{a,b}(t)$

$$W_{\psi} X(a, b) = \langle x(t) | \psi_{a,b}(\tau) \rangle \tag{1}$$

where $\psi_{a,b}(t)$ are dilated (contracted) and shifted versions of a unique *wavelet function* $\psi(t)$

$$\psi_{a,b} = |a|^{-1/2} \psi\left(\frac{t-b}{a}\right) \tag{2}$$

(a, b are the scale and translation parameters, respectively). The WT gives a decomposition of $x(t)$ in different scales, tending to be maximum at those scales and time locations where the wavelet best resembles $x(t)$. Moreover, Eq. 1 can be inverted, thus giving the reconstruction of $x(t)$.

The WT maps a signal of one independent variable t onto a function of two independent variables a, b . This procedure is redundant and not efficient for algorithm implementations. In consequence, it is more practical to define the WT only at discrete scales a and discrete times b by choosing the set of parameters $\{a_j = 2^{-j}; b_j, k = 2^{-j}k\}$, with integers j, k .

Contracted versions of the wavelet function match the high frequency components of the original signal and the dilated versions match low frequency oscillations. Then, by correlating the original signal with wavelet functions of different sizes we can obtain the details of the signal at different scales. The correlations with the different wavelet functions can be arranged in a hierarchical scheme called multiresolution decomposition (60). The multiresolution decomposition separates the signal into “details” at different scales and the remaining part is a coarser representation named “approximation”.

Figure 6 shows the multiresolution decomposition of the average ERP shown in Fig. 4. The left part of the figure shows the wavelet coefficients and the right part shows the corresponding reconstructed waveforms. After a five octave wavelet decomposition using B-Spline wavelets (see Refs. 14,61 for details) the coefficients in the following bands were obtained (in brackets the EEG frequency bands that approximately correspond to these values): D1: 63–125 Hz, D2: 31–62 Hz (gamma), D3: 16–30 Hz (beta), D4:

Figure 6. Multiresolution decomposition (a) and reconstruction (b) of an average evoked potential. D1–D5 and A5 are the different scales in which the signal is decomposed.

8–15 Hz (alpha), D5: 4–7 Hz (theta), and A5: 0.5–4 Hz (delta). Note that the addition of the reconstructed waveforms of all frequency bands returns the original signal. In the first 0.5 s after stimulation there is an increase in the alpha and theta bands (D4, D5) correlated with P100–N200 complex and later there is an increase in the delta band (A5) correlated with the P300. As an example of the use of wavelets for the analysis of event related oscillations, in the following we focus on the responses in the alpha band.

The grand average (across subjects) ERP is shown on left side of Fig. 7. Upper plots correspond to the responses to NT stimuli and lower plots to *T* stimuli. Only left electrodes and Cz are shown, the responses of the right electrodes being qualitatively similar. For both stimulus types we observe the P100–N200 complex and the P300 appears only upon target stimulation. Center and right plots of Fig. 7 show the alpha band wavelet coefficients and the filtered ERPs reconstructed from these coefficients, respectively. Amplitude increases are distributed over the entire scalp for the two stimulus types, best defined in the occipital electrodes. They appear first in the occipital electrodes, with an increasing delay in the parietal, cen-

tral, and frontal locations. The fact that alpha responses are not modulated by the task and the fact that their maximal and earliest appearance is in occipital locations (the primary visual sensory area) point toward a distributed generation and a correlation with sensory processing (14,61). Note that these responses are localized in time, thus stressing the use of wavelets.

In recent years, there have been an increasing number of works applying the WT to the study of event-related oscillations. Several of these studies dealt with gamma oscillations, encouraged by the first results by Gray and coworkers (59). In particular, induced gamma activity has been correlated to face perception (62), coherent visual perception (63), visual search tasks (64) cross-modal integration (64,65), and so on.

Another interesting approach to study event-related oscillations is the one given by the concepts of event-related synchronization (ERS) and event-related desynchronization (ERD), which characterize increases and decreases of the power in a given frequency band (66,67). Briefly, the band limited power is calculated for each single trial and then averaged across trials. Since ERS and ERD are defined as an

Figure 7. Grand average visual EPs to nontarget (NT) and target (T) stimuli in an oddball paradigm (a). Both b+ and c plots shows the wavelet coefficients in the alpha band and the corresponding reconstruction of the signal from them, respectively.

average of the power of the signal, they are sensitive to phase locked as well as nonphase locked oscillations. Interestingly, similar concepts and a simple measure of phase locking can be also defined using wavelets (68).

SINGLE-TRIAL ANALYSIS

As shown in Fig. 4, averaging several trials increases the signal/noise ratio of the EPs. However, it relies on the basic assumption that EPs are an invariant pattern perfectly locked to the stimulus that lays on an independent stationary and stochastic background EEG signal. This assumption is in a strict sense not valid. In fact, averaging implies a loss of information related to systematic or unsystematic variations between the single trials. Furthermore, these variations (e.g., latency jitters) can affect the validity of the average EP as a representation of the single trial responses.

Several techniques have been proposed to improve the visualization of the single-trial EPs. Some of these approaches involve the filtering of single-trial traces by using techniques that are based on the Wiener formalism. This provides an optimal filtering in the mean-square error sense (69,70). However, these approaches assume that the signal is a stationary process and, since the EPs are compositions of transient responses with different time and frequency localizations, they are not likely to give optimal results. A obvious advantage is to implement time-varying strategies. In the following, we describe a recently proposed denoising implementation based on the WT to obtain the EPs at the single trial level (71,72). Other works also reported the use of wavelets for filtering average EPs or for visualizing the EPs in the single trials (73–77) see a brief discussion of these methods in Ref. 72.

In Fig. 6, we already showed the wavelet decomposition and reconstruction of an average visual EP. Note that the

P100–N200 response is mainly correlated with the first poststimulus coefficient in the details D4–D5. The P300 is mainly correlated with the coefficients at ~ 400 –500 ms in A5. This correspondence is easily identified because: (1) the coefficients appear in the same time (and frequency) range as the EPs and (2) they are relatively larger than the rest due to phase-locking between trials (coefficients related with background oscillations are diminished in the average). A straightforward way to avoid the fluctuations related with the ongoing EEG is by equaling to zero those coefficients that are not correlated with the EPs. However, the choice of these coefficients should not be solely based on the average EP and it should also consider the time ranges in which the single-trial EPs are expected to occur (i.e., some neighbor coefficients should be included in order to allow for latency jitters).

Figure 8a shows the coefficients kept for the reconstruction of the P100–N200 and P300 responses. Figure 8b shows the contributions of each level obtained by eliminating all the other coefficients. Note that in the final reconstruction of the average response (uppermost right plot) background EEG oscillations are filtered. We should remark that this is usually difficult to be achieved with a Fourier filtering approach due to the different time and frequency localizations of the P100–N200 and P300 responses, and also due to the overlapping frequency components of these peaks and the ongoing EEG. In this context, the main advantage of Wavelet denoising over conventional filtering is that one can select different time windows for the different scales. Once the coefficients of interest are identified from the average ERP, we can apply the same procedure to each single trial, thus filtering the contribution of background EEG activity.

Figure 9 shows the first 15 single trials and the average ERP for the recording shown in the previous figure. The raw single trials have been already shown in Fig. 4. Note that with denoising (red curves) we can distinguish the P100–N200 and the P300 in most of the trials. Note also that these responses are not easily identified in the original signal (gray traces) due to their similarity with the ongoing EEG. We can also observe some variability between trials. For an easier visualization Fig. 10 shows a contour plot of the single trial ERPs after denoising. This figure is the output of a software package for denoising EPs (EP_den) available at www.vis.caltech.edu/~rodri. In the denoised plot, we observe a gray pattern followed by a black one between 100 and 200 ms, corresponding to the P100–N200 peaks. The more unstable and wider gray pattern at ~ 400 –600 ms corresponds to the P300. In particular, it has been shown that wavelet denoising improves the visualization of the single trial EPs (and the estimation of their amplitudes and latencies) in comparison with the original data and in comparison with previous approaches, such as Wiener filtering (72).

APPLICATIONS OF SINGLE-TRIAL ANALYSIS

The single-trial analysis of EPs has a wide variety of applications. By using correlations between the average EP and the single-trial responses, it is possible to calculate

Figure 8. Principle of wavelet denoising. The reconstruction of the signal is done using only those coefficients correlated with the EPs. See text for details.

selective averages including only trials with good responses (71,72). Moreover, it is possible to eliminate effects of latency jitters by aligning trials according to the latency of the single-trial peaks (71,72). The use of selective averages as well as jitter corrected averages had been proposed long ago (78,79). Wavelet denoising improves the identification of the single-trials responses, thus facilitating the construction of these averages.

Some of the most interesting features to study in single-trial EPs are the changes in amplitude and latency of the peaks from trial to trial. It is possible to calculate amplitude and latency jitters: information that is not avail-

able in the average EPs. For example, trained musicians showed smaller latency jitters of omitted evoked potentials in comparison with nonmusicians (34). Variations in amplitude and latency can be also systematic. Exponential decreases in different EP components have been related to habituation processes both in humans and in rats (80–82). Furthermore, the appearance of a P3-like component in the rat entorhinal cortex has been correlated to the learning of a go/no-go task (83). In humans, it has recently been shown that precise timing of the single-trial evoked responses accounts for a sleep-dependent automatization of perceptual learning (84).

Figure 9. Average EP and the single-trial responses corresponding to the data shown in the previous figure, with (black) and without (gray) denoising. Note that after denoising it is possible to identify the single-trial responses.

Figure 10. Contour plot of the single-trial responses shown in the previous figure. The graphic user interface used to generate this plot is available at www.vis.caltech.edu/~rodri.

CONCLUDING COMMENT

In addition to clinical applications, EPs are very useful to study high level cognitive processes. Their main advantages over other techniques are their low cost, their non-invasiveness and their good temporal resolution. Of particular interest is the study of trial-to-trial variations during recording sessions. Supported by the use of new and powerful methods of signal analysis, the study of single trial EPs and their correlation to different behavioral processes seems one of the most interesting directions of future research. In conclusion, the good and old EEG and its cousin, the EP, have a lot to offer, especially when new and powerful methods of analysis are applied.

EXERCISE STRESS TESTING

HENRY CHEN
Stanford University
Palo Alto, California
VICTOR FROEHLICHER
VA Medical Center
Palo Alto, California

INTRODUCTION

Exercise is the body's most common physiologic stress, and while it affects several systems, it places major demands on the cardiopulmonary system. Because of this interaction, exercise can be considered the most practical test of cardiac perfusion and function. Exercise testing is a noninvasive tool to evaluate the cardiovascular system's response to exercise under carefully controlled conditions.

THEORY

The major cardiopulmonary adaptations that are required during acute exercise make exercise testing a practical evaluation of cardiac perfusion and function. Exercise testing is not only useful in clinical evaluation of coronary status, but also serves as a valuable research tool in the study of cardiovascular disease, evaluating physical performance in athletes, and studying the normal and abnormal physiology of other organ systems.

A major increase and redistribution of cardiac output underlies a series of adjustments that allow the body to increase its resting metabolic rate as much as 10–20 times with exercise. The capacity of the body to deliver and utilize oxygen is expressed as the maximal oxygen uptake, which is defined as the product of maximal cardiac output and maximal arteriovenous oxygen difference. Thus, the cardiopulmonary limits are defined by (1) a central component (cardiac output) that describes the capacity of the heart to function as a pump, and (2) peripheral factors (arteriovenous oxygen difference) that describe the capacity of the lung to oxygenate the blood delivered to it as well as the capacity of the working muscle to extract this oxygen from the blood. Hemodynamic responses to exercise are greatly affected by several parameters, such as presence or absence of disease and type of exercise being performed, as well as age, gender, and fitness of the individual.

Coronary artery disease is characterized by reduced myocardial oxygen supply, which, in the presence of an increased myocardial oxygen demand, can result in myocardial ischemia and reduced cardiac performance. Despite years of study, a number of challenges remain regarding the response to exercise clinically. Although myocardial perfusion and function are intuitively linked, it is often difficult to separate the impact of ischemia from that of left ventricular dysfunction on exercise responses. Indexes of ventricular function and exercise capacity are poorly related. Cardiac output is considered the most important determinant of exercise capacity in normal subjects and in most patients with cardiovascular or pulmonary disease. However, among patients with disease, abnormalities in one or several of the links in the chain that defines oxygen uptake contribute to the determination of exercise capacity.

The transport of oxygen from the air to the mitochondria of the working muscle cell requires the coupling of blood flow and ventilation to cellular metabolism. Energy for muscular contraction is provided by three sources: stored phosphates [adenosine triphosphate (ATP) and creatine phosphate]; oxygen-independent glycolysis, and oxidative metabolism. Oxidative metabolism provides the greatest source of ATP for muscular contraction. Muscular contraction is accomplished by three fiber types that differ in their contraction speed, color, and mitochondrial content. The duration and intensity of activity determine the extent to which these fuel sources and fiber types are called upon.

All of the physiologic responses to exercise are mediated by the autonomic nervous system. As such, the exercise test and the response in recovery after exercise are increasingly recognized as important surrogate measures of autonomic function. The balance between sympathetic and parasym-

pathetic influences to the cardiovascular system is critical, as they determine heart rate, blood pressure, cardiac output redistribution, and vascular resistance during exercise. Furthermore, indirect measures of autonomic function, such as heart rate variability and the rate in which heart rate recovers after exercise, are important prognostic markers in patients with cardiovascular disease (1).

There are several advantages to using the exercise test. These include the test's widespread availability, multiple uses, and high yield of clinically useful information. These factors make it an important "gatekeeper" for more expensive and invasive procedures. However, a major drawback has been the non-uniform application in clinical practices. To approach this problem, excellent guidelines have been developed based on expert consensus and research performed over the last 20 years. These include an update of the AHA/ACC guidelines on exercise testing, the American Thoracic Society/American College of Chest Physicians Statement on Cardiopulmonary Exercise Testing, an AHA Scientific Statement on Exercise and Heart Failure, new editions of the American Association of Cardiovascular and Pulmonary Rehabilitation Guidelines, and American College of Sports Medicine Guidelines on Exercise Testing and Prescription (cardiologyonline.com/guidelines.htm, cardiology.org). These have made substantial contributions to the understanding and greater uniformity of application of exercise testing.

EQUIPMENT

Current technology, although adding both convenience and sophistication, has raised new questions about methodology. For example, all commercially available systems today use computers. Do computer-averaged exercise electrocardiograms (ECGs) improve test performance, and what should the practitioner be cautious of when considering computer measurements? What about the many computer-generated exercise scores? When should ventilatory gas exchange responses be measured during testing and what special considerations are important when using them? The following text is intended to help answer such questions.

Blood Pressure Measurement

While there have been a number of automated devices developed for blood pressure measurement during exercise, our clinical impression is that they are not superior to manual testing. The time-proven method of the physician holding the patient's arm with a stethoscope placed over the brachial artery remains most reliable. An anesthesiologist's auscultatory piece or an electronic microphone can be fastened to the arm. A device that inflates and deflates the cuff with the push of a button can be helpful.

A dropping or a flat systolic response during exercise are ominous and can be the most important indicator of adverse events occurring during testing. If systolic blood pressure fails to increase or appears to be decreasing, it should be taken again immediately. The exercise test should be stopped if the systolic blood pressure drops by

10 mmHg (1.33 kPa) or more or falls below the value of the blood pressure taken in a standing position before testing. Additionally, if the systolic blood pressure exceeds 250 mmHg (33.33 kPa) or the diastolic blood pressure reaches 115 mmHg (15.33 kPa), the test should be stopped.

ECG Recording

Electrodes and Cables. Several disposable electrodes perform adequately for exercise testing. Disposable electrodes can be quickly applied and do not have to be cleaned for reuse. A disposable electrode that has an abrasive center spun by an applicator after the electrode is attached to the skin (Quickprep) is available from Quinton Instrument Co. This approach does not require skin preparation. The applicator of this system has a built-in impedance meter that stops the spinning when the skin impedance has been appropriately lowered.

Previously used buffer amplifiers and digitizers carried by the patient are no longer advantageous. Cables develop continuity problems with use and require replacement rather than repair. It is often found that replacement is necessary after roughly 500 tests. Some systems have used analog-to-digital converters in the electrode junction box carried by the patient. Because digital signals are relatively impervious to noise, the patient cable can be unshielded and is therefore very light.

Careful skin preparation and attention to the electrode-cable interface are important for a safe and successful exercise test and are necessary no matter how elaborate or expensive the ECG recording device used.

Lead Systems

Bipolar Lead Systems. Bipolar leads have been traditionally used owing to the relatively short time required for placement, the relative freedom from motion artifact, and the ease with which noise problems can be located. The usual positive reference is an electrode placed the same as the positive reference for V_5 (2). The negative reference for V_5 is Wilson's central terminal, which consists of connecting the limb electrodes to the right arm, left arm, and left leg. Virtually all current ECG systems, however, use the modified 12-lead system first described by Mason and Likar (3).

Mason-Likar Electrode Placement. Because a 12-lead ECG cannot be obtained accurately during exercise with electrodes placed on the wrists and ankles, the electrodes are placed at the base of the limbs for exercise testing. In addition to lessening noise for exercise testing, the Mason-Likar modified placement has been demonstrated to exhibit no differences in ECG configuration when compared to the standard limb lead placement (3). However, this finding has been disputed by others who have found that the Mason-Likar placement causes amplitude changes and axis shifts when compared with standard placement. Because these could lead to diagnostic changes, it has been recommended that the modified exercise electrode placement not be used for recording a resting ECG. The preexercise ECG has been further complicated by the recommendation that it should be obtained standing, since

that is the same position maintained during exercise. This situation is worsened by the common practice of moving the limb electrodes onto the chest to minimize motion artifact.

In the Mason-Likar torso-mounted limb lead system, the conventional ankle and wrist electrodes are replaced by electrodes mounted on the torso at the base of the limbs. This placement avoids artifact caused by movement of the limbs. The standard precordial leads use Wilson's central terminal as their negative reference, which is formed by connecting the right arm, left arm, and left leg. This triangular configuration around the heart results in a zero voltage reference through the cardiac cycle. The use of Wilson's central terminal for the precordial leads (V leads) requires the negative reference to be a combination of three additional electrodes rather than the single electrode used as the negative reference for bipolar leads.

The modified exercise electrode placement should not be used for routine resting ECGs. However, the changes caused by the exercise electrode placement can be kept to a minimum by keeping the arm electrodes off the chest and putting them on the anterior deltoid and by having the patient supine. In this situation, the modified exercise limb lead placement of Mason-Likar can serve well as the resting ECG reference before an exercise test.

For exercise testing, limb electrodes should be placed as far from the heart as possible, but not on the limbs; the ground electrode (right leg) can be on the back out of the cardiac field and the left leg electrode should be below the umbilicus. The precordial electrodes should be placed in their respective interspaces.

Inferior Lead ST-Segment Depression

One potential area of confusion in interpretation lies in ST-segment depression in the inferior leads. Miranda et al. (4) studied 178 men who had undergone exercise testing and coronary angiography to evaluate the diagnostic value of ST-segment depression occurring in the inferior leads. The area under the curve in lead II was not significantly > 0.50 , suggesting that for the identification of coronary artery disease, isolated ST-segment depression in lead II appears unreliable. The ST depression occurring in the inferior leads alone (II, AVF) can sometimes represent a false positive response. ST elevation in these leads, however, suggests transmural ischemia in the area of RCA blood distribution.

Number of Leads to Record

In patients with normal resting ECGs, a V_5 or similar bipolar lead along the long axis of the heart is usually adequate. The ECG evidence of myocardial infarction or history suggestive of coronary spasm necessitate use of additional leads. As a minimal overall approach, it is advisable to record three leads: a V_5 -type of lead, an anterior V_2 -type of lead, and an inferior lead, such as a V_F . Alternatively, Frank X, Y, and Z leads may be used. Either of these approaches can be helpful additionally for the detection and identification of dysrhythmias. It is also advisable to record a second three-lead grouping consisting of V_4 , V_5 , and V_6 . Occasionally abnormalities seen as borderline in V_5 can be better defined in neighboring V_4 or V_6 .

Because most meaningful ST-segment depression occurs in the lateral leads (V_4 , V_5 , and V_6) when the resting ECG is normal, other leads are only necessary in patients who had a myocardial infarction, those with a history consistent with coronary spasm or variant angina, or those who have exercise-induced dysrhythmias of an uncertain type.

Although as much as 90% of abnormal ST depression occurs in V_5 (or the two adjacent precordial leads), other leads should also be used, particularly in patients with history of known myocardial infarction or variant angina, and especially since ST elevation can localize ischemia to the area beneath the electrodes, and multiple-vector leads can be useful for studying arrhythmias (best diagnosed with inferior and anterior leads where the P waves are best seen).

ECG Recording Instruments

There have been several advances in ECG recorder technology. The medical instrumentation industry has promptly complied with specifications set forth by various professional groups. Machines with a high input impedance ensure that the voltage recorded graphically is equivalent to that on the surface of the body despite the high natural impedance of the skin. Optically isolated buffer amplifiers have ensured patient safety, and machines with a frequency response up to 100 Hz are commercially available. The lower end is possible because direct current (dc) coupling is technically feasible.

Waveform Processing

Analog and digital averaging techniques have made it possible to filter and average ECG signals to remove noise. There is a need for consumer awareness in these areas because most manufacturers do not specify how the use of such procedures modifies the ECG. Both filtering and signal averaging can, in fact, distort the ECG signal. Averaging techniques are nevertheless attractive because they can produce a clean tracing when the raw data is noisy. However, the clean-looking ECG signal produced may not be a true representation of the waveform and in fact may be dangerously misleading. Also, the instruments that make computer ST-segment measurements are not entirely reliable because they are based on imperfect algorithms. While useful in reducing noise, filtering and averaging can cause false ST depression due to distortion of the raw data.

Computerization

There are a host of advantages of digital over analog data processing. These include more accurate measurements, less distortion in recording, and direct accessibility to digital computer analysis and storage techniques. Other advantages are rapid mathematical manipulation (averaging), avoidance of the drift inherent in analog components, digital algorithm control permitting changes in analysis schema with ease (software rather than hardware changes), and no degradation with repetitive playback. When outputting data, digital processing also offers higher plotting resolution and easy repetitive manipulation.

Computerization also helps meet the two critical needs of exercise ECG testing: the reduction of the amount of ECG data collected during testing and the elimination of electrical noise and movement artifact associated with exercise. Because an exercise test can exceed 30 min (including data acquisition during rest and recovery) and many physicians want to analyze all 12 leads during and after testing, the resulting quantity of ECG data and measurements can quickly become excessive. The three-lead vectorcardiographic [or three-dimensional (3D) (i.e., aV_F , V_2 , V_5)] approach would reduce the amount of data; however, clinicians favor the 12-lead ECG. The exercise ECG often includes random and periodic noise of high and low frequency that can be caused by respiration, muscle artifact, electrical interference, wire continuity, and electrode-skin contact problems. In addition to reducing noise and facilitating data collection, computer processing techniques may also make precise and accurate measurements, separate and capture dysrhythmic beats, perform spatial analysis, and apply optimal diagnostic criteria for ischemia.

Although most clinicians agree that computerized analysis simplifies the evaluation of the exercise ECG, there has been disagreement about whether accuracy is enhanced (5). A comparison of computerized resting ECG analysis programs with each other and with the analyses of expert readers led to the conclusion that physician review of any reading is necessary (6). Although computers can record very clean representative ECG complexes and neatly print a wide variety of measurements, the algorithms they use are far from perfect and can result in serious differences from the raw signal. The physician who uses commercially available computer-aided systems to analyze the results of exercise tests should be aware of the problems and always review the raw analog recordings to see whether they are consistent with the processed output.

Even if computerization of the original raw analog ECG data could be accomplished without distortion, the problem of interpretation still remains. Numerous algorithms have been recommended for obtaining the optimal diagnostic value from the exercise ECG. These algorithms have been shown to provide improved sensitivity and specificity compared with standard visual interpretation. Often, however, this improvement has been demonstrated only by the investigator who proposed the new measurement. Furthermore, the ST measurements made by a computer can be erroneous. It is advisable to have the devices mark both the isoelectric level and the point of ST0. Even if the latter is chosen correctly, misplacement of the isoelectric line outside of the PR segment can result in incorrect ST level measurements. Computerized ST measurements require physician over reading; errors can be made both in the choice of the isoelectric line and the beginning of the ST segment.

Causes of Noise

Many of the causes of noise in the exercise ECG signal cannot be corrected, even by meticulous skin preparation. Noise is defined in this context as any electrical signal that

is foreign to or distorts the true ECG waveform. Based on this definition, the types of noise that may be present can be caused by any combination of line-frequency (60 Hz), muscle, motion, respiration, contact, or continuity artifact. Line-frequency noise is generated by the interference of the 60 Hz electrical energy with the ECG. This noise can be reduced by using shielded patient cables. If in spite of these precautions this noise is still present, the simplest way to remove it is to design a 60-Hz notch filter and apply it in series with the ECG amplifier. A notch filter removes only the line frequency; that is, it attenuates all frequencies in a narrow band ~ 60 Hz. This noise can also be removed by attenuating all frequencies > 59 Hz; however, this method of removing line-frequency noise is not recommended because it causes waveform distortion and results in a system that does not meet AHA specifications. The most obvious manifestation of distortion caused by such filters is a decrease in R-wave amplitude; therefore a true notch filter is advisable.

Muscle noise is generated by the activation of muscle groups and is usually of high frequency. This noise, with other types of high frequency noise, can be reduced by signal averaging. Motion noise, another form of high frequency noise, is caused by the movement of skin and the electrodes, which causes a change in the contact resistance. Respiration causes an undulation of the waveform amplitude, so the baseline varies with the respiratory cycle. Baseline wander can be reduced by low-frequency filtering; however, this results in distortion of the ST segment and can cause artifactual ST-segment depression and slope changes. Other baseline removal approaches have been used, including linear interpolation between isoelectric regions, high order polynomial estimates, and cubic-spline techniques, which can each smooth the baseline to various degrees.

Contact noise appears as low frequency noise or sometimes as step discontinuity baseline drift. It can be caused by poor skin preparation resulting in high skin impedance or by air bubble entrapment in the electrode gel. It is reduced by meticulous skin preparation and by rejecting beats that show large baseline drift. Also, by using the median rather than the mean for signal averaging, this type of drift can be reduced. Continuity noise caused by intermittent breaks in the cables is rarely a problem because of technological advances in cable construction, except, of course, when cables are abused or overused.

Most of the sources of noise can be effectively reduced by beat averaging. However, two types of artifact can actually be caused in the signal-averaging process by the introduction of beats that are morphologically different from others in the average and the misalignment of beats during averaging. As the number of beats included in the average increases, the level of noise reduction is greater. The averaging time and the number of beats to be included in the average have to be compromised, though, because the morphology of ECG waveforms changes over time.

For exercise testing, the raw ECG data should be considered first, and then the averages and filtered data may be used to aid interpretation if no distortion is obvious.

ECG Paper Recording

For some patients, it is advantageous to have a recorder with a slow paper speed option of $5 \text{ mm} \cdot \text{s}^{-1}$. This speed is optimal for recording an entire exercise test and reduces the likelihood of missing any dysrhythmias when specifically evaluating such patients. Some exercise systems allow for a total disclosure print out option similar to that provided and many holter systems. In rare instances, a faster paper speed of $50 \text{ mm} \cdot \text{s}^{-1}$ can be helpful for making particular evaluations, such as accurate ST-segment slope measurements.

Thermal head printers have effectively become the industry standard. These recorders are remarkable in that they can use blank thermal paper and write out the grid and ECG, vector loops, and alpha-numerics. They can record graphs, figures, tables, and typed reports. They are digitally driven and can produce very high resolution records. The paper price is comparable with that of other paper, and these devices have a reasonable cost and are very durable, particularly because a stylus is not needed.

Z-fold paper has the advantage over roll paper in that it is easily folded, and the study can be read in a manner similar to paging through a book. Exercise ECGs can be microfilmed on rolls, cartridges, or fiche cards for storage. They can also be stored in digital or analog format on magnetic media or optical disks. The latest technology involves magnetic optical disks that are erasable and have fast access and transfer times. These devices can be easily interfaced with microcomputers and can store megabytes of digital information. Lasers or ink jet printers have a delay making them unsuitable for medical emergencies but offer the advantage of the inexpensiveness of standard paper and long lived images.

Many available recording systems have both thermal head and laser or inkjet printers and use the cheaper, slower printers for final reports and summaries while the thermal head printers are used for live ECG tracings (i.e., real time). The standard 3 lead \times 4 lead groups print out leaves only 2.5 s to assess ST changes or arrhythmias.

Exercise Test Modalities

Types of Exercise. Two types of exercise can be used to stress the cardiovascular system: isometric and dynamic, though most activities are a combination of the two. Isometric exercise, which involves constant muscular contraction with minimal movement (e.g., a handgrip), imposes a disproportionate pressure load on the left ventricle relative to the body's ability to supply oxygen. Dynamic exercise, or rhythmic muscular activity resulting in movement, initiates a more appropriate balance between cardiac output, blood supply, and oxygen exchange. Because a delivered workload can be accurately calibrated and the physiological response easily measured, dynamic exercise is preferred for clinical testing. Dynamic exercise is also superior because it can be more easily graduated and controlled. Using gradual, progressive workloads, patients with coronary artery disease can be protected from rapidly increasing myocardial oxygen demand. Although bicycling is also a dynamic exercise, most individuals perform more work on a treadmill because of greater muscle mass

involved and generally more familiarity with walking than cycling.

Numerous modalities have been used to provide dynamic exercise for exercise testing, including steps, escalators, ladder mills, and arm ergometers. Today, however, the bicycle ergometer and the treadmill are the most commonly used dynamic exercise devices. The bicycle ergometer is usually cheaper, takes up less space, and makes less noise. Upper body motion is usually reduced, but care must be taken so that isometric exercise is not performed by the arms. The workload administered by the simple, manually braked cycle ergometers is not well calibrated and depends on pedaling speed. It can be easy for a patient to slow pedaling speed during exercise testing and decrease the administered workload, making the estimation of exercise capacity unreliable. More expensive electronically braked bicycle ergometers keep the workload at a specified level over a wide range of pedaling speeds, and have become the standard for cycle ergometer testing today.

Dynamic exercise, using a treadmill or a cycle ergometer, is a better measure of cardiovascular function and better method of testing than isometric exercise.

Arm Ergometry. Alternative methods of exercise testing are needed for patients with vascular, orthopedic, or neurological conditions who cannot perform leg exercise. Arm ergometry can be used in such patients (7). However, non-exercise techniques (such as pharmacologic stress testing) are currently more popular for these patients.

Bicycle Ergometer. The bicycle ergometer is usually cheaper, takes up less space, and makes less noise than a treadmill. Upper body motion is usually reduced, but care must be taken so that the arms do not perform isometric exercise. The workload administered by the simple bicycle ergometers is not well calibrated and is dependent on pedaling speed. It can be easy for a patient to slow pedaling speed during exercise testing and decrease the administered workload. More modern electronically braked bicycle ergometers keep the workload at a specified level over a wide range of pedaling speeds and are recommended. Since supine bicycle exercise is so rarely used, we will not address it here except to say that maximal responses are usually lower than with the erect position.

Treadmill. Treadmills should have front and side rails to allow patients to steady themselves. Some patients may benefit from the help of the person administering the test. Patients should not grasp the front or side rails because this decreases the work performed and the oxygen uptake and, in turn, increases exercise time, resulting in an overestimation of exercise capacity. Gripping the handrails also increases ECG muscle artifact. When patients have difficulty maintaining balance while walking, it helps to have them take their hands off the rails, close their fists, and extend one finger to touch the rails after they are accustomed to the treadmill. Some patients may require a few moments to feel comfortable enough to let go of the handrails, but grasping the handrails after the first minute of exercise should be strongly discouraged.

Table 1. Two Basic Principles of Exercise Physiology

Myocardial oxygen consumption	≈ Heart rate × systolic blood pressure (determinants include wall tension ≈ left ventricular pressure × volume; contractility; and heart rate)
Ventilatory oxygen consumption ($\dot{V}O_2$)	≈ External work performed, or cardiac output × a- $\dot{V}O_2$ difference ^a

^aThe arteriovenous O_2 difference is ~ 15–17 vol% at maximal exercise in most individuals; therefore, the $\dot{V}O_2$ max generally reflects the extent to which cardiac output increases.

A small platform or stepping area at the level of the belt is advisable so that the patient can start the test by pedaling the belt with one foot before stepping on. The treadmill should be calibrated at least monthly. Some models can be greatly affected by the weight of the patient and will not deliver the appropriate workload to heavy patients. An emergency stop button should be readily available to the staff only.

Bicycle Ergometer versus Treadmill

Bicycle ergometry has been found to elicit similar maximum heart rate values to treadmill exercise in most studies comparing the methods. However, maximum oxygen uptake has been 6–25% greater during treadmill exercise (8). Some studies have reported similar ECG changes with treadmill testing as compared with bicycle testing (9), whereas others have reported more significant ischemic changes with treadmill testing (10). Nonetheless, the treadmill is the most commonly used dynamic testing modality in the United States, and the treadmill may be advantageous because patients are more familiar with walking than they are with bicycling. Patients are more likely to give the muscular effort necessary to adequately increase myocardial oxygen demand by walking than by bicycling.

Treadmills usually result in a higher MET values, but maximal heart rate is usually the same as with a bike. Thus, bike testing can result in a lower prognosis estimate but has similar ability to predict ischemic disease.

Exercise Protocols

The many different exercise protocols in use have led to some confusion regarding how physicians compare tests between patients and serial tests in the same patient. A recent survey performed among VA exercise laboratories confirmed that the Bruce protocol remains the most commonly used; 83% of laboratories reported using the Bruce test for routine testing. This protocol uses relatively large and unequal increments in work (2–3 MET) every 3 min. Large and uneven work increments, such as these have been shown to result in a tendency to overestimate exercise capacity and the lack of uniform increases in work rate, can complicate the interpretation of some ST segment measurements and ventilatory gas exchange responses (11,12). (Table 1). Thus, exercise testing guidelines have recommended protocols with smaller and more equal increments. It is also important to individualize the test to target duration in the range of 8–12 min.

Ramp Testing

An approach to exercise testing that has gained interest in recent years is the ramp protocol, in which work increases constantly and continuously.

Questionnaires

The key to appropriately targeting a ramp is accurately predicting the individual's maximal work capacity. If a previous test is not available, a pretest estimation of an individual's exercise capacity is quite helpful to set the appropriate ramp rate. Functional classifications are too limited and poorly reproducible. One problem is that usual activities can decrease, so an individual can become greatly limited without having a change in functional class. A better approach is to use the specific activity scale of Goldman et al. (13) (Table 2), the DASI (Table 3), or the VSAQ (Table 4). Alternatively, the patient may be questioned regarding usual activities that have a known MET cost (Table 5) (14).

Borg Scale

Instead of simply tracking heart rate to clinically determine the intensity of exercise, it is preferable to use the 6–20 Borg scale or the nonlinear 1–10 scale of perceived exertion (Table 6) (15). The Borg scale is a simple, valuable way of assessing the relative effort a patient exerts during exercise.

Table 2. Specific Activity Scale of Goldman

Class I (≥ 7 METs)	A patient can perform any of the following activities: Carrying 24 lb (10.88 kg) up eight steps Carrying an 80 lb (16.28 kg) object Shoveling snow Skiing Playing basketball, touch football, squash, or handball Jogging/walking 5 mph
Class II (≥ 5 METs)	A patient does not meet Class I criteria, but can perform any of the following activities to completion without stopping: Carrying anything up eight steps Having sexual intercourse Gardening, raking, weeding Walking 4 mph
Class III (≥ 2 METs)	A patient does not meet Class I or Class II criteria but can perform any of the following activities to completion without stopping: Walking down eight steps Taking a shower Changing bedsheets Mopping floors, cleaning windows Walking 2.5 mph Pushing a power lawnmower Bowling Dressing without stopping
Class IV (≤ 2 METs)	None of the above

Activity	Weight
Can you?	
1. Take care of yourself, that is, eating, dressing, bathing, and using the toilet?	2.75
2. Walk indoors, such as around your house?	1.75
3. Walk a block or two on level ground?	2.75
4. Climb a flight of stairs or walk up a hill?	5.50
5. Run a short distance?	8.00
6. Do light work around the house like dusting or washing dishes?	2.7
7. Do moderate work around the house like vacuuming, sweeping floors, or carrying in groceries?	3.50
8. Do heavy work around the house like scrubbing floors or lifting and moving heavy furniture?	8.00
9. Do yard work like raking leaves, weeding, or pushing a power mower?	4.5
10. Have sexual relations?	5.25
11. Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a basketball or football?	6.00
12. Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?	7.50

^aDuke activity scale index = DASI = sum of weights for “yes” replies.
VO₂ = 0.43 × DASI + 9.6.

Postexercise Period

The patient should assume a supine position in the post-exercise period to achieve greatest sensitivity in exercise testing. It is advisable to record ~ 10 s of ECG data while the patient is motionless, but still experiencing near-maximal heart rate before having the patient lie down. Some patients must be allowed to lie down immediately to avoid hypotension. Letting the patient have a cool-down walk after the test is discouraged, as it can delay or eliminate the appearance of ST-segment depression (16). According to the law of La Place, the increase in venous return and thus ventricular volume in the supine position increases myocardial oxygen demand. Data from our laboratory (17) suggests that having patients lie down may enhance ST-segment abnormalities in recovery. However, a cool-down walk has been suggested to minimize the postexercise chances of dysrhythmic events in this high risk time when catecholamine levels are high. The supine position after exercise is not as important when the test is not being performed for diagnostic purposes, for example, fitness testing. When testing is not performed for diagnostic purposes, it may be preferable to walk slowly (1.0–1.5 mph) or continue cycling against zero or minimal resistance (up to 25 W when testing with a cycle ergometer) for several minutes after the test.

Monitoring should continue for at least 6–8 min after exercise or until changes stabilize. An abnormal response occurring only in the recovery period is not unusual. Such responses are not false positives. Experiments confirm mechanical dysfunction and electrophysiological abnormalities in the ischemic ventricle after exercise. A cool down walk can be helpful when testing patients with an

Table 4. Veterans Specific Activity Questionnaire^{a,b}

1 METs:	Eating; getting dressed; working at a desk
2 METs:	Taking a shower; shopping; cooking; walking down eight steps
3 METs:	Walking slowly on a flat surface for one or two blocks; doing moderate amounts of work around the house like vacuuming, sweeping the floors, or carrying in groceries
4 METs:	Doing light yard work, i.e., raking leaves, weeding, sweeping, or pushing a power mower; painting; light carpentry
5 METs:	Walking briskly; social dancing; washing the car
6 METs:	Playing nine holes of golf, carrying your own clubs; heavy carpentry; mowing lawn with a push mower
7 METs:	Carrying 60 lb; performing heavy outdoor work, that is, digging, spading soil; walking uphill
8 METs:	Carrying groceries upstairs; moving heavy furniture; jogging slowly on flat surface; climbing stairs quickly
9 METs:	Bicycling at a moderate pace; sawing wood; jumping rope (slowly)
10 METs:	Briskly swimming; bicycling up a hill; jogging 6 mph
11 METs:	Carrying a heavy load (i.e., a child or firewood) up two flights of stairs; cross-country skiing; bicycling briskly and continuously
12 METs:	Running briskly and continuously (level ground, 8 mph)
13 METs:	Performing any competitive activity, including those that involve intermittent sprinting; running competitively; rowing competitively; bicycle racing.

^aVeterans Specific Activity Questionnaire = VSAQ

^bBefore beginning your treadmill test today, we need to estimate what your usual limits are during daily activities. Following is a list of activities that increase in difficulty as you read down the page. Think carefully, then underline the first activity that, if you performed it for a period of time, would typically cause fatigue, shortness of breath, chest discomfort, or otherwise cause you to want to stop. If you do not normally perform a particular activity, try to imagine what it would be like if you did.

established diagnosis undergoing testing for other than diagnostic reasons, when testing athletes, or when testing patients with dangerous dysrhythmias.

The recovery period is extremely important for observing ST shifts and should not be interrupted by a cool down walk or failure to monitor for at least 5 min. Changes isolated to the recovery period are not more likely to be false positives.

The recovery period, particularly between the second and fourth minute, are critical for ST analysis. Noise should not be a problem and ST depression at that time has important implications regarding the presence and severity of coronary artery disease (CAD).

Additional Techniques

Several ancillary imaging techniques have been shown to provide a valuable complement to exercise electrocardiography for the evaluation of patients with known or suspected CAD. They can localize ischemia and thus guide interventions. These techniques are particularly helpful among patients with equivocal exercise electrocardiograms or those likely to exhibit false-positive or false-negative responses. The guidelines call for their use when testing patients with more than 1.0 mm of ST depression at rest, LBBB, WPW, and paced rhythms. They are frequently used to clarify abnormal ST segment responses in asymptomatic people or those in whom the cause of chest discomfort remains uncertain, often avoiding angiography. When exercise electrocardiography and an imaging technique are combined, the diagnostic and prognostic accuracy is enhanced. The major imaging procedures are myocardial perfusion and ventricular function studies using radionuclide techniques, and exercise echocardiography. Some of the newer add-ons or substitutes for the exercise test have the advantage of being able to localize ischemia as well as diagnose coronary disease when the baseline ECG exhibits the above-mentioned abnormalities, which negate the usefulness of ST analysis. While the

newer technologies are often suggested to have better diagnostic characteristics, this is not always the case particularly when more than the ST segments from the exercise test are used in scores. Pharmacologic stress testing is used in place of the standard exercise test for patients unable to walk or cycle or unable to give a good effort. These nonexercise stress techniques (persantine or adenosine with nuclear perfusion, dobutamine or arbutamine with echocardiography) permit diagnostic assessment of patients unable to exercise.

The ancillary imaging techniques are indicated when the ECG exhibits more than a millimeter of ST depression at rest, LBBB, WPW, and paced rhythms or when localization of ischemia is important.

Ventilatory Gas Exchange Responses

Because of the inaccuracies associated with estimating METs (ventilatory oxygen uptake) from workload (i.e., treadmill speed and grade), it can be important for many patients to measure physiologic work directly using ventilatory gas exchange responses, commonly referred to as cardiopulmonary exercise testing. Although this requires metabolic equipment, a facemask or mouthpiece and other equipment, advances in technology have made these measurements widely available. Cardiopulmonary exercise testing adds precision to the measurement of work and also permits the assessment of other parameters, including the respiratory exchange ratio, efficiency of ventilation, and the ventilatory anaerobic threshold. The latter measurement is helpful because it usually represents a comfortable sub maximal exercise limit and can be used for setting an optimal exercise prescription or an upper limit for daily activities. Clinically, this technology is often used to more precisely evaluate therapy, for the assessment of disability, and to help determine whether the heart or lungs limit exercise. Computerization of equipment has also led to the widespread use of cardiopulmonary exercise testing in sports medicine. Gas exchange measurements

Roller skating	6.5
Rope skipping	12.0
Skiing (water or downhill)	6.8
Squash	12.0
Surfing	6.0
Swimming (fast)	7.0
Tennis (doubles)	6.0

^aThese activities can often be done at variable intensities if one assumes that the intensity is not excessive and that the courses are flat (no hills) unless so specified.

can supplement the exercise test by increasing precision and providing additional information concerning cardio-pulmonary function during exercise. It is particularly needed to evaluate therapies using serial tests, since workload changes and estimated METs can be misleading. Because of their application for assessing prognosis in patients with heart failure, their use has become a standard part of the work-up for these patients.

Nuclear Techniques

Nuclear Ventricular Function Assessment. One of the first imaging modalities added to exercise testing was radionuclear ventriculography (RNV). This involved the intravenous injection of technetium tagged red blood cells. Using ECG gating of images obtained from a scintillation

camera, images of the blood circulating within the LV chamber could be obtained. While regurgitant blood flow from valvular lesions could not be identified, ejection fraction and ventricular volumes could be estimated. The resting values could be compared to those obtained during supine exercise and criteria were established for abnormal. The most common criteria involved a drop in ejection fraction. This procedure is now rarely performed because its test characteristics have not fulfilled their promise.

Nuclear Perfusion Imaging. After initial popularity, the blood volume techniques have become surpassed by nuclear perfusion techniques. The first agent used was thallium, an isotopic analog of potassium that is taken up at variable rates by metabolically active tissue. When taken up at rest, images of metabolically active muscle such as the heart are possible. With the nuclear camera placed over the heart after intravenous injection of this isotope, images were initially viewed using X-ray film. The normal complete donut shaped images gathered in multiple views would be broken by cold spots where scar was present. Defects viewed after exercise could be due to either scar or ischemia. Follow up imaging confirmed that the cold spots were due to ischemia if they filled in later. As computer imaging techniques were developed, 3D imaging (SPECT) and subtle differences could be plotted and scored. In recent years, ventriculograms based on the imaged wall as apposed to the blood in the chambers (as with RNV) could be constructed.

Because of the technical limitations of thallium (i.e., source and lifespan), it has largely been replaced by chemical compounds called isonitriles which could be tagged with technetium, which has many practical advantages over thallium as an imaging agent. The isonitriles are trapped in the microcirculation permitting imaging of the heart with a scintillation camera. Rather than a single injection as for thallium, these compounds require an injection at maximal exercise then later in recovery. The differences in technology over the years and the differences in expertise and software at different facilities can complicate the comparisons of the results and actual application of this technology. The ventriculograms obtained with gated perfusion scans do not permit the assessment of valvular lesions, or as accurate an assessment of wall motion abnormalities or ejection fraction as echocardiography.

Nuclear perfusion scans can now permit an estimation of ventricular function and wall motion abnormalities.

Echocardiography

Echocardiography has made a significant and impressive impact on the field of cardiology. This imaging technique comes second only to contrast ventriculography via cardiac catheterization for measuring ventricular volumes, wall motion, and ejection fraction. With Doppler added, regurgitant flows can be estimated as well. With such information available, this imaging modality was quickly added by echocardiographers to exercise testing. Most studies showed that supine, posttreadmill assessments were adequate and the more difficult imaging during exercise was not necessary. The patient must be placed supine as soon as possible after treadmill or bicycle exercise and imaging begun. A problem can occur when the imaging requires removal or displacement of the important V_5 electrode where as much as 90% of the important ST changes are observed.

Biomarkers

The latest ancillary measures added to exercise testing in an attempt to improve diagnostic accuracy are biomarkers. The first and most logical biomarker evaluated to detect ischemia brought out by exercise was troponin. Unfortunately, it has been shown that even in patients who develop ischemia during exercise testing, serum elevations in cardiac specific troponin do not occur, demonstrating that myocardial damage does not occur (18,19). B-type natriuretic peptide (BNP) is a hormone produced by the heart that is released by both myocardial stretching and by myocardial hypoxia. Armed with this knowledge, investigators have reported several studies suggesting improvement in exercise test characteristics with BNP and its isomers (20,21). BNP is also used to assess the presence severity of (CHF) coronary heart failure, and has been shown to be a powerful prognostic marker (22,23). The point of contact analysis techniques available for these assays involves a hand held battery powered unit that uses a replaceable cartridge. Finger stick blood samples are adequate for these analyses and the results are available immediately. If validated using appropriate study design (similar to

QUEXTA), biomarker measurements could greatly improve the diagnostic characteristics of the standard office-clinic exercise test.

In summary, use of proper methodology is critical for patient safety and accurate results. Preparing the patient physically and emotionally for testing is necessary. Good skin preparation will cause some discomfort but is necessary for providing good conductance and for avoiding artifact. The use of specific criteria for exclusion and termination, physician interaction with the patient, and appropriate emergency equipment are essential. A brief physical examination is always necessary to rule out important obstructive cardiomyopathy and aortic valve disease. Pretest standard 12-lead ECGs are needed in the supine and standing positions. The changes caused by exercise electrode placement can be kept to a minimum by keeping the arm electrodes off the chest, placing them on the shoulders, placing the leg electrodes below the umbilicus, and recording the baseline ECG supine. In this situation, the Mason-Likar modified exercise limb lead placement, if recorded supine, can serve as the resting ECG reference before an exercise test.

Few studies have correctly evaluated the relative yield or sensitivity and specificity of different electrode placements for exercise-induced ST-segment shifts. Using other leads in addition to V_5 will increase the sensitivity; however, the specificity is decreased. The ST-segment changes isolated to the inferior leads can on occasion be false-positive responses. For clinical purposes, vectorcardiographic and body surface mapping lead systems do not appear to offer any advantage over simpler approaches.

The exercise protocol should be progressive with even increments in speed and grade whenever possible. Smaller, even, and more frequent work increments are preferable to larger, uneven, and less frequent increases, because the former yield a more accurate estimation of exercise capacity. The value of individualizing the exercise protocol rather than using the same protocol for every patient has been emphasized by many investigators. The optimum test duration is from 8 to 12 min; therefore the protocol workloads should be adjusted to permit this duration. Because ramp testing uses small and even increments, it permits a more accurate estimation of exercise capacity and can be individualized to yield targeted test duration. An increasing number of equipment companies manufacture a controller that performs such tests using a treadmill.

Target heart rates based on age is inferior because the relationship between maximum heart rate and age is poor and scatters widely around many different recommended regression lines. Such heart rate targets result in a submaximal test for some individuals, a maximal test for others, and an unrealistic goal for some patients. Blood pressure should be measured with a standard stethoscope and sphygmomanometer; the available automated devices cannot be relied on, particularly for detection of exertional hypotension. Borg scales are an excellent means of quantifying an individual's effort. Exercise capacity should not be reported in total time but rather as the oxygen uptake or MET equivalent of the workload achieved. This method permits the comparison of the results of many different exercise testing protocols. Hyperventilation should be

avoided before testing. Subjects with and without disease may exhibit ST-segment changes with hyperventilation; thus, hyperventilation to identify false-positive responders is no longer considered useful by most researchers. The postexercise period is a critical period diagnostically; therefore the patient should be placed in the supine position immediately after testing.

EVALUATION

Hemodynamics involves studying the body's adaptations to exercise, commonly evaluated in heart rate and blood pressure. However, it also includes changes in cardiac output and its determinants, as well as the influence of cardiovascular disease on cardiac output. Exercise capacity is an important clinical measurement and is also influenced strongly by exercise hemodynamics. There are several factors that affect exercise capacity, and there is an important issue of how normal standards for exercise capacity are expressed.

When interpreting the exercise test, it is important to consider each of its responses separately. Each type of response has a different impact on making a diagnostic or prognostic decision and must be considered along with an individual patient's clinical information. A test should not be called abnormal (or positive) or normal (or negative), but rather the interpretation should specify which responses were abnormal or normal, and each particular response should be recorded. The final report should be directed to the physician who ordered the test and who will receive the report. It should contain clear information that helps in patient management rather than vague "med-speak". Interpretation of the test is highly dependent upon the application for which the test is used and on the population tested.

Predicting Severe Angiographic Disease

Exercise Test Responses. Studies have long attempted to assess for disease in the left main coronary artery using exercise testing (24–26). Different criteria have been used with varying results. Predictive value here refers to the percentage of those with the abnormal criteria that actually had left main disease. Naturally, most of the false positives actually had coronary artery disease, but less severe forms. Sensitivity here refers to the percentage of those with left main disease only that are detected. These criteria have been refined over time and the last study by Weiner using the CASS data deserves further mention (27). A markedly positive exercise test (Table 7) defined as 0.2 mV or more of downsloping ST-segment depression beginning at 4 METs, persisting for at least six minutes into recovery, and involving at least five ECG leads had the

greatest sensitivity (74%) and predictive value (32%) for left main coronary disease. This abnormal pattern identified either left main or three-vessel disease with a sensitivity of 49%, a specificity of 92% and a predictive value of 74%.

It appears that individual clinical or exercise test variables are unable to detect left main coronary disease because of their low sensitivity or predictive value. However, a combination of the amount, pattern, and duration of ST-segment response was highly predictive and reasonably sensitive for left main or three-vessel coronary disease. The question still remains of how to identify those with abnormal resting ejection fractions, those that will benefit the most with prolonged survival after coronary artery bypass surgery. Perhaps those with a normal resting ECG will not need surgery for increased longevity because of the associated high probability of normal ventricular function.

Blumenthal et al. (28) validated the ability of a strongly positive exercise test to predict left main coronary disease even in patients with minimal or no angina. The criteria for a markedly positive test included (1) early ST-segment depression, (2) 0.2 mV or more of depression, (3) downsloping ST depression, (4) exercise-induced hypotension, (5) prolonged ST changes after the test, and (6) multiple areas of ST depression. While Lee et al. (29) included many clinical and exercise test variables, only three variables were found to help predict left main disease: angina type, age, and the amount of exercise-induced ST segment depression.

Meta Analysis of Studies Predicting Angiographic Severity

To evaluate the variability in the reported accuracy of the exercise ECG for predicting severe coronary disease, Detrano et al. (30) applied meta analysis to 60 consecutively published reports comparing exercise-induced ST depression with coronary angiographic findings. The 60 reports included 62 distinct study groups comprising 12,030 patients who underwent both tests. Both technical and methodologic factors were analyzed. Wide variability in sensitivity and specificity was found [mean sensitivity 86% (range 40–100%); mean specificity 53% (range 17–100%)] for left main or triple vessel disease. All three variables found to be significantly and independently related to test performance were methodological. Exclusion of patients with right bundle branch block and receiving digoxin improved the prediction of triple vessel or left main coronary artery disease and comparison with a better exercise test decreased test performance.

Hartz et al. (31) compiled results from the literature on the use of the exercise test to identify patients with severe coronary artery disease. Pooled estimates of sensitivity and specificity were derived for the ability of the exercise test to identify three-vessel or left main coronary artery disease. One millimeter criteria averaged a sensitivity of 75% and a specificity of 66% while two millimeters criteria averaged a sensitivity of 52% and a specificity of 86%. There was great variability among the studies examined in the estimated sensitivity and specificity for severe coronary artery disease that could not be explained by their analysis.

Table 7. Markedly Positive Treadmill Test Responses

Markedly Positive Treadmill Test Responses
More than 0.2 mV downsloping ST-segment depression
Involving five or more leads
Occurring at < 5 METs
Prolonged ST depression late into recovery

Table 8. Summary of Studies Assessing Maximal Heart Rate

Investigator	No. Subjects	Population ^a Studied	Mean Age \pm SD (Range)	Mean HR Max (SD)	Regression Line	Correlation ^a Coefficient	Standard Error of the Estimate, beats/min ^a
Astrand ^b	100	Asymptomatic men	50 (20–69)	166 \pm 22	$y = 211 - 0.922$ (age)	NA	NA
Bruce	2091	Asymptomatic men	44 \pm 8	181 \pm 12	$y = 210 - 0.662$ (age)	-0.44	14
Cooper	2535	Asymptomatic men	43 (11–79)	181 \pm 16	$y = 217 - 0.845$ (age)	NA	NA
Ellestad ^c	2583	Asymptomatic men	42 \pm 7 (10–60)	173 \pm 11	$y = 197 - 0.556$ (age)	NA	NA
Froelicher	1317	Asymptomatic men	38 \pm 8 (28–54)	183	$y = 207 - 0.64$ (age)	-0.43	10
Lester	148	Asymptomatic men	43 (15–75)	187	$y = 205 - 0.411$ (age)	-0.58	NA
Robinson	92	Asymptomatic men	30 (6–76)	189	$y = 212 - 0.775$ (age)	NA	NA
Sheffield	95	Men with CHD	39 (19–69)	176 \pm 14	$y \pm 216 - 0.88$ (age)	-0.58	11 ^d
Bruce	1295	Men with CHD	52 \pm 8	148 \pm 23	$y = 204 - 1.07$ (age)	-0.36	25 ^d
Hammond	156	Men with CHD	53 \pm 9	157 \pm 20	$y = 209 - 1.0$ (age)	-0.30	19
Morris	244	Asymptomatic men	45 (20–72)	167 \pm 19	$y = 200 - 0.72$ (age)	-0.55	15
Graettinger	114	Asymptomatic men	46 \pm 13 (19–73)	168 \pm 18	$y = 199 - 0.63$ (age)	-0.47	NA
Morris	1388	Men referred for evaluation for CHD, normals only	57 (21–89)	144 \pm 20	$y = 196 - 0.9$ (age)	-0.43	21

^aCHD = coronary heart disease; HR max = maximal heart rate; NA = not able to calculate from available data.

^bAstrand used bicycle ergometry; all other studies were performed on a treadmill.

Studies Using Multivariate Techniques to Predict Severe Angiographic CAD

Multiple studies have reported combining the patient's medical history, symptoms of chest pain, hemodynamic data, exercise capacity and exercise test responses to calculate the probability of severe angiographic coronary artery disease (32–43). The results are summarized in Table 8. Of the 13 studies, 9 excluded patients with previous coronary artery bypass surgery or prior percutaneous coronary intervention (PCI) and in the remaining 4 studies, exclusions were unclear. The percentage of patients with one vessel, two vessels and three vessels was described in 10 of the 13 studies. The definition of severe disease or disease extent also differed. In 5 of the 13 studies disease extent was defined as multivessel disease. In the remaining 8 studies, it was defined as three-vessel or left main disease and in one of them as only left main artery disease and in another the impact of disease in the right coronary artery disease on left main disease was considered. The prevalence of severe disease ranged from 16 to 48% in the studies defining disease extent as multivessel disease and from 10 to 28% in the studies using the more strict criterion of three-vessel or left main disease.

Chosen Predictors

Interestingly, some of the variables chosen for predicting disease severity are different than those for predicting disease presence. While gender and chest pain were chosen to be significant in more than half of the severity studies, age was less important and resting ECG abnormalities and diabetes were the only other variables chosen in more than half the studies. In contrast, the most consistent clinical

variables chosen for diagnosis were age, gender, chest pain type, and hypercholesterolemia. ST depression and slope were frequently chosen for severity, but METs and heart rate were less consistently chosen than for diagnosis. Double product and delta SBP were chosen as independent predictors in more than half of the studies predicting severity.

Consensus to Improve Prediction

So far, only two studies [Detrano et al. (41) and Morise et al. (38)] have published equations that have been validated in large patient samples. Even though validated, however, the equations from these studies must be calibrated before they can be applied clinically. For example, a score can be discriminating but provide an estimated probability that is higher or lower than the actual probability. The scores can be calibrated by adjusting them according to disease prevalence; most clinical sites however, do not know their disease prevalence and even so, it could change from month to month.

In NASA trajectories of spacecraft are often determined by agreement between three or more equations calculating the vehicle path. With this in mind, we developed an agreement method to classify patients into high, no agreement, or low risk groups for probability of severe disease by requiring agreement in all three equations [Detrano, Morise, and ours (LB-PA)] (44). This approach adjusts the calibration and makes the equations applicable in clinical populations with varying prevalence of coronary artery disease.

It was demonstrated that using simple clinical and exercise test variables could improve the standard application of

ECG criteria for predicting severe coronary artery disease. By setting probability thresholds for severe disease of < 20% and > 40% for the three prediction equations, the agreement approach divided the test set into populations with low, no agreement, and high risk for severe coronary artery disease. Since the patients in the no agreement group would be sent for further testing and would eventually be correctly classified, the sensitivity of the agreement approach is 89% and the specificity is 96%. The agreement approach appeared to be unaffected by disease prevalence, missing data, variable definitions, or even by angiographic criterion. Cost analysis of the competing strategies revealed that the agreement approach compares favorably with other tests of equivalent predictive value, such as nuclear perfusion imaging, reducing costs by 28% or \$504 per patient in the test set.

Requiring agreement of these three equations to make diagnosis of severe coronary disease has made them widely applicable. Excellent predictive characteristics can be obtained using simple clinical data entered into a computer. Cost analysis suggests that the agreement approach is an efficient method for the evaluation of populations with varying prevalence of coronary artery disease, limiting the use of more expensive noninvasive and invasive testing to patients with a higher probability of left main or three vessel coronary artery disease. This approach provides a strategy for assisting the practitioner in deciding when further evaluation is appropriate or interventions indicated.

Predicting Improved Survival with Coronary Artery Bypass Surgery

Which exercise test variables indicate those patients who would have an improved prognosis if they underwent coronary artery bypass surgery (CABS)? Research in this area is limited by the fact the available studies did not randomize patients to surgery based on the results of their exercise test results and the retrospective nature of the studies.

Bruce et al. (45) demonstrated noninvasive screening criteria for patients who had improved 4 year survival after coronary artery bypass surgery. Their data have come from 2000 men with coronary heart disease enrolled in the Seattle Heart Watch who had a symptom-limited maximal treadmill test; these subjects received usual community care, which resulted in 16% of them having coronary artery bypass surgery in nonrandomized fashion. Patients with cardiomegaly, < 5 MET exercise capacity and/or a maximal systolic blood pressure of < 130 would have a better outcome if treated with surgery. Two or more of the above parameters present the highest risk and the greater differential for improved survival with bypass. Four year survival in this group would be 94% for those that had surgery versus 67% for those who received medical management (in those who had two or more of the above factors). In the European surgery trial (46), patients who had an exercise test response of 1.5 mm of ST segment depression had improved survival with surgery. This also extended to those with baseline ST segment depression and those with claudication.

From the CASS study group (47), in > 5000 nonrandomized patients, though there were definite differences between the surgical and nonsurgical groups, this could be accounted for by stratification in subsets. The surgical benefit regarding mortality was greatest in the 789 patients with 1 mm ST segment depression at < 5 METs. Among the 398 patients with triple vessel disease with this exercise test response, the 7 year survival was 50% in those medically managed versus 81% in those who underwent coronary artery bypass surgery. There was no difference in mortality in randomized patients able to exceed 10 METs. In the VA surgery randomized trial (48), there was a 79% survival rate with CABS versus 42% for medical management in patients with two or more of the following: 2 mm or more of ST depression, heart rate of 140 or greater at 6 METs, and/or exercise-induced PVCs.

Evaluation of Percutaneous Coronary Interventions

One important application of the exercise test is to assess the effects of percutaneous coronary intervention (PCI) on physical function, ischemic responses, and symptoms in the immediate and longer period following the various interventions that now fall under the general term PCI. The exercise test has been used for this purpose in numerous trials of PCI, and a few notable examples are described in the following. Berger et al. (49) reported follow-up data in 183 patients who had undergone PCI at least 1 year earlier. PCI was initially successful in 141 patients (79%). Of the 42 patients in whom PCI was unsuccessful, 26 underwent CABG, while 16 were maintained on medical therapy. When compared to the medical patients at time of follow-up, successful PCI patients experienced less angina (13 vs. 47%), used less nitroglycerin (25 vs. 73%), were hospitalized less often for chest pain (8 vs. 31%), and subjectively felt their condition had improved (96 vs. 20%).

Vandormael and colleagues reported the safety and short-term benefit of multi-lesion PCI in 135 patients (50). Primary success, defined as successful dilation of the most critical lesion or all lesions attempted, occurred in 87% of the 135 patients. Exercise-induced angina occurred in 11 (12%) and an abnormal exercise ECG in 30 (32%) of the 95 patients with post-PCI exercise test data. Of 57 patients who had paired exercise test data before and after angioplasty, exercise-induced angina occurred in 56% of patients before the procedure, compared with only 11% of patients after angioplasty. Exercise-induced ST-segment depression of > 0.1 mV occurred in 75% of patients before PCI versus 32% after the procedure.

Rosing et al. (51) reported that exercise testing after successful PCI exhibited improved ECG and symptomatic responses, as well as improved myocardial perfusion and global and regional left ventricular function.

Prediction of Restenosis with the Exercise Test

To determine whether a treadmill test could predict restenosis after angioplasty, Honan et al. (52) studied 289 patients six months after a successful emergency angioplasty of the infarct-related artery for acute myocardial infarction (MI). After excluding those with interim interventions, medical events, or medical contraindications

to follow-up testing, both a treadmill test and a cardiac catheterization were completed in 144 patients; 88% of those eligible for this assessment. Of six clinical and treadmill variables examined by multivariable logistic analysis, only exercise ST deviation was independently correlated with restenosis. The sensitivity of ST deviation of 0.10 mV or greater for detecting restenosis was only 24% (13 of 55 patients), and the specificity was 88% (75 of 85 patients). Extent or severity of wall motion abnormalities at follow-up did not affect the sensitivity of exercise-induced ST deviation for detection of restenosis, by the timing of thrombolytic therapy or of angioplasty, or by the presence of collateral blood flow at the time of acute angiography. A second multivariable analysis evaluating the association of the same variables with number of vessels with significant coronary disease at the 6 month catheterization found an association with both exercise ST deviation and exercise duration. Angina symptoms and exercise test results in this population had limited value for predicting anatomic restenosis six months after emergency angioplasty for acute myocardial infarction.

Bengtson et al. (53) studied 303 consecutive patients with successful PCI and without a recent myocardial infarction. Among the 228 patients without interval cardiac events, early repeat revascularization or contraindications to treadmill testing, 209 (92%) underwent follow-up angiography, and 200 also had a follow-up treadmill test and formed the study population. Restenosis occurred in 50 patients (25%). Five variables were individually associated with a higher risk of restenosis: recurrent angina, exercise-induced angina, a positive treadmill test, greater exercise ST deviation, and a lower maximum exercise heart rate. However, only exercise-induced angina, recurrent angina, and a positive treadmill test were independent predictors of restenosis. Using these three variables, patient subsets could be identified with restenosis rates ranging from 11 to 83%. The exercise test added independent information to symptom status regarding the risk of restenosis after elective PCI. Nevertheless, 20% of patients with restenosis had neither recurrent angina nor exercise-induced ischemia at follow-up.

The ROSETTA registry was studied to demonstrate the effects of routine post-PCI functional testing on the use of follow-up cardiac procedures and clinical events (54). The ROSETTA (Routine versus Selective Exercise Treadmill Testing after Angioplasty) registry is a prospective multicenter observational study examining the use of functional testing after PCI. A total of 788 patients were enrolled in the registry at 13 clinical centers in 5 countries. The frequencies of exercise testing, cardiac procedures and clinical events were examined during the first 6 months following a successful PCI. Patients were predominantly elderly men (mean age, 61 ± 11 years; 76% male) who underwent single-vessel PCI (85%) with stent implantation (58%). During the 6 month follow-up, a total of 237 patients underwent a routine exercise testing strategy (100% having exercise testing for routine follow-up), while 551 pts underwent a selective (or clinically driven) strategy (73% having no exercise testing and 27% having exercise testing for a clinical indication). Patients in the routine testing group underwent a total of 344 exercise tests

compared with 165 tests performed in the selective testing group (mean, 1.45 tests/patient vs. 0.3 tests/patient). However, clinical events were less common among those who underwent routine exercise testing, for example, unstable angina (6% vs. 14%), myocardial infarction (0.4% vs. 1.6%), death (0% vs. 2%) and composite clinical events (6% vs. 16%). After controlling for baseline clinical and procedural differences, routine exercise testing had a persistent independent association with a reduction in the composite clinical event rate. This association may be attributable to the early identification and treatment of patients at risk for follow-up events, or it may be due to clinical differences between patients who are referred for routine and selective exercise testing.

The ACC/AHA Guidelines for the Prognostic Use of the Standard Exercise Test

The task force to establish guidelines for the use of exercise testing has met and produced guidelines in 1986, 1997, and 2002. The following is a synopsis of these evidence-based guidelines.

Indications for Exercise Testing to Assess Risk and prognosis in patients with symptoms or a prior history of CAD:

Class I (Definitely Appropriate). Conditions for which there is evidence and/or general agreement that the standard exercise test is useful and helpful to assess risk and prognosis in patients with symptoms or a prior history of CAD.

Patients undergoing initial evaluation with suspected or known CAD. Specific exceptions are noted below in Class IIb.

Patients with suspected or known CAD previously evaluated with significant change in clinical status.

Class IIb (Maybe Appropriate). Conditions for which there is conflicting evidence and/or a divergence of opinion that the standard exercise test is useful and helpful to assess risk and prognosis in patients with symptoms or a prior history of coronary artery disease but the usefulness/efficacy is less well established.

Patients who demonstrate the following ECG abnormalities: pre excitation (Wolff–Parkinson White) syndrome; electronically paced ventricular rhythm; > 1 mm of resting ST depression; and complete left bundle branch block.

Patients with a stable clinical course who undergo periodic monitoring to guide management

Class III (Not Appropriate). Conditions for which there is evidence and/or general agreement that the standard exercise test is not useful and helpful to assess risk and prognosis in patients with symptoms or a prior history of CAD and in some cases may be harmful.

Patients with severe comorbidity likely to limit life expectancy and/or candidacy for revascularization.

In summary, the two principal reasons for estimating prognosis are to provide accurate answers to patient's questions regarding the probable outcome of their illness and to identify those patients in whom interventions might improve outcome. There is a lack of consistency in the available studies because patients die along a pathophysiological spectrum ranging from those that die due to CHF with little myocardium remaining to those that die from an ischemic related event with ample myocardium remaining. Clinical and exercise test variables most likely associated with CHF deaths (CHF markers) include a history or symptoms of CHF, prior MI, Q waves, and other indicators of LV dysfunction. Variables most likely associated with ischemic deaths (ischemic markers) are angina, and rest and exercise ST depression. Some variables can be associated with either extremes of the type of CV death; these include exercise capacity, maximal heart rate, and maximal systolic blood pressure that may explain why they are reported most consistently in the available studies. A problem exists that ischemic deaths occur later in follow up and are more likely to occur in those lost to follow up whereas CHF deaths are more likely to occur early (within 2 years) and are more likely to be classified. Work-up bias probably explains why exercise-induced ST depression fails to be a predictor in most of the angiographic studies. Ischemic markers are associated with a later and lesser risk, whereas CHF or left ventricular dysfunction markers are associated with a sooner and greater risk of death.

Recent studies of prognosis have actually not been superior to the earlier studies that considered CV endpoints and removed patients from observation who had interventions. This is because death data is now relatively easy to obtain while previously investigators had to follow the patients and contact them or review their records. CV mortality can be determined by death certificates. While death certificates have their limitations, in general they classify those with accidental, GI, Pulmonary and cancer deaths so that those remaining are most likely to have died of CV causes. This endpoint is more appropriate for a test for CV disease. While all-cause mortality is a more important endpoint for intervention studies, CV mortality is more appropriate for evaluating a CV test (i.e., the exercise test). Identifying those at risk of death of any cause does not make it possible to identify those who might benefit from CV interventions, one of the main goals of prognostication.

The consistencies actually overshadow the differences. Considering simple clinical variables can assess risk. A good exercise capacity, no evidence or history of CHF or ventricular damage (Q waves, history of CHF), no ST depression or only one of these clinical findings are associated with a very low risk. These patients are low risk in exercise programs and need not be considered for interventions to prolong their life. High risk patients can be identified by groupings of the clinical markers; that is, two or more. Exertional hypotension is particularly ominous. Identification of high risk implies that such patients in exercise training programs should have lower goals and should be monitored. Such patients should also be considered for coronary interventions to improve their longevity. Furthermore, with each drop in METs there is a 10–20%

increase in mortality so simple exercise capacity has consistent importance in all patient groups.

The mathematical models for determining prognosis are usually more complex than those used for identifying severe angiographic disease. Diagnostic testing can utilize multivariate discriminant function analysis to determine the probability of severe angiographic disease being present or not. Prognostic testing must utilize survival analysis which includes censoring for patients with uneven follow-up due to "lost to follow up" or other cardiac events (i.e., CABS, PCI) and must account for time-person units of exposure. Survival curves must be developed and the Cox proportional hazards model is often preferred.

From this perspective, it is obvious that there is substantial support for the use of the exercise test as a first noninvasive step after the history, physical exam, and resting ECG in the prognostic evaluation of coronary artery disease patients. It accomplishes both of the purposes of prognostic testing: to provide information regarding the patient's status and to help make recommendations for optimal management. The exercise test results help us make reasonable decisions for selection of patients who should undergo coronary angiography. Since the exercise test can be performed in the doctor's office and provides valuable information for clinical management in regard to activity levels, response to therapy, and disability, the exercise test is the reasonable first choice for prognostic assessment. This assessment should always include calculation of the estimated annual mortality using the Duke treadmill score though its ischemic elements have less power in the elderly.

There has been considerable debate in screening asymptomatic patients. Screening has become a controversial topic because of the incredible efficacy of the statins (drugs that lower cholesterol) even in asymptomatic individuals (55). There are now agents that can cut the risk of cardiac events almost in half. The first step in screening asymptomatic individuals for preclinical coronary disease should be using global risk factor equations, such as the Framingham score. This is available as nomograms that are easily applied by healthcare professionals or it can be calculated as part of a computerized patient record. Additional testing procedures with promise include the simple ankle-brachial index (particularly in the elderly), CRP, carotid ultrasound measurements of intimal thickening, and the resting ECG (particularly spatial QRS-T wave angle). Despite the promotional concept of atherosclerotic burden, EBCT does not have test characteristics superior to the standard exercise test. If any screening test could be used to decide regarding statin therapy and not affect insurance or occupational status, this would be helpful. However, the screening test should not lead to more procedures.

True demonstration of the effectiveness of a screening technique requires randomizing the target population, applying the screening technique to half, taking standardized action in response to the screening test results, and then assessing outcomes. Efficacy of the screening test necessitates that the screened group has lower mortality and/or morbidity. Such a study has been completed for

mammography, but not for any cardiac testing modalities. The next best validation of efficacy is to demonstrate that the technique improves the discrimination of those asymptomatic individuals with higher risk for events over that possible with the available risk factors. Mathematical modeling makes it possible to determine how well a population will be classified if the characteristics of the testing method are known.

Additional follow-up studies and one angiographic study from the CASS population (where 195 individuals with abnormal exercise-induced ST depression and normal coronary angiograms were followed for 7 years) improve our understanding of the application of exercise testing as a screening tool. No increased incidence of cardiac events was found, and so the concerns raised by Erikssen's findings in 36 subjects that they were still at increased risk have not been substantiated.

The later follow-up studies (MRFIT, Seattle Heart Watch, Lipid Research Clinics, and Indiana State Police) have shown different results compared to prior studies, mainly because hard cardiac end points and not angina were required. The first ten prospective studies of exercise testing in asymptomatic individuals included angina as a cardiac disease end point. This led to a bias for individuals with abnormal tests to subsequently report angina or to be diagnosed as having angina. When only hard end points (death or MI) were used, as in the MRFIT, Lipid Research Clinics, Indiana State Police or the Seattle Heart Watch studies, the results were less encouraging. The test could only identify one-third of the patients with hard events and 95% of abnormal responders were false positives; that is, they did not die or have a MI. The predictive value of the abnormal maximal exercise electrocardiogram ranged from 5 to 46% in the studies reviewed. However, in the studies using appropriate endpoints (other than angina pectoris) only 5% of the abnormal responders developed coronary heart disease over the follow-up period. Thus, >90% of the abnormal responders were false positives. However, the exercise test's characteristics as a screening test probably lie in between the results with hard or soft endpoints since some of the subjects who develop chest pain really have angina and coronary disease. The sensitivity is probably between 30 and 50% (at a specificity of 90%) but the critical limitation is the predictive value (and risk ratio) which depends upon the prevalence of disease (which is low in the asymptomatic population).

Although some of these individuals have indolent coronary disease yet to be manifest, angiographic studies have supported this high false positive rate when using the exercise test in asymptomatic populations. Moreover, the CASS study indicates that such individuals have a good prognosis. In a second Lipid Research Clinics study, only patients with elevated cholesterol's were considered, and yet only a 6% positive prediction value was found. If the test is to be used to screen it should be done in groups with a higher estimated prevalence of disease using the Framingham score and not just one risk factor. The iatrogenic problems resulting from screening must be considered. Hopefully, using a threshold from the Framingham score would be more successful in identifying asymptomatic individuals that should be tested.

Some individuals who eventually develop coronary disease will change on retesting from a normal to an abnormal response. However, McHenry and Fleg have reported that a change from a negative to a positive test is no more predictive than is an initially abnormal test. One individual has even been reported who changed from a normal to an abnormal test, but was free of angiographically significant disease (56). In most circumstances an added imaging modality (echocardiographic or nuclear) should be the first choice in evaluating asymptomatic individuals with an abnormal exercise test.

The motivational impact of screening for CAD is not evidence based with one positive study for exercise testing and one negative study for EBCT. Further research in this area certainly is needed.

While the risk of an abnormal exercise test is apparent from these studies, the iatrogenic problems resulting from screening must be considered (i.e., employment, insurance). The recent U.S. Preventive Services Task Force statement states that "false positive tests are common among asymptomatic adults, especially women, and may lead to unnecessary diagnostic testing, over treatment and labeling". This statement summarizes the current U.S. Preventive Services Task Force (USPSTF) recommendations on screening for coronary heart disease and the supporting scientific evidence and updates the 1996 recommendations on this topic. The complete information on which this statement is based, including evidence tables and references, is available in the background article and the systematic evidence review, available through the USPSTF Web site (<http://www.preventiveservices.ahrq.gov>) and through the National Guideline Clearinghouse (<http://www.guideline.gov>) (57). In the majority of asymptomatic people, screening with any test or test add-on, is more likely to yield false positives than true positives. This is the mathematical reality associated with all of the available tests.

There are reasons to include exercise testing in the preventative health recommendations for screening healthy, asymptomatic individuals along with risk factor assessment. The additional risk classification power documented by the data from Norway (2000 men, 26 year follow up), the Cooper Clinic (26,000 men, 8 year follow up), and Framingham (3000 men, 18 year follow up) provide convincing evidence that the exercise test should be added to the screening process. Furthermore, exercise capacity itself has substantial prognostic predictive power. Given the emerging epidemic of physical inactivity, including the exercise test in the screening process sends a strong message to our patients that we consider their exercise status as important.

However, if screening could be performed in a logical way with test results helping to decide on therapies rather than leading to invasive interventions, insurance or occupational problems, then the recent results summarized above should be applied to preventive medicine policy.

Because of the inherent difficulties, few preventive medicine recommendations are based on randomized trials demonstrating improved outcomes but rely on reasonable assumptions from available evidence. There is now enough evidence to consider recommending a routine exercise test every five years for men > 40 and women > 50 years of age,

especially if one of the potential benefits is the adoption of an active lifestyle (58).

CONCLUSION

While there are important technological considerations and the need to be very knowledgeable of the guidelines to insure its proper application, exercise testing remains one of the most widely used and valuable noninvasive tools to assess cardiovascular status.

The following precepts regarding methodology are important to follow:

The treadmill protocol should be adjusted to the patient and one protocol is not appropriate for all patients.

Exercise capacity should be reported in METs not minutes of exercise.

Hyperventilation prior to testing is not indicated, but can be utilized at another time, if a false positive is suspected

ST measurements should be made at ST₀ (J-junction) and ST depression should only be considered abnormal if horizontal or downsloping; 95% of the clinically important ST depression occurs in V₅ particularly in patients with a normal resting ECG.

Patients should be placed supine as soon as possible postexercise with a cool down walk avoided in order for the test to have its greatest diagnostic value.

The 2–4 min recovery period is critical to include in analysis of the ST response.

Measurement of systolic blood pressure during exercise is extremely important and exertional hypotension is ominous; at this point, only manual blood pressure measurement techniques are valid.

Age-predicted heart rate targets are largely useless because of the wide scatter for any age; a relatively low heart rate can be maximal for a given patient and submaximal for another.

The Duke Treadmill Score should be calculated automatically on every test except for the elderly.

Other predictive equations and heart rate recovery should be considered a standard part of the treadmill report.

EYE MOVEMENT, MEASUREMENT TECHNIQUES FOR

JOSHUA BORAH
Applied Science Laboratories
Bedford, Massachusetts

INTRODUCTION

The terms eye movement measurement, eye tracking, and oculography refer to measurement of the orientation and motion of the eye, either with respect to the head, or with respect to the visual environment. This may include not

only rotations of the eye that cause changes in gaze direction, but also rotations of the eyeball about the line of sight, called ocular torsion. Point-of-gaze is the point in the visual environment whose image forms on the small, high acuity area of the retina, called the fovea. Line-of-gaze is the imaginary line connecting the eye to the point-of-gaze. Sometimes the term gaze tracker is used to describe a system whose primary function is to determine a subject's fixation point or line of gaze with respect to the visual environment, rather than the dynamics of eyeball motion with respect to the head.

Eye movement measurement devices have long been used for research in reading, various aspects of visual perception and cognition, neurology, instrument panel layout, and advertising. Technological advances, especially in the areas of digital processing and solid-state sensor technology, have made eye tracking possible under progressively less and less restrictive conditions. In recent years, uses have expanded to include computer application usability research, communication devices for the disabled, sports and gait research, Lasik surgery instrumentation, and research requiring simultaneous fMRI (functional magnetic resonance imaging) measurement. In the past decade it has also become practical to measure ocular torsion with optical, noncontacting methods.

Figure 1 shows some of the structures and dimensions of the eye that are important in eye movement measurement (1,2). In an idealized model, the optical axis of the eye is the line that passes through the centers of curvature of the cornea, and lens, and the center of rotation of the eyeball. The visual axis (or line of sight) is the ray that passes from the fovea, through the nodal points of the lens and inter-

sects the point-of-gaze. It is important to note that the fovea is not centered on the retina, but rather is located $5\text{--}7^\circ$ toward the temporal side. The visual and optical axes are therefore, not identical. An idealized model of the eye usually assumes the pupil and iris to be centered on the optical axis, and assumes that the eyeball and eye socket operate as a perfect ball and socket joint, with the eyeball rotating about a single point within the eye socket.

The idealized model is often perfectly adequate for making good measurements of gaze direction and eye movement dynamics, but is not precisely accurate. For example, the eye does not rotate about a single center of rotation within the eye socket (3). The pupil is not precisely centered with respect to the optical axis, visual axis, or iris, and its center moves as the iris opens and closes (4).

Eye position with respect to the head can be described by a three element rotation vector, by a four element rotation specification called a quaternion, or by a set of three angles that describe the positions of an imaginary set of nested gimbals, with the outer gimbal fastened to the head, and the eye attached to the inner most gimbal. In the latter case, the three angles are usually referred to as Fick or Euler angles, and consist of an azimuth (or horizontal) angle, an elevation (or vertical) angle, and a roll (or torsion) angle. In all cases rotations are measured from a somewhat arbitrary reference position that loosely corresponds to looking straight ahead when the head is upright. A complete description of the methods and underlying mathematics for specifying eye rotation is available in an article by Haslwanter (5).

Gaze tracking devices usually report point-of-gaze in terms of a coordinate system defined on a surface in the

Figure 1. Schematic diagram of the eye showing typical values of dimensions that are important in eye movement measurement. The dimension values, which do vary between individuals, are derived from Refs. 1 and 2.

environment; or an eye location in space plus a gaze direction vector, with respect to an environment coordinate frame.

Normal human eye movements fall into the broad categories of conjugate and nonconjugate movements. Conjugate movements, in which both eyes move together, include the rapid, ballistic jumps between fixation points, called saccades; smooth compensatory movements to hold the gaze steady in the presence of head motion; smooth movements to track objects that are moving across the visual field; and the saw tooth pattern of movement called nystagmus that occurs in response to an inertial rotation of the body or a rotation of the visual field. There are also miniature motions during the relatively stationary fixation periods, which are $< 1^\circ$ and are not perceived. Vergence is a nonconjugate motion used to keep a visual target at the same position on both retinas. As a visual target moves closer, the visual axes of the two eyes rotate toward each other. Ocular torsion occurs in response to inertial rotation or lateral acceleration, or rotation of the visual field about a horizontal axis. It is associated with perceptions of tilt. A thorough review of eye movement behavior can be found in Hallett (6).

The eye movement measurement techniques currently in most frequent use fall into the major categories of magnetic search coil, a technique that measures magnetically induced current in a tiny wire coil fastened to the eye; electrooculography, which uses surface electrodes to measure the direction of an electrical potential between the cornea and retina; and optical techniques that rely on optical sensors to detect the position or motion of features on the eye. Their optical technique category includes many subcategories, and has the largest variety of different systems in current use. Background theory and system descriptions for eye movement measurement devices, in all of these categories, are presented in the following sections.

Eye tracker performance is usually described by some subset of the following parameters. *Accuracy* is the expected difference between the measured value and the true

value. *Resolution* is the smallest change that can be reported by the device. *Precision* is the expected difference in repeated measurements of the same true value. *Range* describes the span of values that can be measured by the device. *Linearity* is the degree to which a given change in the real quantity results in a proportional change in the measured value, usually expressed as percent of the measurement range. *Update rate* is the frequency with which data is output (samples per second). *Bandwidth* is the range of sinusoidal input frequencies that can be measured without significant distortion or attenuation. *Transport delay* is the time required for data to pass through the system and become available for use.

SCLERAL SEARCH COIL

The scleral search coil technique, first described by Robinson (7), requires that a sensing element be placed on the eye. The technique is based on the principle that a changing electric field can induce a current in a coil of wire. If the coil lies in a plane parallel to a uniform, alternating current (ac) magnetic field, no current is induced. If the plane of the coil is not parallel to the field lines, an ac current *will* be induced in the coil. Current amplitude will be proportional to the coil area projected onto the plane that is perpendicular to the magnetic field lines. For example, if the plane of the coil is tilted about an axis perpendicular to the magnetic field lines, the induced current will be proportional to the sine of the tilt angle. A tilt in the opposite direction results in an induced current with the opposite phase (180° phase shift). The sign of the tilt angle can, therefore, be deduced from the phase of the induced current.

As shown in Fig. 2, a pair of Helmholtz coils, which set up uniform ac magnetic fields in both vertical and horizontal axes, surrounds the subject's head. The driving circuitry ensures that the two fields are exactly 90° out of phase. An induction coil, made of very fine wire, is held on the eye so

Figure 2. Schematic illustrating the scleral search coil method of measuring eye movement. (Adapted from a diagram in Ref. 8.)

that it forms a circle about the limbus (iris-sclera boundary). Robinson embedded the coil in a scleral contact lens, which was held to the limbus by the action of a tiny suction tube. Collewijn et al. (9) developed a technique for using an annular ring made of silicone rubber and having a slightly hollow inner surface. The ring adheres to the limbic area by capillary action and does not require the suction tube. Fine wire leads, from the induction coil, extend out of the eye at the canthus (the corner of the eye). A drop of anesthetic is generally administered prior to insertion, but the devise is usually tolerated well once the anesthetic wears off (9).

The induction coil encloses an area that is approximately in the plane of the pupil. Horizontal eye movement varies the current induced by the horizontal ac magnetic field, and vertical motion varies the current induced by the vertical field. By detecting the phase, as well as the amplitude of the induced current, it is possible to obtain separate analog signals proportional to the sine of vertical and horizontal eye rotations. A simple calibration is required to find the initial reference orientation of the eye.

It is possible to embed, in the annular ring, a second induction coil that encloses an area having a component parallel to the optical axis of the eye. The second coil is shown in Fig. 3. Torsional eye movement can be computed from the current induced in this second coil.

When used with nonhuman primates, a magnetic induction coil is often implanted surgically, using a method described by Judge et al. (10).

Scleral search coil systems can be expected to measure with a resolution > 1 arc-min over a range of ± 15 – 20° , and accuracy of ~ 1 – 2% of the range. Slippage of the annular ring on the eyeball is possible, and can produce significant additional error. Temporal bandwidth is a function of the coil excitation frequency and filtering, and depends on the

Figure 3. Schematic showing the configuration of the second coil in a dual induction coil system. The second coil forms a loop whose enclosed area has a component parallel to the optical axis of the eye (perpendicular to the plane of the pupil), and is used to measure torsional movement. Although the diagram shows only one winding for each coil, the actual device uses multiple windings.

specific implementation, but 0–200 Hz or better is probably achievable. The accuracy of the torsional measurement is generally assumed to be a fraction of a degree, but may be affected by slippage of the annulus as well as variation in eyeball curvature, and is not well documented.

The method is distinctly invasive, and requires the head to be confined within the Helmholtz coil assembly, but does not require the head to be rigidly fixed. It offers good measurement performance, measures all three axes of rotation simultaneously, and is not affected by eyelid closure, or ambient illumination. In the past, complete systems for use with humans have been commercially available from C-N-C Engineering, Seattle, WA; and Skalar Medical BV (11), The Netherlands. Current commercial availability is uncertain. Systems for use with animals are available from Riverbend Instruments, Inc., Birmingham, AL (12).

ELECTRO-OCULOGRAPHY

Electro-oculography (EOG) has a relatively long history, dating from the 1920s and 1930s (13–17). The retina of the eye carries a slightly negative electrical charge, varying from ~ 0.4 to 1.0 mV, with respect to the cornea, probably because the retina has a higher metabolic rate. This charge difference constitutes an electrical dipole, which is approximately, although not exactly, aligned with the optical axis of the eye. Electro oculography refers to the use of surface skin electrodes to measure the position of the cornea-retinal dipole. When used with ac recording techniques to measure nystagmus, or when used in a neurological test setting to measure any type of eye movement, it is often called electronystagmography (ENG).

Ideally, when the electrical dipole is midway between two electrodes that have been placed near the eye, the differential voltage between the electrodes would be zero, and as the eye rotates from this position, the differential voltage would increase with the sine of the angle. Although this is indeed the qualitative result, in practice there is a great deal of direct current (dc) drift. Skin conductance varies over time, and the corneo-retinal potential changes with light adaptation, alertness, and the diurnal cycle. In fact, EOG is sometimes used explicitly to measure the changes in corneo-retinal potential as a function of light stimuli, rather than eye movement (18,19). Electromyographic activity from facial muscles can also interfere with EOG measurement.

After cleaning the skin with an alcohol swab, electrodes are often placed as shown in Fig. 4. In this case, the differential voltage between the electrodes placed near the outer canthi (junction of upper and lower eyelid) of each eye is used to measure horizontal motion of the two eyes together. It is also possible to use additional electrodes near the nose, or on the bridge of the nose, to measure the two horizontal eye positions independently. The vertically positioned electrode pairs measure both eyes together when wired as shown in the diagram, but can also be used to measure vertical position of each eye, independently. The electrode at the center of the forehead is used as a reference. Other placement patterns can be used as well.

Figure 4. Schematic illustrating the EOG method of measuring eye movement. (Adapted from a diagram in Ref. 8.)

The electrodes most often used are silver–silver chloride, self-adhesive models, designed as infant heart monitor electrodes. They are connected to high gain, low impedance, low noise, differential amplifiers. The output from the differential amplifiers is now most commonly digitized and input to digital processors for linearization, scaling, and other processing. The ac coupling or frequent rezeroing is required to keep the analog signal in range of the analog to digital converters.

The high and unpredictable rate of dc drift makes this technique less suitable than others for point of gaze measurement. However, the drift is usually slower than eye movement velocities, and EOG provides an excellent means for measuring eye velocity profiles, slow and fast phases of nystagmus, and patterns of fixations and saccades, as long as the precise point of regard is unimportant. Research laboratories often assemble their own EOG devices from commercially available amplifiers, electrodes, and digital data processing software packages. Both EOG and ENG devices are sometimes used for neurological testing in clinical settings, and commercially available EOG or ENG devices are most often packaged as part of neurological testing suites.

The EOG and ENG systems are commercially available from: Cambridge Research Systems Ltd., UK (20); GN Otometrics, Denmark (21); Guymark UK Ltd., UK (22); Metrovision, Pérenchies, France (23), and Neuro Kinetics, Inc., Pittsburgh, PA (24).

OPTICAL TECHNIQUES

Noncontacting optical sensors can be used to deduce the orientation of the eyeball from the position of optical features, optically detectable geometry, or the pattern of reflectivity on the eye and the facial area surrounding

the eye. The sensors may range from a small number of individual photodiodes to CCD or CMOS arrays, which provide two-dimensional (2D) gray scale image data. In most cases the eye area is illuminated with a near infrared (IR) light that is within the sensitive spectral region for solid-state light sensors, but minimally visible to the human eye. Optics may be mounted to head gear and move with the head, the head may be restrained to prevent or limit motion with respect to optics that are not head mounted, or movement with respect to non-head-mounted optics may be allowed. In the latter case the sensor field of view must either be large enough to accommodate the expected head movement, or some component of the optical assembly must automatically move to keep the sensor aimed at the eye being measured.

OPTICAL SENSORS

Sensors used by optical eye trackers include the following: *Quadrant and bicell photodetectors*: The disk shaped detector surface is divided into two (bicell) or four (quadrant) discrete photosensitive areas. The devices are configured to produce analog signals (one for bicell detectors, and two for quadrant detectors) proportional to the difference in light intensity sensed on adjacent areas. The signals are monotonically related to small displacements of a light spot from the center of the detector either in one (bicell) or two (quadrant) dimensions. The light spot must remain completely on the detector surface, and displacements must be smaller than the diameter of the spot. *Lateral effect photo diodes (position sensitive detectors)*: A solid-state detector provides analog information proportional to the one (1D) or two dimensional location of the incident light center of gravity. *Small arrays of discreet solid state photosensors*: The array provides a small number of

analog light intensity signals. *Large, linear, photo-sensor arrays*: The array provides gray scale image data in a single dimension. *Large, 2D, solid-state, photosensor arrays (CCD and CMOS)*: The array provides two dimensional gray scale image data. Commercially available video cameras, based on CCD and CMOS sensors provide analog and digital signals in standard formats, usually at 50 or 60 fields/second. Using a CCD chip that supports double the normal pixel output rate, a small number of cameras are available that output 120 fields/second. By using a subset of the video lines for each field, these devices can also deliver field update rates that are higher than 120 Hz. Some CMOS sensor chips allow even more flexibility to receive data from a dynamically determined subset of the pixels and to vary the update rate. Higher update rates always mean that each pixel has less time to accumulate charge, resulting in less effective sensitivity and lower signal to noise ratios.

Quadrant detectors, lateral effect photo diodes, and small arrays of discrete photo sensors provide information with low spatial bandwidth content. The information can usually be processed at high temporal bandwidth with relatively little digital processing requirement. Large linear and 2D arrays offer much richer spatial information, but require more processing power to interpret the information, often leading to reduced temporal bandwidth.

FEATURES OF THE EYE

The eye image features most often used for eye movement measurement are *Limbus*: Boundary between the colored iris and white sclera. *Iris*: “Colored” ring that opens and

closes to adjust pupil size. *Pupil*: Circular opening defined by inner boundary of iris. *First Purkinje image (corneal reflection)*: Reflection of a light source from the outer surface of the cornea. *Fourth Purkinje image*: Reflection of a light source from the inner surface of the lens.

These features are shown schematically in Fig. 5.

The pattern of blood vessels on the retina, if imaged with an ophthalmoscope or fundus camera, also constitute markings that can be used to track eye movement, but this is a less commonly used technique.

In some cases facial landmarks, such as the canthus (corner of the eye, where the upper and lower eyelid meet), another facial feature, or a dot placed on the skin, may be used to compare with the location of features on the eye. As discussed later on, facial features can also be used to guide remote camera based trackers.

The iris has a distinctive pattern of radial markings that can be used to track ocular torsion. Its inner boundary, defining the pupil, is nominally circular and centered with respect to the limbus. Detailed examination, however, reveals a slightly noncircular shape that is off center (usually toward the nasal side) with respect to the limbus. Furthermore, both the shape and position of the pupil change slightly with pupil diameter and vary across the population. The characteristics of the pupil form are described and quantified in considerable detail by Wyatt (4). He found that pupil position tends to shift in the nasal and superior directions (with respect to the limbus) as the pupil contracts, and that pupil diameter and circularity tend to decrease with age.

Light rays that enter the eye through the pupil are reflected by the retina and directed back toward their

Figure 5. Schematic illustrating the various features of the eye often used by optical eye movement measurement techniques. (Adapted from a diagram in Ref. 8.)

Figure 6. Illustration of bright and dark pupil optics. In the bright pupil example, retroreflected light from the retina will beam back into the camera lens, resulting in a bright, back lit, pupil image.

source. The eye therefore acts as a retroreflector. If the eye is viewed by a detector that is coaxial with an illumination beam, as shown in Fig. 6, the retroreflected light from the retina makes the pupil appear to be a bright, back lit circle. Some of the retinal reflection can be received slightly off axis from the illumination beam (25). Although the bright pupil effect falls off sharply as the detector moves off axis, this accounts for the “red eye” effect in flash photography. In an idealized case, the apparent brightness of the pupil retroreflexion will vary inversely with the square of pupil diameter (26). As shown by Nguyen et al. (25), brightness of the retinal reflection also varies between individuals and as a function of gaze direction with respect to the illumination source, but these variations are small compared to the effect of pupil diameter.

If the detector is off axis from the illumination beam, the retroreflected light does not enter the detector and the pupil appears as the familiar dark circle.

The corneal reflection is a virtual image that appears to be just behind the plane of the pupil. If the cornea is assumed to be spherical, the corneal reflection image will form at point half way between the surface of the cornea and its center of curvature, along a ray that is parallel to the illumination beam and passing through the corneal center of curvature. If the light source is far away compared to the radius of the eyeball, then as the eye rotates, the corneal reflection always appears to move the same amount as the corneal center of curvature. A similar analysis will show that the fourth Purkinje image forms in almost the same plane as the corneal reflection, but appears to move the same amount as the posterior lens surface center of curvature.

FEATURE RECOGNITION

Systems that use 2D detector arrays typically perform a pattern recognition task to identify features in the 2D

image. Digital processing power has always been a critical limitation. When video cameras were first used as sensors, analog preprocessing was often used to find edge points, or other pixel subgroups, and thereby reduce the amount of data that needed to be processed digitally. Algorithms requiring relatively few computational steps were used to process the reduced digital information in order to recognize features and find their centers.

Increased digital processing capability has very significantly eased, although by no means eliminated, this limitation. It is now practical to digitally process 2D, gray scale image buffers while maintaining reasonable, real-time update rates. It has become possible to use, in real-time, elements of classical digital image processing such as Sobel or other convolution based edge detection algorithms, and circle or ellipse best-fit algorithms. Less computationally intensive algorithms are still often used, however, to maximize update rates.

Digital processing components in current use range from commercially available PCs and frame grabbers to custom processing boards that include field programmable gate arrays (FPGAs) and digital signal processors (DSPs), and microcontrollers.

When using an array sensor, the location of individual boundary points on an image feature (e. g., the pupil) are often identified with only single pixel resolution. If the object covers multiple pixels, knowledge of the object shape allows its position to be computed with subpixel resolution. For example, if a group of pixels are thought to define the edge of circular object, a least mean squared error circle fit will define the circle center location with sub pixel resolution. If sufficient computation time is available, it is also possible to use gray scale information to define edge points with subpixel accuracy.

Pupil Recognition

The pupil is generally recognized as a circular or elliptical area that is darker (in the case of a dark pupil image) or

brighter (in the case of a bright pupil image) than surrounding features. The pupil is often partially occluded by eyelids and corneal reflections, and algorithms must therefore recognize the circular or elliptical shape even when occluded to some degree. Furthermore, it is important that only the real pupil boundaries be used to determine the center of the object, rather than the occlusion boundaries. Examples of pupil detection algorithms can be found in Zhu (27), Mulligan (28), Ohno et al. (29), Charlier et al. (30), and Sheena (31).

The retroreflective property of the eye makes possible a signal enhancement technique that can be exploited to help identify the pupil (32–35). If a camera is equipped with both a coaxial and off-axis illuminator, a bright pupil image will be produced when only the coaxial illuminator is on, and a dark pupil image will be produced when only the off-axis source is on. If the illuminators are alternately activated for sequential camera images, the result will be alternating bright and dark pupil images. Assuming elements in the camera field of view have not moved between images, all other image features, which are not retroreflectors, will remain essentially unchanged.

If two such images are subtracted, one from the other, the result should leave only the pupil image. In practice, there will still be small differences in all parts of the image due to the different illumination angles, but contrast between the retroreflective pupil and the rest of the image is still greatly enhanced. There are some drawbacks to the technique. If the eye moves significantly between the sequential images, subtraction results in a distorted pupil image. The need to digitize and subtract two images increases memory and processing requirements, and the fact that two sequential images are required to create one data sample limits the temporal bandwidth of the measurement. Note that a similar result can be obtained with images from two cameras that are carefully aligned with respect to the same image plane, and an illumination source that is coaxial with only one of them.

Corneal Reflection Recognition

The corneal reflection (first Purkinje image) is usually recognized, within a larger 2D image, by its intense brightness, predictable size and shape, and proximity to the pupil. It can, however, be confused with small reflections from tear ducts or eyeglass frames, and reflections from external sources emitting light in same spectral band as the intended source. Its center can be identified with subpixel accuracy only if it is large enough to cover multiple pixels. Eizenman et al. (36) describe a technique for using knowledge of brightness pattern across the corneal reflection (first Purkinje image) to find its position, on a linear array, with subpixel resolution. To accomplish this they used a precisely designed illumination source to insure a known pattern of luminance.

Fourth Purkinje Image Recognition

The fourth Purkinje image is very dim and very difficult to reliably identify in a larger image. The one system in common use that requires the fourth Purkinje image relies on careful initial alignment to focus the image on a quad-

rant detector. The detector is not much larger than the Purkinje image; and, in this case, automatic recognition in a larger field is not necessary.

Face Recognition

In some cases wide-angle images are now used to recognize the presence of a face, and to find the location of one or both eyes. If the eye is identified in a wide angle image, and assuming the camera is well calibrated to account for lens or sensor distortions, it is reasonably straight forward to compute the direction of the line extending from the camera to the eye. Finding the distance to the eye is more difficult. If the eye is identified on the images from two cameras, it is possible to triangulate. If both eyes are identified on a single camera image, knowledge of the true interpupillary distance can be used to compute distance to the face. However, head rotation with respect to the camera will cause some error if not taken into account. Some face recognition systems are able to determine head orientation. For example, Xiao et al. (37) and Matthew and Baker (38) describe a method, based on a technique known as active appearance modeling (39), to make real-time measurements of the position and 3D orientation of a face.

Information about eye location can be used to direct a separate sensor to obtain a more magnified view of the eye, or the wide-angle image itself may also be used to find the position of features within the eye. In the latter case, there is a clear trade off between spatial resolution and wide-angle coverage. Recognition of facial features can also be exploited in order to use a facial landmark, such as the canthus or the center of the eyeball as one of the elements in a dual feature-tracking algorithm (40,41). However, the plasticity of facial features makes it difficult to determine their position with the same precision as the pupil and Purkinje images.

EYE ORIENTATION AS A FUNCTION OF SINGLE OR DUAL FEATURE POSITION

If we have a sphere of radius r , with a mark on its outer surface as shown in Fig. 7, and if we assume the center of the sphere is fixed with respect to an observer, then the observer can compute the rotation (θ) of the sphere about its center by noting the displacement (d) of the surface mark.

$$\theta = \arcsin(d/r)$$

This is the principle behind single feature eye tracking. However, if the center of the sphere moves with respect to the observer, observation of a single mark provides no way to distinguish such motion from rotation.

If there are two visible marks on the sphere, which are fixed to the sphere at different distances from its center, then observing the relative position of these marks does allow rotation of the sphere to be distinguished from translations. So long as the distance between the sphere and observer remains the same or is independently known, translation with respect to the observer can be unambiguously distinguished from rotation.

Figure 7. Schematic illustrating the principle behind single feature tracking. Observation of a single land mark on the sphere allows determination of its orientation, so long as the center of the sphere does not move.

If the two marks are located along the same radius line, at distances r_1 and r_2 from the center of the sphere, as shown in Fig. 8, then the rotation angle (θ) of this radius line, with respect to the line connecting the sphere and observer, is

$$\theta = \arcsin(\Delta d / (r_1 r_2))$$

where Δd is the observed separation between the marks. This is the basic principle behind dual feature tracking techniques. The underlying sine function has a steep slope at small angles, maximizing the sensitivity of the technique. Note that if the distance between the observer and sphere changes, the dual feature relation still leaves some

Figure 8. Schematic illustrating the principle behind dual feature tracking. The relative position of the two landmarks defines the orientation of the sphere, even if its center moves in a direction parallel to the plane of the detector.

ambiguity since the apparent separation between the marks will change as a function of distance.

In the case of the eye, referring to Fig. 1, the center of the pupil or center of the iris is a mark that is ~ 9.8 mm from the center of the eyeball. Although both images appear to be just behind the plane of the pupil, the first Purkinje image moves the same amount, with eye rotation, as would a mark ~ 5.6 mm from the center of the eyeball (the position of the anterior corneal surface center of curvature); and the fourth Purkinje image moves the same amount as would a mark ~ 11.5 mm from the center of the eyeball (the position of the posterior lens surface center of curvature).

Eye Orientation as a Function of Just Pupil or Corneal Reflection Position

The pupil, and corneal reflection (first Purkinje image) are the features most commonly used for single-feature tracking. If a sensor and light source are mounted so that they do not move with respect to a person's head, either of these features can be used as a marker to compute eye rotation in the eye socket. Either the head must be stabilized with some type of head restraint mechanism, or the sensor must be mounted to head gear that moves with the subject.

When measuring only a single feature, any translation of the head with respect to the sensor will be erroneously interpreted as eye rotation. For example, if using pupil position, a 1 mm motion of the head parallel to the detector image plane may be mistaken for about a 5° eye rotation. If the corneal reflection is the feature being tracked, a 1 mm slippage will be indistinguishable from an $\sim 12^\circ$ eye rotation.

Eye Orientation as a Function of Relative Pupil and Corneal Reflection Positions (CR/Pupil)

The pupil and first Purkinje image (corneal reflection), or the first and fourth Purkinje image are the most commonly used feature pairs for dual feature tracking. The pupil to corneal reflection technique (CR/Pupil) was first described by Merchant et al. (42). As shown in Fig. 9, if the sensor is close to the light source that produces the corneal reflection, the angle (θ) of the eye optical axis with respect to the sensor is described by

$$\theta = \arcsin(d/k)$$

where d is the apparent distance between the pupil and corneal reflection (from the point of view of the sensor), and k is the distance from the pupil to the corneal center of curvature. If the sensor is not close to the illumination source, the relation changes only slightly so long as the sensor does not move with respect to the illumination source.

$$\theta = \arcsin((d - k_d)/k)$$

$$k_d = k_{cr} \sin(\gamma)$$

where k_{cr} is half the cornea radius of curvature and γ is the angle between the illumination beam and the sensor line of sight (see Fig. 10). If the sensor and illumination source are very far away, compared to the radius of the eyeball, then γ ,

Figure 9. Schematic illustrating the basic relationship behind the pupil-to-corneal-reflection technique for measurement eye movement. The diagram assumes that the detector and illumination source are coaxial, or very close together, and are very far from the eye, compared to the radius of the eyeball. The optical axis of the eye is rotated away from the detector by an angle θ . From the vantage point of the detector, the pupil and corneal reflection appear to be separated by distance d .

and hence k_d , are constants. One drawback to the pupil to corneal reflection technique is that the pupil center is not completely stable with respect to the optical or visual axis, but moves slightly as the pupil size changes (4). Theoretically, this effect can be measured in an individual and accounted for (43,44), but would add to the time and effort required to calibrate an individual. Note also that the pupil-to-corneal-reflection vector is less sensitive to eye rotation than either of the individual features. A 5° eye rotation, from an initial position in which the pupil and corneal reflections are aligned, causes the pupil and corneal reflection images to separate by only ~ 0.4 mm, whereas the pupil center moves ~ 1 mm.

The equations given above describe the major effect, but not all secondary effects, and are not precise. For example, the cornea is not perfectly spherical, the eyeball does not rotate about a perfectly stable central point, and the pupil image is slightly magnified by the refractive power of the cornea. To the extent that secondary effects are large enough to be detected, they are often accounted for by the results of an empirical calibration procedure, as discussed later.

The range of gaze angles that can be measured by the pupil to corneal reflection technique is limited by the range over which the corneal reflection remains visible to

the detector. In the horizontal axis, this range is usually $\sim 70^\circ$ visual angle for a given illumination source and sensor pair. It is usually less in the vertical axis due to occlusion of either the pupil or corneal reflection by the eyelids. The range can be extended by using multiple illumination sources, at different positions, to create multiple corneal reflections, but the system must be able to uniquely recognize each reflection even when not all are visible.

Eye Orientation as a Function of Relative First and Fourth Purkinje Image Positions (CR/4PI)

As described by Cornsweet and Crane (45), the first and fourth Purkinje images can also be used for dual feature tracking. The same type of arcsine relation applies, but with d the apparent distance between the two Purkinje images, and with k equal to the distance between the corneal center of curvature and the posterior lens surface center of curvature. The technique has the advantage that the Purkinje image positions can be more precisely defined than the pupil center. In addition, the separation of the posterior lens surface and corneal centers of curvature (~ 6 mm) is greater than that between the pupil and corneal centers of curvature (~ 4.2 mm), yielding greater

Figure 10. Schematic illustrating the detected pupil to corneal reflection separation (d) when the detector and illuminator optical paths are not coaxial. The diagram assumes that the detector and illumination source are far from the eye, so that lines from the detector to various points on the eye are essentially parallel, as are rays from the illumination source to various points on the eye. The angle θ is between the eye and detector optical axes, and γ is the angle between the detector optical axis and the illumination beam.

sensitivity to eye rotation than the pupil to corneal reflection technique. Drawbacks are that the fourth Purkinje image is relatively dim and difficult to find, and is only visible within the iris opening.

Eye Orientation as a Function of Relative Pupil or Iris and Facial Landmark Positions

The relative position of the pupil or iris and a facial landmark can also be used to measure eye orientation. This is sometimes done when image magnification and resolution is such that the smaller Purkinje images cannot be reliably detected, or the relative motion of the pupil and corneal reflection cannot be sufficiently resolved. Since the facial landmark does not move with eye rotation, the governing relationship is described by

$$\theta = \arcsin((d-d_i)/r)$$

where d is the distance (in the camera image plane) from the facial landmark to the pupil or iris center, d_i is the distance (also in the camera image plane) from the facial landmark to the eye center of rotation, r is the distance from the pupil or iris center to the eyeball center of rotation, and θ is the angle of the eye optical axis with respect to the detector. If the head rotates with respect to the detector, d_i will appear to shorten, in the direction perpendicular to the rotation axis, by an amount proportional to the cosine of the rotation angle. Advantages over other dual feature techniques are greater sensitivity (larger change of the measured quantity for a given eye rotation), and the possibility of identifying the features in wider, less magnified images. Disadvantages are that facial image features are not stable, but usually move at least slightly as a function of facial muscle activity, and head orientation must also be measured or must remain stable with respect to the detector. Zhu and Yang (40) describe a dual feature technique using the relative position of the canthus and iris; and Tomono et al. (41) describe an algorithm for using the relative position of the pupil, and a computed position of the center of the eyeball.

EYE ORIENTATION AS A FUNCTION OF FEATURE SHAPE

It is also possible to extract eye orientation information from feature shape. A circle (e. g., the pupil outline or outer boundary of the iris) appears elliptical if viewed from an angle. As the circle tilts, the minor axis of the ellipse, which is perpendicular to the axis of rotation, appears shortened by the cosine of the rotation angle. A major drawback to using pupil or iris ellipticity as an orientation measure is that, due to symmetry considerations, the direction of rotation about the rotation axis remains ambiguous. A second major limitation is that the underlying cosine function has a shallow slope at small angles resulting in poor sensitivity.

EYE ORIENTATION AS A FUNCTION OF REFLECTIVITY PATTERN MOVEMENT

Different structures on the eye, primarily the pupil, iris, and sclera have different reflectivity properties. As the eye

rotates this reflectivity pattern moves, and that property can be exploited to measure eye movement. Movement of the reflectivity pattern can be detected with small numbers of individual photodetectors, and this, in turn, makes it possible to achieve relatively high temporal bandwidth. The technique was pioneered by Torok et al. (46) and Smith and Warter (47), using a photomultiplier as the detector, and further developed by Stark and Sandberg (48), Wheelless et al. (49), Young (50), Findlay (51) and Reulen et al. (52). The most prominent contrast feature in the pattern is generally produced by the boundary between the iris and sclera. Therefore, devices that use small arrays of photodetectors to measure motion of this pattern are often called limbus trackers.

The iris sclera boundary is easily visible along the horizontal axis, but along the vertical axis it is usually obscured by the eyelids. In fact the boundary between the eyelids and iris are often the most prominent reflectivity boundaries along the vertical axis. The eyelids do tend to move in proportion to vertical eye motion, and are useful as measures of vertical eye position; but motion of the reflectivity pattern remains a much less dependable function of vertical (as opposed to horizontal) eye rotation.

In principle, reflectivity pattern tracking is similar to single feature tracking. As with single feature tracking, any movement of the sensors with respect to the eye produces erroneous measurements.

MEASURING POINT-OF-GAZE IN THE PRESENCE OF HEAD MOTION

Dual feature techniques, such as the pupil to corneal reflection method, permit computation of gaze direction with respect to a detector. However, head motion may still need to be measured in order to accurately determine the point of gaze on other objects in the environment.

First, consider an example in which the head is free to move with respect to a stationary detector, and the task is to measure point of gaze on other stationary objects in the environment. This is illustrated by the two dimensional example in Fig. 11. The point of gaze, defined by x , is dependent not only on θ , which can be measured by one of the dual feature tracking methods previously described, but also on ϕ and d_1 , which define head position. If head motion is small compared to distance to the detector and scene surface, then changes in head position will have little effect and can be ignored.

If the location of the eye in the environment space can be independently measured, and if the detector and scene surface positions are known with respect to the same environment space, the following general algorithm can be used to determine point of gaze on a surface. Use a dual feature technique to determine direction of the gaze vector with respect to the detector, and knowledge of the detector orientation to express this as a direction in the environment space. Use the gaze direction and known start point (the location of the eye in space) to write the parametric equation for a line in the environment coordinate space. Use knowledge of the scene surface position to solve for the intersection of a line and a plane. Ohno et al. (29) describe a version of this strategy.

Figure 11. Relationship, in one plane, between point-of-gaze on a flat scene and relative eye, detector, and scene positions. (From Ref. 26.)

Next, consider an example in which the detector is fastened to headgear worn by the subject. Single as well as dual feature techniques may be adequate to measure gaze direction with respect to the head (although single feature methods will have larger errors if there is any slippage of the headgear). In order to find point-of-gaze on objects in the environment it is clearly necessary to know the position and orientation of the head with respect to those objects. The following strategies can be used.

1. A second camera can be mounted to the head gear so that it shares the same reference frame as the eye sensor, but points toward the subject's field of view. Point-of-gaze can be indicated as a cursor superimposed on the image from this scene camera.
2. Light-emitting diodes (LEDs) or other special emitters can be fastened to an object in the environment, such as the bezel of a computer monitor, and detected by head mounted sensors to locate the object in the head reference frame. Measurement of gaze in the

head reference frame can then be related to position on that object.

3. A separate head tracking system can be used to measure head position and orientation with respect to the environment. This information can then be used to compute the location and direction of the gaze vector in the environment coordinate frame. If the locations of surfaces are also known in the same environment reference frame, it is possible to solve for the intersection of a line (line-of-gaze) with a surface, to find point-of-gaze on various surfaces in the environment. A general method for doing this computation is described in Appendix E of Leger et al. (8). Duchowski (53) also describes specific algorithms for handling this type of task.

In the case of the head mounted scene camera described above, it is important to be aware of possible parallax error. The scene camera is usually not viewing the scene from exactly the same vantage point as the eye being tracked. As shown in Fig. 12, eye rotation angle data can be mapped to the scene camera image plane at a particular image plane distance, but the relation changes as the image plane distance changes. The resulting parallax error can be easily corrected if there is knowledge of the distance, from the subject to the gaze point. The parallax error may be negligible if the distance to the gaze point is large compared to the distance of the scene camera from the eye. It is also possible, as shown in Fig. 13, to minimize parallax by bending the scene camera optical path with a beam splitter, such that the scene camera has the same vantage point as the eye being measured (54).

If a person with normal ocular function is fixating a point not infinitely far away, the lines of gaze from the two eyes should converge. If the gaze angles of both eyes are measured with head mounted optics, the intersection of the two lines-of-gaze theoretically indicates the three-dimensional (3D) point-of-gaze in space, with respect to a head fixed coordinate system. If head position and orientation are known, this can be transformed to a position in environment space. Duchowski (53) describes an algorithm for this computation. It should be noted that, in practice, the measured lines-of-gaze from the two eyes will almost

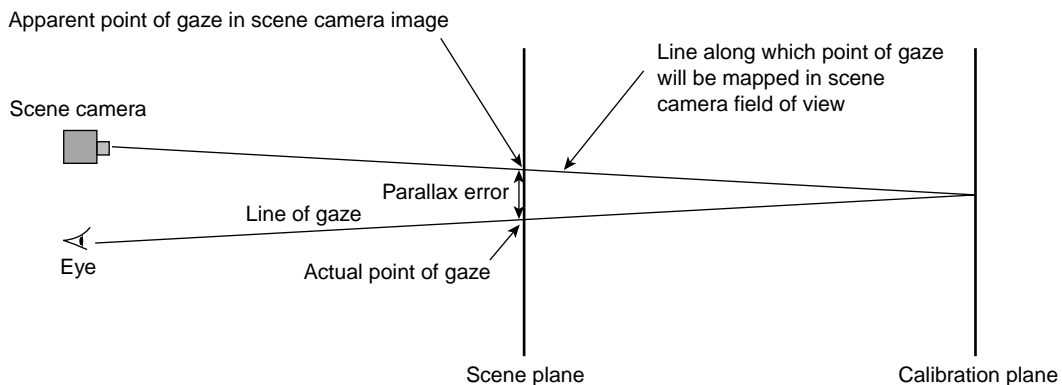

Figure 12. Parallax error when gaze direction is mapped (calibrated) to a scene camera image plane that is different from the plane being fixated.

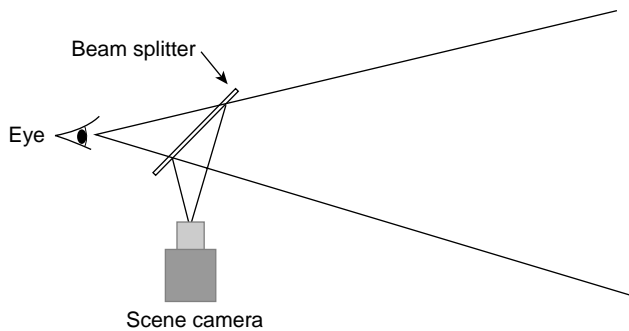

Figure 13. Use of a beam splitter to minimize scene camera parallax.

never intersect. Neither the measurement nor the system being measured is infinitely precise. The discrepancy can be resolved as follows. Consider the two planes that are parallel to the “vertical” axis of the head and which contain the gaze vector from each of the two eyes. If the two lines-of-gaze converge, these two planes will intersect along a line, which is also intersected by the line-of-gaze from each eye. The 3D point-of-gaze can be chosen to be either of these intersection points or a point half way between the two.

As the point-of-gaze moves farther from the head, the vergence angle (the angle formed by the gaze vector from each eye) diminishes. The relation is reasonably sensitive at close distances. As distances become longer, a very small change in vergence corresponds to an increasingly large change in distance, and moderate measurement noise or error in the eye tracker may result in a very noisy or inaccurate point of gaze computation.

MEASUREMENT OF TORSIONAL EYE MOVEMENT

Optical measurement of torsional eye movement was first accomplished by offline photographic analysis techniques and later by tracking artificial marks placed on the eye. For example, Edelmann (55) created a visible mark by sandwiching a human hair between two contact lenses. Use of standard surgical markers, applied just outside the limbus, has also been reported (56), although this requires that a local anesthetic be applied to the cornea.

Over the last decade or so it has become practical to make real time measurements using the patterns that are naturally visible on the iris, as captured by CCD or CMOS cameras. This has generally been done either by using a cross-correlation technique, or a template-matching scheme to compare the iris over sequential video frames. The first method, first described by Hatamian and Anderson (57), and further developed and automated by Clarke et al. (58) and Bucher et al. (59), cross-correlates the pixel sequence from a 1 pixel wide path around the pupil, sampled from each video frame, with that from an initial reference frame.

It is important that the same strip of iris be sampled each time, so unless the eye is stationary in the two nontorsional degrees of freedom, the pupil center must be accurately tracked. Even so, at eccentric eye positions, geometric image distortions can cause errors. The points on

the iris that form a circle on the camera image plane when the subject looks directly at the camera, begin to form a more elliptical shape on the camera image plane as the subject looks farther away from the camera. Moore et al. (60), and Peterka et al. (61) describe a method for avoiding this type of error by correctly computing the projection of the eye onto the camera image plane and empirically solving for parameters that correspond to physical characteristics of the eye or eye-to-camera geometry. A template-matching scheme described by Groen (62) and further developed by Zhu et al. (63) is also designed to minimize geometrical perspective errors by tracking distinctive landmarks on the iris. Changes in pupil diameter can affect the pattern of radial markings on the iris and lead to some torsion measurement error. Guillemant et al. (64) describes a technique using neural network software to identify the pupil and iral patterns for torsion measurement.

CALIBRATION

Most eye tracking systems require a practical method to relate a measured quantity, such as the relative position of the pupil and corneal reflection, to a desired quantity, such as point of gaze on a particular scene space. The underlying relationships behind several techniques for measuring eye orientation have been presented in preceding sections. In practice, however, eye tracking systems often rely on completely empirical techniques to map the measured quantity to gaze points on a scene space. The measured quantity is recorded as a subject looks at several known points in the scene space and either a polynomial curve fit, an interpolation scheme, or some combination is used to map (transform) one to the other.

The process of gathering data to compute the transform is referred to as the calibration. In this way, the precise physical dimensions, such as the corneal radius of curvature or angle between the optical and visual axis of the eye, and precise geometrical relationships between detectors, illumination sources and scene surfaces do not have to be explicitly determined. Rather, these relations are automatically incorporated in the implicitly determined function.

Theoretically, the calibration transformation can remove any systematic error that is a function of the measured variables. More calibration data points allow higher order polynomial transforms or more interpolation points, and usually improve the result, but with diminishing returns. Too many calibration points also result in a time consuming and onerous procedure. Systems often require subjects to look at either five or nine target points, and rarely > 20. In some cases, precise knowledge of the geometrical relation between components, along with knowledge of the underlying mechanism, can be used to reduce the number or calibration points required while preserving accuracy. Ohno et al. (29) describes a scheme using this type of strategy.

A cascaded polynomial curve fit scheme, used with pupil to corneal reflection method eye trackers, is described by Sheena and Borah (43). The same paper describes a method to account for changes in pupil position associated with change in pupil diameter. A 2D interpolation scheme is

described by McConkie (65), and Kliegle and Olson (66). Possible variations are unlimited, and available systems employ a wide variety of calibration schemes. Sometimes, in order to further reduce systematic error, the users of commercially produced eye trackers add their own calibration and transform process onto data that has already been processed by the manufacturer's calibration and transform scheme. Jacob (67) and Duchowsky (53) describe specific examples.

Amir et al. (68) describe a method for using two cameras and illumination sources to compute the location of the eye optical axis with no calibration requirement. The pupil and corneal reflection images, on each camera, can be used to determine a plane that must contain the eye optical axis. The intersection of the two planes, one computed from each camera image, defines the optical axis. The orientation of the visual axis relative to the optical axis of the eye varies across the population, however, and this uncertainty cannot be removed without requiring at least one calibration point.

If eye tracker optics are head mounted, the calibration transform is often designed to map gaze to the image plane of a head mounted scene camera or a similar imaginary plane that travels with the head. Head position and orientation measurements can then be combined with this result, as described in the previous section, to derive the line-of-gaze in space, and to compute its intersection with known surfaces.

COMPATIBILITY WITH EYEGASSES AND CONTACT LENSES

Eye glasses may present mechanical problems for systems that require sensors to be very close to the eye. Systems having sensors that are farther away and that view the eye through the spectacle lens must contend with mirror reflections from the spectacle lens and frame, or obstruction by elements of the frame. Distortion of the image by the spectacle lens usually does not present a significant problem since such effects are removed by the calibration scheme. The biggest reflection problem is often posed by the illumination source that is part of the eye tracking system, especially since the sensor must be sensitive in the spectral region of this light. Antireflective coatings are usually not good enough to eliminate the problem.

The position of the specular reflection (mirror image of the illumination source) is determined by the incidence angle of the illumination beam with the spectacle lens surface, and it is often possible to position the source so that the specular reflection does not cover a feature of interest, although this can become more difficult in the case of very high power (high curvature) spectacle lenses. If the specular reflection is not occluding an important feature, but is still in the sensor field of view, the system must be able to distinguish the features of interest from the specular reflection without confusion. This ability varies among systems, but video based systems can often be used successfully with eyeglasses.

Contact lenses also are often tolerated well by optical eyetracking devices, but may sometimes present the fol-

lowing problems. An edge of the contact lens may sometimes be visible or generate a bright reflection, and may confuse feature recognition, especially if the edge intersects a feature of interest.

When a light source reflection from the outer surface of the contact lens is visible to the detector, it usually appears to replace the first Purkinje image (corneal reflection). This is not a problem for systems that use the corneal reflection, so long as the visible corneal reflection is always the reflection from the contact lens. Although the contact lens surface will have a slightly different position and curvature than the cornea, the difference in the motion of this reflection from that of the real corneal reflection is easily accounted for by whatever calibration scheme is used. However, if the contact lens moves so that the reflection appears to fall off the edge of the contact lens and onto the cornea, there will be a shift in the computed gaze position. Hard contact lenses, which tend to be relatively small and float about on the tear film, are more likely to cause this problem than the larger soft lenses.

The contact lens surface may be less reflective than the cornea, resulting in a dimmer first Purkinje image, and making detection more difficult.

ILLUMINATION SAFETY

Most eye trackers that use optical sensors also include a means to illuminate the eye, usually with nonlaser light at the lower end of the near-infrared (IR-A) spectral region. The IR-A region spans the wavelengths between 770 and 1400 nm. To prevent harming the eye, it is important to avoid excessively heating the cornea and lens, and to avoid focusing too much energy on too small a spot on the retina.

The American Conference of Governmental Industrial Hygienists (ACGIH) suggests the following safety criteria for extended exposure to nonlaser, near-IR light (69). To protect the cornea and lens from thermal injury, irradiance at the eye should be no $> 10 \text{ mW}\cdot\text{cm}^{-2}$. To protect the retina, near-IR radiance, expressed in units of $\text{W}\cdot(\text{cm}^2 \cdot \text{sr})^{-1}$, should be limited to no $> 0.6/\alpha$, where α is the angular subtense, in radians, of the source as seen by the subject.

Various safety standards are specified by many other organizations, including the American National Standards Institute (ANSI), The U. S. Food and Drug Administration (FDA), the International Electrotechnical Commission (IEC), and others, although some of these are intended specifically for laser sources. A comprehensive review of light safety issues can be found in a book by Sliney and Wolbarsht (70).

SPECIFIC IMPLEMENTATIONS OF OPTICAL TECHNIQUES

Photo Electric, Reflectivity Pattern (Limbus) Trackers

There are a small number of commercially available systems that use a photo electric reflectivity pattern (limbus) tracking technique to measure eye movements. Figure 14 shows a schematic for a basic system measuring horizontal eye position. The difference in the signal received by the two photodetectors is roughly proportional to the

Figure 14. Schematic showing simple reflectivity pattern (limbus) tracker for horizontal measurement. (Adapted from a diagram in Ref. 8.)

horizontal position of the reflectivity pattern across the eye, with the most prominent feature of the pattern being the contrast between the white sclera and darker iris (limbus). Modulation of the LED, typically at 2 kHz or higher, and corresponding demodulation of photosensor signals diminishes the effect of ambient light. The signal is low pass filtered to remove modulation artifacts; and is either scaled and linearized with analog controls, or sampled and processed digitally, in order to scale and linearize the values.

Vertical position can be measured by orienting a similar LED and sensor array vertically, instead of horizontally. The results are less dependable because the high contrast iris to sclera boundary is often obscured by the eyelids. Alternately, vertical position is measured by aiming the horizontally oriented LED and sensor array at the boundary between the eye and the lower eyelid, and summing (instead of differencing) the photodetector signals. The result is really a measure of lower eyelid position, and takes advantage of the fact that the lower eyelid moves roughly in proportion to vertical eye motion. In either case, the vertical measurement is less accurate and less repeatable than the horizontal measure.

The LED and photosensors are positioned within ~ 2 cm of the eye, and are mounted to a head band, goggles, or spectacle frames. The detector assembly inevitably obscures some of the visual field. Since the reflectivity pattern moves more or less as would a landmark on the eyeball surface, a 1 mm shift of the optics on the head is expected to produce an error of $\sim 5^\circ$. There is often a distinct cross-talk effect. The horizontal measurement values are affected by vertical eye position, and visa versa.

If vertical eye position is also measured, the calibration transform can attempt to correct cross-talk.

System bandwidth is limited, primarily, by the low pass filtering needed due to the modulation scheme, and is typically 50–100 Hz. If the signal is processed digitally, sample rates are often at least 1000 Hz. It is possible to achieve resolutions of $> 0.05^\circ$ visual angle. While bandwidth and resolution are very good, accuracy is somewhat un dependable because of headgear slippage affects, cross-talk effects, and, especially in the vertical axis, eye lid effects. Accuracy of 1° along a horizontal axis and 2° along a vertical axis may be achievable over a short period, but errors of several degrees would not be unusual, especially over longer periods or in the presence of vigorous head motion. Devices that use one LED and two photo sensors for a given axis tend to become very nonlinear, and difficult to calibrate over > 30 or 40° in either axis. The range can be extended somewhat by using multiple LEDs and sensors for each axis. Neither torsional eye movements, nor pupil diameter is measured.

Photoelectric, reflectivity pattern (limbus) trackers are best suited to measure dynamics of horizontal eye movements as opposed to point of regard measurement, although they are sometimes used for point of regard measurement as well. Systems in this category are commercially available from Applied Science Laboratories Bedford, MA (71), Cambridge Research Systems Ltd, UK (20), and Optomotor Laboratory, Freiburg, Germany (72).

Cambridge Research Systems offers a version of their device designed for use in fMRI environments. In this case, the LEDs and photodiodes are located outside of the magnet bore, and connected to the eye piece, within the magnet bore, via fiber optic cables (20).

Dual Purkinje Image Measurement (CR/4PI)

A technique was described by Cornsweet and Crane (45) and further developed by Crane and Steele (73,74) in which the eye is illuminated with a modulated IR source, and servo controlled mirrors are used to image the first and fourth Purkinje images onto solid state quadrant detectors. Demodulated, analog signals from the quadrant detectors are used, in separate feed back loops, to move the mirrors and keep the images centered on the detectors. The resulting mirror positions constitute measures of the feature positions, and can be used to compute eye rotation with respect to the optics.

A schematic representation of the system is shown in Fig. 15. The entire optics platform is mounted to a servo controlled XYZ stage, which automatically moves to optimize overall system alignment. A hot mirror beam splitter is used to direct light to and from the optical unit, which is positioned off to one side of the subject. By looking through the beam splitter, the subject has an unimpeded view of the forward visual field. Not shown in the simplified schematic is an autofocus mechanism, implemented with a beam splitter, off axis aperture, and bicell detector, in the first Purkinje image optical path.

The subject's motion is usually restricted with a head rest or bite bar assembly. Because the fourth Purkinje image is visible only through the iris opening, measurement range is

Figure 15. Schematic representation of Double Purkinje image eye tracker. (Redrawn from Ref. 73.)

restricted to about $\pm 10^\circ$ visual angle, although this can be extended to about $\pm 15^\circ$ by using drops to dilate the pupil. Accuracy is ~ 1 min of arc, and the sampling rate is 1000 Hz. Using a model eye, Crane and Steele (74) empirically measured a bandwidth of ~ 500 Hz (for small eye movements of several degrees), noise levels of 20 arc-s rms, response delay of 0.25 ms, and linear tracking of slew rates up to $\sim 2000^\circ$.s. The manufacturer of a current version of the device specifies a bandwidth of 400 Hz and a 1 ms response time (75).

Although the subject's motion is restricted and the measurement range is small, the accuracy, precision and temporal bandwidth are exceptionally good. The Dual Purkinje image eye-tracking device can provide a precise enough and fast enough measurement, for example, to allow another device to effectively stabilize an image on the retina (74). Neither torsional eye movement nor pupil diameter is measured, but it is possible to attach an infrared optometer, which provides a real-time, analog measure of changes in eye accommodation (75). An updated version of the device described by Crane and Steele (74) is offered commercially by Fourward Technologies, Inc, Buena Vista, VA. (75).

Systems Using Two-Dimensional Video Sensor Arrays

Eye tracking devices that use 2D CCD or CMOS sensor arrays exist in wide variety, and are commercially available

from numerous sources. The term video oculography (VOG) is often used to describe this type of system. Most current systems in this category use the pupil to corneal reflection technique (CR/Pupil) to measure gaze direction, but there are exceptions. Some systems designed primarily to measure ocular torsion might rely on a fixed position of the head with respect to the sensor, and use only pupil position to correct for gaze direction changes. Some systems that normally use the pupil-to-corneal reflection technique have options to measure with only pupil position or only corneal reflection position under certain circumstances. Other systems are designed to measure the position of the head in space, and use a camera (or cameras) with a wide-angle view on which the corneal reflection can not easily be resolved. These systems may use the pupil position relative to a facial feature to compute gaze direction.

Note that a pupil-only or corneal-reflection-only measurement offers some advantages if it can be assured that the head does not move with respect to the camera. Pupil and corneal reflection motion have greater sensitivity to eye rotation than the pupil-to-corneal reflection vector, and the measurement is therefore more precise (less noisy).

Figure 16 is a functional diagram consistent with most current video-based eye tracking systems. The functions may be distributed among physical components in various ways, and a separate head tracking system may or may not be included.

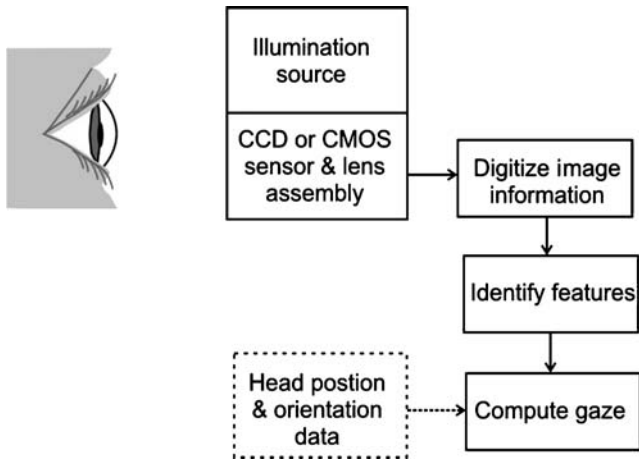

Figure 16. Schematic showing the basic functional architecture of most video-based eye tracking systems.

Some systems input video from the eye camera to PC memory via a USB or firewire connection, either directly from a camera with compatible output, or via a video–firewire converter. The PC CPU then does all the processing. Alternately, a frame grabber installed on the PC may be used to digitize a composite video signal. In some cases, the resulting digitized signal is processed by the PC, or in other cases, a frame grabber that also has image processing capabilities may do some portion of the processing before making a reduced information set available to the PC. In still other cases, the eye video is input to a completely custom processing board or board set, often populated with some combination of field programmable gate array (FPGA) and digital signal processing (DSP) components. The custom processor may do virtually all of the processing or may send a reduced data set to a PC. Other workstations may be used in place of the PCs referred to above. In short, there is enormous variety possible. Systems that support > 60 Hz update rates often make some use of custom processing components to help achieve the high speed. Although not yet capable of the same temporal bandwidth as several other types of system, camera based systems are now available with high enough update rates to make them useful for study of eye movement dynamics. Video-based systems almost always measure pupil diameter as a byproduct of computations for eye rotation measurement, and these systems are sometimes used as pupillometers.

The two main subcategories within this group are head mounted systems, having the sensor and small optics packages mounted to headgear; and remote systems, relying on optics mounted to the environment (table, instrument panel, etc.). In both cases these are often used as real time point of regard systems. The following sections describe video based, head mounted and remote eye tracking systems, respectively; followed by a section describing systems designed to handle the special problem of operation in MRI devices.

Head Mounted, Video Based Systems. Head mounted sensors are often designed to view a reflection of the eye from a beam splitter, as shown in Fig. 17, so that the

Figure 17. The head mounted module directly over the subject's right eye contains both a camera and illuminator, which are aimed down at the tilted, hot mirror beam splitter. The camera views a reflection of the eye from the hot mirror. The module just to the nasal side of the eye camera module is a scene camera, aimed toward the subject's field of view. (Courtesy of Applied Science Laboratories, Bedford, MA.)

sensor, lens, and illumination source need not be in the subject's field of view. The beam splitter is coated to be a hot mirror, very reflective in the near-IR, but not in the visible spectrum. In some cases, however, the module containing the sensor is positioned on a stalk (Fig. 18), so that it can obtain a direct view of the eye. Illumination is most often provided by one or more near infrared LEDs. Both dark-pupil and bright-pupil type optics are represented among available systems.

The image of the eye produced by a head mounted sensor yields information about eye orientation with respect to the head. In other words, line of gaze is measured in the head reference frame. In some cases, this is the

Figure 18. Head mounted camera and illuminator module is mounted on a stalk, and is aimed directly at the eye. (Courtesy of SR Research, Inc. Ontario.)

desired quantity, but in other cases the desired measurement is point of gaze in the environment. In order to find point of gaze on objects in the environment, it is necessary either to detect the positions of those objects with respect to the head, or to detect the position and orientation of the head with respect to the environment containing the objects. Techniques for accomplishing this were discussed in the previous section titled "Measuring point of gaze in the presence of head motion". All of these methods have been used by commercially available, pupil–corneal reflection-type systems.

Head tracking devices commonly used with head mounted eye trackers include magnetic systems that measure the position and orientation of a small, head gear mounted, set of coils with respect to a larger set of stationary coils; optical systems that use head mounted sensors to detect moving laser beams from a stationary source; and a system which uses a head mounted inertial package for high frequency measurements, corrected by lower frequency measurements from ultrasonic emitter–receiver pairs (8).

Head tracking systems capable of sufficient 6 degree of freedom accuracy usually restrict subject to 1 or 2 m of movement. Applications requiring a subject to walk or run a significant distance usually rely on a head mounted scene camera to capture information about point of gaze on the environment. There are available systems that allow subjects to move about with no physical connection to stationary components while either recording data on a recording device attached to the subject, or using wireless transmission to send data to a base station.

Systems intended for neurological testing are usually concerned with eye movement with respect to the head rather than point of gaze in the environment. Some of these systems measure ocular torsion as well as measuring gaze direction with either pupil-to-corneal-reflection or pupil position techniques.

Measurement accuracy, of head mounted, video-based, eye trackers, tends to be from ~ 0.5 – 1.0° visual angle, with resolutions varying from 0.01 to 0.1° visual angle. Measurement range is 60 – 70° visual angle in the horizontal axis and usually $\sim 20^\circ$ less in the vertical axis due to eye lid interference. These figures refer to measurement of gaze direction with respect to the head. The measurable field of view with respect to the environment is unrestricted because subjects are free to turn their heads and bodies. Measurement update rates range from 25 to 360 Hz, with at least one commercially available system offering 500 Hz with pupil-only (as opposed to pupil-to-corneal-reflection) measurements.

When a head mounted eye tracker is used in combination with a head tracking device, in order to measure point of gaze in the environment, error in the final measurement is increased due to noise and error in the head position and orientation measurement. The result can vary widely depending on the particular combination of equipment being used and the conditions under which measurements are being made. It is probably not unreasonable to expect additional errors corresponding to ~ 0.2 – 1.0° visual when using a head mounted eye tracker to measure point of gaze on elements in the environment. Conditions that create

difficulties for either the eye or head tracking components, for example a heavily metallic environment when using a magnetic head tracker, or occlusion of the pupil image by reflection from some external light source, may cause errors to increase dramatically or make the measurement impossible.

Manufacturers of systems that include ocular torsion measurement usually specify torsion measurement range of 18 – 20° , resolution of $\sim 0.1^\circ$, and linearity between 1 and 4% of full scale. Video-based, head mounted systems, using the pupil to corneal reflection measurement technique, currently allow point of gaze measurement in the most diverse environments, and with the greatest freedom of subject motion and measurable field of view. They do not have as high a temporal bandwidth as scleral search coil, double Purkinje image, EOG, or reflectivity (limbus) tracking systems, and are not as accurate or precise as scleral search coil, or double Purkinje image systems. They do require that the subject wear head gear, but the size and obtrusiveness of the headgear has been steadily reduced over the past decade. It is becoming practical to use this type of system in ever more flexible and varied settings. The amount and severity of subject motion, the amount of variation in ambient light environment, and the length of time over which continuous measurements must be made, all tend to trade off somewhat against the accuracy and dependability of the measurements.

Video-based eye trackers, with head mounted optics, are offered commercially by: Alphabio, France (76); Applied Science Laboratories, Bedford, MA (71); Arrington Research, Inc., Scottsdale, AZ (77); Chronos Vision GmbH, Berlin, Germany (78); Guymark UK Ltd, UK (22); EL-MAR Inc, Downsview, ON (79); ISCAN, Inc., Burlington, MA (80); Neuro Kinetics Inc. Pittsburgh, PA (24); SensoMotoric Instruments GmbH, Berlin, Germany (81); and SR Research Ltd, Osgoode, ON (82).

Head mounted systems that measure ocular torsion are available from: Alphabio, France (72); Arrington Research, Inc, Scottsdale, AZ (77); Chronos Vision GmbH, Berlin, Germany (78); Neuro Kinetics Inc. Pittsburgh, PA (24); and SensoMotoric Instruments GmbH, Berlin, Germany (81).

Remote, Video-Based Systems. Remote (nonhead mounted) systems have one or more videosensors and illumination sources that are fixed to the environment and aimed toward the subject. The optics may sit on a table next to or underneath a monitor being viewed by the subject, may be mounted on a vehicle (or vehicle simulator) instrument panel, or mounted to the environment in some other way. Both bright and dark pupil optics are used. In the case of bright pupil optics, the illuminator may be a ring of LEDs placed close enough to the lens to produce the bright pupil effect, an LED actually mounted over the front of the lens so that it blocks only a small portion of the lens surface, or a beam splitter arrangement like that shown in Fig. 6.

Some system configurations require the subject's head to be stabilized. This maximizes achievable accuracy and dependability. A chin and forehead rest, or cheek and forehead rest are commonly used, although these do allow

a small amount of head motion. A bite bar with a dental impression can be used to completely stabilize the head. In the case of nonhuman primate research the head is often stabilized by other means appropriate for neural recording. The camera, lens, and illumination sources can all be stationary (after manual positioning) and may safely be designed with a field of view just large enough to comfortably accommodate pupil and corneal reflection motion due to eye rotation. If the subject's head is sufficiently stabilized there is no need to differentiate between eye rotation and head translation, and, as previously discussed, there is a precision advantage to using a pupil-only (rather than pupil-to-corneal-reflection) measurement. Some systems allow a choice between pupil-to-corneal-reflection and pupil-only or corneal-reflection-only measurement.

Alternately, the eye camera field of view may be wide enough to accommodate the motions of a seated subject who is not restrained, but is voluntarily remaining still. If the subjects are provided with feedback, so that they know when they are moving out of the legal space, it is only necessary to allow ~ 5 cm of head motion.

Many remote systems are designed to allow enough head motion to accommodate normal motions of a person working at a computer terminal or driving a car, and so on. This is accomplished either by dynamically rotating the camera optical axis so that it always points toward the eye being tracked, by using a camera field of view wide enough to accommodate the desired head motion, using multiple cameras, or some combination of these. Head motion toward and away from the eye camera must either be small enough to remain within the lens system depth-of-field, or must be accommodated by an autofocus mechanism. Figure 19 shows an example of an eye camera that automatically moves in azimuth (pan) and elevation (tilt) to follow the eye as the head moves about. Figure 20 is an example of a camera with a moving mirror used to direct

the optical path, and Fig. 21 shows a system with stationary sensor and illumination components in an enclosure.

Systems with a moving camera or moving mirrors often use a closed loop control, based on the detected position of the pupil in the camera field of view. The moving element is driven to move the image toward center. If the pupil is completely lost from the camera field of view, the system may execute a search pattern, use information from a separate head tracking system to reacquire the eye, or require that a human operator intervene to reacquire the eye image. Such systems can have a relatively narrow eye camera field of view, thus maximizing image resolution for the features of interest. The disadvantage is the need for moving parts, and the possibility of failing to maintain the eye image in the camera field of view.

Systems that do not require moving parts have a significant advantage in terms of system simplicity and dependability. Furthermore, there is the possibility of using the same image to measure head position and to track the movement of both eyes. The trade-off is that as the field of view is increased, resolution is reduced (the pupil and corneal reflection are imaged onto fewer pixels) and the features of interest must be identified within a larger, more complex image.

The pupil-to-corneal-reflection method alone can be used to determine gaze angle with respect to the eye camera. However, in the presence of significant head motion, this is not sufficient to accurately determine point of gaze on other surfaces. Some remote systems use head trackers to find the position of the eye in space, and use the information to more accurately compute point of gaze on other stationary surfaces. Head position information can also be used to help aim moving cameras or mirrors. The same types of head tracker mentioned in the previous section, as being appropriate for use with head mounted eye trackers, are sometimes used in conjunction with remote eye trackers.

Figure 19. Example of a remote eye tracker optics module that moves in azimuth (pan) and elevation (tilt) to keep a telephoto eye image within the camera field of view. (Courtesy of Applied Science Laboratories, Bedford, MA.)

Figure 20. Example of a remote eye tracker optics module that uses a moving mirror to keep a telephoto eye image within the camera field of view. The optics module is shown with its cover removed. (Courtesy of Applied Science Laboratories, Bedford, MA.)

In the case of remote eye trackers, it is also possible to use one or more wide angle cameras to locate the head and eyes. The head tracking camera (or cameras) may be separate from the eye tracking camera, or alternately, the same cameras (or cameras) may be used for both.

At present, remote systems that offer > 60 Hz update rates either require the head to be stabilized, or use a narrow field image that is dynamically directed to follow head motions. Systems that use stationary wide-angle optics typically update at 60 Hz or less, probably because of the extra processing required for feature recognition in the more complex wide-angle image. Systems that either require the head to be stabilized or direct a narrow field of camera to follow head motion are available with update rates of up to 360 Hz. As with head mounted systems, higher update rates result in lower signal/noise ratios for the sensor.

Figure 21. Example of a remote eye tracker optics module using stationary wide angle optics. Sensor, lens, and illumination components are within the enclosure. (Courtesy of Tobii Tehnology AB, Stockholm, Sweden.)

For configurations that stabilize the subject's head, accuracy of remote, video-based eye tracking systems tends to be ~ 0.5 – 1.0° visual angle, with resolutions varying from 0.01 to 0.1° visual angle. When a remote eye tracker is used to measure point of gaze on a stationary surface, and head motion is allowed, some additional error can be expected. If no attempt is made to account for head motion, the equation in Fig. 11 can be used to estimate the amount of error expected from a given change in head position. If an attempt is made to correct for head movement, the amount of additional error depends on the accuracy of the head position measurements, and the way the information is used in the point-of-gain computation, as well as the range of head motion. It is probably not unreasonable to expect an additional 0.5 – 1.5° of error when there is significant head motion. Data may also have additional error, or even be briefly lost, during fast head motion, due to instability of the eye image on the eye-camera field of view.

Remote systems using one eye-camera and one illumination source, and the pupil-to-corneal-reflection method, can generally measure gaze directions that are within ~ 25 – 35° visual angle from the eye-camera lens. At more eccentric angles the corneal reflection is either not visible to the eye camera, or easily confused with multiple reflections from the sclera. The exception is that when line of gaze is below the eye-camera, the upper eyelid often begins to occlude part of the pupil. The amount of eye lid occlusion under this condition varies from subject to subject. Furthermore, different eye tracking systems, using different recognition and center computation algorithms, are tolerant of different amounts of occlusion. This often limits measurement range to 5 – 10° visual angle below the eye-camera, and for this reason, the environment is usually arranged with the eye-camera at the bottom of the scene space that is of interest. The result is a horizontal gaze measurement range of ~ 50 – 70° visual angle, and a vertical range of ~ 35 – 45° .

Figure 22. Example of eye tracker optical path in an fMRI system. The drawing shows the magnet in cutaway view. One mirror, just above the subject's face, reflects the eye image to the eye tracker camera, while another allows the subject to view a stimulus on a rear projection screen. Many variations to this arrangement are used, including configurations in which both the projection screen and eye tracker optics module are at the same end of the magnet. (Courtesy of Applied Science Laboratories, Bedford, MA.)

The range of measurable gaze directions, using the pupil-to-corneal-reflection method, can be increased by using multiple illumination sources (and thus multiple corneal reflections). The horizontal range can be increased to as much as 90° by widely spacing illumination sources. Only a more modest range expansion is possible in the vertical axis because of eyelid interference.

Remote, video-based, eye trackers, offer the possibility of measuring eye movement very unobtrusively. Unlike head mounted systems, nothing need be worn by the subject (unless using a type of head tracker that requires a head mounted sensor), and the optics can be hidden from obvious view by a filter that is transmissive in the near-IR. The range of subject motion and measurable field of view is significantly more restricted than for systems with head mounted optics, although less so than for most other techniques. Measurement accuracy, resolution, and temporal bandwidth are not as good as that available with the much more restrictive and obtrusive double Purkinje image method, or scleral search coil method.

Remote, video-based, eye movement measurement systems are commercially available from: Applied Science Laboratories, Bedford, MA (71); Arrington Research, Inc., Scottsdale, AZ (77); Cambridge Research Systems Ltd, UK (20); ISCAN, Inc., Burlington, MA (80); LC Technologies Inc., Fairfax, VA (83); Metrovision, Pérenchies, France (23); Seeing Machines, Canberra, Australia (84); SensoMotoric Instruments GmbH, Berlin, Germany (81); SR Research Ltd, Osgoode, ON (82); and Tobii Technology AB, Stockholm, Sweden (85).

Video-Based Systems for use in Conjunction with fMRI.

There are commercially available, video-based eye tracker systems, which use the pupil-to-corneal-reflection method, and are specifically configured to be used in conjunction with fMRI measurements of brain activity.

During fMRI measurements, the subject's head and torso are inside the main MRI magnet bore, and a smaller head coil is placed fairly closely around the subject's head. The head coil always has an opening over the subject's eyes, and there is usually some provision for the subject to look at a visual display, often with the help of a mirror or set of mirrors. The environment is challenging because there is

not much room in which to arrange an optical path from the subject's eye to a camera, and also because any electronic equipment used must operate in a high magnetic field, without creating even small amounts of magnetic field noise that would interfere with the MRI measurement.

One approach is to use a camera equipped with a telephoto lens, and placed outside of the magnet. The camera is aimed down the magnet bore, and views a reflection of the eye on a small mirror placed inside of the magnet, near the subject's head. The optical path length from the camera lens to the eye is typically at least 2.5–3 m, necessitating a fairly large telephoto lens, and powerful illumination source. An example is shown in Fig. 22, and is similar to a setup described by Gitleman et al. (86). The system shown is using a bright pupil technique, so there is only one coaxial path for both the camera and illumination beam. In this case, a second mirror allows the subject to look at a display screen. Many variations of both the eye camera and display screen optical paths are possible.

Other systems bring the eye image out of the magnet, to the sensor, with a coherent, fiber optic bundle. This has the advantage of not requiring large, telephoto optics, but the resolution of fiber bundles are limited and light is attenuated somewhat unevenly by the individual fibers that comprise the bundle. Fiber optics may also be used to relay the output from an illumination source into the magnet. It is possible to place a small camera inside the magnet, but it can be difficult to avoid some interference with the magnetic field and resulting degradation of the fMRI measurement.

Video-based, eye tracking systems designed for use during fMRI measurement, are commercially available from Applied Science Laboratories, Bedford, MA (71); Arrington Research, Inc., Scottsdale, AZ (77); ISCAN, Inc., Burlington, MA (80); and SensoMotoric Instruments GmbH, Berlin, Germany (81).

COMPARISON OF EYE MOVEMENT MEASUREMENT TECHNIQUES

Table 1 is an abbreviated comparison of the various techniques discussed.

Table 1. Summary of Most Prevalent Eye Tracking Techniques^a

Method	Typical Applications	Typical Attributes	Typical Reference Frame(s)	Typical Performance
EOG	Dynamics of saccades smooth pursuit nystagmus	High bandwidth Eyes can be closed In expensive Drift problem (poor position accuracy) Requires skin electrodes - otherwise unobtrusive	head	static accuracy: $\sim 3\text{-}7^\circ$ resolution: with low pass filtering and periodic rezero, virtually infinite bandwidth: ~ 100 Hz
Scleral Coil	Dynamics of saccades, smooth pursuit, nystagmus Miniature eye movements Point of gaze Scan path Torsion	Very high accuracy and precision Invasive Very obtrusive High bandwidth	Room	accuracy: $\sim 0.2^\circ$ resolution: ~ 1 arc min. range: $\sim 30^\circ$ bandwidth: ~ 200 Hz
Limbus (using small number of photo sensors)	Dynamics of saccades, smooth pursuit, nystagmus Point of gaze Scan path	High bandwidth Inexpensive Poor vertical accuracy Obtrusive (sensors close to eye) Head gear slip errors	head gear	accuracy: varies resolution: 0.1° (much better res. possible) range: $\sim 30^\circ$ update rate: 1000 samples/s
CR/Pupil	Point of gaze Line of gaze Scan path Dynamics of eye movements (only with subset of systems offering high update rates) Torsion (available only on some systems)	Minimal head gear slip error Unobtrusive Low to medium bandwidth Problems with sunlight Wide variety of configurations and environments	Head gear Room Cockpit	accuracy: $\sim 1^\circ$ resolution: $\sim 0.2^\circ$ hor. range: $\sim 50^\circ$ vert. range: $\sim 40^\circ$ update rate: 50 or 60 samples/s. Update rates up to 360 samples/s available on some systems (higher for pupil only measurement);
CR/4PI	Dynamics of saccades, smooth pursuit, nystagmus Miniature eye movements Point of gaze Scan path Image stabilization on retina Accommodation	Very high accuracy and precision High bandwidth Obtrusive (large optics package, restricted head motion) Limited range	Room	accuracy: ~ 1 arc min. resolution: < 1 arc min range: $\sim 20^\circ$ bandwidth: ~ 400 Hz

An earlier, but comprehensive and still pertinent review of eye movement measurement techniques, can be found in Young and Sheena (87). A book by Duchowski (53) presents a detailed treatment of many aspects of eye tracking methodology. The journal *Computer Vision and Image Understanding* has devoted an entire special edition to developments in optical eye tracking, with an emphasis on real-time, noninvasive techniques (88). A database of commercially available eye movement measurement equipment is available at a web site hosted by the University of Derby (89).

FETAL MONITORING

MICHAEL R. NEUMAN
Michigan Technological
University
Houghton, Michigan

INTRODUCTION

Fetal monitoring is a special type of electronic patient monitoring aimed at obtaining a record of vital physiologic functions during pregnancy and birth. Such monitoring is applied in assessing the progress of pregnancy and labor, and it can identify conditions that concern the clinician caring for the patient. These nonreassuring recordings can lead to special considerations in caring for the pregnant patient and in managing her labor. Although these recordings are no longer considered to be definitive in identifying most forms of fetal distress, they can help to reassure patient and clinician that the fetus is able to withstand the physiologic stress of labor and delivery. The technology is also useful in assessing high risk pregnancies, which, in most cases, is only reassuring as opposed to giving a definitive diagnosis. Although this technology is now recognized to have diagnostic limitations, it is still frequently used in the hospital and clinics as an adjunct to other diagnostic evaluations.

PHYSIOLOGIC VARIABLES MONITORED

The goal of fetal monitoring is to ensure that vital fetus organs receive adequate perfusion and oxygen so that metabolic processes can proceed without compromise and these organs can carry out their functions. Thus, an ideal situation for monitoring from the physiologic standpoint would be to monitor the perfusion and oxygen tension in the fetal central nervous system, heart, kidneys, and brain, with the brain being by far the most important. It is also important to know that the fetus is receiving adequate oxygen and nutrients from the mother through the placenta. Unfortunately, it is not possible to directly or even indirectly measure these variables in the fetus *in utero* using currently available technology. One, therefore, must look for related secondary variables that are practical for monitoring and are related to these critical variables. In the following paragraphs, some of these variables and the methods used to obtain them are described.

METHODS OF MONITORING BY A HUMAN OBSERVER

Any discussion of fetal monitoring must begin by pointing out an obvious, but often overlooked, fact that fetal mon-

itoring does not always require expensive electronic equipment. Basic fetal monitoring can be carried out by a trained clinician using his or her hands, ears, and brain. A fetoscope is a stethoscope especially designed for listening to the fetal heart sounds through the maternal abdomen, which can be used to follow the fetal heart rate (FHR), and a hand placed on the abdomen over the uterus can be used to detect the relative strength, frequency, and duration of uterine contractions during the third trimester of pregnancy and labor. Any woman who has experienced labor will point out that the patient is also able to detect the occurrence of uterine contractions during labor. Although these techniques are only qualitative, they can be quite effective in providing information on the patient in labor and frequently represent the only fetal monitoring that is necessary in following a patient.

The main problems with this type of fetal monitoring are associated with convenience, fatigue, data storage and retrieval, and the difficulty of simultaneously processing multiple inputs. Electronic instrumentation can help to overcome these types of problems. Although electronic devices are less flexible and, at the present time, unable to interpret data as well as their human counterparts, the electronic devices can provide quantitative data, continuously monitor patients with minimal interruption of hospital routines, monitor for extended periods of time without fatigue, store data in forms that can be reevaluated at a later time, and, in some circumstances, make elementary logical decisions and calculations based on the data. Thus, the electronic monitor can serve as an extension of the clinician's data-gathering senses and provide a convenient method of recording and summarizing these data. Such a monitoring apparatus has the potential of allowing the clinician to optimize his or her limited available time.

FETAL HEART RATE MONITORING

The widespread use of electronic fetal monitoring was the result of the development of a practical method of sensing the fetal electrocardiogram and determining the instantaneous fetal heart rate from it. Much of the early work in this area was carried out by Dr. Edward Hon and associates who demonstrated a practical technique for directly obtaining the fetal electrocardiogram during labor (1). Techniques for obtaining the fetal heart rate can be classified as direct or indirect. The former involves invasive procedures in which a sensor must come into contact with the fetus to pick up the fetal electrocardiogram; the latter techniques are relatively noninvasive procedures where the mother's body serves as an intermediary between the fetus and the electronic instrumentation. In this case, the maternal tissue conducts a signal (electrical or mechanical) between the fetus and the surface of the mother's abdomen.

Direct Determination of Fetal Heart Rate

Direct FHR determinations are made from the fetal electrocardiogram (FECG). This signal is obtained by placing an electrode on the fetus and a second electrode in the maternal vaginal fluids as a reference point. These electrodes are connected to a high input impedance, high common-mode rejection ratio bioelectric amplifier. Such a direct connection to the fetus can be made only when the mother is committed to labor, the uterine cervix has dilated at least 2 cm, and the chorioamniotic membranes have been ruptured. In principle, it is possible to pass a wire through the maternal abdominal wall into the uterine cavity and beneath the fetal skin to obtain the FECG, and this technique was experimentally reported in the past (2). The method, however, places the mother and fetus at risk and is not used or suitable for routine clinical application. Indirect methods of determining the FHR that are available today make the application of such a technique unnecessary. Thus, the method that is directly used to obtain the FECG is to attach an electrode to the fetal presenting part through the cervix once the mother is committed to labor and the fetal membranes can be ruptured.

Although many different types of electrodes for obtaining the FECG have been described, best results are obtained when the electrode actually penetrates the fetal skin. The reason is illustrated in Fig. 1. The fetus lies in a bath of a amniotic fluid that is electrically conductive due to its electrolyte content. This amniotic fluid tends to short-out the fetal electrocardiogram on the skin surface, therefore, those potentials that are seen on the surface are relatively weak and affected by noise. Even if it were physically possible to place conventional chest electrodes on the fetus for picking up the electrocardiogram, a poor-quality signal would be obtained because of this shunting effect. The amniotic fluid does, however, provide a good central terminal voltage for the fetal electrocardiogram because it contacts most of the fetal body surface.

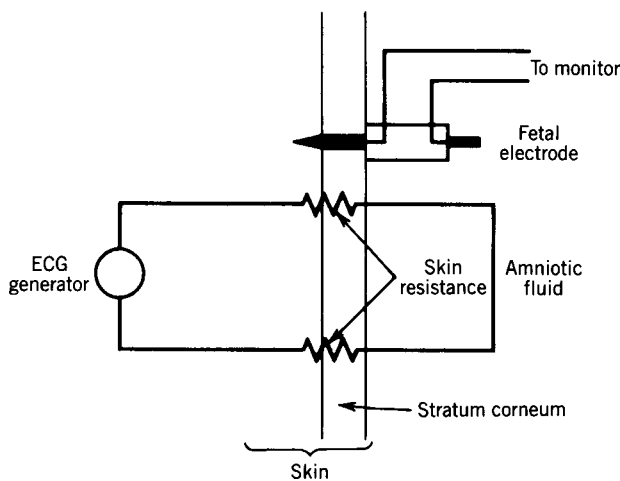

Figure 1. Schematic view and equivalent circuit of a direct fetal ECG electrode penetrating the fetal skin.

The fetal head is normally positioned against the dilating cervix when the mother is in labor, but it is possible for the fetal buttocks or other parts to present first. As the cervix dilates, the skin on the presenting part can be observed through the vagina, and it is possible to place an electrode on or within this skin. If this electrode penetrates the fetal scalp (or other exposed skin surface), it contacts the subcutaneous tissue. As an electrical resistance associated with the surface layers of the fetal skin exists, as indicated in Fig. 1, placing the electrode subcutaneously bypasses this resistance and gives a stronger, more reliable signal. Penetrating the skin also helps to physically keep the electrode in place on the fetus during movement associated with labor.

Various types of penetrating fetal electrodes ranging from fish hooks (3) to wound chips (4) have been developed over the years. Today, the most frequently applied electrode in the helical electrode originally described by Hon et al. (5). This electrode, as illustrated in Fig. 2, consists of a section of a helix of stainless-steel wire on an electrically insulating support. The tip of the wire is sharpened to a point that can penetrate the fetal skin when pressed against it and rotated to advance the helix. Typical dimensions of the wire helix are 5 mm in diameter with 1.25 turn of the wire exposed so that the tip of the helix is 2 mm from the surface of the insulator. A second stainless-steel electrode consisting of a metal strip is located on the opposite end of the insulator from the helix and is used to establish contact with the amniotic fluid through the fluid in the vagina. Lead wires connect the two electrodes to the external monitor.

The electrode is attached to the fetal presenting part by means of a special applicator device, which allows the electrode helix to be pressed against the fetal head to penetrate the skin and be twisted so that the entire wire is advanced beneath the surface of the skin until the insulating portion of the electrode contacts the skin. The flexible lead wires then exit through the vagina and can be connected to the monitoring electronics.

Signal Processing

In fetal heart monitoring, it is desired to have a continuous recording of the instantaneous heart rate. A fetal monitor must, therefore, process the electrocardiogram sensed by

Figure 2. A helical direct fetal ECG scalp electrode of the type described by Hon et al. (5).

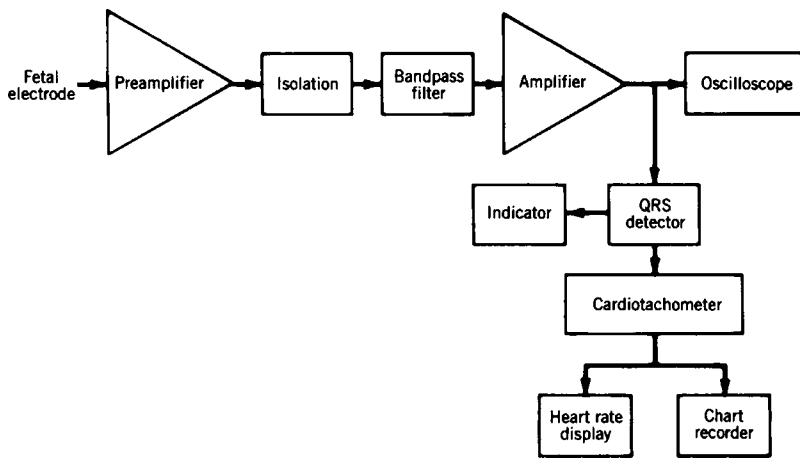

Figure 3. Block diagram of the electronic circuit of a direct fetal heart rate monitor.

the electrode and present the results on a computer monitor or paper printout. A typical electronic system for doing this recording is illustrated in Fig. 3. The signal from the fetal electrode has an amplitude ranging from $50\ \mu\text{V}$ to $1.2\ \text{mV}$, which is amplified to a more suitable level for processing by an amplifier stage. The input of this amplifier is electrically isolated and must have a very high input impedance and low leakage current because of the polarizable nature of most fetal electrodes. A high common-mode rejection ratio is also important, because a relatively strong maternal electrocardiogram signal is present on both electrodes. Another characteristic of the amplifier system is that it includes filtering to minimize the amplification of noise and motion artifact from the fetal electrode. As the purpose of the electronics is primarily to display the instantaneous heart rate, the filtering can distort the configuration of the fetal electrocardiogram as long as it does not affect the time at which the QRS complex appears, as it is used to determine the heart rate. For this reason, a relatively narrow band-pass filter is often used. The QRS complex contains higher frequencies than the rest of the electrocardiogram, and noise frequently has a predominance of the lower frequencies. For this reason, the band-pass filter can be centered at frequencies as high as 40 Hz.

Many ways exist for the QRS complex can be detected. The simplest of these is a threshold detector that indicates whenever the output voltage from the amplifier exceeds a preset threshold. The level of this threshold is adjusted such that it is usually greater than the noise level but less than the minimum amplitude of a typical QRS complex. The major limitation of this method lies in the fact that wide variation exists in fetal QRS complex amplitudes. If the threshold level were fixed such that the minimum fetal QRS complex would cross it, this would mean that, for stronger signals, the threshold would not be optimal and interference from noise exceeding the threshold level would be quite possible. One way to get around this problem is to use some type of adaptive threshold. In this case, the threshold level is adjusted based on the amplitude of the electrocardiogram. A simple example of how this can be done is illustrated in Fig. 3. An automatic gain control circuit determines the amplitude of the fetal electrocardiogram at the output of the amplifier, and uses this amplitude to set the gain of that amplifier. This closed-loop

control system, therefore, results in a constant-amplitude electrocardiogram appearing at the output of the amplifier even though the actual signal from the fetal electrode at the input might vary in amplitude from one patient to the next. Using a simple threshold detector with this automatic gain control will greatly improve the reliability of the fetal monitor in detecting true fetal heartbeats. Often, instead of using a simple threshold detector, a detector with hysteresis is used to minimize multiple triggers in the presence of noise. One can also use matched filters in the amplifier to recognize only true QRS complexes. A peak detector may be used to locate the true peak of the QRS complex (the R wave) for better timing, and pattern-recognition algorithms can be used to confirm that the detected pulse is most likely to be a fetal heartbeat. Of course, the best consideration for an accurate determination of the instantaneous fetal heart rate is to have a good signal at the input to the electronic instrumentation. Thus, care should always be taken to have the fetal electrode well positioned on the fetal presenting part so that one has the best possible input to the electronic system.

The cardiotachometer block of the fetal monitor determines the time interval between successive fetal QRS complexes and calculates the heart rate for that interval by taking the reciprocal of that time. Although it is obvious that such a cardiotachometer can introduce errors when it erroneously detects a noise pulse rather than a fetal QRS complex, other errors resulting from the method of heartbeat detection can exist. For a cardiotachometer to accurately determine the heart rate, it must measure the time interval over one complete cycle of the electrocardiogram. In other words, it must detect each QRS complex at the same point on the complex to ensure that the complete cycle period has been recorded. If one beat is detected near the peak of the R wave and the next beat is detected lower on the QR segment, the beat-to-beat interval measured in that case will be too short and the heart rate determined from it will be slightly greater than it should be. Normally, such a concern would be of only minimal significance, because the Q-R interval of the fetal electrocardiogram is short. However, because the variability in fetal heart rate from one interval to the next may be important in interpreting the fetal heart rate pattern, detection problems of this type can affect the apparent variability of the signal

and, perhaps, influence the interpretation of the pattern. The output from the cardi tachometer is recorded on one channel of a strip chart recorder and is also often indicated on a digital display. In both cases, the output is presented in the units of beats per minute, and standard chart speeds of 1 and 3 cm·mm⁻¹ are used.

Indirect Sensors of Fetal Heart Rate

Indirect methods of sensing the fetal heart rate involve measurement of a physiologic variable related to the fetal heartbeat from the surface of the maternal abdomen. Unlike the fetal scalp ECG electrode, these methods are noninvasive and can be used prior to committing the patient to labor. The most frequently applied method is transabdominal Doppler ultrasound. Lesser used techniques involve transabdominal phonocardiography and electrodiography. Each of these techniques will be described in the paragraphs that follow.

Transabdominal Doppler Ultrasound. Ultrasonic energy propagates relatively easily through soft tissue, and a portion of it is reflected at surfaces where the acoustic impedance of the tissue changes such as at interfaces between different tissues. If such an interface is in motion relative to the source of the ultrasound, the frequency of the reflected signal radiation will be shifted from that of the incident signal according to the Doppler effect. This principle can be used to detect the fetal heartbeat from the maternal abdominal surface. A beam of ultrasound is passed through the abdomen from a transducer acoustically coupled to the abdominal surface. Frequencies around 2 MHz are generally used, because ultrasound of moderate source energy at this frequency can penetrate deep enough into the abdomen to sufficiently illuminate the fetus. Wherever this ultrasound beam encounters an abrupt change in tissue acoustical impedance, some of it is reflected back toward the transducer. If the incident ultrasound illuminates the fetal heart, some of it will be reflected from the various heart-blood interfaces in this organ. Many of these interfaces, such as the valve leaflets, experience periodic movement at the rate of the cardiac cycle. In the case of the valve leaflets, relatively high velocities can be obtained during portions of the cardiac cycle. Ultrasound reflected from these interfaces can, therefore, be significantly shifted in frequency so that the reflected wave can be identified at the maternal abdominal surface because of its frequency shift. This frequency shift will be related to the velocity of the reflecting surface and, hence, will be able to indicate each fetal heartbeat. Thus, by detecting and processing this reflected Doppler-shifted ultrasonic wave, it is possible to determine each heartbeat and, hence, the fetal heart rate.

A block diagram of a typical indirect fetal heart rate monitoring system using Doppler ultrasound is shown in Fig. 4(b). As continuous wave ultrasound is used, separate adjacent transducers are employed to establish the ultrasonic beam and detect the Doppler-shifted reflected waves. The reflected ultrasound signal is mixed with the transmitted wave, and beat frequencies are produced when a Doppler shift in frequency occurs for the reflected wave.

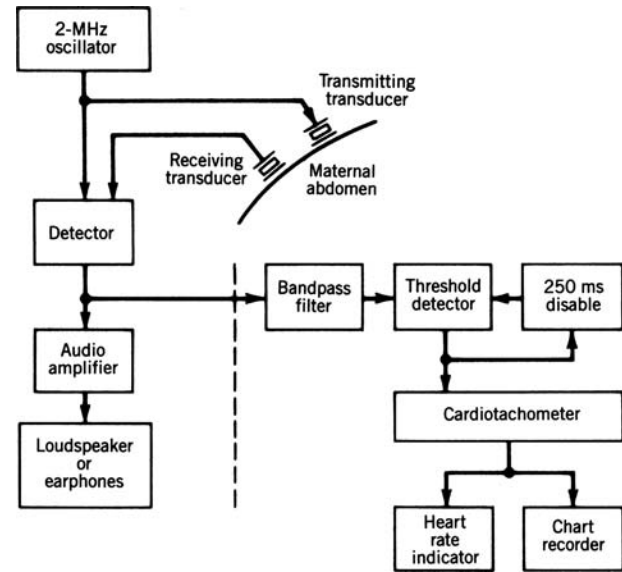

Figure 4. Block diagram of a Doppler ultrasound indirect fetal heart rate monitor. [Reprinted with permission from CRC Press (6).]

This beat frequency is amplified and used to indicate the occurrence of a heartbeat to a cardi tachometer. Many monitors also provide this signal to a loudspeaker to assist the clinical personnel in positioning the transducers for optimal signal pickup or for auditory monitoring.

The reflected ultrasound signal is different from an electrocardiogram, although it can also be used to identify various events in the cardiac cycle. A typical signal is illustrated in Fig. 5. Here one sees two principal peaks per heartbeat, one corresponding to valve opening and the other to valve closing. Actually, such signals can be quite useful in measuring fetal systolic time intervals, but from the standpoint of the cardi tachometer for determining heart rate, they can create problems. If the cardi tachometer is set to trigger at the peak of each wave it sees, as it is for the electrocardiogram, it could measure two beats per cardiac cycle and would give an erroneously high fetal heart rate. One way to avoid this problem is to detect only the first peak of the signal, and, once it is detected, to disable the detection circuit for a period of time that is less than the shortest expected beat-to-beat interval but longer than the time necessary for the second Doppler-shifted signal to occur. In this way, only one peak per cardiac cycle will be registered.

A second, more sophisticated method for detecting the fetal heartbeat involves the use of short-range autocorrelation techniques. The monitor recognizes the beat signal from the reflected wave for a given cardiac cycle and looks for a signal that most closely correlates with this signal over the period of time in which the next heartbeat is likely to occur. The time interval between that time when the initial wave was measured and the point of best correlation corresponds to a beat-to-beat interval of the fetal heart. Thus, instead of relying only on the peaks of the ultrasound signal, this method looks at the entire signal and, therefore, is more accurate. Some manufacturers of commercial fetal monitors claim their ultrasonic systems using this

Figure 5. Illustration of the raw reflected ultrasound signal from the beating fetal heart *in utero*. Note that two ultrasonic bursts occur per cardiac cycle.

type of autocorrelation technique can detect fetal heartbeats as well as can be done by the direct electrocardiographic technique.

The major limitations of the Doppler ultrasound technique are related to its sensitivity to movement. As the Doppler effect will respond to movements of any tissue interfaces illuminated by the ultrasound beam with respect to the signal source, movement of the mother or fetus can result in Doppler-shifted reflected waves that are stronger than the cardiac signal, which, with artifact, can completely obliterate the signal of interest. Thus, this technique is really only reliable when the patient is resting quietly, and it often fails to provide reliable information in the active phase of labor. The other movement-related problem is that the fetus can move *in utero* so that the heart is no longer illuminated by the ultrasound beam or the orientation of the heart with respect to the ultrasonic beam is such that it produces only a minimum Doppler shift in the reflected ultrasonic wave. Thus, while monitoring a patient, it sometimes necessary to reposition the ultrasonic sensors on the maternal abdomen from time to time because of the movement of the fetus.

Acoustic Pickup of the Fetal Heart. Until the advent of electronic fetal monitoring, the standard method of detecting the fetal heartbeat to measure the fetal heart rate was to use a fetoscope. When the bell of this instrument was firmly pressed against the maternal abdomen, fetal heart sounds could be heard and the heart rate could be determined from them. The acoustic method of indirect fetal heart monitoring follows the fetal heartbeat by a similar technique (7). A sensitive contact microphone is placed on the maternal abdomen over the point where the loudest fetal heart sounds are heard with a fetoscope. The signal picked up by this microphone is filtered to improve the signal-to-noise ratio, and the resulting signal drives a cardiometer to give the instantaneous fetal heart rate. The acoustic signal from the fetal heart is similar to the Doppler ultrasound signal in that it generally has two components per heartbeat. The cardiometer is set to trigger when the peak signal comes from the acoustic transducer, so it is possible that two apparent fetal heartbeats can exist for each cardiac cycle. Thus, as was the case for the Doppler ultrasound, it is wise to have a processing circuit that selects only the first of the two heart sounds to trigger the cardiometer. Unlike the ultrasonic Doppler signal, the fetal heart sounds produce

sharp pulses that are narrower so that the detection of the time of the peak can be more precise. Thus, it is generally more accurate to measure the beat-to-beat interval using a peak detector with the acoustic signal than it is with the Doppler ultrasound. The use of the electrocardiogram still represents the best way to measure beat-to-beat cardiac intervals.

The major limitation of the acoustic method of detecting fetal heart sounds is the poor selectivity of the acoustic transducer. It not only is sensitive to the fetal heart sounds, but it will also respond to any other intraabdominal sounds in its vicinity. Also, a finite sensitivity to environmental sounds, exists which is an especially severe limitation for patients in active labor on a busy, noisy delivery service. For this reason, the acoustic method is limited primarily to patients who can lie quietly in a quiet environment to be monitored. The advent and use of the home-like labor/delivery rooms has helped to create an atmosphere that is more conducive to acoustic fetal heart monitoring, yet it is still not a widely applied approach.

The acoustic technique also has the limitation that when used for antepartum (before labor and delivery) monitoring the fetus can move such that the microphone is no longer ideally positioned to pick up the fetal heart sounds. Thus, it is frequently necessary to relocate the microphone on the maternal abdomen with this monitoring approach.

The major advantages of the acoustic method lie in the fact that not only is there better accuracy in determining the instantaneous fetal heart rate, but unlike the ultrasound method, which must illuminate the fetus with ultrasonic energy, the acoustic method derives its energy entirely from the fetus, and no possibility exists of placing the fetus at risk due to exogenous energy. As a result, investigators have considered the possibility of using the acoustic method for monitoring the high-risk fetus at home (8).

Abdominal Electrocardiogram. Although the fetus is bathed in amniotic fluid located within the electrically conductive uterus and maternal abdomen, one can still see small potentials on the surface of the maternal abdomen that correspond to the fetal electrocardiogram. These signals are generally very weak, ranging in amplitude from 50 to 300 μV . Methods of obtaining the abdominal fetal electrocardiogram and clinical application of the information have been known for many years as described by

Larks (9), yet signal quality remains a major problem. Nevertheless, some methods of improving the quality of the signal have been developed. These methods can allow a much more detailed fetal electrocardiogram to be obtained from the maternal abdomen under ideal conditions, and such electrocardiograms can be used in some cases for more detailed diagnosis than from just looking at heart rate. One of these methods involves applying signal-averaging techniques to several subsequent fetal heartbeats using the fetal R wave as the time reference (10). In this way, the full P-QRS-T wave configuration can be shown, but heart rate information and its variability will be lost.

As the fetal electrocardiogram at the maternal abdominal surface is very weak, it is easy for other signals and noise to provide sufficient interference to completely obliterate the fetal signal. Having the subject rest quietly during the examination and removing the stratum corneum of the skin at the electrode sites can reduce noise due to motion artifact and electromyograms from the abdominal muscles. Nevertheless, one major interference source exists that requires other types of signal processing to eliminate. This source is the component of the maternal electrocardiogram seen on the abdominal leads. This signal is generally considerably higher in amplitude than the fetal signal. Thus, observation of the fetal electrocardiogram could be greatly improved by the elimination or at least the reduction of the maternal signal. One method of reducing this signal involves simultaneously recording the maternal electrocardiogram from chest electrodes and subtracting an appropriate component of this signal from the abdominal lead so that only the fetal signal remains. Under idealized circumstances, this process can give a greatly improved abdominal fetal electrocardiogram, but the conditions for subtraction of the maternal signal are likely to vary during a recording session so that frequent adjustments may be necessary to maintain the absence of the maternal signal (11).

The abdominal fetal electrocardiogram can be used for antepartum fetal heart monitoring. In this case, the goal of the instrumentation is to collect fetal R-R intervals as done with the direct monitoring of the fetal electrocardiogram and to determine the instantaneous heart rate from these intervals, which strong maternal component in the abdominal fetal electrocardiogram can make a very difficult task electronically, and so most abdominal fetal electrocardiogram fetal heart rate monitors need to eliminate the maternal component of the abdominal signal. The subtraction method described in the previous paragraph would be ideal for this purpose because if fetal and maternal heartbeats occur in approximately the same time, subtracting the maternal component should leave the fetal component unaffected. Unfortunately, because the conditions under which the maternal component is added to the fetal signal change from one minute to the next, it is not always practical to use this subtraction technique. Thus, a simpler technique that loses more information is used.

A typical abdominal fetal electrocardiogram is shown in Fig. 6 (lower panel) along with a direct fetal electrocardiogram taken from a scalp electrode and the maternal electrocardiogram taken from a chest lead. In the abdominal

Figure 6. An example of a fetal electrocardiogram as obtained from the maternal abdomen. F, fetal QRS complexes; M, maternal QRS complexes. The direct fetal electrocardiogram and maternal electrocardiogram are recorded simultaneously for comparison. [Reprinted with permission from CRC Press (6).]

fetal electrocardiogram, fetal heartbeats are indicated by F and maternal heartbeats by M. Note that some beats exist where the fetal and maternal heartbeats occur at the same time. The strategy of the abdominal fetal electrocardiogram/fetal heart rate monitor is to monitor two signals, the maternal electrocardiogram from a chest lead and the fetal and maternal electrocardiograms from an abdominal lead. As shown in the block diagram in Fig. 7, the maternal electrocardiogram triggers a gate such that the input from the abdominal lead is interrupted every time a maternal beat occurs. Thus, this process eliminates the maternal component from the abdominal signal, but it can also eliminate a fetal QRS complex if it occurs at a time close to or during the maternal QRS complex. Thus, the cardiometer estimates the intervals where one or more fetal beats is missing. Due to the random relationship between maternal and fetal heartbeats, it is most likely that only one fetal beat would be missing at a time because of this mechanism, and so when maternal and fetal beats coincide, the fetal R-R interval should be approximately double the previous interval. Some monitors look for this condition and imply that it is the result of simultaneous maternal and fetal beats. The monitor, therefore, artificially introduces a fetal beat at the time of the maternal beat so that an abrupt (and presumably incorrect) change in the fetal heart rate will not occur.

Although such processing of the fetal signal makes the resulting heart rate recordings appear to have less artifact, this technique can lose some important information. For example, if the fetus suffers from a cardiac arrhythmia such as second-degree heart block, in which the fetal heart can miss a beat every so often, the monitor would reintroduce the missing beat, and this arrhythmia would not be detected. The principal advantage of the abdominal electrocardiogram method of fetal heart rate monitoring is that it can, under optimal conditions, provide the closest indirect observation of the fetal heart rate as compared with direct observations. No risk to the patient exists from this procedure, and inexpensive disposable electrodes can be used as the sensors.

Figure 7. Block diagram of a monitor for processing the abdominal electrocardiogram shown in Fig. 6 using the anticoincidence detector method. [Reprinted with permission from CRC Press (6).]

The limitations of this method include its being based on a very weak signal in an environment that can contain a great amount of artifact. Thus, low signal-to-noise ratios are frequently encountered. Patients must be resting quietly for the method to work. Furthermore, electrodes must be optimally placed for good results, which requires some experimentation with different electrode sites, and skill is required on the part of the user in finding optimal electrode positions for a particular patient. Various signal processing techniques have been used over the years to get a more reliable fetal signal from the abdominal surface, but most of these techniques only improve signal quality under very special circumstances (12,13).

UTERINE CONTRACTIONS

Although the fetal heart rate is an important fetal variable for clinical monitoring, an equally important maternal variable is uterine activity. In fetal monitoring, one must detect the occurrence of uterine contractions, their frequency, their duration, and their intensity. As was the case with the fetal heart rate, it is possible to monitor uterine contractions by both direct methods and indirect methods.

Direct Monitoring of Uterine Contractions

Uterine contractions are periodic coordinated contractions of the myometrium, the muscle of the uterine wall. In an ideal method of direct measurement of uterine contractions, the tension and displacement of the myometrium would be measured, but this measurement cannot be done for routine fetal monitoring as only invasive methods of making this measurement exist. Uterine contractions, however, are reflected in increases in hydrostatic pressure of the amniotic fluid within the pregnant uterus. If this fluid is continuous and in a closed system, pressure increases resulting from uterine contractions should be seen throughout the amniotic fluid and should be related to the overall strength of the contraction but not necessa-

rily to the tension at any one particular location in the myometrium.

The pressure change in the amniotic fluid during a contraction can be measured directly by coupling the amniotic fluid to a manometer, which consists of an electrical pressure sensor and the appropriate electronic circuitry for processing and indicating or recording the measured pressure. Intrauterine pressure can be measured by placing the pressure sensor directly in the amniotic fluid or by using a fluid-filled catheter to couple the amniotic fluid to an external pressure sensor. This latter method is the method most frequently employed in clinical fetal monitoring. The catheter used for coupling the amniotic fluid to an external pressure sensor can be placed only when the membranes surrounding the fetus have been ruptured, which should only be done if the patient is in labor. Unfortunately, rupture of the fetal membranes sometimes occurs spontaneously before the patient goes into labor or when the patient is in premature labor. It is unwise to place a catheter under these circumstances unless labor will be induced and the patient will deliver within 24 h. The reason is that the catheter can serve as a conduit for introducing infectious agents into the uterus or such agents can be introduced during the process of placing the catheter. When the distal tip of the catheter is within the amniotic fluid and its proximal end is connected to a pressure sensor at the same elevation as the distal end, the pressure seen at the sensor will, according to Pascal's law, be the same as that in the amniotic fluid. Thus, when a contraction occurs, the pressure increase will be transmitted along the catheter to the external pressure sensor.

Although the fluid-filled catheter provides a direct conduit from the amniotic fluid to the externally located pressure sensor, it can also be responsible for measurement errors. As was pointed out earlier, the proximal and distal ends of the catheter must be at the same level if one is to avoid the gravitational hydrostatic errors that give incorrect baseline pressure readings. Pascal's law applies only to the static solution where no fluid movement exists in the system. Once fluid movement occurs in the catheter,

pressure drops along the length of the catheter can result. Such fluid movement can occur when a small leak in the plumbing system exists at the sensor end of the catheter. Movement of the catheter itself or of the patient with respect to the pressure sensor can also produce alterations in the observed dynamic pressure. The most serious violation of Pascal's law is that once the fetal membranes have been ruptured, a truly closed system no longer exists. The fetal head or other presenting part approximated against the cervix does, indeed, isolate the intrauterine amniotic fluid from the outside world, but amniotic fluid can leak through the cervix, thus, no longer providing a static situation. Furthermore, after membranes have been ruptured, the total amount of amniotic fluid in the uterine cavity is reduced. It is possible that there might be local non-communicating pools of amniotic fluid delineated by fetal parts on one side and by the uterine wall on the other. The pressure in one of these isolated pools possibly can be different from that of another. The measured pressure will, therefore, be dependent on which pool contains the distal tip of the catheter. A statistical study by Knoke et al. has shown that when three identical catheters are placed in the pregnant uterus, the pressure measured by each can be considerably different, and differences of more than 10 mmHg (1.3 kPa) can be seen between different sensors (14), which is probably due to the fact that the distal tip of each catheter is located in a different part of the uterus and is coupled to a pocket of amniotic fluid at a different pressure.

Other problems exist that can affect the quality of intrauterine pressure measurement with the catheter-external sensor method. Poor recordings are obtained when catheter placement is not optimal and when limited communication exists between the fluid in the catheter and the intrauterine amniotic fluid. Many catheters in use today have a single hole either in the end or at the side of the catheter that communicates with the amniotic fluid. Mucus or vernix caseosa (a substance of a consistency similar to soft cheese that is found on the fetus) can obstruct or partially obstruct this opening resulting in poor quality recordings. When the distal tip of an open-ended intrauterine catheter becomes obstructed, the obstruction can frequently be "blown" off by forcing fluid through the catheter. In practice, this procedure is done by attaching a syringe filled with normal physiologic saline at the proximal end of the catheter near the pressure sensor and introducing fluid into the catheter when an obstruction is suspected.

It is possible to minimize these obstruction problems by modifying the catheter (15). Increasing the number of openings at the catheter tip is one of the simplest ways of minimizing obstructions. By placing an open-celled sponge on the catheter tip, it is possible to obtain a greater surface area in contact with the amniotic fluid because of the multiple openings of the sponge, which also tends to keep the tip of the catheter away from fetal or uterine structures, minimizing the possibility of complete obstruction or injury to the fetus. A small balloon placed at the distal tip of the catheter will prevent the fluid in the catheter from making actual contact with the amniotic fluid, and so this interface cannot be obstructed. As the

wall of the balloon is flexible, the pressure in the fluid within the balloon will be equal to the pressure in the fluid surrounding the balloon plus the pressure resulting from the tension in the balloon wall itself. This system, however, has the disadvantage that it will respond to a direct force on the balloon as well as to hydrostatic pressure in the fluid outside of the balloon; thus, fetal movements or the entrapment of the balloon between the fetus and the uterine wall during a contraction can lead to erroneous pressure measurements.

Interuterine pressure can be directly measured using a miniature pressure sensor that can be placed in the intrauterine cavity (16). These devices are based on a miniature silicon pressure sensor that can be placed on the tip of a probe that has a similar appearance to an intrauterine catheter. In some cases, the probe at the catheter tip is no longer than the catheter itself, so the method of placement is the same as that used for the catheter. The advantage of the intrauterine pressure sensor is its location within the uterine cavity, which avoids artifact introduced by the fluid-filled catheter, and the problem of zeroing the pressure measurement system due to elevation differences is avoided because the sensor is at the pressure source. Investigators have compared the performance of intrauterine sensors with that of intrauterine catheters and have found the newer devices to provide equivalent data to the previously accepted technology (17).

Indirect Monitoring of Uterine Contractions

The clinician is able to sense uterine contractions by palpating (feeling) the maternal abdomen. Indirect uterine contraction sensors known as tocodynamometers are electrical sensors for doing the same thing. The basic principle of operation of these sensors is to press against the abdomen to measure the firmness of the underlying tissues. A contracting muscle will feel much more firm than a relaxed one. Most tocodynamometers carry out this function by pressing a probe against the abdomen and measuring its displacement.

The construction of a typical tocodynamometer is shown in Fig. 8. The sensor is held in place against the surface of

Figure 8. Schematic cross-sectional view of a tocodynamometer. [Reprinted with permission from CRC Press (6).]

the abdomen with an elastic strap. A movable probe protrudes beyond the surface of the sensor so that it causes a slight indentation in the abdominal wall. It is loaded by a spring, which makes it somewhat compliant; it can be either extended further into the abdominal wall or retracted into the body of the sensor depending on the firmness of the tissue of the abdominal wall under the probe. In some tocodynamometers, the spring tension, and hence the force that the probe exerts on the abdomen wall, can be adjusted by means of a small knob so that optimal operation of the sensor can be achieved. What a uterine contraction occurs, the abdominal wall will become tense, and it tends to push the probe back into the housing of the tocodynamometer. Following the contraction, the spring is again able to push the probe deeper into the abdomen. In some tocodynamometers this actual movement is very slight, whereas in others it can be as great as a few millimeters.

A displacement sensor inside the tocodynamometer provides an electrical signal proportional to the position of the probe. This displacement reflects myometrial activity. Different types of displacement sensors can be used in tocodynamometers. Including a strain gage on a cantilever arm, mutual inductance coils, a linear variable differential transformer, or a piezoelectric crystal.

The principal advantage of the tocodynamometer is the noninvasive way in which it measures uterine contractions. It is the only method that can be safely used before the patient is in active labor. It has serious limitations, however, in the quantitative assessment of labor. The method can be used only to quantitatively determine the frequency and duration of uterine contractions. Its output is only qualitative with respect to the strength of the contractions. Signal levels seen are a function of the position of the sensor on the maternal abdomen and the tension of the belt holding it in place. Signal amplitudes are also strongly related to maternal anatomy, and the method is virtually useless in obese patients. Many patients in active labor complain that the use of the tocodynamometer with a tight belt is uncomfortable and irritating.

Electronic Signal Processing

A block diagram for the uterine contraction channel of an electronic fetal monitor is illustrated in Fig. 9. The sensor can be either an internal or external pressure transducer or

a tocodynamometer. Signals are sometimes filtered in the amplifier stages of the monitor because the uterine contraction information includes only dc and very low ac frequencies. Nevertheless, filtering is generally not necessary for high quality signals, and often the presence of artifact due to breathing movements of the patient is useful in demonstrating that the pressure measuring system is functional.

In some cases, it is necessary to adjust the baseline pressure to establish a zero reference pressure when using the monitor. In the case of direct uterine contraction monitoring when a single pressure sensor is always used with the same monitor, this adjustment should be made by the manufacturer, and additional adjustment should not be necessary. As a matter of fact, making such a zero-level adjustment control available to the operator of the monitor runs the risk of having significantly altered baseline pressures that can affect the interpretation of uterine basal tone. The adjustment of a zero-level control should not replace the requirement of having the proximal and distal end of the fluid-filled catheter at the same level. It is far better to adjust zero levels in uterine pressure monitoring by raising or lowering the external pressure transducer than by adjusting the electrical zero. On the other hand, when the tocodynamometer is used, no physiologically significant zero level exists. It is not possible to establish uterine basal tone with a tocodynamometer. Baseline levels are frequently dependent on how the tocodynamometer is attached to the patient and the structure of the sensor itself. In this case, it is reasonable to adjust the baseline level between uterine contractions so that the tracing conveniently fits on the chart. When doing so, it is important that the chart indicates that the uterine contractions were measured using a tocodynamometer so that the individual reading the chart does not ascribe inappropriate information to the baseline.

Uterine Electromyogram

The uterus is a muscle, and electrical signals are associated with its contraction as they are for any kind of muscle. These signals can be detected from electrodes on the maternal abdomen or the uterine cervix during uterine contractions. Garfield and others have studied these signals and suggested that they might be useful in managing

Figure 9. Block diagram of the signal processing electronics for intrauterine pressure measurement.

patients during pregnancy and, perhaps, even during labor (18–20). These techniques are still experimental and not yet ready for clinical application. Nevertheless, they offer a new approach to assessing uterine activity and the possibility of differentiating contractions leading to cervical dilatation from those that are nonprogressive.

THE FETAL CARDIOTOCOGRAPH

Electronic fetal monitoring is accomplished using a fetal cardiograph, such as illustrated in Fig. 10, which is basically a two-channel instrument with a two-channel chart recorder as the output indicator. One of the channels records the fetal heart rate, whereas the second channel records the uterine contractions. Most cardiographs are capable of accepting direct or indirect signals as inputs for each channel, although specialized monitors for antepartum assessment have only the indirect signal input capability. To aid clinicians in interpreting monitored patterns, most instruments use chart paper that is 70 mm wide for the fetal heart rate channel and calibrated from 30 to 240 beats·min⁻¹. The uterine contraction channel is 40 mm wide and calibrated with a scale from 0 to 100. The scale is only qualitative when a tocodynamometer is the input source, but corresponds to the pressure in millimeters of mercury when direct sensors of uterine contractions are used. The standard speeds for the chart paper are 1 or 3 cm/min. The use of a standardized chart and chart speed results in fetal heart rate—uterine contraction patterns that appear the same no matter what monitoring device is used—which is important because cardiographs are read by visually recognizing patterns on the chart. Changing the chart speed and scale significantly changes the appearance of the patterns even though the data remain unchanged. Thus, a clinician would have to learn to interpret patterns from each of the different types of monitors used if they each had different chart speeds and scales, because the same pattern can appear quite different when the chart speed or signal amplitude is changed.

Information Obtained from Fetal Cardiography

In interpreting a cardiograph, a clinician considers the heart rate and uterine contraction information separately

Figure 10. A commercially available fetal cardiograph. (Courtesy of Portage Health System, Hancock, Michigan.)

as well as the interaction between the two signals. The frequency, duration, and, in the case of direct monitoring, amplitude and baseline information have already been discussed. Similar types of information can be obtained from the directly and indirectly monitored fetal heart rate recordings. Specifically in the fetal heart rate channel, one looks for the average baseline value of the fetal heart rate, which should generally be in the range 120–160 beats·min⁻¹ and when outside of this range can be cause for concern. The beat-to-beat variability of the fetal heart rate can also be an important indicator of fetal condition, and so the use of an instantaneous cardiometer in a cardiograph is mandatory. Certain recurring patterns in the fetal heart rate recording can also be important indicators of fetal condition. Sinusoidally varying fetal heart rate has been described as an ominous sign (21), and sometimes fetal cardiac arrhythmias can be detected by observing the heart rate pattern.

The information that is most frequently obtained from the cardiograph and applied clinically comes from both the heart rate and uterine contraction channels and is concerned with the relationship between these two signals. One can consider a uterine contraction as a stress applied to the fetus and the resulting changes in the fetal heart rate as the response to this stress. When the changes occur in direct relationship to the uterine contractions, they are referred to as periodic changes in the fetal heart rate. Several possibilities exist for fetal heart rate changes during and following a uterine contraction. One can see no change, an acceleration, or a deceleration in the fetal heart rate. In the case of decelerations, three basic patterns are seen, and representative examples of these are shown in Fig. 11. The different patterns are characterized by the shape of the deceleration curve and the temporal relationship of its onset and conclusion with the uterine contraction.

Early decelerations begin during the rising phase of the uterine contraction and return to baseline during the falling phase. They frequently appear to be almost the inverse of the uterine contraction waveform. Periodic decelerations of this type are thought to not represent a serious clinical problems.

Late decelerations refer to fetal heart rate decelerations that begin during a uterine contraction but late in the duration of that contraction. The rate of heart rate descent is not rapid, and the deceleration lasts beyond the end of the contraction and then slowly returns to baseline. Such patterns sometimes can be associated with fetal distress, although they should not be considered definitive of fetal distress.

The third type of periodic deceleration of the fetal heart rate is known as a variable deceleration. In this pattern, the deceleration of heart rate is sharp and can occur either early or late in the duration of the uterine contraction. Following the contraction, a rapid return to baseline values occurs. Sometimes one sees rapid return to baseline while the uterus is still contracting and then a rapid fall back to the reduced heart rate. Variable decelerations have a flat “U” shape, whereas early and late decelerations represent a more smooth curve that could be characterized as shaped as the letter “V” with the negative peak rounded. Variable

Figure 11. Examples of fetal cardiocograms showing the three basic patterns: (a) early deceleration, (b) late deceleration, and (c) variable deceleration.

decelerations can be sometimes associated with involvement of the umbilical cord, and, in some cases, they can indicate the presence of fetal distress. As more recent clinical studies have shown that a simple relationship between late and variable decelerations and fetal compromise, does not exist these patterns are not considered to indicate fetal distress as they once were. Now clinicians refer to them as being “nonreassuring,” and their presence should encourage the application of other clinical measures to evaluate the fetus.

These basic thoughts for interpreting the fetal cardiocogram are very elementary and should not be used for diagnostic purposes. The reader is referred to the current

obstetrical literature for more detailed descriptions of fetal cardiocogram and their clinical significance.

Clinical Applications of Fetal Cardiotocography

Electronic fetal monitoring can be applied during the antepartum (before labor and delivery) and intrapartum (during labor and delivery) periods of pregnancy. In the antepartum period, only indirect methods of fetal monitoring can be used. A primary application of fetal cardiotocography in this period is in nonstress testing. In this test, a cardiocogram is applied to a patient who is resting quietly. In the United States, the ultrasonic Doppler method of detecting the fetal heart rate and the tocodynamometer are the sensors of choice. The patient is monitored for 1–2 h, and the cardiocogram is examined for spontaneously occurring uterine contractions or fetal movements, which can also be indicated by the tocodynamometer. In some cases, the mother is asked to activate an event marker on the chart when she feels a fetal movement. The response of the fetal heart rate to these stimuli is noted in interpreting the cardiocogram. In a reactive nonstress test, a response to these stimuli occurs, which is usually in the form of a brief fetal heart rate acceleration following the uterine contraction or fetal movement. Although nonstress testing is not routinely applied to apparently normal pregnancies, it is indicated for complications of pregnancy such as maternal diabetes, Rh sensitization, intrauterine growth retardation, decreased fetal movement, known fetal anomalies, oligohydramnios or polyhydramnios (too little or too much amniotic fluid), pregnancy-induced hypertension, pregnancy lasting beyond the normal 40 weeks, and other maternal and fetal complications.

A second antepartum test involving fetal cardiotocography is the oxytocin challenge test, which is usually applied when the nonstress test yields positive results, such as when fetal heart rate decelerations follow spontaneous uterine contractions or fetal movements. In this test, the patient is given intravenous oxytocin, a hormone that stimulates uterine contractions. The response of the fetal heart rate to the induced contractions is then examined, looking for the periodic changes described before.

Intrapartum monitoring of the fetal heart and uterine contractions can be carried out using the indirect techniques in early labor with the direct techniques applied during active labor. The indications for intrapartum fetal monitoring are controversial. Some obstetricians feel that all labors should be monitored whether they are complicated or not, whereas others feel that only those patients considered being at risk should have monitors. As monitoring is no longer considered to give a definitive diagnosis of fetal distress, some clinicians find it of little value and do not make use of the technology. As internal monitoring gives the most efficacious results, this modality is recommended in cases when it can be applied and the indirect methods do not give satisfactory results. Otherwise, indirect methods can be used as long as they give readable results.

The preceding paragraphs describe fetal cardiotocography as clinically applied in most major medical centers. Although this technology has the advantage of providing

continuous surveillance of the mother and fetus, it also has some limitations that prevent it from providing optimal information to obtain the earliest indications of fetal or maternal problems. The major limitation is in the data. Although uterine contractions provide a good indication of the intensity of labor, they do not necessarily indicate its effectiveness in dilating the cervix and expelling the fetus. If, in addition to uterine contractions, one should monitor whether labor is progressing, better information about some maternal aspects of labor and delivery could be obtained.

A similar argument can be made for the use of the fetal heart rate as the primary variable for evaluating the status of the fetus. Heart rate is a very non specific variable, and, in some cases, the fetus must be seriously compromised before any problem is detected by the heart rate. The goal of fetal monitoring as mentioned at the beginning of this article is to make certain that vital organs such as the fetal brain are adequately perfused so as to receive necessary nutrients and oxygen. Although the heart rate is related, it is not the principal variable for determining this perfusion.

Accepting these principal limitations for the variables measured, limitations still exist to the practical application of the cardiocotograph. Sensor placement, especially for indirect monitoring, is important for optimal recordings. The operator of the instrumentation, therefore, must be skilled in determining the best placement for the sensors. Most cardiocotographs are connected to the sensors on the patients by wires and catheters. Although this method is quite adequate while the patient is in bed, it can become quite inconvenient when it is necessary to transfer the patient to another location or to have the patient stand up and walk around. Many of these problems have been overcome by the use of biotelemetry for fetal monitoring (see Biotelemetry).

A final limitation of fetal cardiocotography is associated with the fact that some of the monitored patterns are not easily recognized and interpreted, which means that different clinicians looking at the data can see different things, lead to uncertain diagnoses. Periodic decelerations are usually not as clear, as illustrated in Fig. 11. Again, experience is an important factor here. Even when patterns can be readily determined, the relationship between certain patterns and pathology is not completely clear. As is so often the case in medicine, one can only suggest from monitored tracings that certain problems might be present, and other tests need to be performed for confirmation.

OTHER METHODS OF FETAL MONITORING

Although the cardiocotogram is the usual method used to monitor the fetus, other techniques have been developed and experimentally employed to more accurately assess fetal status during the antepartum and intrapartum periods. One of these techniques, fetal microblood analysis is routinely used at major medical centers that care for patients deemed to have high risk pregnancies; the other techniques are still experimental or relatively new and have not enjoyed routine application at the time of this writing.

Fetal Microblood Analysis

About the time when electronic fetal monitoring was developed, Saling (22) was working on a new technique for taking a small sample of fetal capillary blood during active labor and measuring its hydrogen ion activity. This technique, known as fetal microblood analysis, made it possible to determine whether acidosis that could be associated with fetal distress was present during the labor. The technique involves observing a portion of the fetal presenting part (usually the scalp) through the cervix using a vaginal endoscope. By cleaning this portion of fetal skin and even, in some cases, shaving a small amount of hair from the scalp, the obstetrician is able to make a small superficial incision in the skin using a scalpel blade. A droplet of capillary blood will form at this site, and it can be collected in a miniature heparinized glass pipet. Generally, 100–300 μL of blood can be collected in this way. The blood sample is transferred to a special instrument designed to measure the pH of very small blood specimens. This instrument can be a part of a more extensive blood gas analysis instruments in a blood gas laboratory or it can be a relatively simple bedside device that uses disposable pH sensor cartridges. In either case, it is possible to measure the pH of this small sample and get the results back to the clinician within a few minutes of collecting the sample.

Chronic hypoxia can cause tissue and, hence, blood pH to drop as a result of the formation of acidic products of anaerobic metabolism such as lactic acid. Thus, if a blood sample is found to have a low pH (most clinical guidelines say lower than 7.2 or in some cases 7.15), it is possible that the fetus is experiencing some form of distress. Often, this technique is used in conjunction with fetal cardiocotography. When the cardiocotograph indicates possible fetal distress, such as when late decelerations are seen, the clinician can get a better idea as to whether distress is indeed present by performing a fetal microblood analysis. If the results indicate acidosis, the probability of actual fetal distress is higher, and appropriate actions can be taken.

A major limitation of the Saling technique is that it gives only an indication of the fetal acid-base status at the time the blood sample was taken. It would be far better to have a continuous or quasi-continuous measure of fetal tissue pH. Stamm et al. (23) have described a technique in which a miniature glass pH sensor is placed in the fetal scalp during active labor. This sensor can continuously record the pH of the fetal scalp. Clinical studies of this technique have shown that a drop in fetal tissue pH can occur along with a cardiocotographic indication of fetal distress (24). The major limitation of this as yet experimental technique is technical. The sensor is fragile, and it is not always possible to obtain efficacious recordings from it. Other sensors are under development in an attempt to overcome some of these limitations (25), yet this technique remains experimental due to the lack of practical devices.

Monitoring of Fetal Blood Gases

Many investigators have been interested in developing technology to continuously monitor fetal oxygenation during active labor and delivery. A review of some of the earlier techniques showed different types of oxygen sensors that

could be placed in the fetal scalp using structures similar to electrodes for directly obtaining the fetal electrocardiogram. Investigators also have used transcutaneous oxygen sensors on the fetus (26), and the most recent approach has been the uses of fetal pulse oximetry (27–29). In the transcutaneous oxygen case (see Blood Gas Measurement, Transcutaneous), a miniature sensor is attached to the fetal scalp once the cervix has dilated enough to make this physically possible, and fetal membranes have been ruptured. The technique is considerably more difficult than that for neonates, and it is important to have a preparation where the sensor surface is well approximated to the fetal skin so no chance exists for environmental air to enter the electrode, as fetal PO_2 is much lower than that of the air. Most investigators who use this technique experimentally find that gluing the sensor to a shaved region of fetal scalp is the best technique to maintain contact (26).

Fetal pulse oximetry is performed in a similar way, but the sensor probe does not have to be physically fixed to the fetus as was the case for the transcutaneous oxygen tension measurement described above (27–29). Instead, the probe is a flat, flexible structure that contains light-emitting diodes at two different wavelengths and photodetector for sensing the reflected light. It is slid between the fetal head and the cervix once the head is engaged and membranes have been ruptured and is oriented so that the light sources and detector are pressed against the fetal skin by the uterine wall. The reflected light at each wavelength will vary in intensity as the blood volume in the fetal tissue changes over the cardiac cycle. As with the routine clinical pulse oximeter, the ratio of amplitudes of the reflected light at the different wavelengths is used to determine the oxygen saturation of the fetal arterial blood.

Recent improvements in the technology of making transcutaneous carbon dioxide sensors have allowed miniature transcutaneous sensors to be built in the laboratory. These have been applied to the fetus during active labor to continuously measure carbon dioxide tensions (30). All of these transcutaneous methods of measuring fetal blood gases are experimental at the time of this writing and have limitations regarding the technique of application and the quality of recorded information. Nevertheless, they present an interesting new approach to monitoring the fetus using variables more closely related to fetal metabolism and, hence, with greater potential for accurately detecting fetal distress.

Fetal Activity and Movements

The amount of time that the fetus spends in different activity states may be an important indicator of fetal condition. The fetus, as does the neonate, spends time in different activity states. Part of the time it may be awake and active, moving around in the uterus; at other times, it may be quiet and resting or sleeping. By establishing norms for the percentage of time that the fetus spends in these states, one can measure the activity of a particular fetus over a period of time and determine whether it falls within the normal classifications as a means of evaluating fetal condition.

One of the simplest ways to measure fetal activity is to have the mother indicate whether she feels fetal

movements over a period of time, which can be done and recorded for several days as an assessment of fetal well-being. Fetal movements can also be detected by tocodynamometers. If the fetus is located under the probe of a tocodynamometer and moves or kicks, it can be detected as a short-duration pulse of activity on the chart recording from the sensor. Maternal movements can appear on this sensor as well, and so it is not easy to differentiate between the two. Timor-Trich et al. have developed a technique using two tocodynamometers to minimize this problem (31). By placing one over the fundus of the uterus and the second at a lower level, and recording the signals on adjacent channels of a chart recorder, fetal movements very often either are seen only on one sensor or produce pulses of opposite sign on the two sensors. Maternal movements, on the other hand, are usually seen on both sensors and are similar in shape and sign.

One of the most elegant methods of measuring fetal movements is to directly observe these movements using real-time ultrasonic imaging (see Ultrasonic Imaging). The main limitation of this technique is that an ultrasonographer must continuously operate the apparatus and reposition the ultrasonic transducer to maintain the best image. It also requires the subject to rest quietly during the examination. Although not believed to be a problem, no definite evidence currently exists that long-term exposure of the fetus to ultrasonic energy is completely safe.

One special type of fetal movement that is of interest to obstetricians is fetal breathing movement. The fetus goes through periods of *in utero* movement that are very similar to breathing movements. The relative percentage of these movements during a period of time may be indicative of fetal condition (32). Such movements can be observed using real-time ultrasound as described above. One can also select specific points on the chest and abdomen and use the ultrasonic instrument to record movements of these points as a function of time as one does for echocardiography (see Echocardiography). Measurement of fetal breathing movements by this technique also requires an experienced ultrasonographer to operate and position the instrumentation during examinations. For this reason, it is not a very practical technique for routine clinical application.

Fetal Electroencephalography

As one of the principal objectives of fetal monitoring is to determine if conditions are adequate to maintain fetal brain function, it is logical to consider a measure of this function as an appropriate measurement variable. The electroencephalogram (EEG) is one such measure that is routinely used in the neurological evaluation of patients. The EEG from the fetus during labor has been measured and shown to undergo changes commensurate with other indicators of fetal distress during labor and delivery (33,34). The monitoring of fetal EEG involves placement of two electrodes on the fetal scalp and measurement of the differential signal between them. These electrodes can be similar to the electrodes used for detecting the fetal electrocardiogram, or they can be electrodes especially designed for EEG. Of course, when either of these electrodes is used in the unipolar mode, the fetal electrocardiogram can be obtained.

Rosen et al. obtained good-quality fetal EEG recordings using a specially designed suction electrode (34). By observation of configurational or power spectrum changes in the EEG, it may be possible to indicate conditions of fetal distress.

Continuous Monitoring of Cervical Dilatation

In the routine method used to assess the progress of labor, the examiner places his or her fingers in the vagina and feels the uterine cervix to determine its length, position, and dilatation. Although this technique is simple and quick and requires no special apparatus, it has some limitations as well. It is an infrequent sampling method, and each time a measurement is made there can be discomfort for the patients as well as risk of intrauterine infection. The technique is also very subjective and depends on the experience of the examiner. A more reliable and reproducible technique that is capable of giving continuous records could be useful in the care of high-risk patients and patients with increased risk of intrauterine infection. Mechanical, caliper-like devices attached to opposite sides of the cervix have been described by Friedman (35) and others. These devices measure a cervical diameter with an electrical angular displacement transducer attached to the calipers. These devices are somewhat big and awkward, and Richardson et al. have optimized the mechanical structure by reducing its size (36). Other investigators have eliminated the mechanical calipers and used a magnetic field to measure the distance between two points on diametrically opposed sides of the cervix (37). In another technique for continuously monitoring cervical dilatation reported by Zador et al., ultrasound is used to measure the cervical diameter (38). A brief pulse of ultrasound is generated at a transducer on one side of the cervix and is detected, after propagating across the cervical canal, by a similar transducer on the opposite side. By measuring the transit time of the ultrasonic pulse between the two transducers, one can determine the distance between them, because ultrasound propagates through soft tissue a nearly constant known velocity. By generating an ultrasonic pulse once a second, a continuous recording of cervical dilatation as a function of time can be produced, which can be recorded either on an adjacent channel with the fetal cardiogram or on a separate display that generates a curve of cervical dilatation as a function of time known as a labor graph. Many clinicians plot such a curve as a result of their digital examinations of the cervix.

SUMMARY

As seen from this article, the use of biomedical instrumentation in obstetrical monitoring is fairly extensive, but the variables measured are not optimal in achieving the goals of fetal monitoring. Some of the newer and yet experimental techniques offer promise of getting closer to the question of whether vital structures in the fetus are being adequately perfused, but at the present time, none of these techniques are ready for general widespread application. Fetal monitoring is important if it can detect correctable fetal distress, as the results of such distress can remain with the newborn for life. It is important that the fetal

monitoring techniques used will eventually benefit this patient. Some critics of currently applied fetal cardiotocography claim that the only result of fetal monitoring has been increase in the number of cesarean sections performed, and this might have a negative rather than positive effect on patient care. It is important that as this area of biomedical instrumentation progresses, biomedical engineers, clinicians, and device manufacturers are not only concerned with the technology. Instead, true progress will be seen when measured variables and their analysis are more closely and more specifically related to fetal status, and measurements can be made in a less invasive way without disturbance or discomfort. The application of this technology must be a benefit to the patients and to society.

FIBER OPTICS IN MEDICINE

MARK D. MODELL
 LEV T. PERELMAN
 Harvard Medical School
 Beth Israel Deaconess Medical
 Center
 Boston, Massachusetts

INTRODUCTION

In the first edition of the Wiley *Encyclopedia of Medical Devices and Instrumentation*, our friend and colleague Max Epstein, Professor Emeritus at Northwestern University, wrote an excellent article on Fiber Optics in Medicine. Now, almost 20 years later, applications of fiberoptics in medicine underwent dramatic changes and expansions. Thus on Max's recommendation, this article has been updated and rewritten for the application of fiber optics in medicine for the second edition while keeping, where it was appropriate, the original text.

For a long time optical fibers in medicine have been primarily used in endoscopy, where they have been employed for transmission of illumination to the distal end of the fiberoptic endoscope and for conveying images for the visualization of otherwise inaccessible organs and tissues. However, in the past 20 years, the science of biomedical optics of the light–tissue interaction has been dramatically advanced. The new methods of imaging, often based on substantial utilization of the optical fibers, for example, optical coherence tomography (OCT) and fiber-based confocal microscopy have been introduced. Also, the new methods of the diagnostics employing various spectroscopic techniques, for example reflectance spectroscopy, light scattering spectroscopy (LSS), fluorescence spectroscopy, and Raman spectroscopy have been developed. To be useful in the diagnosis of tissue in the lumens of the human body, these methods utilize fiber-based catheters. Phototherapy and diagnoses of internal organs also require optical fiber catheters.

The goal of this article is to give the reader basic tools necessary to understand principles of biomedical fiber optics and its applications. In addition to diagnostic, imaging, and therapeutic applications that are described in this article, optical fibers have been employed in a number of biomedical applications, for example, laser surgery and fiber-based transducers for monitoring physiologically important parameters (temperature, pressure, oxygen saturation, blood flow). All those subjects have been covered in detail in the dedicated articles of this encyclopedia.

The structure of this article is the following. The first section provides general physical and engineering principles of fiber optics needed to understand the rest of the article. It discusses the physics of total internal reflection and through-put, fiber propagation modes, optical fiber construction, and

types of fibers. The next section provides the reader with the review of illumination applications of fibers in medicine. The third section discusses the diagnostic applications of the biomedical fibers, including imaging and spectroscopy. The last section reviews therapeutic applications of fibers.

GENERAL PRINCIPLES OF FIBER OPTICS

The Physics of Fiber Optics: Total Internal Reflection

For almost 400 years, it has been well known from classical optics that when light enters a medium with a lower refractive index it bends away from the imaginary line perpendicular to the surface of the medium. However, if the angle of incidence is sufficiently large, the angle in the medium with lower refractive index can reach 90° . Since the maximum possible angle of refraction is 90° , the light with higher angles of incidence would not enter the second medium and will be reflected entirely back in the medium from which it was coming. This particular angle is called the critical angle and the effect is called total internal reflection.

The effect of total internal reflection that makes an optical fiber possible is depicted in Fig. 1. The light in an optical fiber propagates through the medium with high refractive index, which is called core (usually the silica glass). The core is surrounded by another medium with lower refractive index, which is called cladding (usually another type of the silica glass). If light reaches the core-cladding interface with an incident angle higher than the critical angle it will be entirely reflected back into the optical fiber. However, if light reaches the core-cladding interface with an incident angle lower than the critical angle, it will leave the core and will be lost. Thus, optical fibers can propagate light only at a certain angular composition, which depends on the critical angle of the core-cladding interface and thus on the refractive indexes of the core and the cladding.

Light, being continuously reflected from the core-cladding interface, can propagate very far through an

Figure 1. Total internal reflection confines light within optical fibers. (From *The Basics Of Fiber Optic Cable*, ARC Electronics.)

optical fiber, even if the fiber is bent or is placed in a highly absorptive medium. However, if the fiber is bent too much some of the light can escape the core of the fiber. Other sources of losses are impurities in the glass. Typical optical fiber has 50–60% losses per kilometer of its length.

Throughput

There is a limit on how much light an optical fiber can transmit. Intuitively, it should be limited by an acceptance angle of a fiber and its area. This rule is often formulated as a conservation of throughput principle, which is a very general principle in optics.

For a given aperture in an optical system, the throughput T is defined by

$$T = S(\text{NA})^2$$

where S is the area of the aperture, and NA is numerical aperture of the optical element equal to the sine of the maximum divergence angle of radiation passing through the aperture (1). Conservation of throughput says that it can be no greater than the lowest throughput of any aperture in the system (2). It is very important to take the throughput of the fiber into consideration when one calculates the power, which can pass through the fiber.

Propagation Modes

By solving Maxwell's equations for an optical fiber one can find various patterns of the electromagnetic field inside the fiber. Those patterns are modes of the fiber. There are two main types of an optical fiber. The fiber can be either single mode or multimode (see Fig. 2). The difference between these types is the number of modes that the fiber can propagate.

A single-mode fiber is a fiber through which only one mode can propagate. Usually, a single-mode fiber has a very small core, $\sim 5\text{--}10\ \mu\text{m}$ in diameter. Due to their size and also because of their small NA, these fibers have a very small throughput. In medicine, such fibers are used, for example, in confocal microscopy because of the requirement for the small core diameter of the fiber tip (see the section *Fiber-Based Confocal Microscopy*) and OCT. However, in OCT they are used not for their size, but because the coherence of the light pulse is critical for OCT to work (this is described in detail in the section *Optical Coherence Tomography characterization of flexible imaging fiber Bundles*).

Figure 2. Types of fibers. (From *Basic Principles of Fiber Optics*, Corning Incorporated © 2005.)

Figure 3. Fiber components. (From Basic Principles of Fiber Optics, Corning Incorporated © 2005.)

The core of the multimode fiber can be much larger, somewhere between 50 and 1500 μm in diameter. These fibers are ideal for light delivery and collection, and are used in medicine when the throughput is important (see the Section Spectroscopy).

In addition to the single-mode and multimode fibers, there is another important type, that is, a polarization-maintaining fiber. The polarization-maintaining capability of a fiber is provided by the induced birefringence in the core of the fiber. This birefringence causes the polarization in these fibers to remain in the axis that it was launched into the fiber and is not changing randomly as in the regular fiber.

There are two main types of the polarization-maintaining fibers: one with the geometrical birefringence and another with the stress-induced birefringence. Geometrical birefringence is created by the elliptically shaped core. The stress-induced birefringence is created by using two stress rods as a core.

In the application where fibers are exposed to the physical stress and temperature changes, the former type is used mostly since it maintains its polarization.

Optical Fiber Construction

Optical fiber consists of three main components: core, cladding, and coating as shown in Fig. 3. The fiber is constructed by drawing a solid glass rod in a high purity graphite furnace. The rod consists of a core with high refractive index inside a low refractive index cladding. Thus both core and cladding are produced from a single piece of glass.

After core and cladding are formed, the protective coating is applied to the fiber. This protective coating is called a jacket and it guarantees that the fiber is protected from the outside environment.

Types of Fibers

Transmission ranges of materials used for fibers are shown in Fig. 4 (3). Most lasers operate in the range from 300 to 2500 nm, where silica fibers have the best overall properties and thus are commonly used.

Ultraviolet, Visible, and Near-Infrared Fibers. Ultraviolet(UV), visible, and near-infrared (NIR) light spans the range from 200 nm to 2.5 μm . Visible and near-IR light

Figure 4. Transmission ranges of materials used for fibers (From Ref. 3)

propagates in the silica-based fibers with practically no losses due to the low absorption of the order of tenths of percent per meter. In the IR range (wavelength $>2.4 \mu\text{m}$) and UV (wavelength $<400 \text{ nm}$) absorption is higher. The silica-based fiber absorption is caused primarily by hydroxyl radicals (OH), and thus is determined by OH concentration resulting from the presence of free water during the fiber production. Low OH concentration determines excellent transmission of these fibers in the NIR range up to 2.4 μm . At wavelengths longer than 2.5 μm , the absorption of silica limits the use of silica fibers. In the UV range, most of the silica fibers are usable down to 300 nm, particular the fibers with a high OH concentration. For shorter wavelengths fibers with both core and cladding made of silica, silica-silica fibers are used.

For applications in wavelengths $<230 \text{ nm}$, special attention should be paid to the solarization effect caused by the exposure to the deep UV light. The solarization effect is induced by the formation of "color centers" with an absorbance at the wavelength of 214 nm. These color centers are formed when impurities (like Cl) exist in the core and cladding fiber materials, and form unbound electron pairs in the Si atom, which are affected by the deep UV radiation. Recently, solarization resistant fibers have been developed. It consist of a silica core, surrounded by silica cladding that is coated in aluminum, which prevents the optical fiber from solarizing. The fiber preform (a high grade silica rod used to make the fiber) is hydrogen loaded in a hydrogen-rich environment that helps to heal the silicone-oxygen bonds broken down by UV radiation.

As far as power-handling capability is concerned, the typical glass optical fiber is quite adequate in applications where the laser beam energy is delivered continuously or in relatively long pulses such that the peak power in the optical fiber does not exceed power densities of several megawatts per square millimeter. When the laser energy is delivered in very short pulses, however, even a moderate energy per pulse may result in unacceptable levels of-peak power. Such may be the case of Nd-YAG lasers, operating in mode-locked or Q-switched configurations, which produce laser beam energy in the form of pulses of nanosecond duration or less. On the other hand, excimer lasers, which are attractive in a number of applications (4), generate energy in the UV range of the spectrum (200–400 nm) in

very short pulses; they, therefore, require solarization-resistant silica-silica fibers, which can transmit light energy at such short wavelengths and, at the same time, carry the high power densities.

The limitation on power-handling capability of a glass optical fiber is due to several nonlinear effects, for example, Raman and Brillouin scattering (5), avalanche breakdown (6), and self-focusing (7). Stimulated Raman scattering, which occurs when, because of molecular vibrations, a photon of one wavelength, say that of the laser, is absorbed and a photon of another wavelength, known as a Stoke's photon, is emitted, has been observed at power densities of $6 \text{ MW}\cdot\text{mm}^{-2}$. The time varying electric field of the laser beam generates, by electrostriction, an acoustic wave, which in turn modulates the refractive index of the medium and gives rise to Brillouin scattering. Thus, Brillouin scattering is analogous to stimulated Raman scattering wherein the acoustic waves play the same role as the molecular vibrations. Although the Brillouin gain is higher than the one measured for the stimulated Raman scattering, the latter is usually the dominant process in multi-mode fibers (8).

Under the influence of an intense electromagnetic field, free electrons, which may exist in the optical fiber as a result of ionized impurities, metallic inclusions, background radiation, or multiphoton ionization, are accelerated to energies high enough to cause impact ionization within the medium. If the rate of electron production due to ionization exceeds the electron loss by diffusion out of the region, by trapping, or by recombination, then an avalanche breakdown may occur, resulting in material damage. If high enough power densities ($>100 \text{ MW}\cdot\text{mm}^{-2}$) are applied to the fiber core, avalanche breakdown is the main mechanism of permanent damage to the optical fiber. The fiber surface should be polished and chemically processed with great care to avoid reduction in the damage threshold level of the fiber surfaces. The latter is usually lower by two orders of magnitude than that of the bulk material as a result of the presence of foreign materials embedded during improper polishing or because of mechanical defects. The threshold of induced Raman and Brillouin scattering and avalanche breakdown can be further substantially reduced by self-focusing of the laser beam. Self-focusing may occur when the refractive index of the nonlinear medium increases with beam intensity. The possible physical mechanisms involved are vibration, reorientation, and redistribution of molecules, electrostrictive deformation of electronic clouds, heating, and so on. Thus, a laser beam with a transverse Gaussian profile causes an increase in the refraction index in the central portion of its path of propagation, and becomes focused toward the center. Self-focusing is counteracted by the diffraction of the beam and the balancing effects of the two determine the threshold of power that causes self-focusing; for glass it was found to be $\sim 4 \text{ MW}$. Damage to optical fibers can also occur if a pulsed-laser beam is not properly aligned with the entrance face of the fiber (8,9).

IR Fibers. For the IR region beyond 2500 nm, materials other than silica are being used. These IR fibers can be classified into three categories: IR glasses fibers, crystal-

line fibers, and hollow fibers (10,11). Fluorozirconate and fluoroaluminate glass fibers can be used in the 0.5–4.5 μm region. Commercially, they are produced in diameters from 100 to 400 μm . Because of their low melting point, they cannot be used $>150^\circ\text{C}$; however, they have a high damage threshold. The refractive index is similar to silica (~ 1.5) and the transmission is $>95\%$ for several meters. For longer wavelengths (4–11 μm) chalcogenide glass fibers are available in diameters of 150–500 μm . The disadvantage of these fibers is that they are mechanically inferior to silica fibers and are toxic. They have high Fresnel reflection because of the high refractive index (2.8) and relatively high absorption; as a result they have low transmission [losses are several tens of percent per meter (12)].

The crystalline fibers can be better candidates for the mid-IR range. Sapphire can be grown to a single crystal with a diameter of 200–400 μm , which is strong, hard, and flexible (13). It can be used up to a wave length of 4 μm . Sapphire, however, has a high index of refraction (1.75), which produces rather high reflection losses at each surface. Silver halide and thallium halide polycrystalline alloys (e.g., KRS-13), in contrast, can successfully transmit even high power CO_2 light (14). From these alloys, good quality fibers are manufactured with high transmission of a few $\text{dB}\cdot\text{m}^{-1}$ and that are insoluble in water, are nontoxic, and are fairly flexible.

Hollow fibers are built as flexible tubes, which are hollow inside, that is with air. They transmit light in the whole IR range with high efficiency (15–17). One type of these fibers comprises metallic, plastic, or glass tubing that is coated on the inside with a metallic or dielectric film with a refractive index $n > 1$ (18). Another type has the tubing coated with a dielectric coating of $n < 1$ for 10.6 μm on the inside of hollow glass (15) or crystalline tubes (19). The losses are 0.4–7 $\text{dB}\cdot\text{m}^{-1}$ depending on the core size. The losses due to bending are inversely proportional to the core radius. Power transmissions $>100 \text{ W}$ have been achieved. The damage threshold for high power densities is comparable with that of solid core fibers. It has been reported that the dielectric-coated metallic hollow fiber is the most promising candidate for IR laser light transmission. The standard hollow fiber is 2 m in length with an inner diameter of 0.7 mm and has transmission $>75\%$ of Er-YAG or CO_2 laser light under practical usage conditions (20).

ILLUMINATION APPLICATIONS

Introduction and Applications

Optical fibers are used for various illumination needs. The use of fiber optics bundles allows illuminating the desired area without the problem associated with the presence of the lamp-based light source.

For example, the fiber bundle brings the visible light to illuminate the area under examination with the colposcope and surgical microscope while the light source is placed in the area not interfering with the physician's activities.

In endoscopy, the fiber optic bundles are incorporated into the small diameter flexible cylindrical body of the endoscope, which is dictated by the necessity to pass through narrow ($<2 \text{ cm}$ at the most) pathway of lumens

Figure 5. Headlight attached to the head bend on the surgeon head. The light from the lamp is transmitted through the fiber bundle to the output lens. (From www.luxtec.com.)

of the human body. The fiber optic bundles are used to bring the light down to the distal end and illuminate the target tissue, which the physician is examining through the imaging channel of the endoscopes.

In surgery, especially in microsurgery, dentistry, and so on fiber optic bundles are used to build a headlight, which creates bright illumination of the surgery area where the

surgeon eyes are pointed. Here, the fiberoptic illumination allows mounting the output lens on the headband of the surgeon and leaving their hands free for the operation (see Fig. 5). Recent development in the fiber optics flat and flexible illumination panels (see below) allows bringing the visible light inside the deep cavities of the human body for illumination during surgery.

In ophthalmology, early application of fiber optic illumination has included its use as a light source in the indirect ophthalmoscope. The resulting small light spot at the distal end of the optical fibers allows for the use of variable apertures and provides sharply focused and uniformly illuminated circles of light upon the retina (21). Fiber optic illuminators are also used in conjunction with intraocular surgery. Thus a variety of miniature devices are available for the visualization of the interior of the eye to provide improved illumination in microsurgery of the retina and vitreous.

Currently, a number of companies are developing the “solid-state” light based on the light emitting diodes (LED). The advantages of this type of illumination is that it produces much less heat and emits in the visible spectral range thus making the illumination fiber bundle less useful for some applications. However, it will take another decade before this type of the light will become commercially viable.

In addition to transmitting the light through the fiber bundle to the target for illumination, the fiber optics often serves to shape the light in the form most advantages for the application. For example, in the form of the rigid or flexible flat panel that can be used during almost any deep cavity surgery. These fiberoptic panels are made of woven plastic optical fibers as shown in Fig. 6.

Figure 6. Principle of the fiber optics panels with the side emission. (From www.lumitex.com.) (a) All fiber optics illumination bundles, light enters the panel through each highly polished fiber end. Here, the computer controlled “macrobends” in the fibers cause the transmitted light to be emitted from the sides of the fibers through the cladding. Precisely engineered construction causes all light to be emitted uniformly along the length of the panel. (b) Layers of fiber optic weave are assembled together with double-sided adhesive into as many as eight layers. A mylar reflector is laminated to the back and a clear vinyl top layer is added for extra durability. For some applications (e.g., LCD backlighting), a semitransparent diffuser layer is placed between the top weave layer and the clear vinyl. The optical fibers extend from the panel in cable form and are bundled into a brass ferrule and highly polished. These ferrules are then connected to a remote light source.

Requirements for Illumination Fibers

A thin optical fiber is obtained by drawing in a furnace a glass rod inside glass tubing, which together form the high refractive index core and the low refractive index cladding, respectively. The core material usually used for the illumination fibers is silica, which, as was discussed earlier, is the best material for the visible spectral range. When drawn to a core diameter of 25 μm or less, the optical fiber is quite flexible, allowing for bending radii of $<1\text{ cm}$.

Light Sources Used with Illumination Fibers. The light sources for the fiberoptic illuminators are tungsten or quartz halogen projection lamps, mercury or xenon high pressure arc in quartz glass enclosures, and metal halide lamps. Color temperatures of tungsten sources vary between 2800 and 3500 K, which is a low color temperature with the illumination appearing yellow. Arc and halide lamps are used in the commercially available illuminators and provide light at the color temperature of $\sim 5400\text{ K}$.

These light sources are a black body type radiator, thus they radiate into the sphere, that is, solid angle of 4π steradian and the amount of the output light they emit is almost proportional to the emitting body (filament, for the tungsten lamps, and arc, for other types). Thus they have the emitting body of $>1\text{ mm}^2$ for the arc lamp and much greater for the tungsten and quartz halogen lamps.

Coupling Efficiency. The fact that the light source radiates in 4π steradian from the emitting body lead to requirements that the optical fibers used for the illumination have a high aperture and sufficient cross-section. To transmit the required illumination through the bundle and keep the fibers flexible, the conventional practice is to gather a lot of thin flexible fibers into a bundle, with the ends bound and polished. This bundle is almost as flexible as the single fiber. The fibers in the ends of the illumination fiber bundles are arranged at random and these bundles are called incoherent. This organization of the fibers in a bundle, in addition to being inexpensive to assemble, is also sometimes useful to provide uniform illumination at the output end.

Various schemes have been employed to maximize the light intensity delivered from the source to the fiber or fiber bundle and to obtain uniform illumination at the distal end of the fiber. For example, a special reflecting mirror, in the form of an ellipsoid of revolution, has the light source and the fiber input at the focal points with the major axis of the ellipsoid at an angle to the receiving fiber. However, note that light lamp sources, as opposed to lasers, could not be focused or concentrated onto areas smaller than their emitting body without considerable loss of the luminous flux. This follows from the fundamental relationship in radiometry, which states that the radiance of an image cannot exceed that of an object for the case when both lie in a medium with the same index of refraction (22). Consequently, the optimum illumination from an optical fiber is obtained when the image of the source completely fills the entry face of the fiber and the cone of light forming this image is equal to the numerical aperture of the fiber. In some cases, when the light source consists of a

filament, the use of reflectors increases the effective area of the source by redirecting light rays through the voids in the filament.

Removal of Heat, UV, and IR Radiation. All lamps produce heat directly or by absorption of light in the visible to IR spectral ranges. Also, the UV radiation portion of the spectrum may be hazardous to the eyes and illuminated tissue. The high intensity light sources needed to deliver adequate illumination to and through the optical fiber cause the latter to become very hot. In the case of fiber bundles, the heat generated at the proximal end of the fibers requires that they not be bonded with epoxy, but instead be fused together. In some cases this may also apply to the distal end if enough heat is conducted through the fiber or is generated by absorption of light in the fiber. Of course, this is highly undesirable and should be avoided. After all, one of the main objectives of the use of illumination fibers is to keep the heat of the light source away from the area being illuminated. Indeed, the early applications of optical fibers were referred to as "cold-light" illumination. Special provisions must, therefore, be made to dissipate and divert large amounts of heat. Most light sources utilize dichroic reflectors and/or heat filters to block the heat from reaching the fiber.

Transmission. The light propagating through the optical fiber is attenuated by bulk absorption and scattering losses. These losses vary with the wavelength of light and are usually higher at short wavelengths, that is, the blue end of the visible spectrum of 400–700 nm. In most illumination applications, the typical length of the fibers does not exceed 2 m and thus the attenuation of light due to absorption is of no consequence. Antireflection coating can reduce Fresnel losses due to reflection at the end faces of the fiber.

The faithful rendition of color in viewing depends on the spectral content of the light illumination. This is of particular significance in medicine where the diagnosis of disease is often determined by the appearance and color of organs and tissue. Hence, optical fibers made of plastic materials, for example, polystyrene for the core and Lucite, polymethylene methacrylate (PMMA), for the cladding, despite their flexibility and low cost, do not find extensive use as illumination fibers.

DIAGNOSTIC APPLICATIONS

Introduction

One of the earliest applications of optical fiber in medicine were in imaging. The bundle of the optical fibers has been used to transmit image from the distal to the proximal end, where the physician could see the image of the target tissue in real time. The device using this technique is known as an endoscope. The endoscopes are used widely in current medical practice for imaging of lumens in the human body.

In the past 20 years, many new diagnostic applications of fiber optics have appeared as a result of the developments in biomedical optics (23). Most all of them utilize a single or a few fibers. Some of them, for example OCT (24)

and confocal imaging (CI) (25) use scanning to produce the images of the lateral or axial cross-sections of the body. Others are utilizing the spectroscopic differentiation of the tissue, using natural (23) or man-made markers (26). Among these techniques, fluorescence (23), reflectance (23), light scattering, and Raman spectroscopic methods (27) are most promising and thus most developed.

Another new area for the application of fiber optics in medicine is the fiberoptic biosensor (FOBS). This is a sensor consisting of optical fiber with a light source and detector and an integrated biological component that provides the selective reaction to the biochemical conditions of the tissue and body fluids. These sensors have been applied for glucose and blood gas measurements, catheter-based oximetry, bilirubin, and so on. The detailed discussion about the principle and applications of these sensors is in "Optical Sensors" article of this encyclopedia.

Imaging

Endoscopy. The word endoscopy derives from two Greek words meaning "inside" and "viewing". Its use is limited to applications in medicine and is concerned with visualization of organs and tissue by passing the instrument through natural openings and cavities in the human body or through the skin, that is percutaneously. The endoscope has become an important and versatile tool in medicine. It provides a greater flexibility than it is possible with instruments that consist of a train of optical lenses, and transmits illumination to the distal end of the probe. The greater flexibility of the flexible endoscope enables the visualization around corners and the elimination of "blind areas" obtained with the rigid instrument. It should be noted that optical fibers are used to deliver illumination light in rigid endoscopes that in some cases may employ lenses for image transmission.

Endoscopes, which utilize optical fibers to transmit the image from the distal to the proximal end, are often called fiberscopes to differentiate them from the video or electronic endoscopes where a semiconductor imager is placed at the distal end and the image is transmitted electronically. Progress in the production of the relatively inexpensive high quality miniature semiconductor imagers based on Charge Coupled Device (CCD) technology and Complementary Metal Oxide Semiconductor (CMOS) led to the development of the high quality electronic (video) endoscopes. Currently, most of the endoscope vendors produce such endoscopes. It appears that these video endoscopes produce higher quality images with considerably higher magnification (28) and are replacing the fiberscopes where it is practical (29–31). However, a large number of fiberscopes are still used in the clinics and new fiberscopes are being sold (e.g., see www.olympusamerica.com). Moreover, in the areas that require thin and ultrathin endoscopes of <2–4 mm (32), fiberscopes are still the only practical solutions. The general discussion on endoscopy, its features, and applications is presented in the Endoscopy article. This article will primarily discuss fiberscopes.

In addition to the imaging and illumination channels, a typical endoscope includes channels to accommodate tools for biopsy to aspirate liquids from the region being

inspected, and to inflate the cavity or to inject clear fluids to allow for better visualization. The overall dimensions of such instruments vary between 5 and 16 mm in diameter, the thinner versions being smaller and more versatile than the corresponding rigid systems. The fiberscope can be made as long as necessary, since the light losses in most fibers made of glass cores and cladding are tolerable over distances of up to several meters. These images can be recorded using film, analog and digital still, and video cameras.

Most of the fiberscopes use similar optical structures and vary mainly in length, total diameter, maneuverability, and accessories, for example, biopsy forceps. The diameter of the individual glass fibers in the image-conveying aligned bundle are made as small as possible limited only by the wavelength of the light to be transmitted. In practical applications, the diameter is ranging from 2 to 15 μm . Moreover, if the fibers are densely packed, cross-talk problems may arise due to the evanescent electromagnetic field (light waves) in each individual fiber (33).

A variety of fiberscopes have been developed, each with features that are best suited for specific applications.

Transmission of Images Through Optical Fibers. As shown in the section General Principles of Fiber Optics, an optical fiber cannot usually transmit images. However, a flexible bundle of thin optical fibers (obviously, with silica core) can be constructed in a manner that does allow for the transmission of images. If the individual fibers in the bundle are aligned with respect to each other, each optical fiber can transmit the intensity and color of one object point. This type of fiber bundles is usually called a "coherent" or "aligned" bundle. The resulting array of aligned fibers then conveys a halftone image of the viewed object, which is in contact with the entrance face of the fiber array. To obtain the image of objects that are at a distance from and larger than the imaging bundle, or imaging guide, it is necessary to use a distal lens or lens system that images the distal object onto the entrance face of the aligned fiberoptic bundle. The halftone screen-like image formed on the proximal or exit face of a bundle of aligned fibers can be viewed through magnifying systems or on the video monitor if this exit face is projected onto the video camera.

Fabrication of Flexible Imaging Bundles. The fabrication of flexible imaging bundles involves winding of the optical fibers on a highly polished and uniform cylinder or drum, with the circumference of the latter determining the length of the imaging structure. The aligned fibers can be wound directly from the fiber-drawing furnace or a separate spool of individual fibers. When the entire bundle is obtained in a single winding process, similar to a coil, an overhang of fibers wound on the outer layers develops after the structure is removed from the winding cylinder. Such overhang can be eliminated by winding single or a small number of layers and cutting them into strips to form the aligned fiber bundle. This process, although more laborious, usually renders better uniformity in the imaging bundles. Some users find the evenness of the fiber arrangement distracting and prefer the irregular structure. This may be compared

with the viewing of a television image wherein the horizontal line scan has accentuated by imperfect interlacing. In either method, the diameter of the fibers is on the order of $10\ \mu\text{m}$, which is thinner than hair or about the size of a strand in a cottonball, and must therefore be soaked in binding epoxy during the winding process. When the completed imaging bundle is cut and removed from the drum, its ends are bound to secure the alignment and the epoxy is removed along the structure to let the individual fibers remain loose, and thus flexible. A flexible imaging bundle can also be obtained by first drawing a rigid preform made up of individual optical fibers, each with a double coating, where the outer cladding is chosen to be selectively etched afterwards. Such a structure has nearly perfect alignment, since the preform can be constructed of fibers thick enough to allow parallel arrangement and the individual fibers in the drawn bundle are fused together without any voids between them. Moreover, such fabrication technique, as compared with the winding method, is far less expensive since it permits batch processing.

The size of the imaging bundle varies from 1 to 2 mm in diameter for miniature endoscopes, for example, angioscopes or pediatric bronchoscopes, where the fiberscopes are currently primarily utilized, to 6 mm in diameter for large colonoscopes, and lengths exceeding 2 m. Large imaging bundles may consist of as many as 100,000 individual fibers (28), each fiber providing one point of resolution or pixel. For such large numbers of fibers, it is often necessary to fabricate the final device by drawing first fiber bundles containing a smaller number of fibers and then joining them together to form a larger structure.

Characterization of Flexible Imaging Fiber Bundles. The resolution attainable with a perfectly aligned fiberoptic imaging structure is determined by the fiber diameter. For a hexagonal configuration, the resolution in optical line pairs per millimeter is, at best, equal to, and usually slightly $<1/2d$, where d is the fiber diameter in millimeters. Figure 7 shows a cross-section of an imaging bundle of fibers aligned in a closely packed hexagonal pattern, i.e., each fiber has six closest neighbors. In Fig. 7a are shown two opaque stripes separated by a distance equal to their width, which are placed at the distal end of an entrance face of the imaging bundle. When this end is illuminated, the corresponding fibers at the output or proximal exit end of the bundle will be either partially or totally darkened, depending on the relative location of the opaque stripes with respect to the fiber pattern. In Fig. 7b, the partially illuminated fibers indicate that the smallest resolvable separation of the two stripes is equal to twice the fiber diameter. In practice, the packing of the fiber bundle is often not perfect, leaving spaces between the fibers; thus, the line resolution is further reduced and is usually $<1/2d$. For a typical imaging bundle in endoscopy, the diameter of the individual fiber is $\sim 10\ \mu\text{m}$ and, therefore, the resolution is better than $50\ \text{line-pairs}\cdot\text{mm}^{-1}$. This resolution is considerably poorer than in most lens systems.

The line resolution for the hexagonally aligned imaging bundle does depend on the orientation of the stripes (Fig. 7). Thus, for an orientation different from that shown in Fig. 7, the line resolution may be somewhat different from that

Figure 7. Image transmission of two opaque stripes from (a) distal end to (b) proximal face of an imaging fiber optics bundle.

obtained. The spatial variance of the image transfer properties of imaging bundle has led to the use of averaging techniques in the evaluation of their limits of image resolution (34). The modulation-transfer function (MTF) of an imaging bundle is the contrast response at its exit face to a sinusoidal test pattern of varying spatial periodicity imaged onto the input or entrance face. The fabrication of an imaging bundle may result in the misalignment or deviation from perfect alignment of the adjacent fibers. A method of evaluation of the image-conveying properties of practical imaging bundles has been developed (35), which takes into account the fact that the arrangement of the fibers may differ at the input and output faces of the imaging bundle. It also uses a statistical approach in determining an average modulation-transfer function. The aligned fiber bundle exhibits a mosaic pattern that represents the boundaries of the individual fibers and that appears superimposed on the viewed image. Hence, the viewer sees the image as if through a screen or mesh. Any broken fiber in the imaging bundle appears as a dark spot. In some applications, these two features can be very annoying and distracting, although most medical practitioners have become accustomed to these peculiarities and have learned to discount them. In some sense, it is comparable to viewing through a window with a wire screen, which in most cases is unnoticed.

Rigid Imaging Bundles. Fiberoptic bundles composed of individual optical fibers far smaller than those described earlier can be obtained by drawing the entire assembly in the furnace in a manner that preserves their alignment. This method is similar to that employed in the preparation of flexible imaging structures by etching a double-clad rigid imaging bundle. However, since the fibers become fused together during the drawing process, the structure

Figure 8. Cross-section of the imaging bundle.

remains a rigid solid-glass rod. A segment of a cross-section of such an imaging bundle, which is 0.5 mm in diameter and contains 11,000 fibers, each 4.2 μm in diameter, is shown in Fig. 8. The honeycomb pattern represents the boundaries of the individual fibers and is superimposed on the image, similar to the flexible fiberoptic imaging bundle.

Fiber-Based Confocal Microscopy. Confocal imaging (CI) is based on illuminating a single point on the sample and collecting scattered light from the same single point of the sample (Fig. 9a). The illumination point on the sample is the image of the illumination pinhole and is imaged into the detector pinhole, thus making both pinholes and the illuminated spot on the sample optically conjugated. In this way, stray light from points outside the collection volume is effectively filtered, improving contrast, particularly for scattering media, for examples, biological tissues. Scanning the position of this point on the sample and acquiring the signal from each position creates a lateral image of the sample. For axial cross-sectional imaging, the focal point on the sample is axially moved while acquiring the signal from each position. Combining both lateral and axial scans provides a perpendicular cross-sectional image of the tissue. The nature of the signal from the illuminated

point depends on the specific embodiment. Either back-scattered or fluorescent signals are most often used for CI; however, other signals have been collected and proven clinically useful.

Both pinholes contribute to depth sectioning ability. The source pinhole causes the illuminating irradiance to be strongly peaked at the image formed by the objective and to fall off rapidly both transversely and along the line of sight (depth). There is, therefore, very little light available to illuminate out-of-focus volumes. This implies that these volumes will not significantly mask the image of the more brightly illuminated focal region. The detector pinhole acts similarly. It is most efficient in gathering the radiation from the volume at the focal point, and its efficiency falls off rapidly with distance, both transversely and in depth. Together they assure that the totality of the out-of-focus signal is strongly rejected.

Confocal imaging provides enhanced lateral and axial resolutions and improved rejection of light from the out-of-focus tissue. As a result, the confocal imaging (CI) can achieve a resolution sufficient for imaging cells to depths of several hundreds of microns. At these depths, CI has been especially helpful in imaging the epithelium of many organs, including internal organs via endoscopic access. Images displayed by the CI system are similar to images of histopathology slides under high resolution conventional microscope, thus, are familiar to the physicians.

The fiberoptic confocal microscope has been introduced in late 1980s and early 1990s (see, e.g., Ref. 37). In this kind of the CI microscope, the light source is not a point source, but the tip of an optical fiber, and the signal is collected by another optical fiber that delivers the signal to a detector. This makes the CI system compact and thus convenient in numerous biomedical applications.

There are a variety of optical systems and scanning arrangements, which allows for optimization of the CI device for the required image and particular clinical application (25). For example, the scanning can be organized by moving the fiber tips, especially, when the common fiber is used for the illumination and detection as shown in Fig. 10b, or by moving the objective lens or by placing in

Figure 9. Confocal microscopy. (a) Principle of confocal arrangement. (From MPE Tutorial, Coherent Incorporated © 2000.) (b) Possible implementation of fiber-based confocal microscope (36).

the pinhole plane an output face of coherent fiber bundle and scanning an image of a pinhole at the entrance end of it.

The CI system can provide a cellular level resolution: A lateral integrated image of tissue (similar to C-scan imaging), a lateral cross-sectional image of tissue at the desirable depth of tissue, a perpendicular-to-the-surface cross-sectional image of the tissue (similar to B-scan imaging), and a combination of the above images, thus a three-dimensional (3D) image of tissue. In each case, the CI system could be optimized to achieve the best overall performance while utilizing the same basic platform. The application of the CI imaging has been successfully demonstrated in diagnostics of intraepithelial neoplasia and cancer of the colon (39). It is reasonable to envision that the CI-based endoscope will be used for the screening of Barrett's esophagus and cancer and other areas of the upper GI tract. It appears that there is potential for application of the CI device combined with one of the scattering-based spectroscopies for the vulnerable plaque screening and triage.

The optical fibers used for the CI application are usually a single mode type because of the requirement for the small core diameter of the fiber tip as discussed above.

Optical Coherence Tomography. Optical coherence tomography is a relatively new technology and has been developed and investigated for the past 15 years (38). It uses the wave property of light called coherence to perform ranging and cross-sectional imaging. In OCT systems, a light beam from a light source is split into a reference light beam and a sample light beam (see Fig. 10a). The sample light beam is directed onto a point on the sample and the light scattered from the sample is combined with the reference light beam. The combined reference and sample light beams interfere if the difference of their optical paths is less than the coherence length. The reference and the collected sample beam are mixed in a photodetector, which detects the interference signal. The light source used in OCT has a low coherence length so that only the light scattered from the sample within the close proximity around a certain depth will satisfy this condition. The strength of the interference signal corresponds to the scattering around this depth. To acquire the signal from another depth in the sample the optical path of one of the beams

is changed so that the same condition is now satisfied by the light scattered from another depth of the sample. The component of the OCT system providing this change is called an optical delay line. By sequentially changing the optical path of one of the beams and processing the photodetector output, a cross sectional image of the sample is generated. By laterally moving the sample beam along the sample provides a perpendicular cross-sectional image of the sample. The OCT image is similar to high frequency ultrasound B-scan images.

Usually a moving mirror in the optical path of one of the beams performs the continuous scan of the optical path. The shortest coherence length of available light sources allows the OCT systems to achieve a depth resolution higher than in high frequency ultrasound imagers, but lower than in confocal imaging. As a direct correlate, the depth penetration of OCT systems is lower than the high frequency ultrasound imagers and higher than the confocal imaging. These parameters make OCT a useful technology in the biological and medical examinations and procedures that require good resolutions to 2 mm depths.

The OCT systems utilizing the fiberoptic components are most often used (Fig. 10b). These systems are compact, portable, and modular in design. The sample arm of the OCT can contain a variety of beam-delivery options including fiberoptic radial- and linear-scanning catheter-probes for clinical endoscopic imaging. The aiming beam is used so that the clinicians could see the location on the tissue where the OCT catheter is acquiring image. The optical fiber based OCT systems require using single mode fibers in both reference and sample arms to keep the coherence of the light guided by the fiber. In some cases, when the OCT system is using the polarization properties of the light, it must utilize the polarization-maintaining fibers.

There is a variety of OCT optical systems and scanning arrangements, which provide room for optimization of the OCT device for the specific clinical application. Recently, several system modifications of the basic OCT have been reported; for example, Fourier transform OCT (40,41), spectroscopic OCT (42), and polarization OCT (43). Some of them appear to promise practical OCT systems with higher data acquisition rates, higher resolution (comparable with

the resolution of CI), better noise immunity, or capabilities to acquire additional information on tissue.

In the endoscopic applications, the sample arm fiber is designed as a probe that goes through the endoscope to the target tissue. There are a number of OCT probes developed and suggested designs (44–54) that provide room for optimization of the OCT device for the specific clinical application. A number of successful clinical studies have been carried out demonstrating the clinical applicability of the endoscopic fiber OCT technique for clinical imaging, for example, for imaging of Barrett's esophagus (54) and esophageal cancer (55), bile duct (56), and colon cancer (55).

Spectroscopy

Reflectance and Fluorescence Spectroscopy. Diffuse reflectance spectroscopy is one of the simplest spectroscopic techniques for studying biological tissue. Light delivered to the tissue surface undergoes multiple elastic scattering and absorption, and part of it returns as diffuse reflectance carrying quantitative information about tissue structure and composition.

This technique can serve as a valuable supplement to standard histological techniques. Histology entails the removal, fixation, sectioning, staining, and visual examination of a tissue sample under the microscope. Tissue removal is subject to sampling errors, particularly when the lesions are not visible to the eye. Also, the multiple-stage sample preparation process is time-consuming, labor intensive, and can introduce artifacts that are due to cutting, freezing, and staining of the tissue. Most importantly, the result is largely qualitative in nature, even though quantitative information is available through techniques, for example, morphometry and DNA multiploidy analysis.

Spectroscopy, in contrast, can provide information in real time, is not greatly affected by artifacts or sampling errors, and can provide quantitative information that is largely free of subjective interpretation. Because it does not require tissue removal, it can be conveniently used to examine extended tissue areas.

Usually, light is delivered and collected using an optical fiber probe that can be advanced through the accessory channel of the endoscope and brought into contact with the tissue. The probe can consist of several delivery and collection fibers. Probably the simplest geometry is a central optical fiber for light delivery and six fibers for light collection arranged in a circle around the central fiber. In Zonios et al. (57), all fibers had a 200 μm core diameter and a NA of 0.22, and were packed tightly with no gap between them. The probe tip was fitted with a quartz shield ~ 1.5 mm in length and in diameter, which provided a fixed delivery and collection geometry with uniform circular delivery and collection spots in the form of overlapping cones. The tip was beveled at an angle of 17° to eliminate unwanted specular reflections from the shield–tissue interface (see Fig. 11).

To extract quantitative properties of tissue collected with the above probe the model of light transport in tissue should take into account probe geometry. To find the total light collected by the probe, diffuse reflectance from a point source must be integrated over the spatial extent of the light delivery and collection areas, characterized by

Figure 11. Configuration of fibers in a typical reflectance and fluorescence optical probe. Probe contains six fibers for light collection arranged in a circle around the central fiber.

radii r_d and r_c , respectively. Assuming the incident light intensity to be uniform over the entire delivery area, the diffuse reflectance $R_p(\lambda)$ collected by the probe is given by (57).

$$R_p(\lambda) = \frac{1}{r_d^2} \int_0^{r_c} r dr \int_0^{2\pi} d\phi \int_0^{r_d} R(\lambda, |\mathbf{r} - \mathbf{r}'|) r' dr'$$

where r_d and r_c are radii of the delivery and collection spots of the fiber optics diffuse reflectance probe and $R(\lambda, |\mathbf{r} - \mathbf{r}'|)$ is diffuse reflectance predicted by the physical model, which depends on tissue morphological and biochemical composition.

A similar probe (Fig. 11) can be used for fluorescence spectroscopy measurements. For fluorescence measurements, it is especially important that delivery and collection signals are delivered over the separate optical fibers. This is because intense illumination light can easily induce certain amount of fluorescence in the delivery fiber. This fluorescence of the fiber is likely to be weak, however, tissue fluorescence is also very weak. Thus if the delivery and collection fibers coincide, the fluorescence from the probe itself would significantly perturb the tissue fluorescence observed by the instrument. Hence, fluorescence fiber probes should always have separate delivery and collection fibers.

Light Scattering Spectroscopy. In addition to the multiply scattered light described by the diffuse reflectance, there is a single scattering component of the returned light that contains information about the structure of the uppermost epithelial cells (58). It has been shown that light scattering spectroscopy (LSS) (Fig. 12) enables

Figure 12. Schematic diagram of the LSS system (59).

quantitative characterization of some of the most important changes in tissues associated with precancerous and early cancerous transformations, namely, enlargement and crowding of epithelial cell nuclei (58,60). Typical nondysplastic epithelial cell nuclei range in size from 4 to 10 μm . In contrast, dysplastic and malignant cell nuclei can be as large as 20 μm . Single scattering events from such particles, which are large compared to the wavelength of visible light (0.5–1 μm), can be described by the Mie theory. This theory predicts that the scattered light undergoes small but significant spectral variations. In particular, the spectrum of scattered light contains a component that oscillates as a function of wavelength. The frequency of these oscillations is proportional to the particle size. Typically, normal nuclei undergo one such oscillation cycle as the wavelength varies from blue to red, whereas dysplastic/malignant nuclei exhibit up to two such oscillatory cycles. Such spectral features were observed in the white light directly backscattered from the uppermost epithelial cell nuclei in human mucosae (60,61).

When the epithelial nuclei are distributed in size, the resulting signal is a superposition of these single frequency oscillations, with amplitudes proportional to the number of particles of each size. Thus, the nuclear size distribution can be obtained from the amplitude of the inverse Fourier transform of the oscillatory component of light scattered from the nuclei. Once the nuclear size distribution is known, quantitative measures of nuclear enlargement (shift of the distribution toward larger sizes) and crowding (increase in area under the distribution) can be obtained. This information quantifies the key features used by pathologists in the histological diagnosis of dysplasia and Carcinoma *in situ* (CIS), and can be important in assessing premalignant and noninvasive malignant changes in biological tissue *in situ*.

However, single scattering events cannot be directly observed in tissue *in vivo*. Only a small portion of the light incident on the tissue is directly backscattered. The rest enters the tissue and undergoes multiple scattering from a variety of tissue constituents, where it becomes randomized in direction, producing a large background of diffusely scattered light. Light returned after a single scattering event must be distinguished from this diffuse background. This requires special techniques because the diffusive background itself exhibits prominent spectral features dominated by the characteristic absorption bands of hemoglobin and scattering of collagen fibers (there is abundance of them in the connective tissue laying below the epithelium). The first technique of diffusive background removal uses a standard reflectance probe described in the section References and Fluorescence Spectroscopy. This technique is based on observation that the diffuse background is typically responsible for >95–98% of the total reflectance signal. Therefore, the diffusive background is responsible for the coarse features of the reflectance spectra. The diffusion approximation-based model may account for this component by fitting to its coarse features. After the model fit is subtracted, the single backscattering component becomes apparent and can be further analyzed to obtain nuclear size distribution (58).

Figure 13. Design of the polarized fiber probe (62).

Another technique would use a special polarized probe. One possible implementation of the polarized probe is described by Utzinger and Richards-Kortum (62) (see Fig. 13). Recently, similar polarized fiber probe was developed by Optimum Technologies, Inc. The working principle of this probe is based on the fact that initially polarized light loses its polarization when traversing a turbid medium such as biological tissue. Consider a mucosal tissue illuminated by linearly polarized light. A small portion of the incident light will be backscattered by the epithelial cell nuclei. The rest of the signal diffuses into the underlying tissue and is depolarized by multiple scattering. In contrast, the polarization of the light scattered backward after a single scattering event is preserved. Thus, by subtracting the unpolarized component of the reflected light, the contribution due to the backscattering from epithelial cell nuclei can be readily distinguished. The residual spectrum can then be analyzed to extract the size distribution of the nuclei, their population density, and their refractive index.

Raman Spectroscopy. Raman spectroscopy is a very powerful technique, which should be capable of performing detailed analysis of tissue biochemical composition. However, in biological tissues the intensity of the Raman signal is only 10^{-9} – 10^{-11} of the intensity of the incident light. What makes it even worse is the fact that fluorescence signal excited in tissue by the same incident light is much higher, $\sim 10^{-3}$ – 10^{-5} of the incident light. And if the signal is detected by the regular optical fiber probe it will also overlap with the fluorescence signal originated in the fiber

Figure 14. Design of the fiber tip of a typical fiber optic probe for Raman spectroscopy (62).

itself. Hence, development of a reliable biomedical Raman fiber probe is still a challenge.

In Fig. 14 one can see the design of a Raman fiber optic probe developed by Visionex Inc. It consists of a central delivery fiber and seven collection fibers. A bandpass filter is located in front of the delivery fiber and a longpass filter in front of the collection fibers. Those filters ensure that no laser light and fluorescence light originated in the delivery fiber can enter the collection fiber.

THERAPEUTIC APPLICATIONS

Introduction

In therapeutic application, fibers are used primarily as a part of light delivery system. Utilization of fibers allows for flexible and convenient methods of delivering light from bulky high energy light sources to the diseased location. Often, using the fiber optics delivery system makes otherwise inaccessible locations accessible. Variety of applications, light sources and energy requirements require different fibers with different features.

Fiber Surgical Applications

The monochromatic nature of laser beam energy, temporal coherence, and the ability to focus it onto a very small spot because of its spatial coherence, allow for efficient surgical methods, for example, tissue cutting or ablation, as well for the transmission of large amounts of power through a single optical fiber. This localized energy can be used to cauterize tissue by evaporation while reducing bleeding by coagulation. The use of lasers in surgical and other therapeutic applications is most effective when employed in conjunction with the flexible delivery systems and, in particular, with laser-beam delivery which is compatible with the endoscopy. Lasers utilized in medical applications range in wavelength from vacuum UV (excimer laser at 193 nm) to infrared (IR) (CO_2 laser at 10.6/11.1 μm).

Laser-beam-delivery systems depend on the wavelength laser energy. At the present time there is no single delivery system that can be used over the entire range of medical lasers. The primary design considerations in such systems are efficiency, maximum power delivered, preservation of

beam quality, and mechanical properties (flexibility, degrees of freedom, range, size, and weight).

Low efficiency (output power/input power) results in losses in the delivery system, which, in turn, requires higher power and thus more expensive lasers. Moreover, the power lost in the delivery system is generally dissipated as heat, resulting in a temperature rise that causes damage to the device, leading to a further deterioration of efficiency or catastrophic failure. Hence, efficiency, together with heat dissipation, can be considered to be the limiting factors in maximum power delivery.

A well-designed laser oscillator emits a highly collimated beam of radiation, which can then be focused to a spot size of just a few wavelengths, yielding power densities not achievable with conventional light sources. A useful delivery system should, therefore, preserve this quality of the beam as much as possible; otherwise the main advantages of using a laser are lost.

The most desirable flexible system should be easy to handle mechanically, perform a large variety of tasks, and, of course, still satisfy the above properties. From a mechanical point of view, the ideal laser-beam guide would be an optical fiber of small cross section and long enough to reach any site, at any orientation, over a wide range of curvatures, through openings and inside complex structures.

The choice of fibers for such system is mainly determined by the wavelength of the laser (see Fig. 4) and discussion in the section Types of Fibers.

Most lasers operate in the range of 300–2500 nm, where silica fibers have the best overall properties and, thus, are commonly used.

Outside this range, there are few wavelengths used for laser surgery, in IR, 2.94 μm of the erbium:YAG laser, 5–6 μm of the CO laser, 10.6/11.1 μm of the CO_2 laser and in the UV, the 193 and 248 nm of the ArF and KF excimer lasers, respectively. In the infrared range, silver halide and sapphire are being used for the fiber core. Also, hollow fibers have become available for efficient guidance of infrared light with minimal losses (20,63). In the UV range, the solarization resistant silica/silica fibers are available (64) and hollow fibers have been reported recently (16,17). For pulsed lasers, utilization of fibers can be limited by the high peak powers, which could damage the fiber; for example, the peak power of 106 $\text{kW}\cdot\text{cm}^{-2}$ is a threshold for silica. In this case, the flexible arms with reflective surfaces have to be used.

As far as power-handling capability is concerned, the typical glass optical fiber is quite adequate in applications where the laser beam energy is delivered continuously or in relatively long pulses such that the peak power in the optical fiber does not exceed power densities of several megawatts per square millimeter. When the laser energy is delivered in very short pulses, however, even a moderate energy per pulse may result in unacceptable levels of peak power. Such may be the case of Nd-YAG lasers, operating in a mode-locked or Q-switched configuration, which produces laser beam energy in the form of pulses of nanosecond duration or less. On the other hand, excimer lasers, which are attractive in a number of applications (4), generate energy in the UV range of the spectrum (200–400 nm) in very short pulses; they, therefore, require

solarization-resistant silica/silica fibers, which can transmit light energy at such short wavelengths and, at the same time, carry the high power densities.

For lasers in the IR region beyond 2500 nm, fibers made of materials other than silica are being used as shown in the section Types of Fibers.

Photodynamic Therapy

Photodynamic therapy utilizes the unique properties of a substance known as photosensitizer (65). When administered systemically it is retained selectively by cancerous tissue. The substance is photosensitive and produces two effects: When excited by light at a photosensitizer-specific wavelength it fluoresces. This effect is used in photodynamic diagnostics. When irradiated with light, the photosensitizer undergoes a photochemical reaction, which results in the formation of a singlet oxygen and the subsequent destruction of the cell (usually malignant cell) that retained the substance.

In photodynamic diagnostics, since the fluorescence efficiency of the photosensitizer is low, high intensity illumination at the photosensitizer-specific wavelength and high gain imaging systems are required to detect very small tumors. The excitation is in the spectral range, where silica fibers have excellent properties thus glass (silica) fibers are used for delivery of the excitation light.

In order to obtain an effective cure rate in photodynamic therapy, it is essential that the optical fibers, which deliver the light energy to the tumor site, provide uniform light distribution. Since an optical fiber, even if uniformly irradiated, yields a nonuniform output light distribution, it is necessary to employ special beam shapers at the exit face of the fiber (66). The specifics of the fiber used for the delivery is determined by the absorption wavelength of the selected photosensitizer, the laser power and mode of operation, and the site being treated. These are the same consideration as in the fiber delivery for the laser surgery as discussed in the section Surgical Application of Fibers.

It is noteworthy that the illumination in photodynamic therapy does not require that it be obtained with coherent light. The only reason that lasers are used is that unlike conventional light sources, spatially coherent radiation can be efficiently focused onto and transmitted through a small diameter fiber. Light emitting diodes are often used as a compromise between efficient but expensive lasers and inexpensive and inefficient conventional light sources.

The application of photodynamic therapy in oncology has been investigated over the past 25 years. It appears that this modality is being used more often now (67) for variety of cutaneous and subcutaneous tumors.

INTRODUCTION

The observation that atoms of each element can emit and absorb light at specific wavelengths is a fundamental property of matter that fostered the study of chemistry and development of structural models of atoms during the past century. The interaction of light and matter can be traced to use of the lens of Aristophanes ~ 423 BC, and to studies of mirrors by Euclid (300 BC) and Hero (100 BC). Seneca (40 AD) observed the ability of prisms to scatter

Table 1. Selected Wavelengths and Excitation Energies for Alkali and Alkaline Earth Elements

Element	Wavelength, nm Light Emission	Excitation Energy, eV
Lithium	670.7	1.85
Sodium	589.0/589.6	2.1
Magnesium	285.2	4.34
Potassium	766.5/769.9	1.61
Calcium	422.7	2.93
Manganese	403.1/403.3/403.4	3.07
Rubidium	780.0/794.8/ 420.2/421.6	1.56/1.59/ 2.95/2.94
Strontium	460.7	2.69
Cesium	894.3/852.1/ 455.5/459.3	1.39/1.45/ 2.72/2.69
Barium	553.6	2.24

light and Ptolemy (100 AD) studied angles of incidence and refraction. Sir Isaac Newton (1642–1727) performed many experiments to separate light into its component spectrum described in the 1718 volume *Opticks: or, a treatise of the reflections, refractions, inflections and colours of light* (sic).

The scientific basis of flame emission spectrometry (also called flame photometry) arose from studies of the light emitting and absorbing behaviors of matter when introduced into a flame. Observations can be traced to Thomas Melvill (1752), who observed the change of color and intensity of light when different materials were introduced into flames (1). Wollaston (1802) separated candlelight by a prism and noted that it contained a bright yellow line (2). The term line spectra is used to describe spectra composed of discontinuous narrow bands of light wavelengths or lines of different colors. Herschel (1822) observed different spectral diagrams for different salts and Talbot suggested that the yellow light indicated the presence of soda (various forms of sodium carbonate) (3,4). In 1860, Kirchhoff and Bunsen reported the correlation of spectral lines with specific elements by introducing solutions into a Bunsen burner using a platinum wire or hydrogen spray (5). This body of work is Table 1 is depicted in Fig. 1 and summarized by Kirchhoff's laws of spectroscopy that describe emission and absorption of light by matter. Kirchhoff's laws are a hot solid, liquid, or gas, under high pressure, gives off a continuous spectrum; a hot gas, under low pressure, produces a bright line or emission line spectrum; a dark line or absorption line spectrum is seen when a source of continuous spectrum is viewed behind a cool gas at low pressure.

In 1930, Lundegardh developed the first practical method for quantitative spectrochemical analysis by showing that the intensity of light emitted at specific wavelengths represented the concentration of an element being introduced into a flame (6,7). Flame emission methods were rapidly developed to determine alkali and alkaline earth metals. With the introduction of interference filters by Leyton and Ivanov in the 1950s to select narrow bands of wavelengths of light, multichannel flame emission photometers were developed that allow quantification of several elements simultaneously (potassium, sodium, lithium) from a single flame (8,9).

Figure 1. Emission and absorption spectra: (a) A continuous spectrum emitted from a hot solid, liquid, or gas under pressure. (b) A line spectrum emitted from a low pressure hot gas. (c) A dark line or absorption spectrum observed when a continuous spectrum is viewed behind a cool gas at low pressure.

Following the development of commercial flame emission photometers, clinical laboratories used the analyzers to measure sodium and potassium concentrations in body fluids from the mid-1950s until the mid-1970s, when potentiometric technologies largely replaced this technology. Flame emission photometers were initially retained in clinical laboratories to allow monitoring of serum lithium in patients treated with oral lithium salts as a therapy for manic depressive disorders. The rugged and reliable flame emission photometers are still used in specialized clinical laboratories to analyze fluid matrices that can render potentiometric analyses unstable (e.g., the analysis of stool electrolyte concentrations).

In addition to flame, other energy sources can be used to produce atomic emission spectra in the ultraviolet (UV) and visible regions including electric arc, electric spark, or inductively coupled plasma. The use of higher temperature energy sources to induce emission allows this technology to assess quantitative elemental composition of materials. These high energy instruments are used to support analysis of specimens for geology, manufacturing, and clinical toxicology.

Kirchhoff's third law describes the absorption of specific wavelengths of light by cool gases, the basis of atomic absorption spectrometry. In the 1950s, Walsh (10) and Alkemade and Milatz (11) independently reported the analytical potential of light absorption by atoms in a flame, extending the observation that Woodson (12) reported for determination of mercury in air. The temperature of the flame is sufficient to disperse atoms in a low density gaseous phase, enabling the atoms of individual elements to absorb light at specific wavelengths. An intermittent external light source is used to assess light absorption by atoms in the flame while the continuous light emission from the flame is measured and subtracted. Hollow cathode lamps were subsequently developed that enabled atomic absorption methods to achieve both greater sensitivity and selectivity than flame emission photometry and many more analytical applications. The development of electrothermal atomic absorption spectrometers and preanalytical derivitization of chemicals into compounds that minimize interference during analysis make this technology a valuable part of analytical laboratories. Clinical laboratories continue to use atomic absorption spectrometric methods to evaluate the concentration of lead, copper, zinc, and other trace metal elements in body fluids.

THEORY: FLAME ATOMIC EMISSION SPECTROMETRY

A theoretical basis for flame emission spectrometry can be described using a model of the atom, where the atom is composed of a nucleus surrounded by a cloud of electrons that fluctuate between different energy levels. The temperature of a solution of salt is rapidly elevated when the solution is introduced into a flame. The solvent evaporates and most metallic ions are reduced to the elemental neutral atom state by free electrons in the flame. A small propor-

tion of monatomic ions are also formed. The temperature of the flame can confer sufficient quantum energy to excite electrons in a low energy level to a higher energy state, however, the higher energy state is inherently unstable. When the unstable high energy electron returns to the ground state, energy is released from the atom in the form of monochromatic light; a spectral line that is characteristic of that atom and energy transition. The analysis of the intensity and wavelengths of the line spectra emitted from materials in high temperature sources is the basis of flame atomic emission spectrometry, Fig. 2.

The intensity of light in the line spectra is related to the number of atoms with electrons in the higher energy level. The relationship between number of atoms in each energy state (N_0 : ground state or N_1 elevated energy state) is dependent on the temperature: T , and the size of the energy interval between the ground state and elevated energy state: $E_1 - E_0$. This relationship is depicted by the Boltzmann equation:

$$\frac{N_1}{N_0} = \frac{P_1}{P_0} e^{-(E_1 - E_0)/kT}$$

The important features of this equation are that the ratio of atoms in each energy state (N_1/N_0) is dependent on the magnitude of the quantity $-(E_1 - E_0)/kT$. As temperature increases, the number of atoms in the high energy state increases in an exponential manner. The values P_1 and P_0 are the quantum mechanical properties called statistical weights and represent the number of ways in which an atom can be arranged in a given state.

The Boltzmann equation describes the proportion of atoms with electrons in an excited or high energy state at specific temperatures. As electrons decay from excited states to lower energy states, light energy is released in discrete energy intervals associated with the line spectrum for that element. The relationship between the light energy

Figure 2. A model of the atom depicting (left panel) the absorption of energy associated with an electron moving to a higher energy state or (right panel) the emission of light energy associated with an electron moving to a lower energy state.

released and the wavelength or color of light emitted is described by Planck's law: E : Energy of electron transition (J), h : Planck's constant (J·s), c : speed of light (m/s), λ : wavelength of light (m⁻¹).

$$E = hc/\lambda$$

Atoms can have electrons at many different energy levels and this results in line spectra emissions at many different wavelengths. When a flame has limited energy and the atoms are at low density, only a small fraction of atoms are excited and only a simple line spectrum of low energy wavelengths is observed. Line spectra are characteristic of each element allowing analysts to measure emitted light to determine the chemical composition of solutions in a flame or the chemical composition of a star, based on starlight Table 1 (13). For example, the line spectrum of sodium is characterized by an intense doublet of yellow lines at 589 and 589.6 nm. The intensity of light at 588–590 nm can be measured in a flame photometer to measure the concentration of sodium in a fluid. Other alkali metals have low excitation energy that results in emission of light at longer wavelengths. Lithium and rubidium produce a red color and potassium a red-violet color when introduced into a flame. Higher energy associated with higher temperatures is required for many other elements to emit light in the visible or UV regions. To achieve the higher temperatures, electrical arc, spark, ionized gases or plasmas are used to induce light emission instead of a cooler conventional flame. The inductively coupled plasma atomic emission spectrometer (ICP–AES) (also called an inductively coupled plasma optical emission spectrometer, ICP–OES) devices are versatile instruments capable of measuring elemental composition with high sensitivity and accuracy and are currently used to detect trace elements and heavy metals in human urine or serum. The ICP–AES devices use temperatures in excess of 5000 °C and can achieve resolution of 0.0075–0.024 nm.

The line spectra of pure elements often contains doublets, triplets, or multiplets of emission lines. Planck's law implies there is very little difference in energy level associated with spectral lines that have similar wavelengths. Spectral line splitting is attributed to the quality of electron spin that can have two quantum values of slightly different energy. Doublets are observed from atoms with a single outer electron (with two possible electron spin values), triplets from atoms with two outer electrons and multiplets from atoms with several outer electrons. High resolution instruments are required to distinguish some of the multiplet lines. With use of high temperature flames or ICP source and high resolution instruments, the spectra of atoms, ions, and molecules can be observed. Alkaline earth metals can become ionized and the resulting cations can generate emission spectra. Oxides and hydroxides of alkaline earth metals can be present in samples or generated in the flame and can also generate emission spectra. In practice, an emission wavelength used to measure an element is selected when the line provides sufficient intensity to provide adequate sensitivity and the line is free from interference from other lines near the selected wavelength. The amount of light emitted at a specific emission wavelength may not be sufficient for analysis. For this reason, flame

emission spectrometry methods may not be applicable and alternate methods, such as atomic absorption spectrometry or inductively coupled plasma mass spectrometry, may be preferred.

THEORY: ATOMIC ABSORPTION SPECTROMETRY

Atomic absorption spectrometry developed from the observations used to establish Kirchoff's third law: 'That a dark line or absorption line spectrum is seen when a source of continuous spectrum is viewed behind a cool gas under pressure' (Fig. 1). When a sample is introduced into a flame, only a small fraction of the atoms are in an excited or high energy state (according to the Boltzmann equation) and most atoms of the element remain in the unexcited or ground state and are capable of absorbing energy. If light energy is provided as a continuous spectrum, ground-state atoms will selectively absorb wavelengths of light that correspond with the energy intervals required to excite electrons from low energy to higher energy levels. The wavelengths of light that are absorbed as electrons are excited from ground state to higher energy levels are analogous to the wavelengths of light emitted as high energy electrons return to the ground state. The advantage of atomic absorption spectrometry is that most of the atoms in a flame remain in the unexcited ground state and are capable of light absorption, allowing this method to be ~100-fold more sensitive than flame emission spectrometry.

Atomic absorption of light is described by an equation analogous to the Lambert–Beer law. The absorbance of light, A , is defined as the logarithm of the ratio of initial light beam intensity I_0 to the intensity of the beam after light absorption, I . The absorbance of light is directly proportional to the concentration of absorbing atoms c and the path length of the light beam in the atoms d . The value k is a constant referred to as the absorptivity constant.

$$A = \log\left(\frac{I_0}{I}\right) = kcd$$

The emission of characteristic wavelengths or colors of light from materials in a flame was initially observed by the unaided human eye and preceded the measurement of atomic absorption that required instrumentation. To observe atomic absorption of light, a beam of light was passed through atoms introduced to a flame and the ratio of initial and postabsorption light beams was determined. However, the light beam emitted from the flame also contains light derived from the combustion of materials in the flame that was not present in the initial light beam. To measure the atomic absorption of light, the intensity of background light emitted from the flame itself must be subtracted from the postabsorption light beam intensity prior to calculating the absorbance. Electrothermal atomic absorption (also called flameless atomic absorption or graphite furnace atomic absorption) uses an electrically heated furnace to atomize the sample. By design, the electrothermal instruments have greater sensitivity and lower detection limits because analyte atoms can achieve higher gaseous

Figure 3. Components of a flame atomic emission spectrometer.

concentrations and residence time in the light beam and there is less background light emission.

The sensitivity of atomic absorption methods was improved by using light sources that generated wavelengths of light that exactly matched the wavelength of maximum absorption by the element undergoing analysis. The light sources are referred to as hollow cathode lamps. These lamps heat a small amount of the element of interest and generate line spectra emission for the light beam at wavelengths that exactly match the wavelengths maximally absorbed by atoms of that element in the ground state in the flame. Often hollow cathode lamps contain a single element, however, multielement lamp sources with six or more elements are commercially available.

EQUIPMENT

Flame Atomic Emission Spectrometry

The components of a flame photometer are illustrated schematically in Fig. 3 and consist of a nebulizer within a spray chamber, a premix burner, flame, monochromator, detector, and readout system. The monochromator, detector, and readout systems are similar to those used in a spectrophotometer: monochromatic light is obtained by means of an interference filter or diffraction grating, a detector consisting of a photomultiplier tube, result display (visual meter, digital display, or data capture a computer system), and the flame serves as a light source and sample compartment.

Each of the basic components of the instrument contributes to the analytical process. Various combinations of combustible gases and oxidants can be used to create flames with different temperatures (e.g., acetylene, propane, natural gas, oxygen, compressed air). The nebulizer is an important component responsible for mixing the analyte liquid with compressed air and converting it into a fine mist that enters the flame. For precise analytical measurements, the nebulizer must create a mist of consistent composition (10–15% of the aspirated sample) and mix the mist into the gases that combust to create a consistent flame. Within the spray chamber, large droplets settle out and are drained to waste, and only a fine mist enters the flame. A wetting agent (e.g., a nonionic detergent) may be added to standards and samples to minimize changes in nebulizer flow rates that result from differences in the viscosity or matrix of samples.

The intensity of emitted line spectra from atoms excited in the flame must be discriminated from other light in the flame. Less sophisticated instruments (e.g., flame photo-

meters) rely on filters with narrow bandpass to eliminate background light emitted from the flame. Diffraction gratings are used as monochromators in more sophisticated instruments with a slit to limit the bandwidth of light being detected.

To improve the reliability, an internal standard may be used when designing a method. Usually an element not present in the sample is introduced into the calibration standards, quality control, and unknown solutions. In biological applications, lithium or cesium is frequently used for this purpose. By measuring the ratio of emission light intensity of the target element to the internal standard, there is compensation for small variation in nebulization rate, flame stability and solution viscosity, and methods perform with greater precision. Addition of either lithium or cesium to all solutions can also prevent interference by acting as an ionization buffer (previously referred to as a radiation buffer). A relatively high concentration of an alkali metal ion in the solutions creates a buffer mixture of its ionic and atomic species and free electrons in the flame. The elevated free-electron concentration in the flame represses and stabilizes the degree of ionization of analyte atoms and improves the atomic emission signal.

Inductively coupled plasma emission spectrometers have similar components. The sample is nebulized into argon gas that is heated to extreme temperatures (>5000 °C) that efficiently breaks molecular bonds to generate gaseous atoms. Because few molecules exist at these temperatures, ICP–AES has few chemical interferences compared to flame techniques, however, because of the high temperature and large proportion of atoms and ions that emit light, ICP–AES methods are more prone to spectral interferences associated with inadequate resolution of spectral lines.

Atomic Absorption Spectrometry

The components of a flame atomic absorption spectrometer are illustrated schematically in Fig. 4 and consist of a nebulizer, premix burner, hollow cathode lamp, modulation system or beam chopper, flame, monochromator, detector, and readout system. The monochromator, detector, and readout systems are similar to those used in a spectrophotometer. Monochromatic light is obtained by isolating a single spectral line emitted from a hollow cathode lamp using an interference filter. The detector is a photomultiplier tube and the results can be displayed by a visual meter, digital display, or captured by a computer system. The flame serves as a sample compartment and

Figure 4. Components of a flame atomic absorption spectrometer.

light from the hollow cathode lamp is passed through the flame to measure absorption. Electronic modulation or a mechanical beam chopper is used to interrupt the light from the hollow cathode lamp into pulses so the extraneous light emitted from the flame alone can be measured and subtracted prior to measuring atomic absorption.

Electrothermal atomic absorption instruments typically use a graphite furnace to rapidly heat a sample in a uniform manner to $\sim 2600^\circ\text{C}$. Samples are typically introduced into the furnace on a carbon rod. As the temperature is raised, the samples are dried, charred, rendered to ash, and atomized (e.g., Table 2). Hollow cathode lamps are used as a source of monochromatic light to determine atomic absorption. In contrast to flame-based methods that rapidly dilute and disperse analyte atoms, electrothermal methods retain atoms at higher concentrations with longer residence time in the light beam. In addition, there is less extraneous background light. These advantages allow electrothermal atomic absorption instruments to measure many trace elements and heavy metals not capable of measurement with flame atomic absorption instruments (15).

There are four categories of interference that can occur with atomic absorption spectrometry: chemical, spectral, ionization, and matrix. The element undergoing analysis may exist or form stable molecules within the flame. The atoms in the stable molecules do not generate line spectra at the characteristic wavelengths of the free atoms and this chemical interference results in a negative analytic bias for the method. Spectral interference can occur when there is nonspecific absorption of light by material in the sample. Nonspecific absorption of light can be caused by solids or

particles in the flame. Spectral interference can often be reduced by performing maintenance on the burner head to remove residues and assure a steady flame is maintained. Emission of light from other components in the flame can interfere with analysis and can often be removed with a background correction method. Ionization interference occurs when atoms in the flame are converted to ions that will not absorb the line spectra at the characteristic wavelengths for the atoms. Ionization interference can be reduced by an ionization buffer or by lowering flame temperature to reduce the extent of ionization. Matrix interferences occur when the calibration standards have a different composition than the samples (e.g., viscosity, salt concentration or composition, pH, or presence of colloids, e.g., protein). Matrix interferences can be avoided in the method design by assuring calibrator solutions have similar composition to the samples or that samples are highly diluted so they acquire a matrix similar to the calibrator solutions.

Several methods have been developed to improve the sensitivity of atomic absorption by reducing background radiation spectral interference. Electronically modulated light beams or mechanical beam choppers have been used to generate pulsed light so the background emission of light from the flame can be distinguished, measured and subtracted. Analogous to molecular absorption spectrophotometers, atomic absorption spectrometers can have a single beam design (Fig. 4) or a split double-beam design where the beam modulator acts as a beam splitter to create the light beam that passes through the sample and a second beam that acts as a reference. Split double-beam instrumentation has an advantage of compensating for variation in light intensity from the lamp or variation of detector sensitivity.

In electrothermal atomic absorption methods, the rapid heating of samples can cause the release of smoke or nonspecific vapor that blocks some light from reaching the detector. To correct for this nonspecific light scatter, in addition to the beam from a hollow cathode lamp, a beam from a deuterium continuum lamp can be directed through the sample chamber and light intensity measured at a wavelength other than that used for the assay to assess the extent of light scatter.

A third method of background correction is based on the Zeeman effect. When atoms are placed in a strong magnetic

field, the emission and absorption line spectra are dramatically altered as the single line spectra are split into triplets or more complex patterns. Splitting of a spectral line into two different wavelengths implies that the electrons involved have slightly different energy levels, according to Planck's law. The small difference in the energy levels is attributed to slightly different quantum numbers for the electrons involved and this difference in energy level can only be detected in the presence of the magnetic field. In the absence of the magnetic field, slight differences in energy levels are not apparent and a single wavelength of absorption or emission is observed. By turning the magnetic field off and on during atomic absorption spectrometry, the population of atoms being tested is modulated from a uniform population to discrete populations with different quantum numbers. By measuring the element-specific difference in atomic absorption as the magnetic field is modulated, nonspecific background absorption or emission can be accurately subtracted. Implementation of instruments with Zeeman correction is complex, expensive, and requires optimization of the magnetic field for each element. Consequently, Zeeman correction approaches are usually reserved for methods involving strong background interferences.

MEDICAL APPLICATIONS

Flame emission spectrometry and atomic absorption spectrometry are sophisticated methods of elemental analyses that are robust and flexible techniques that have been applied to the analysis of many different types of biological or clinical samples. In the 1950s and 1960s, use of flame photometers provided state-of-the-art accurate and precise determinations of serum, sodium, and potassium. Stable, reliable, and inexpensive potentiometric methods for determination of electrolyte concentrations were developed and replaced flame photometric methods for most medical applications. The hardy reliable nature of flame photometers is still used for some analysis (e.g., the determination of stool electrolytes). While flame emission photometric methods can be applied to determine the concentration of trace elements or heavy metals in biological specimens, many clinical laboratories use electrothermal atomic absorption spectrometry or inductively coupled plasma mass spectrometry that offer greater specificity, sensitivity, precision, and adaptability.

Flame emission spectrometric determinations are prone to negative bias when biological samples undergoing analysis have high concentrations of lipid or protein (16). Biological samples are mixed with a diluent to create a mist in the nebulizer and the mist is created by mixing constant proportions of each fluid. However, when a biological fluid has a high concentration of lipid or protein, the constant volume of sample fluid has a reduced amount of aqueous dissolved ions because lipid particles suspended in the fluid occupy volume and reduce the volume of water available to dissolve the ions. In a similar manner, proteins bind water molecules creating a hydration shell and at high concentration in an aqueous solution, the proteins occupy volume in the sample and reduce the volume of water available to dissolve ions. This negative bias is known as

Figure 5. Typical detection limit ranges for major spectrometry techniques. Flame atomic absorption, inductively coupled plasma-atomic emission spectrometry, graphite furnace atomic absorption, inductively coupled plasma-mass spectrometry (19).

the volume exclusion effect. The term pseudohyponatremia is used to describe the misleading low serum sodium concentrations attributed to this bias. This volume exclusion effect was initially characterized with flame photometers and it remains a concern with potentiometric instruments that use indirect electrodes and rely on sample dilution (17).

The use of atomic absorption spectrometers in clinical laboratories for the determination of calcium, magnesium, and other metal cations reached a peak in the 1970s. In the following decades, potentiometric methods became commercially available for the most common tests (e.g., calcium, magnesium, sodium, and potassium) and atomic absorption spectrometers were not commonly used in each hospital laboratory. A concise review of the history of atomic absorption spectrometry application in clinical chemistry was published in 1993 (18). The atomic absorption spectrometer remained an important platform for the determination of serum zinc, copper, and lead. Medical laboratory services have often been consolidated, and infrequent tests (e.g., serum zinc, copper, lead, trace elements, and heavy metals) are shipped to reference laboratories for analyses. While inductively coupled plasma mass spectrometry offers greater sensitivity and flexibility of analysis, flame and electrothermal atomic absorption spectroscopic methods remain cost-effective, precise analytic methods, widely used in clinical reference laboratories to support the evaluation of serum or blood concentrations of zinc, copper, aluminum, chromium, cadmium, mercury and lead (Fig. 5).

FLOWMETERS

ARNOLD A. FONTAINE
STEVEN DEUTSCH
KEEFE B. MANNING
Pennsylvania State University
University Park, Pennsylvania

INTRODUCTION

Fluid flow occurs throughout biomedical engineering in areas as different as air flow in the lungs (1,2) to diffusion of nutrients or wastes through membranes (3–5). Flow-related problems can involve fluid media in the form of gas,

liquid, or multiphase flows of both liquids and gas together or in combination with solid matter. Biomedical flows occur in both *in vivo* (6) and *in vitro* (7,8). They can involve relatively benign flows like that of saline through an intravenous tube to a biochemically active flow of a non-Newtonian fluid such as blood. Many biomedical or bioengineering processes require the quantification of some flow field that may be directly or indirectly related to the process. Such quantification can involve the measurement of volume or mass flow, the static and dynamic pressures, the local velocity of the fluid, the motion (speed and direction) of particles such as cells, the flow-related shear, or the diffusion of a chemical species.

Interest in understanding fluid flows and attempts to measure flow-related phenomena has had a long history in the scientific and medical communities with early work by Newton, DaVinci, and others. Early studies often involved observations of flow-related phenomena that can be characterized as simple flow visualization or particle tracking (9) or the estimation of a pressure by the displacement of a fluid. Rouse and Ince (10) provide a historical review of these early works. Throughout the years, flow measurement techniques have advanced significantly in capability (what is measured and how), versatility, and in many ways, complexity. Some techniques, such as photographic flow visualization, have changed little in over 100 years, whereas others are only possible because of advances in electronics, optics, and physics. Improved capability and versatility are evidenced through the increased ease of use in some systems and the ability to measure more quantities with increased accuracy and resolution. However, this improved capability and versatility has, in some cases, come at the cost of increased complexity in system hardware, calibration requirements, and application complexity.

Measurement techniques can be characterized as invasive or noninvasive and direct or indirect. Invasive measurement techniques require the insertion of a sensing or a sampling element directly into the flow field. As a result of this direct insertion, invasive probes may alter the flow field characteristics or induce bias errors associated with the presence of the probe in the flow field or by the operation of the probe (11,12). Invasive probes are often designed to minimize flow disturbance by miniaturizing the sensing elements or by displacing the sensing elements some distance from the hardware holding the probe in the flow, as illustrated in Fig. 1. Invasive probes also require some type of closure at the penetration site through the boundary of the flow, which must be accounted for in the test design and can be particularly important in *in vivo* applications to prevent fluid loss or infection. White et al. (13) measured wall shear stress in the abdominal aorta of dogs using an invasive, flush-mounted hot-film probe and described how the probe tip is modified to provide an effective entry mechanism through the arterial wall with an adequate seal.

Noninvasive techniques do not involve direct insertion of a sensor into the flow but provide sensing capability through either access to the flow at the flow boundary or through the use of some form of electromagnetic radiation (EMR) transfer or propagation. Wall-mounted thermal sensors, static pressure taps and transducers, or surface

Figure 1. Examples of invasive velocity measurement sensors with displaced sensing elements relative to their probe supports. (a) a boundary layer style hot-wire probe for thermal anemometry. Picture from TSI Inc. catalog, probe catalog 1261A. (b) Pitot static probe for velocity measurement.

sampling probes are examples of noninvasive techniques that require access to the boundary of the flow field through a wall penetration (13). Ultrasound (14) magnetic resonance (MR), X-ray, and optical techniques are all examples of electromagnetic radiation that can be used to probe flow fields (15). Unlike the wall-mounted invasive probes describe above, EMR-based measurement systems do not require physical penetration into the flow field or access through the flow field boundary. They do, however, require a “window” into the flow through the boundary enclosing the flow field of interest. This “window” depends on the type of technique being used. Optical-based techniques require an optically clear window that may not be suitable for *in vivo* applications, whereas ultrasound and X-ray techniques require that the material properties of the flow boundaries are transparent to these forms of EMR waves. For example, lead will shield X-ray penetration and metal objects on a surface or in the flow may create local artifacts (noise or error) in MR measurements.

Direct and indirect measurements are defined by how quantities of interest are measured. The displacement of a particle or cell in a flow can be directly measured by photographing the movement of the particle over a finite time interval (16). Most flow-related measurement systems, however, are indirect. In general, velocity or flow is indirectly calculated from the direct measurement of a quantity and the application of a calibration that relates the magnitude of the measured quantity to the parameter of interest. This calibration may involve not only a conversion of a measured quantity like a voltage to a physical quantity such as a pressure, but may also involve the application of a functional relationship (i.e., Bernoulli’s equation), which requires assumptions about the flow. For example, volume flow probes often assume a characteristic velocity profile at the location of the probe (17). Blood flow in the microcirculation can be estimated by indirectly measuring the cell velocity using a time-of-flight optical technique where the time a cell takes to move a known distance is measured and the cell velocity is calculated by the ratio of the distance divided by the transit time (18).

Indirect measurement can also impact the uncertainty in the estimated quantity. The measurement of velocity using a Pitot probe is one example of an indirect measurement (19). The Pitot probe measures the local dynamic and static pressures in the flow. These pressures are most often measured using a pressure transducer that provides a voltage output in response to an applied pressure. A cali-

bration is then applied to the measured voltage to convert it to pressure. Velocity is indirectly calculated from the estimated pressures using the Bernoulli equation. The error in Pitot probe velocity measurements includes the pressure transducer calibration uncertainty, noise and statistical uncertainty during the pressure measurement, electronic noise in the acquisition of the transducer output voltage, and transducer drift and potential bias due to the physical size of the probe relative to the flow scales being measured. These errors are nonlinearly propagated into the estimate of the velocity uncertainty.

Measurement accuracy is also a function of the physical and operating characteristics of the probe itself. Many flows exhibit a range of spatial and temporal scales. The physical size and the frequency response of the sensing element must be taken into account when choosing a measurement system for a particular application. A large sensing element or an element with poor frequency response has the effect of low pass filtering the measured signal (20). This low pass filtering will cause a bias in the measured quantity. The total measurement uncertainty must also take into account statistical errors associated with random processes, cycle-to-cycle variability in pulsatile systems, and noise. The reader is referred to the texts by Coleman and Steele (21) and Montgomery (22) for a detailed approach to experimental uncertainty analysis. The focus of this chapter will be on measurement techniques, their fundamentals of operation, their advantages and disadvantages, and examples of their use.

The name flow measurement is a broad term that can encompass the measurement of many different flow-related parameters. In this chapter, the authors will focus on the measurement of those parameters that are most often desired in a biomedical/bioengineering application, volume flow rate, and velocity. Imaging, Doppler echocardiography, and MR techniques are addressed in other chapters within the encyclopedia and, thus, will only be briefly introduced in this article when applicable. This chapter is subdivided into sections that will address volume flow and velocity separately, with a detailed presentation of systems that are available for the measurement of each. Although ultrasound and MR techniques are often used to measure flow-related parameters, a detailed discussion of the principles of operation will not be presented here as these topics are covered in depth in other chapters of this Encyclopedia.

FLOW MEASUREMENT APPLICATIONS

Volume Flow Measurement

In both the clinical environment and the laboratory environment, the measurement of the volume flow rate of a fluid as a function of time can be an important parameter. In internal flow applications, which comprise most biomedical flows of interest, the volume flow of a fluid (Q) is related to the local fluid velocity (V) through the integration of the velocity over the cross sectional area of the duct or vessel (19,23).

$$Q = \int V dA \quad (1)$$

The flow rate Q , velocity V , and area A have dimensions of volume per time, length per time, and length squared, respectively. The SI units are typically used in the bioengineering field with mass units of grams or kilograms, length units of meters (millimeter and centimeters), and time units of seconds. The mass flow (M) is directly related to the flow volume through the fluid density, ρ , with units of mass/volume.

$$M = \rho \cdot Q \quad (2)$$

Fluid pressure and velocity are related through the Navier–Stokes equations, which govern the flow of fluids in internal and external flows [see White (23)].

The volume flow rate of blood is often measured in many cardiovascular applications (24). For example, cardiac output (CO) is the integrated average of the instantaneous volume flow rate of blood (Q_b) exiting the aortic valve over one cardiac cycle (T_c):

$$CO = \left[\int Q_b dt \right] / T_c \quad (3)$$

The cardiac output has units of volume flow rate, volume per unit time. The following subsections will provide an overview of measurement techniques typically used for both volume flow and velocity measurement in *in vivo* and *in vitro* studies. This article will be limited to those flow measurement techniques most often used in the biomedical and bioengineering fields. Specialized measurement techniques, such as concentration or species measurement through laser-induced fluorescence (LIF) or mass spectrometry, will not be addressed.

Electromagnetic Flow Probes. Carolina Medical Inc. developed the first commercially available electromagnetic flow meter in 1955. The design provided scientists and clinicians with a noninvasive tool that could directly measure the volume flow rate (17). Clinical probes were developed that could be attached to a vessel for extravascular measurement of blood flow without the need for cannulation of a surgically exposed vessel.

Electromagnetic flow meters are volumetric flow measuring devices designed to measure the flow of an electrically conducting liquid in a closed vessel or pipe. Commercial meters, used in the biomedical and general engineering fields, come in a variety of sizes and designs that can measure flow rates from $\sim 1 \text{ mL} \cdot \text{min}^{-1}$ to $>100,000 \text{ L} \cdot \text{min}^{-1}$.

Reported uncertainties are typically on the order of a few percent, but can be as low as 0.5% of reading in some specialized meter designs. Low uncertainties are dependent on proper use and installation of the meter. Improper use or installation (mounting the meter in a location with a complex flow profile) will increase measurement uncertainty. Most clinical quality meters that are mounted externally to a vessel exhibit uncertainties that can approach 15% in some applications (Carolina Medical Inc., product support literature). In cardiovascular applications, these meters may also be susceptible to electrical interference by the heart or by measurement anomalies due to motion of the probe.

The principle governing the operation of an electromagnetic flow meter is Faraday's law of electromagnetic induction. This law states that an induced electrode voltage is proportional to the velocity of flow of a conductor through a magnetic field of a known density. Mathematically, this law is represented as:

$$E_e = K[V \cdot B \cdot L_e] \quad (4)$$

Here, E_e is the induced voltage between two electrodes (with units of volts) separated by a known conductor length L_e (provided by the conducting fluid between the electrodes) in units of millimeters or centimeters, B is the magnetic field strength in units of Tesla's, and V is the conducting fluid average velocity in units of length per time. The parameter K is a dimensionless constant. Meter output is linear and proportional to flow velocity.

Fluid properties such as viscosity and density are absent from Eq. 4. Thus, the output of an electromagnetic flow meter is independent of these properties and its calibration is independent of the type of fluid, provided the fluid meets minimum conductivity levels. This meter can then be used for highly viscous fluids, Newtonian fluids, and nonNewtonian fluids such as blood. The requirement of an electrically conductive fluid can disqualify an electromagnetic meter in some applications. Typical meters require a minimum fluid conductivity of $\sim 1 \mu\text{S}/\text{cm}^{-1}$. However, low conductivity designs are capable of operating with fluid conductivities as low as $0.1 \mu\text{S}/\text{cm}^{-1}$. The presence of gas bubbles in the fluid can cause erratic behavior in the meter output.

A typical meter design has electromagnetic coils mounted on opposing sides of an electrically insulated duct with two opposing electrodes mounted 90° relative to the electromagnets. The two electrodes are mounted such that they are in contact with the conducting fluid. Figure 2 illustrates the typical configuration.

The meter is designed to generate a magnetic field that is perpendicular to the axis of motion of the flowing fluid. A voltage is generated when the conducting fluid flows through the magnetic field. This voltage is sensed by the two opposing electrodes. The supporting material around the meter is made of a nonconducting material to prevent leakage of the voltage generated in the moving fluid into the surrounding material. In practice, the conductor length, L_e , is not the simple path illustrated, but is rather the integral of all possible path lengths between the two electrodes across the cross section of the duct or vessel. The

Figure 2. Illustration of the principle of operation of the electromagnetic flow meter. Note, the magnetic field, electrodes, and flow direction are all mutually perpendicular to one another.

signal generated along each path length is proportional to the fluid velocity across that path. Thus, the two electrodes measure the integrated sum of all velocities across every possible path in the vessel cross section. This signal is then directly proportional to the volume flow rate of the fluid passing through the magnetic field.

The magnetic field generated in commercial meters may be anything from a uniform field to a specifically designed field with prescribed characteristics. Meters with uniform magnetic fields can exhibit some sensitivity to the conducting liquid's velocity profile. Fluid flowing through a vessel does not have the same velocity at all locations across the vessel. The no-slip condition at the walls of the duct ensures that the fluid velocity at the wall is zero (19). Viscosity then generates a gradient between the flowing fluid in the vessel and the stationary fluid at the wall. In complex geometries, secondary flows may occur and velocity gradients in other directions may also develop (25,26). This variation in fluid velocity across the magnetic field coupled with variations in the conductor length generates a variation in the magnitude of the voltage measured across the duct. As a result, installation of these meters must be carefully performed to ensure that the velocity profile of the liquid in the tube is close to that used during calibration.

A number of commercial meters shape the magnetic field coils to generate a magnetic field that exhibits a field strength with a prescribed pattern across the duct. This field shaping compensates for some velocity variations in the duct and provides a meter with a reduced sensitivity to flow profile. As a result, this type of meter is better able to measure in vessels with upstream and downstream characteristics, such as curvature and nonuniformity in the vessel cross section, that generate asymmetric flow profiles with secondary flow velocity components.

Commercial meters generate magnetic fields using either an ac excitation or a pulsed dc excitation. The ac excitation generates a magnetic field with a strength that varies with the frequency of the applied ac voltage. This

configuration produces a meter with a relatively high frequency response but with the disadvantage that the output signal not only varies with the flow velocity but also with the magnitude of the alternating excitation voltage. Thus, the output of the meter for a flow with constant velocity across the vessel will exhibit a sinusoidal pattern. In addition, zero flow will produce an offset output due to the presence of the nonmoving conductor in a moving magnetic field. Quadrature signal rejection techniques can be used to filter the unwanted signal generated by the ac excitation from the desired signal generated by the flowing liquid, but this correction requires careful compensation and zeroing of the meter in the flow field before data acquisition.

The pulsed dc excitation was developed to reduce or eliminate the zero shift encountered with ac excitation. This improvement has the cost of reduced frequency response and increased sensitivity to the presence of particulates in a fluid. Particles that impact the electrodes in a pulsed dc operated meter produce output fluctuations that can be characterized as noise. The accuracy in each system is comparable.

A low sensing voltage at the electrodes requires a signal conditioning unit to provide a measurable output with a good signal-to-noise ratio. Meter calibrations typically involve one of two calibration techniques. The meter and signal conditioning unit are calibrated separately or the meter and signal conditioning unit are calibrated as a system. The latter provides the most accurate calibration with accuracies that can approach 0.5% of reading in certain applications. The reader is referred to literature by various manufacturers of electromagnetic flow meters for a more comprehensive discussion of the techniques, operation, and use for specific applications.

Ultrasound Techniques – Transit Time Volume Flow Meters. Ultrasonic transit time flow meters provide a direct measure of volume flow by correlating the change in the transit time of sound waves across a pipe or vessel with the average velocity of the liquid flowing through the pipe (17,27,28). Transit time ultrasonic flow meters are widely used in clinical cardiovascular applications. In recent years, a number of studies have been performed to evaluate and compare transit time ultrasonic flow measurement techniques with other techniques used clinically (29). The typical configuration for an ultrasonic flow probe involves one or two ultrasonic transducers (transmitters/receivers) and possibly an ultrasonic reflector. Transducers and reflectors are positioned in opposing configurations across a tube or vessel as illustrated in Fig. 3. The time it takes an ultrasound wave to propagate across a fluid depends on the distance of propagation and the acoustic velocity in the fluid. If the fluid is moving, the motion of the fluid will positively or negatively add a phase shift to the time of propagation (transit time) through the fluid, which can be written mathematically as:

$$T_t = D_p / (c \pm V \cdot \cos \theta) \quad (5)$$

Here, T_t is the measured transit time (s), D_p is the total propagation distance of the wave (length units), c is the acoustic speed of the fluid (units of length per time), V is

Figure 3. Illustration of principal of transit time ultrasonic flow probe operation.

the average velocity of the fluid (units of length per time) over the propagation length, and θ is the angle between the flow direction and the propagation direction of the wave. The configurations illustrated in Fig. 3 have an inherent dependency of the measured transit time on the coupling of the transducer with the vessel. Acoustic impedance characteristics of the vessel wall, and mismatches in impedance at the vessel wall–transducer and wall–fluid interfaces will affect the accuracy of the flow rate measurement.

The approach to using equation 5 in a metering device is to incorporate bidirectional wave propagation in opposing directions, as shown in Fig. 4, which will produce two independent transit time measurements (T_{t1} and T_{t2}), one from each direction of propagation. The forward direction transit time T_{t1} is defined by Eq. 5 with a plus sign before V , and T_{t2} is defined by the minus sign. The fluid velocity can then be obtained by taking the difference of the transit times ($T_{t1} - T_{t2}$). It can be shown that, for fluid velocities small relative to the acoustic velocity of the fluid ($V^2 \ll c^2$), this difference reduces to:

$$(T_{t1} - T_{t2}) = 2D_p(V \cdot \cos \theta) / c^2 \quad (6)$$

With the probe geometry defined (the propagation distance and propagation angle relative to the vessel or flow direction) and with the fluid properties known (acoustic speed of the fluid), the average speed of the fluid along the propagation path of a narrow beam can be calculated from the transit times. Wide beam illumination, where the beam width is wider than the vessel diameter, effectively integrates the measured transit time phase shift over the cross section of the vessel. The wide beam transmission can be approximated by the summation of many infinitesimally narrow beams adjacent to one another. Thus, the measured

Figure 4. Bidirectional wave propagation.

wide beam phase shift is proportional to the sum of these narrow beams propagating through the vessel. As the phase shift encountered in a narrow beam transmission is proportional to the average fluid velocity times the beam path length, integrating or summing over all narrow beams across the vessel results in a measured total transit time phase shift that is proportional to the average fluid velocity times the area of the vessel sliced by the ultrasound beam, or the volume flow rate.

The popular Transonic Systems Inc. flow meter uses bidirectional transmission with two transducers operating in transmit and receive modes, and a single reflector configured as illustrated in the left schematic of Fig. 4. This approach increases the propagation length while effectively reducing sensitivity to wall coupling or misalignment of the probe with the wall. The increased path length improves uncertainty and provides a probe body with a relatively small footprint, an advantage in *in vivo* or surgical applications.

The basic operation of a bidirectional transit time meter involves the transmission of an ultrasound plane wave at a specific frequency. This wave propagates through the vessel wall and fluid where it is either received at the opposite side or is reflected to another transducer operating as an acoustic receiver. This received signal is recorded, processed, and digitized before the transducer is reconfigured to transmit a second pulse in the opposite direction. The overall frequency response of such a probe is dependent on the pulse time, the time delay between the forward and reverse pulses, the acoustic speed through the medium, the propagation distance, and the signal conditioning electronics, which can include analog signal acquisition and filtering. The meter size governs the propagation distance and, thus, the size of the vessel that the meter can be mounted on.

The frequency response of commercial probes varies from approximately 100 Hz to more the 1 kHz, where the highest frequency responses are obtained in the smaller probes. As a result, commercial probes have sufficient frequency response for most clinically or biomedically relevant flow regimes. Velocity and flow resolution is governed, in part, by the propagation length over which the flow is integrated and the resolution of the transit time measurement. The reader is referred to the meter manufacturers for detailed information about the operating specifications of particular meters. Reported uncertainties in transit time meters can be better than 15%. Actual uncertainties will depend on meter use, the experience of the operator, the meter calibration, and the acoustic properties of the

Figure 5. Schematic of the operation of a Doppler ultrasound probe.

fluid measured and how these properties differ from those of the calibration fluid.

Ultrasound Techniques – Doppler Volume Flow Meters.

Flow can also be measured by ultrasound using the Doppler shift in a propagating sound wave generated by moving objects in a fluid flow (17,30). The primary difference is in the principal of operation. Devices using the Doppler approach measure the Doppler frequency shift of the transmitted beam due to the motion of particles encountered along the beam path, as illustrated in Fig. 5. The Doppler shift due to reflection of an incident wave by a moving particle is given by

$$F_D = 2 F_0 V \cos \theta / c \quad (7)$$

The shift frequency F_D (units of $L \cdot s^{-1}$) is linearly related to the component of the speed of a particle, V , in the direction of the wave propagation, the initial transmission frequency of the wave, F_0 , and the speed of sound in the fluid, c . The reader is referred elsewhere in this Encyclopedic series and to the text by Weyman (30) for a detailed presentation of the Doppler technique.

The Doppler meter provides a direct measure of velocity that can be used to calculate the volume flow rate indirectly. Most biomedical applications involving volume flow measurement are performed on flow through a duct or vessel of given shape and size. Thus, the volume flow is the integral of the measured velocity profile across the vessel cross sectional area as defined in equation 1. The integral in equation 1 can be related to the average velocity \bar{U} across the duct multiplied by the cross-sectional area of the duct (23). The Doppler technique then requires not only an estimate of the average velocity in the vessel but knowledge of the vessel area as well.

Commercially available Doppler volume flow meters, although not commonly used in biomedical applications, can be attached to a pipe or duct wall as with transit time meters. The commercial Doppler flow meters measure volume flow by integrating the measured Doppler shift frequency generated by particles throughout the flow. This integration is performed over a predefined path length in the flow, and is dependent on the number and type of particles, their size and distribution. The meter accuracy

is also dependent on the velocity profile in the flow. Careful *in situ* calibrations are often needed to obtain accuracies of less than 10%. The Doppler meter has several disadvantages when compared with the transit time meter. It requires a fluid that contains a sufficient concentration of suspended particles to act as scattering sites on the incident ultrasound wave. These particles must be large enough to scatter the incident beam with a high intensity level but small enough to ensure that they follow the fluid flow (31). As a result of their dependence on flow profile, Doppler flow meters are not well-suited for measurement of flow in vessels with curvature or branching. Doppler flow meter measurements in blood rely on blood cells to act as scatterers. Clinical Doppler ultrasound machines, commonly used in echocardiography, can also be used to indirectly infer volume flow through the direct measure of the fluid velocity, and will be discussed later in the subsection on velocity measurements.

Invasive or Inline Volume Flow Measurement. Invasive or inline flow meters must be installed inline as a part of the piping or vessel network and involve hardware that is in contact with the fluid. These meters often have a non-negligible pressure drop and may adversely interact with the flowing fluid. As a result, these meters are not often used in *in vivo* applications. Meters that fall in this category are variable area rotameters, turbine/paddle wheel meters, and vortex shedding meters. The primary advantage of these meters, is low cost and ease of use. However, these meters typically exhibit sensitivity both to fluid properties, which can be dependent on temperature and pressure, and to flow profile, White (23).

Variable area rotameters are simple measurement devices that can be used with a variety of liquids and gases. The flow of fluid through the meter raises a float in a tapered tube, as shown in Fig 6. The higher the float is raised, the larger the diameter of the tapered tube, increasing the cross-sectional area of the tube for passage of the fluid. As the flow rate increases, the float is elevated higher in the tube. The height of the float is directly proportional to the fluid flow rate. In liquid flow, the float is raised by the combination of the buoyancy of the liquid and the fluid drag on the float. Buoyancy is negligible in gaseous flows

Figure 6. Schematic of a variable area flowmeter.

and the float moves in response to the drag by the gas flow. For constant flow, the float reaches a stable position in the tube when the upward force generated by the flowing fluid equals the downward force of gravity. The float will move to a new equilibrium position in response to a change in flow. These meters must be installed vertically to operate properly, although spring-loaded meters have been designed to eliminate the need for gravity and permit installation in other orientations.

Rotameters are designed and calibrated for the type of fluid (fluid properties such as viscosity and density) and flow range expected. They do not function properly in nonNewtonian fluids. Use of a meter with a fluid different from that the meter was calibrated for, or with, a fluid at a different temperature or pressure requires a correction to the meter reading. Meter uncertainty and repeatability will vary with operation of the meter, but can approach a few percent with proper operation.

Turbine and paddle wheel meters measure volume flow rate through the rotation of a vaned rotor in contact with the flowing fluid. These meters are intrusive flow measurement devices that produce higher pressure drops than others in the class of invasive flow probes. The turbine meter has a turbine mounted across the pipe or duct in full contact with the flow, whereas the paddle wheel meter has a vaned wheel mounted on the side of the duct with half of the wheel in contact with the flow. Accuracy and repeatability is best with the turbine meter, but the pressure drop is also higher. An ac voltage is induced in a magnetic pickup coil as the turbine or paddle wheel rotates. Each pulse in the ac signal represents the passage of one blade of the turbine. As the turbine fills the flow path, a pulse represents a distinct volume of fluid being displaced between two turbine blades. This design provides an accurate direct measure of the volume flow rate.

Flowmeter selection must take into account the type of fluid, the flow rate range under study, and the acceptable pressure drop for a given flow application. In general, these meters have a sensitivity to flow profile, and the pressure drop is dependent on the fluid properties. The meters incorporate moving parts within the flow and thus use bearings to ensure smooth operation. Bearing wear will affect the meter accuracy and must be monitored for the life of the meter. The paddle wheel meter operates in a similar manner as the turbine meter. The primary difference is that only part of the rotor is in contact with the fluid and, thus, as the paddle wheel meter is more sensitive to flow profile it has a smaller pressure drop. Installation of these

Figure 7. Vortex shedding from a circular cylinder. Picture from White (23), courtesy of the U.S. Naval Research Laboratory.

meters often involves a specified number of straight pipe sections upstream and downstream of the meter and may also require installation of a flow straightener inline upstream of the meter.

Vortex meters operate on the principal of Strouhal shedding. Separating flow over an obstruction such as a cylinder or sharp-edged bar results in a pulsatile or oscillatory pattern as shown in Fig. 7. The shedding frequency, ω (units of $L \cdot s^{-1}$), is related to the fluid velocity by

$$\omega = V \cdot S_t / L \quad (8)$$

where S_t is the Strouhal number, which is a nondimensional number that is a function of the flow Reynolds number and geometry of the obstruction, and L is a characteristic length scale (23). For a cylinder, L is the diameter of the cylinder. The Reynolds number is a dimensionless number that is the ratio of inertial to viscous forces in the flow, and is defined as

$$Re = V \cdot L / \nu \quad (9)$$

Here, V and L are defined as in Eq. 8 and ν is the kinematic viscosity of the fluid with units of length squared per time.

The vortex meter is an intrusive meter that has a “shedder bar” installed across the diameter of the duct. The flow separates off this bar and generates a shedding frequency that is transmitted through the bar to a piezoelectric sensor attached to the bar. The meter is sensitive to flow and fluid properties, and rated accuracy and pressure drop depend on application.

Volume flow rate can also be estimated through an indirect measure of the velocity profile in the flow and the use of Eq. 1. A number of instruments are available that measure fluid velocity in biomedical engineering applications. Doppler ultrasound and MR phase velocity encoding are standard clinical techniques used to measure velocity of a flowing fluid noninvasively. *In vitro* systems that are commonly used to measure fluid velocity, in addition to Doppler and MR, are laser Doppler velocimetry (LDV), particle image velocimetry (PIV), and thermal anemometry. Besides an estimate of volume flow rate, fluid velocity measurement can provide quantification of flow profiles, fluid wall shear, pressure gradient, and flow

mixing. The following section summarizes velocity measurement techniques commonly used in biomedical/bioengineering applications.

Velocity Measurements

Thermal Anemometry. Thermal anemometry is an invasive technique used to measure fluid velocity or wall shear. A heated element is inserted into the flow, and specialized electronic circuitry is used to measure the rate of change in heat input into the element in response to changes in the flow field (32). Thermal anemometry, when used properly, is characterized by high accuracy, low noise, and high spatial and temporal resolution. Its main disadvantages are sensitivity to changes in fluid temperature and properties, particulates and bubbles suspended in a fluid, nonlinear response to velocity, and its invasive characteristics (geometry, size, vibration, etc.).

Hot-film anemometry has been used to measure blood velocity and wall shear in biomedical and bioengineering applications both *in vitro* and *in vivo*. Arterial blood flow velocity measurements were performed by Nerem et al. (33,34) in horses and by Falsetti et al. (35) in dogs. Tarbell et al. (36) used flush-mounted hot films to measure wall shear in the abdominal aorta of a dog. *In vitro* applications of hot-film anemometry include the measurement of wall shear in an LVAD device (37), and the *in vitro* measurement of flow in rigid models of arterial bifurcations by Batten and Nerem (38). Although rarely used in biomedical applications now, we will briefly present hot-film anemometry here for completeness. The reader is referred to the text by Bruun (39) and the symposium proceedings by Stock (40) for a detailed presentation of thermal anemometry.

Thermal anemometry operates on the principal of convective cooling of a heated element. A thin wire or coated quartz element, mounted between supports, is heated and exposed to a fluid flow, as shown in Fig. 8. The element is heated by passing a current through the wire or element. The amount of heat generated is proportional to the current, I (A), and the resistance of the element, R (Ω), by I^2R . The element is convectively cooled by flow until an equilibrium state is reached between electrical heating of the

Figure 8. Illustration of a hot wire or film element.

element and flow-induced convective cooling, $DE/Dt = W + H$, where E is the thermal energy stored in the element, W is the heat added by joule heating, and H is the heat loss to the environment by cooling. At equilibrium, $DE/Dt = 0$ and $W = H$.

Changes in flow velocity will increase or decrease the amount of convective cooling and produce changes in the equilibrium state of the element or the temperature of the element. Commercial anemometers employ a four-arm electronic bridge circuit to maintain constant element temperature, current, or voltage in response to changes in convective cooling. As convective cooling changes, the anemometer output, current, or voltage changes in response to maintaining the desired set condition. This equilibrium condition assumes that radiation losses are small, conduction to supports is small, temperature is uniform over length of sensor, velocity impinges normally on the sensor, velocity is uniform over sensor length and is small compared with the sonic speed, and finally, the fluid temperature and density are constant.

An energy balance between convective heat cooling and joule heating can be performed to derive a set of governing equations that relate input current, I , to convective velocity, V . The "King's law" is the classic result of this energy balance:

$$I^2 R^2 = V_o^2 = (T_w - T_a)(A + B \cdot V^n) \quad (10)$$

where V_o is the measured voltage drop in response to a velocity, V , and T_w and T_a are the wire and ambient fluid temperatures ($^{\circ}\text{C}$), respectively. The coefficients, A and B , and power, n , are determined through careful calibration over the velocity and temperature range that will be observed experimentally. In the event of a three-component flow, the probe must be calibrated for yaw and pitch angles between the probe and the flow velocity vector, and the velocity, V , in Eq. 10 must be replaced by a term related to the velocity vector magnitude. Bridge-type circuits are also prone to stable and unstable performance under unsteady operation. Thus, the overall calibration of a hot-wire/film system must involve the element and electronics as a system and must also involve dynamic calibrations to characterize the frequency response of the system.

Hot-wire/film probes come in a variety of sizes, shapes, and configurations. Probes are manufactured from platinum, gold-plated tungsten, or nickel-plated quartz, and come in single-element or multielement configurations for measurement in a variety of flow conditions. The reader is referred to the hot-wire/film manufacturers for a complete summary of probe types and conditions for use. In general, wire probes are used when possible due to lower cost, improved frequency response, and ease of repair. However, wire probes are more fragile compared with film-type probes and are usually restricted to air flows. Film probes are used in rough environments, such as liquid flows.

The following considerations should be addressed to ensure accurate measurements when using thermal anemometry. The type of flow should be assessed for velocity range, flow scales, and fluid properties (clean gas or particle contaminated liquid, etc.). The flow characteristics will define the right probe, anemometer configuration, and

A/D setup to use. Perform appropriate calibrations with complete hardware setup. Perform the experiment and post calibrations to ensure that the anemometer/probe calibration has not changed.

Doppler Ultrasound And Magnetic Resonance Flow Mapping. The focus of this subsection is to introduce the concept of Doppler ultrasound and MR flow mapping for local velocity measurement. Flow measurement using clinical Doppler can suffer from the same limitations as the small Doppler meter, but has several advantages over these small meters. Most ultrasound machines can operate in continuous wave or pulsed Doppler modes of operation; see Weyman (30) for a more detailed discussion of the modes of operation.

Pulsed Doppler ultrasound offers the advantage of localizing a velocity measurement within a flow and can be used to measure the velocity profile across a vessel or lesion. This information coupled with echocardiographic imaging of the geometry can be used to calculate the flow rate from Eq. 1. Unfortunately, the implementation of this technique is not straightforward due to limitations in resolution, velocity aliasing, and the need to know the relative angle between the transmitted ultrasound beam and the local flow.

Velocity aliasing in pulsed-mode Doppler occurs because the signal can only be sampled once per pulse transmission (e.g., the pulse repetition frequency). Frequency aliasing, or the ambiguous characterization of a waveform, occurs in signal processing when a waveform is sampled at less than one-half of its fundamental frequency, referred to as the Nyquist condition in signal processing. In a pulsed Doppler system, velocity aliasing will occur when the Doppler shift of the moving particles exceeds half of the pulse repetition frequency. As the pulse repetition frequency is a function of the depth at which a sample is measured, the alias velocity will vary with imaging depth. Increasing the imaging depth will lower the velocity at which aliasing will occur. Continuous wave Doppler signals are typically digitized at higher sampling frequencies, limited by the Nyquist frequency associated with the frequency of the transmission wave. Velocities observed clinically produce Doppler shifts that are generally lower than sampling frequencies used in continuous wave Doppler. As a result, velocity alias is not usually observed with continuous mode Doppler in clinical applications.

Aliased signals that are processed by the measuring system are not directly proportional to the Doppler shift generated by the velocity of the particle but can be related to the Doppler shift. Undersampling a wave underestimates the frequency and produces a phase shift. Most clinical Doppler machines use the frequency and phase of the sampled wave to infer velocity magnitude and direction. Velocity alias will produce a lower velocity magnitude with increasing Doppler shift above the alias limit. As frequency is, by definition, positive and Doppler machines use the signal phase to determine direction, the measured frequency is usually reported as a negative velocity above the alias limit, which is often displayed as an increasing positive velocity magnitude with increasing Doppler shift up to the alias limit. Further increases in the Doppler shift

(particle velocity) result in a sign change at the velocity magnitude of the alias velocity with a continued decrease in velocity with increasing Doppler shift. Velocity alias can be reduced or eliminated by frequency unwrapping and baseline shifting, or through the careful selection of machine settings during data acquisition.

Frequency unwrapping is simply correcting the reported aliased velocity by a factor that is related to the alias velocity limit and the magnitude of the reported negative velocity. This correction is, roughly speaking, adding the relative difference in magnitude between the measured aliased velocity and the velocity alias limit to the velocity alias limit. This method of addressing velocity alias is often accomplished by baseline shifting in commercial Doppler machines. In baseline shifting, the phase angle at which a negative velocity is defined is shifted with the effect of a relative shift in the reported alias velocity. Baseline shifting or frequency unwrapping does not eliminate velocity alias but provides a correction to extend the measurement to higher frequencies.

Velocity alias can be "eliminated" by reducing the Doppler frequency of moving particles and thereby shifting the measurable range below the alias limit, which can be accomplished by reducing the carrier frequency of the ultrasound wave that will, in turn, reduce the Doppler frequency shift induced by a moving particle and increase the maximum velocity that can be recorded before reaching the Nyquist limit. Alternatively, the Doppler shift frequency can be reduced by increasing the angle between the propagation of the ultrasound wave and the velocity vector, which reduces the magnitude of the Doppler shift frequency by the cosine of this included angle. Angle correction has limitations in that the flow direction must be known and the uncertainty in the correction increases with increasing included angle. As color flow mappers operate in the pulsed Doppler mode, they are subject to velocity alias. Color flow mappers indicate velocity direction by a color series (for example, shades of red or blue). Velocity alias is displayed as a change in a color series from red-to-blue or blue-to-red.

The clinical measurement of many velocity ensembles across a vessel and the integration across the vessel geometry can be time-consuming and problematic in pulsatile flow through a compliant duct. Furthermore, lesions are often complex in shape and cannot be adequately defined by echo. Doppler echocardiographers and scientists have exploited the physics of fluid flow to develop diagnostic tools that complement these capabilities of commercial Doppler systems. The text by Otto (41) provides an excellent review of these diagnostic tools. Techniques such as the PISA or proximal flow convergence use the capability of color Doppler flow mapping machines to estimate volume flow through an orifice, such as a heart valve. Figure 9 illustrates the concept of the proximal flow convergence method.

The flow accelerating toward a small circular orifice will increase in velocity V_a , until a maximum velocity at the orifice V_j is reached. This acceleration occurs in a symmetric pattern around the orifice and is characterized by hemispheres of constant velocity. As the orifice is approached, the velocity increases and the radius of the

Figure 9. Illustration of the proximal isovelocity surface area (PISA) concept.

hemisphere decreases. The regurgitant flow through the orifice can then be calculated as:

$$Q = (2\pi r^2)V_a \quad (11)$$

The combined imaging and Doppler characteristics of color Doppler flow mapping are exploited in the PISA approach. The location of the alias velocity in the flow map provides a measure of V_a , which is then coupled with a measure of the radial location from the orifice using the imaging capability of color flow mapping. As flow is velocity times area, the hemispheric assumption provides a shell with a surface area of $2\pi r^2$ that velocity V_a is passing through. Figure 10 illustrates the concept of PISA with a color Doppler flow image of valvular regurgitation in a patient.

The PISA approach assumes a round orifice with a hemispherical acceleration zone. In clinical applications, orifices are rarely round and the acceleration zone is not hemispherical with the result of under or over estimation of the flow rate depending on what radial velocity contour is used in Eq. 11. The semielliptic method is one approach at considering nonhemispheric geometries in an attempt to correct for errors associated with the PISA technique.

The combination of continuous wave and pulsed Doppler ultrasound is exploited in the turbulent jet decay method of measuring flow through a stenotic lesion or a regurgitant valve. While continuous wave Doppler does not suffer from velocity alias as does pulsed Doppler, it cannot provide spatial localization of the velocity. The turbulent

jet decay method uses continuous wave Doppler to measure the high velocity at the lesion orifice and then uses pulsed Doppler to measure the velocity decay at specified location downstream of the orifice. Turbulent jet theory can be used to relate the flow rate of the turbulent jet to the decay of the jet velocity downstream of the orifice, as in Eq. 12

$$Q = (\pi V_m^2 x^2)/160 V_j \quad (12)$$

The velocity V_m is measured by pulsed Doppler at location x measured from the jet orifice, whereas the orifice velocity, V_j , is measured by continuous wave Doppler; Fig. 10b illustrates this decay phenomenon. This equation is valid for round jets and has been extended to jets with other geometries by Cape et al. (42) with the resulting change to Eq. 12:

$$Q = (V_m^2 H x)/5.78 V_j \quad (13)$$

where H is the width of the jet measured by color Doppler.

Doppler velocity measurements are also used to estimate pressure gradients in various cardiovascular applications. The Bernoulli equation can be used to estimate the pressure drop across a stenotic lesion or through a valve by measuring the velocity both upstream and downstream of the lesion or valve. The Bernoulli equation is

$$\Delta P = (P_1 - P_2) = 1/2 \cdot \rho (V_2^2 - V_1^2)$$

where position 1 is often measured upstream of the lesion and position 2 is at the lesion or downstream. In this equation, the pressure drop ΔP has units of Pascal's (Pa). A Pascal is a Newton (N) per square meter, where a Newton has units of mass (kg) times length (meter) per time squared. Bioengineering and biomedical applications often use the units of millimeters of mercury (mmHg) in defining a pressure value. A mmHg is related to a Pa by the conversion; 1 mmHg = 133.32 Pa.

Magnetic resonance flow mapping has the advantage over Doppler that it can measure the full three-component velocity field over a volume region (43–45), which eliminates the uncertainty in flow direction and enables the use of standard fluid dynamic control volume analysis. The advantages of MR flow mapping come at the cost of long imaging times and increased sensitivity to motion artifacts in *in vivo* applications, where phase locking to the heart rate or breathing cycle can increase complexity.

The velocity of moving tissue can be detected by a time-of-flight technique (46) and by phase velocity encoding (47,48). The time-of-flight method tracks a selected number of protons in a plane and measures the displacement of the protons over a time interval defined by the imaging rate. *In vivo* (49) and phantom (50) studies have shown that the time-of-flight technique is capable of accurate velocity measurement up to velocities at least as high as $0.5 \text{ m}\cdot\text{s}^{-1}$. However, the time-of-flight method requires a straight length of vessel on the order of several centimeters for accurate velocity estimation. This requirement reduces its usability in most *in vivo* applications. The phase velocity encoding method has become the preferred technique in most clinical applications.

Phase velocity encoding directly relates the local velocity of nuclei to the induced phase shift in an imaging voxel.

Figure 10. (a) Color Doppler flow map image of the proximal isovelocity surface area (PISA) in valvular regurgitation. (b) Illustration of the jet decay downstream of an orifice. The parameter V is the jet velocity and x is measured from the orifice.

Properly defined bipolar magnetic field gradients are produced in the direction of interest for velocity measurement. The velocity of hydrogen nuclei are then encoded into the phase of the detected signal (51). Chatzimavroudis et al. (52) and Firmin et al. (53) provide a discussion of the phase encoding technique with an assessment of its accuracy and limitations for flow measurement.

The technique uses two image acquisitions to provide velocity compensation and velocity encoding. Velocity information in each voxel is obtained by a voxel-by-voxel subtraction of the two images with respect to the phase of the signal. Like Doppler ultrasound, phase velocity encoding can suffer from aliasing effects, alignment error, and limits in spatial and temporal resolution. Velocity estimation using phase shift measurement is limited to a maximum range of phase of 2π radians without ambiguity or aliasing. However, the estimation of the phase shift using phase subtraction between two images reduces that sensitivity to this problem. Studies have been conducted that show MR phase velocity encoding can measure velocities covering the complete physiologic range up to several meters per second (54). Misalignment of the flow direction with the encoding direction will produce a negative bias in the measured flow where the measured velocity will be lower than the true velocity. Like Doppler, this bias follows a cosine behavior where $V_{\text{meas}} = V_{\text{act}} \cos(\theta)$, where V_{meas} is the measured velocity, V_{act} is the actual velocity, and θ is the misalignment angle. This error is typically less than 1% in most applications.

The size of a voxel and the sampling capabilities of the hardware characterize the spatial and temporal resolution of the system. Spatial resolution affects the size of a flow structure that can be measured without spatially filtering or averaging the structure or velocity measurement. Spatial velocity gradients that are small relative to the voxel size will not be adequately resolved and will be averaged over the voxel volume (55). In addition, rapidly varying velocity fluctuations in time will produce a similar low pass frequency filtering effect if these fluctuations occur with a time scale that is much smaller than the imaging time scale of the measurements. Turbulent flow can produce spatial and temporal scales that could be small relative to the imaging characteristics and can result in what is referred to as signal loss in the image (56). Stenotic lesions and valvular regurgitation are clinical examples where turbulent flow can occur with spatial and temporal scales that could compromise measurement accuracy.

Phase velocity encoding has the drawback of fairly long imaging or magnet residence times, which is particularly true for three-component velocity mapping. Although this may be acceptable for *in vitro* testing with flow loop phantoms, it can present problems and concerns with clinical measurements. Patients can be exposed to long time intervals in the magnetic with the associated problems of patient comfort and care. *In vivo* velocity measurements are often phase-locked with cardiac cycle or breathing rhythm. Long imaging times can increase potential for measurement error due to patient movement and variability in the cardiac cycle or breathing rhythm, which can cause noise in the phase-averaged, three-component velocity measurements. Research, in recent years, has focused

on hardware and software improvements to increase spatial resolution and reduce imaging time [see, e.g., Zhang et al. (57)].

Magnetic resonance phase velocity encoding provides coupled 3D geometric imaging using traditional MR imaging methods with three-component velocity information. This coupled database provides a powerful diagnostic tool for blood flow analysis and has been used extensively in *in vitro* and clinical applications. Jin et al. (6) used this coupled imaging flow mapping capability to study the effects of wall motion and compliance on flow patterns in the ascending aorta. Standard imaging was used to measure aortic wall movement and the range of lumen area and diameter change over the cardiac cycle. This aortic wall motion was phase-matched with phase velocity encoded axial velocity distributions in the ascending aorta. Similar to the PISA approach in Doppler ultrasound, a control volume approach using phase velocity encoded MR velocities can be applied to the assessment of valvular regurgitation (58,59). The control volume approach is illustrated in Fig. 11.

Laser Doppler Velocimetry. The Doppler shift of laser light scattered by particles or cells in a fluid is the basis of laser Doppler velocimetry (LDV). Detailed presentations of the LDV technique are provided in the works by Drain (60) and Durst et al. (61). The scattered radiation, from a laser beam directed at moving particles in a fluid, has a Doppler-shifted frequency defined as:

$$f_D \sim (1 - V/C_1) f' \quad (14)$$

where C_1 is the speed of light in a vacuum, V is the particle velocity, and f' is incident light frequency. The Doppler-shifted frequency is very small relative to the frequency of

Figure 11. Illustration of the control volume method in MR phase velocity assessment of valvular regurgitation. The control volume (CV) is the heavy dotted line box around the mitral regurgitant orifice. The box edges are usually selected to correspond with rows and columns in the MR image. V_1 represents the three-component velocities measured with MR through the i faces of the box. Faces 4 and 5 are in the plane of the image at $\pm Z$ offsets from the plane of the image. The regurgitant flow Q_r is the sum of the V_{iA_i} on each face.

Figure 12. Illustration of the dual-beam or fringe mode LDV setup.

light and, thus, dual-beam or fringe mode LDV is the system configuration of choice. The dual-beam mode of operation is schematically shown in Fig. 12. In fringe mode LDV, two coherent laser beams of the same wavelength or frequency are focused to a common point (control volume) in the flow field. The scattered light from a particle moving through the control volume is received by a photodetector.

The crossing of two coherent, collimated laser beams forms interference fringes as the propagating light waves constructively and destructively interfere with one another. This interference creates a series of light and dark bands with spacing, d_f , of

$$d_f = \lambda/2 \sin(\kappa) \quad (15)$$

The number of fringes, N_{FR} , in the measurement volume is given by

$$N_{FR} = 1.27d/D_e^{-2} \quad (16)$$

where d is the spacing between the two parallel laser beams before the focusing lens and D_e^{-2} is the beam diameter before the lens. Figure 13 illustrates the probe geometry generated by the intersection of two focused coherent laser beams with a common wavelength.

The spatial resolution of a dual-beam system is affected by the distribution of the light intensity at the intersection of the two focused beams, referred to as the probe or measurement volume. When the laser is operating in the TEM_{00} mode, the laser cavity sustains a purely longitudinal standing wave oscillation along its axis with no transverse modes. The laser output has an axisymmetric intensity profile that is approximately a Gaussian function

Figure 13. Illustration of the measurement volume generated in fringe mode LDV.

of radial distance from the axis. In the far field, the beam divergence is small enough to appear as a spherical wave from a point source located at the front of the lens. A lens is used to focus the beam into a converging spherical wave. The radius of this wave decreases until the focal point of the lens is reached. At the focal point, the beam has almost a constant radius and planar behavior. The beam is focused to its minimum diameter or focal waist, d_e^{-2} , and is defined as:

$$d_e^{-2} = (4\lambda f)/(\pi D_e^{-2})$$

where λ is the wavelength of the laser beam and f is the focal length of the lens. A single pair of laser beams generates an ellipsoidal geometry having dimensions of major axis l_m and minor axis d_m given by

$$l_m = d_e^{-2}/\sin(\kappa) \text{ and } d_m = d_e^{-2}/\cos(\kappa) \quad (17)$$

where κ is the half angle between the two laser beams, as illustrated in Fig. 13.

The particle velocity is calculated by the fluctuating light intensity collected by the receiver as the particle passes through the measurement volume and scatters light from the fringes. The intensity change of the scattered light from the light and dark fringes is converted into an electrical signal by a photomultiplier tube (PMT). The electrical signal represents an amplitude-modulated sine wave, with frequency proportional to the Doppler frequency shift (f_D) of the particle traveling through the measurement volume. The particle velocity is then equal to the Doppler frequency multiplied by the fringe spacing. In a two-beam LDV system, the measured velocity component is in the plane of the two laser beams and in the direction perpendicular to the long axis of the measurement volume.

Coherent laser beams with the same frequency produce stationary fringes. A particle moving in either direction across the fringes will produce the same frequency independent of sign, such that a stationary fringe system can only determine the magnitude of the velocity, not the direction. To avoid this directional ambiguity, one of the laser beams of a beam pair is shifted to a different frequency, using a Bragg cell, to provide a moving fringe pattern. One laser beam from each beam pair passes through a transparent medium such as glass, in which acoustic waves, generated by a piezoelectric transducer, are traveling. If the angle between the laser beam and the acoustic waves satisfies the Bragg condition, reflections from successive acoustic wave fronts reinforce the laser beam. The beam exits at a higher frequency and a prism

directs the beam to its original direction. The Bragg shift causes the fringes in the probe volume to move at a constant speed in either the positive or negative direction relative to the flow. The measured frequency by the PMT and processor is then the sum or difference of the Bragg cell frequency (typically 40 MHz) and the Doppler shift frequency. This measured frequency is then downmixed with a frequency that is a percent of the Bragg frequency (called the shift frequency) producing a frequency that has a zero shifted to a higher baseline frequency (usually on the order of several MHz). This zero shift eliminates directional ambiguity in LDV signal processing.

Laser Doppler velocimetry has excellent spatial and temporal frequency response compared with most other measurement systems. It is considered a gold standard measurement technique in biomedical applications and is the noninvasive measurement system of choice for turbulence measurements. Two disadvantages of LDV worth noting are (1) LDV noise and (2) velocity bias. The LDV is noisy when compared with other turbulence measurement systems, such as thermal anemometry, due to the use of photomultiplier tubes. These optical detectors, used for their sensitivity and high frequency response, suffer from higher noise floors than other photo detectors.

Velocity bias is a result of the random sampling characteristics of LDV. As a velocity ensemble is randomly recorded when a particle passes through a probe volume, the statistics of the measured velocity ensembles are not independent of the particle velocity. A greater number of higher speed particles will cross the measurement volume over a specified time than will slower speed particles. Standard ensemble averaging will produce mean velocity estimates that are biased toward higher velocities. This velocity bias can have a significant impact on the velocity statistics, particularly in turbulent flow. In addition to velocity bias, two other biases may occur, fringe bias and gradient bias.

Fringe bias is an error that is minimized by frequency shifting. This type of bias is created by not having enough fringe crossings to satisfy processor validation criteria when calculating a velocity, which occurs when a particle crosses the edge of the probe volume or if the particle velocity is nearly parallel to the fringes. Thus, velocity ensemble averages weight velocities from particles traveling near the center of the measurement volume or those particles that cross more fringes than others. By frequency shifting with a fringe velocity at least two times greater than the flow velocity, particles moving parallel to the fringes can cross the minimum number of fringes for validation by a processor.

Gradient bias results from a nonnegligible mean gradient across the probe volume. This bias depends on the fluid flow and the measurement volume dimensions. The mean velocity and the odd order moments are the only statistics affected by gradient bias. In general, LDV-transmitting optics are chosen to provide as small a measurement volume as possible to increase spatial resolution and reduce gradient bias. As the LDV measurement volume is longer than it is wide, experiments should be designed to ensure that the LDV optical setup is oriented to position the measurement volume diameter in the direction of the maximum gradients in the flow.

Several post processing techniques have been developed to reduce velocity bias. The recommended technique is to use a transit time weighting when computing the velocity statistics. This transit time weighting approximates the ensemble average as a time average. The reader is referred to Edwards (62) for a detailed discussion of the transit time technique and its implementation in LDV data processing.

Multiple pairs of laser beams with different wavelength (color) or polarization can be used to produce a multicomponent velocity measuring system. Two or three laser beam pairs can be focused to the same point in the flow. Each beam pair can then be used to independently measure a different component of the velocity vector. As more than one particle can pass through a measurement volume at one time, it is possible to get valid velocity component estimates from different particles. The ellipsoidal geometry of the measurement volumes exaggerates this problem. As a result, LDV data are often processed in one of two modes, random and coincident.

Random mode processing records every valid velocity ensemble as it arrives at the measurement volume, which can generate uneven sample distributions in the different velocity components or LDV channels being measured. Random mode processing has a negligible impact on mean velocity statistics but can be detrimental to turbulence estimates. Coincident mode processing uses hardware or software filters to ensure that each velocity component ensemble is measured from the same particle. Filters are used to ensure that the Doppler bursts measured on the different LDV channels overlap in time. Bursts generated by one particle should be measured on each channel with perfect overlap. Time window filters are used to reject bursts that do not occur within a window defined by a percentage of the burst length. The effect of coincident mode processing is usually a reduction in the overall data rate by a factor of at least two but provides the necessary data quality for turbulence measurements.

Laser Doppler velocimetry is primarily an *in vitro* tool, although systems have been developed for blood flow measurement (17,63). Blood is a multiphase fluid composed of a carrier liquid, plasma, and a variety of cells and other biochemical components. Plasma is optically clear to the wavelengths of light used in LDV. The optical opacity of blood is due to the high concentration of cells, in particular red cells. On the microscopic level, however, blood can transmit light over a short distance due to the plasma carrier fluid. Clinical-style probes have been developed to measure the velocity of blood cells in blood using catheter-type insertion into vessels of suitable size or through transcutaneous measurement of capillary flow below the skin. These *in vivo* systems are designed with very short focal length transmitting lenses providing a small measurement volume located a very short distance from the transmitting lens. Laser light is propagated through the plasma and focused a few millimeters from the probe tip. Blood cells act as particles in the fluid and scatter light that is collected by the transmitting lens and directed to a PMT system for recording of the Doppler bursts. Manning et al. (64) and Ellis et al. (65) have used LDV to measure the velocity fields around mechanical heart valves in *in vitro* studies. Figure 14 shows the measured velocity

distributions associated with impact of a Bjork–Shiley monostrut valve (64).

Particle Image Velocimetry and Particle Tracking Velocimetry. Particle image velocimetry (PIV) and particle tracking velocimetry (PTV) have been applied in fluid flow applications for over a decade. They are noninvasive experimental techniques that provides a quantitative, instantaneous velocity vector field with good spatial resolution, an appealing feature when studying complex, time-dependent fluid flows that can occur in biomedical applications. The method allows the quantitative visualization of instantaneous flow structures over a spatial region, as opposed to a point measurement like LDV, which can provide insight into the flow physics. The two techniques, PIV and PTV, differ in the way particle displacements are measured. Particle tracking follows and tracks the motion of individual particles whereas PIV measures the displacement of groups of particles within the flow. Particle tracking velocimetry, although not commonly used, is a subset of the more common PIV technique and is still used in specific applications of PIV. Raffel et al. (66) provide a comprehensive discussion of the PIV and PTV technique with a detailed presentation of the physics, processing tools, capabilities, and errors.

The instantaneous velocity field is computed by measuring an instantaneous particle displacement field over a specified, finite time interval. Laser-based PIV and PTV

are noninvasive velocity measurement tools that require good optical access to the flow field. As a result, they are essentially *in vitro* tools (8,67) that are of limited use *in vivo*. Figure 15 shows an example of the use of PIV in a bioengineering application of flow through one chamber of an artificial heart (68). X-ray-based PTV systems are being developed and will be capable of *in vivo* use. In this section, the authors will focus on PIV; however, system concepts (seeding, acquisition, processing, noise, and errors) would be applicable to some degree to systems like X-ray PTV (69).

Particle image velocimetry uses a double-pulsed light source, usually a laser, to illuminate a thin sheet in the flow field. Particles suspended in the fluid scatter light during each pulse, and this scattered light is recorded on a digital camera. The optimal setup has the recording device located 90° to the illumination sheet. Figure 16 illustrates the typical PIV setup. (66)

Two lasers with coincident beam paths are used to illuminate a desired plane of the flow by incorporating optics to produce thin laser sheets. During image acquisition, the two lasers are pulsed with the specified time separation (typically between 1 and $1000\ \mu\text{s}$). A trigger system, referred to as a synchronizer, controls the firing of the two lasers relative to the shuttering of a CCD camera. The camera, usually placed orthogonal to the laser sheet, collects the light scattered by tracer particles in the flow and records an image. The synchronizer, used in cross-correlation-based PIV systems, delays the firing of the first

Figure 15. Phase-average velocity maps from mid to late diastole for a prototype artificial heart ventricular chamber (time reference is from the onset of diastole, $4.7 \text{ L}\cdot\text{min}^{-1} \text{ CO}$, 75 bpm) (68).

laser such that the camera shutter is centered between the firing of the two lasers. This synchronization technique is called frame straddling and produces two sequential images of each laser beam pulse. Although the time between successive camera frames may be much larger than the time duration between laser pulses, the two images of the particle field created are separated by the specified time interval between the two laser pulses.

A discussion of PIV must begin with a brief introduction of the terminology commonly used. Figure 17 provides a schematic representation of geometric imaging (66). The “light plane” is the “volume” of the fluid illuminated by the light sheet. The “image plane” is the image from the light plane captured on the CCD sensor. It is important to note that the light plane is a 3D space or volume, whereas the image plane is a 2D space or “surface.” The subvolume

selected from the light plane for cross correlation is called the interrogation subvolume. The corresponding location of this interrogation volume captured on the image plane is called the interrogation subregion. Please note that the displacement vectors in an interrogation volume are three-component vectors, whereas those in an interrogation area are two-component vectors. “Particle” is the physical particle suspended in the fluid volume. “Particle image” is the image of each particle in the image plane. Particle density, intensity, and pair refer to particle properties, whereas image density, intensity, and pair refer to particle image properties.

Most commercial systems use a cross-correlation-based image processing technique to compute the particle displacement. Images are subdivided into small interrogation regions, typically a fraction of the overall image size, and

Figure 16. Schematic of a PIV setup (66). (With kind permission of Springer Science and Business Media.)

Figure 17. Schematic representation of geometric imaging (66). (With kind permission of Springer Science and Business Media.)

the same two subregions are cross-correlated between the two images to obtain the average displacement of the particles within that subregion. From this displacement and the known time delay, the velocities within the interrogation region are obtained.

Statistical PIV assumes all particles in an interrogation subregion move a similar distance and direction. The processing algorithm then computes the mean displacement vector for the particles in the interrogation volume. Therefore, the local particle distribution pattern captured on each exposure should be similar; but the group of local particles is displaced from image to image. Statistical PIV is then “pattern recognition” of the particle distribution within an interrogation subregion, instead of the averaged

particle displacements. Sophisticated pattern recognition schemes have been developed by a number of researchers; however, the cross-correlation tends to be the algorithm of choice. The use of a cross-correlation as opposed to an autocorrelation eliminates directional ambiguity in the velocity measurement. Most commercial systems use advanced cross-correlation algorithms, such as the Hart-Correlation, developed to improve signal to noise in the correlation estimate and enhance resolution (70,71).

The cross-correlation function for two interrogation subregions of frames A and B is defined by:

$$R_{II}(s, \Gamma, D) = \langle I(x, \Gamma)I'(x + s, \Gamma', D) \rangle \quad (18)$$

where s is the shifting vector of the second interrogation window, Γ is the series of location vectors for each particle in the interrogation volume, D is the displacement vector for each particle, x is the spatial domain vectors within the interrogation area, I is the intensity matrix for the interrogation area from frame A, and I' is the intensity matrix for the interrogation area from frame B. A detailed mathematical derivation of the cross-correlation for (group) particle tracking is beyond the scope of this presentation. The location of the maximum value of cross-correlation function represents the mean particle displacement for the interrogation image. Figure 18 is an example of a cross-correlation function between two images.

The location of the cross-correlation peak should be determined with subpixel accuracy. Several curve-fitting algorithms have been developed to identify the peak in the cross-correlation. Gaussian, parabolic, and centroid are three commonly used methods in commercial software, although others exist. A Gaussian peak fit is most commonly used because the cross-correlation function of two Gaussian functions also yields a Gaussian function, which

Figure 18. Representative cross-correlation map between frames A and B.

means that if the intensities of individual particle images in the interrogation area fit a Gaussian shape, the cross-correlation function can be accurately approximated by the Gaussian function, which occurs only under the condition of low displacement gradient, so that the particle distribution pattern is preserved in windows A and B. The cross-correlation function in distorted, particle image intensity distribution patterns are less accurately approximated by a Gaussian distribution. A three-point estimator for Gaussian fit works better with a narrow and symmetric peak. Centroid peak finding should be considered when the cross-correlation peak is expected to have asymmetric and irregular patterns. Such cases occur for particle images larger than 2–3 pixels in diameter, for a low intensity ratio of particle image to background noise, or for a high gradient displacement field. For “correlation-based correction,” the centroid peak finding might be more suitable than Gaussian because the multiplications could distort the cross-correlation peak.

The use of a digital CCD camera presents an error source known as “peak locking.” This error impacts the accuracy of the subpixel estimation in the correlation peak and thus impacts the velocity measurement. This error will be discussed later.

Like LDV and Doppler, PIV and PTV require that the fluid be seeded with tracer particles that follow the fluid motion. The particle density, the number of particles per unit volume of fluid, determines what technique should be used, PIV or PTV. Flows with a low particle density are more suited to PTV, whereas PIV works best in high particle density flows. It is assumed that the tracer particles follow the flow accurately to give an exact representation of the flow field at various times and locations. The particle density, however, should be sufficiently low to preserve the original flow dynamics. Such a dilute condition is expressed by the inequality:

$$(\rho_p \pi d_p^4 v_r) / (18 \mu \delta_p^3) < 1 \quad (19)$$

where d_p and ρ_p are the particle diameter and density, respectively, μ is fluid viscosity, v_r is the averaged particle velocity relative to neighboring particles, and δ_p is the average distance between particles.

Particles must be small enough to follow the fluid flow but large enough to be seen. The particle relaxation time, τ_s , should be small relative to the flow time scales.

$$\tau_s = d_p^2 (\rho_p / 18 \mu) \quad (20)$$

In practice, τ_s is made small by using very small particles. The Stokes number for PIV experiments, St_{PIV} , can be defined as τ_s / τ_{PIV} , where τ_{PIV} is the small finite separation time between two observations (pulse separation time). St_{PIV} should be much less than 1 to assure negligible particle-fluid velocity differences over the pulse separation. However, particles must be large enough to scatter sufficient light energy to be visualized on the recording device (e.g., a CCD camera) with the goal that a particle image is at least several pixels in size. Increasing the light source energy can improve visibility, but a saturation point is reached where increasing light source energy does not help. Furthermore, high energy can damage windows and plastic test models.

The time separation of the two laser pulses must be small enough to minimize particle loss through too large a particle displacement between the first and second frames of the interrogation window. However, the time separation must be long enough both to permit adequate displacement of particles at the lowest measurable velocities in each velocity component and to minimize the impact of pixel peak locking (72). Complex and highly 3D flows can be biased in a 2D PIV system. PIV can provide very high spatial resolution, but suffers from low temporal resolution. Furthermore, high magnification imaging used in high resolution PIV introduces additional constraints and limitations that must be overcome to achieve high quality vector maps.

The challenge for PIV is to correctly track particle motion. Figure 19 shows an example of a PIV particle image. The statistical cross-correlation approach is used to track the displacement of a “group” of particles within an indicated small volume or subregion. The location of a velocity vector is at the center of the subregion spot. The spatial resolution for a “velocity vector” in PIV is the size of the interrogation subregion. Overlapping adjacent interrogation subregions is commonly used to reduce the distance between adjacent vectors and provide additional vectors in the overall vector map. However, this overlapping does not increase the spatial resolution of the velocity field, which is limited to the size of the interrogation subregion.

Commercial PIV systems use a multigrid recursive method to reduce interrogation subregion size. In the hierarchical approach, a PIV measurement with large interrogation subregions is first computed. Subsequently, the initial interrogation area is evenly divided into smaller areas for processing. Each smaller interrogation area is offset by the displacement obtained from its parent interrogation area. This process is repeated until the smallest possible interrogation size is reached (e.g., $128 \times 128 \rightarrow 64 \times 64 \rightarrow 32 \times 32 \rightarrow 16 \times 16$) for the given flow field. An iterative method can be applied at the final grid level.
